The type of load sharing depends on several factors, with a deciding one being the interface between the two lining layers. If a sheet waterproofing membrane is used, it is assumed that shear stresses are not transferred between the linings (Combined Linings). With spray on membranes, an increased adhesion can be expected and therefore a part of the shear stresses is assumed to be transferred, with the overall support acting as a Composite Lining.

A basic requirement for the design of combined or composite linings is the use of advanced numerical modelling with special focus on the simulation of the interface between the two support layers.

6 CASE STUDIES

6.1 Eglinton crosstown LRT, Toronto

Three mined stations of Eglinton Crosstown LRT, two of which included also long crossovers with a total length of 1km, were excavated in glacial deposits encountering highly permeable soft ground units with high water tables. The project requirements specified a double shell approach for the mined elements with the initial linings serving only as temporary supports.

The 18.7m wide by 15m high Platform Caverns were constructed from the previously excavated Cross-Cut tunnels (15.6m wide by 18.2m high) as shown in Figure 5 for one of the mined stations (Avenue).

Figure 5. 3D FE model east part of Avenue station.

In order to design these rather complex intersections which introduced sizeable openings into the Cross-Cut tunnels (Figure 6), 3D soil-structure interaction FE analyses using Abaqus were executed. The analyses included the actual excavation and support steps and utilised an advanced Hardening Mohr-Coulomb material for the soil and the CDP model for the linings. The CDP model, which was calibrated against experimental data from the project, allowed capturing the stress redistribution during the formation of the openings in the initial linings and resulted in no additional reinforcement or thickening requirements. The same approach was used in the design of the final linings optimising the reinforcement requirements.

Figure 6. Section along the Cross-Cut tunnels indicating the openings for the Platform Caverns.

As a result, the overall steel savings through the optimised design, compared to a standard design with linear elastic models considered for the linings (SEM standard in Figure 7), were approximately 1,960 tons of steel or 3,670 tons of CO₂.

Figure 7. Comparison of steel quantities in the mined Caverns of the Eglinton Crosstown LRT between the optimised and a standard design.

Furthermore, after gaining experience from the excavation of the main station Caverns and with the agreement of the project owner, a combined lining approach was implemented in areas where no bar reinforcement was required, i.e., where the Cavern linings were not subjected to high bending forces due to connections of internal structures or nearby intersections of different underground structures.

The final linings following the combined lining approach were executed with fibre-reinforced poured concrete throughout the tunnel section.

The waterproofing system consisted of compartmentalized PVC membrane with grids of water barriers (sectioning system) and arrays of grout pipes to allow grouting of the gap between primary and secondary lining which will establish the watertightness of tunnel lining and ensure transmission of contact forces between both linings.

To account for some degradation of shotcrete in direct contact with soil, the initial lining was divided into two shells: a 100 mm thick sacrificial layer and a 350 mm thick, durable initial shotcrete lining (Figure 8). The 350 mm thick final lining for long-term performance was also sub-divided into two shells: a 300 mm thick long-term poured concrete lining and a 50 mm thick layer to account for the fire damage on the intrados of combined lining (following a heat-transfer analysis).

The numerical simulation was executed with Abaqus using 1m long 3D models to enable advanced simulation of the contact between the various elements (Figure 9). The waterproofing membrane was modelled with a frictionless tensile contact to prevent shear stress and a hard normal contact allowing transfer of normal forces and separation between the linings. The initial and final linings were simulated with shell elements and the poured invert was modelled with continuum

elements tied to the final lining. The steps of the analysis were the following:

1. Geostatic step establishing in-situ stresses.
2. Excavation and installation of the initial lining taking full-short term loads.
3. Installation of the final lining on the deformed mesh of the initial lining and activation of the pore water pressures acting on the extrados of the final lining.
4. De-activation of the 100mm sacrificial layer of the initial lining.
5. Application of zero tensile strength at the location of the initial lining construction joints (sidewalls and temporary invert connections to outer lining), to investigate the effect of rebar corrosion.
6. Reduction of strength/stiffness of the initial lining to simulate long-term creep effects.
7. De-activation of the 50mm fire damage layer of the final lining.
8. Reduction of strength/stiffness of the final lining to simulate long-term creep effects.

Additionally, the final lining was checked against the contact grouting pressures and against self-weight at 1-day strength.

Indicative results for the final lining at stage 8 are shown in Figure 10.

As a result of the combined lining approach, the thickness of the final linings was reduced from the nominal 500mm (double-shell approach) to 350mm.

Figure 8. Thickness of linings used in FEA.

Figure 9. Combined lining FE Mesh.

6.2 Bank station capacity upgrade, London

The Bank station upgrade project involved among others the excavation of multiple new sprayed concrete tunnels in the stiff London clay deposits, aimed to increase the capacity of this busy transportation

Figure 10. FEA results - final lining at creep step. SF – axial hoop force (N), SM – bending moment in hoop direction (Nm), E-max – maximum strain and E-min – minimum strain.

hub. An overview of the FE models deployed for the design of the new tunnels is shown in Figure 11.

Figure 11. Overview of models for the new sprayed concrete tunnels at Bank station upgrade (Nasekhian & Spyridis 2017).

The tunnel lining system was double shell with both primary and secondary linings considered part of the permanent structure. The minimum thickness of the secondary lining was set to 150mm to allow all fixings to be installed preventing penetration of the membrane.

Between the two linings, a double bonded spray-on waterproofing layer was applied. The detailed composition is shown in Figure 12.

The designed distinguished between the short-term (5 years) and the long-term (120 years) periods. The load sharing between the two linings was defined by numerical analyses. The CDP material model was used for both linings to account for the non-behaviour, assuming conservatively a linear-elastic behaviour under compression and realistic behaviour under tension accounting for the residual flexural capacity of the fibre reinforced shotcrete.

During the short-term steps, the excavation and installation of the primary lining was simulated under undrained conditions. In the long-term steps, the secondary lining was installed, and the water pressures were applied assuming effective stress parameters.

Figure 12. Sprayed concrete lining composition at Bank station upgrade project (Nasekhian & Feiersinger 2019).

The results of the combined lining approach at Bank, led to an optimisation of the lining thickness and to significant savings in excavation volumes and shotcrete quantities (up to 50% reduction of the thickness of the secondary lining) as well as in overall construction time.

7 CONCLUSIONS

Tunnelling projects, despite providing infrastructure with long service life and supporting low emission transportation and sustainable energy projects, still contribute significantly to the CO₂ emissions of the construction industry. Immediate action is required to lower the impact to the environment and provide more sustainable infrastructure. This means that the tunnelling industry needs to rethink the way its operating by incorporating the environmental impact on several aspects of tunnelling projects.

The selection of the optimal construction method, for example between TBM or conventional tunnelling for longer tunnels or cut and cover versus conventional tunnelling for deep stations, needs to consider among others the environmental impact.

A collaborative approach involving all stakeholders is deemed essential for reducing construction emissions. Contrary to the current common practice of awarding projects based on the lowest price, there is an imminent need for establishing carbon reduction as a fundamental project requirement during the early design phases. Similarly, the project codes and standards need to be chosen carefully as they may have significant impact on reducing the carbon footprint of a tunnelling project.

Steel and concrete, the main materials used in tunnelling, carry a significant ‘environmental cost’. Using low emission materials and focusing on local resources, recycling, and reusing the excavation material play an important role. Focusing on reducing the actual material quantities by minimising excavation and support element size through

advanced design is imperative. This is aided by the implementation of advanced material models in numerical analyses, also for the support elements. For the optimisation of the tunnel shape, probabilistic analyses can be used to derive the minimum excavation volume thus providing significant material savings. Considering the permanent action of the initial tunnel lining in combined/composite lining concepts is also pivotal in reducing the overall lining thickness.

Case studies from the Eglinton Crosstown LRT project and the Bank Station Capacity Upgrade underscore the tangible benefits of advanced design, including substantial material savings and overall construction time.

In conclusion, the article presents a compelling case for reshaping tunnelling practices to align with sustainability goals. Through innovative construction methods, collaborative, and the integration of advanced design principles, the tunnelling industry can contribute to global efforts aimed at achieving a more sustainable built environment.

Advanced joint non-linear design analysis and verification of the arched cut and cover tunnels at High Speed 2 project (UK)

Nayef Al Haddid*, Sotiris Psomas & Mengxiao Li
COWI UK Ltd, London, UK

ABSTRACT: Conventional rectangular cut-and-cover tunnel linings, although tried and tested, present an inefficient solution to load dissipation. This design often leads to either limitations in height of backfill or oversized tunnel sections wasting time, materials and contributing unnecessary carbon to the environment. In the High Speed 2 project arched cut-and-cover tunnels have been adopted and bring about several benefits by addressing a few of the problems rectangular linings encounter. At the same time, they introduce a controlled-mechanism (frictional knuckle-joint) in the arch that enables the designer to create a break in the tensile stress load path, reducing moments via limiting the length of development, while simultaneously maintaining stabilizing axial forces. In this Paper the non-linear finite-element analysis of frictional knuckle-joints in a twin-arch concrete lining, illustrates the behaviour of these joints and highlight important modelling considerations; with focus on contact modelling, joint articulation, local stresses and bursting at the joints. This Paper aims to share the findings of the advanced non-linear finite element analysis of knuckle-joints and their verification as well as to demonstrate the benefits of utilizing such type of construction in cut-and-cover tunnels for Rail infrastructure.

Keywords: Tunnelling, TBM, Performance prediction, Simulation, Friction joint, Contact, Sensitivity analysis

1 INTRODUCTION

The High Speed 2 (HS2) is Britain's new high speed rail line running between London and Birmingham. Forming parts of the route will be six green tunnels, three of which are cut-and-cover tunnels, and two of those are twin horseshoe tunnels; each horseshoe is formed from a precast concrete side wall and roof segments, and a common precast concrete central wall segment.

The precast segments are fabricated off-site in 2.49 m wide modules. These are later delivered to site for installation. The wall segments are landed and levelled first, followed by the roof segments. The roof and wall segments make contact via 'dry' concrete-to-concrete knuckle joints. An in-situ RC invert base slab is then cast which ties the bottom of the precast walls together. The in-situ slab is monolithic with the precast components, achieved via reinforcement continuity through a loop-to-loop rebar connection. The completed structure is then back-filled in a balanced, controlled manner. The final tunnel height and breadth are approximately 9.5m

and 20.0 m respectively. All concrete is strength class C50/60 with steel grade 500B reinforcement.

This paper will mainly focus on the analysis of the tunnel lining, using the LUSAS finite element analysis software, with explicit modelling of the knuckle-joints utilising contact elements, to accurately capture the joint behaviour, and its effect on the global structural behaviour of the lining.

Figure 1. Diagram showing lining structure.

*Corresponding author: n.alhaddid@gmail.com

2 THE JOINT

The knuckle-joint utilised in the precast segments is made of up of two parts, the convex part of on the roof unit and the concave part on the wall units.

Figure 2. Geometry of the convex and concave parts of the joint.

As Figure 2 shows, the central section of both parts of the joint are formed by circular arches of different radii, that taper off towards the lining extrados. The intrados is capped with a relief zone that allows a 15mm gap, at perfect installation.

Joints in tunnel linings have been extensively researched and various paradigms developed to address their effects. Those paradigms have ranged from closed-form solutions, such as *Muir-Wood (1975)*, to joint idealization approaches such as *Duddeck and Erdmann (1985)* to more advanced uses of rotational springs in beam and shell models to account for joint non-linearity, such as *Leonhardt and Reimann (1965)*, *Janssen (1983)*, *Blom (2002)* and most recently *Tvede-Jensen et al. (2017)*.

However, the primary assumption of a flat contact face between the considered segments limits the use of those models in applications where curved contact faces are utilised. Other sources for predicting contact areas and stresses, such as those presented in Roark's Formulas for Stress and Strain, are based on linear-elastic materials in geometrically linear scenarios. As such explicit modelling of the knuckle-joint was necessary to fully understand the structural behaviour of the joint itself and cascading effects on the rest of the lining.

3 SCOPE

This paper aims to demonstrate the merits and concerns of an arch with two pin joints. The paper will also investigate the effects of the following attributes on the curved joint behaviour, in hopes of providing insights to future designer and modellers:

- Mesh size
- Contact stiffness
- Friction coefficient
- Modelling reinforcement

The metrics used to quantify the effects of the above factors on local joint behaviour and global lining behaviour will include, local metrics:

- Peak contact axial stress: the peak axial stress within the contact width, in MPa.

- Peak contact shear stress: the peak shear stress within the contact width, in MPa.
- Contact width: the width of contact established, in mm.
- Contact penetration: the amount of interpenetration between the contact elements, in mm.
- Bursting force in the lining: the bursting force generated within the roof and wall units, in kN.
- Joint rotation: the total joint rotation, i.e. the difference between the wall joint rotation and the roof joint rotation, in degrees.

and global metrics:

- Axial force: axial force at various points of interest, in kN.
- Bending moment: bending moment at various points of interest, in kN.
- Shear force: shear force at various points of interest, in kN.

Metrics will only be discussed where there are notable observations. The points of interest for the global effects are shown on Figure 3.

Figure 3. Points of interest for the calculation of the global effects; AW: Arch wall.

4 THE MODEL

4.1 Geometry

The analysis consist of half-space 2D plane-strain finite element model, with symmetry supports along the line of symmetry, to limit the size of the model, as shown in Figure 4.

The actual reinforcement arrangement in the crown and wall units was accurately modelled, with limited rationalization to control element shapes. The plane-strain elements were assigned a breadth of 1000mm (into the page).

The roof unit thickness is 400mm, with arch wall unit beginning at 400mm until mid-height where it begins to increase reaching a thickness of 894mm at the base. The footings of the arch wall and central wall start at a thickness of 1000mm and reduce to the thickness of the invert slab, which is 650mm. The thickness

Figure 4. LUSAS 2D plane-strain model showing modelled reinforcement and line of symmetry.

of the central wall is 550mm and flares to form a concave joint on each side.

4.2 Elements

Plane-stress continuum plate elements were used for the model, those elements are 4-noded quads with two degrees of freedom at each node. While these nodes cannot capture curvature (would require quadratic elements at the expense of model run times), at fine mesh conditions and appropriate use, they are capable of approximating curves. The model was meshed to ensure fine mesh density and aspect ratios near 1 in the vicinity of the joints, with elements size ranging between 15mm – 25mm. To optimize run times the mesh size increase gradually moving away from the joints and less scrutiny is applied regarding aspect ratios.

4.3 Materials

Linear-elastic concrete properties, shown in Table 1, were applied to the majority of the model except for the joints, where a smeared multi-crack non-linear concrete material model was used to avoid development on unrealistic stresses, properties shown in Table 2. The steel reinforcement was assigned linear-elastic steel properties, summarised in.

Table 1. Linear-elastic concrete material.

Elastic Modulus	37 GPa
Poisson's ratio	0.20
Unit density	2.50 tonnes/m ³

Table 2. Smeared multi-crack non-linear concrete material.

Initial elastic Modulus	37 GPa
Poisson's ratio	0.20
Unit density	2.50 tonnes/m ³
Uniaxial Characteristic Compressive Strength	50 MPa
Uniaxial Characteristic Tensile Strength	3 MPa
Strain at peak compressive strength	0.0022
Fracture energy per unit area	0.1516

Table 3. Linear-elastic steel material.

Elastic Modulus	210 GPa
Poisson's ratio	0.20
Unit density	7.849 tonnes/m ³

4.4 The contact elements

The contact elements are modelled using 'slidelines' in LUSAS, these elements allow for the modelling of smooth contact, frictional contact, fully tied (rigid connection) and sliding only contact. The contact element formulation is simplistic, focussing on detecting and monitoring contact throughout the analysis via a double-pass approach between parent and child bodies/surfaces. When contact is detected, interaction forces are introduced to prevent penetration between surfaces/bodies.

The contact stiffness is calculated using the following equation, based on the averaged material and geometric properties of the elements adjacent to the contact node:

$$\varepsilon_i = S_{fac,i} \frac{k_i l_i}{2t_i} \quad (1)$$

where ε_i is the contact stiffness at node i , $S_{fac,i}$ is the stiffness scale factor, k_i is the bulk modulus, l_i and t_i are the element length and thickness respectively.

The stiffness scale factor is made accessible to the user to modify the contact stiffness and indirectly affect contact widths, stresses, and penetrations.

The relevant properties made accessible to the user are the parent element stiffness factor, child element stiffness factor, coulomb friction coefficient and a means to control the zone around each node where the contact search occurs.

4.5 Supports

The support regime adopted for the analysis was simple, 17kN/m² compression-only spring were applied to the base of the tunnel, and fixed horizontal springs applied along the vertical line of symmetry running through the centre of the central wall.

4.6 Loads

The loads considered in the analysis were also simplified in self-weight applied via a vertical acceleration of 9.81 m/s^2 , and the weight of the backfill, applied via a variation with depth from finished ground level (24m above formation level – 14m above crown level). The bulk unit weight of backfill adopted was 20 kN/m^3 . No factors were applied to the loads.

5 DOUBLE PIN JOINT ARCH ANALYSIS

By analysing three models of the double arch lining with; no joint, pin joint and a frictional knuckle-joint (the design), it was observed that no change occurred to axial or shear performance of the lining whereas the arch wall experiences significant reduction in bending moment. This can be seen in, showing over 80% drop in the moment at the middle of the arch wall and over 33% at the top, with only a 7.8% increase at the base of the wall where moment is already critical and therefore designed for.

Figure 5. Percentage change in bending moment for the frictional joint and pin joint linings compared to the no joint lining model. Bars portray the percentage change and the line plot shows the bending moment for the frictional joint model.

However, by introducing the joints, the roof unit experiences higher bending forces at its centre due to the increased displacement/rotation and subsequent alteration of the line of thrust within the lining.

6 FINDINGS

6.1 Mesh size

The local mesh size at the joint was varied to investigate the effects of mesh size on joint behaviour; the adopted values were 5mm, 10mm, 15mm, 20mm and 25mm.

The mesh size analysis shows that the contact width is sensitive to the mesh discretization adopted, specifically at higher loads. Figure 7 shows that:

1. At lower loads, the difference between the contact width on the concave and convex parts of the joint is large. this difference reduces at higher loads.

Figure 6. (a) 5mm mesh size (b) 25mm mesh size.

2. Finer mesh discretization shows significantly better agreement between the contact widths registered by the contact elements on the concave and convex parts of the joint, specifically for 5mm and 10mm meshes.
3. The concave part of the joint (wall) tends to underestimate the contact width while the convex part (crown) tends to overestimate the contact width; increasingly divergent with coarser meshes.

Figure 7. Variation of contact width with mesh size; where a load factor of 0.0 represents self-weight.

Figure 8. Variation of inter-surface penetration with mesh size; where a load factor of 0.0 represents self-weight.

The inter-penetration between the surfaces in Figure 8, shows similar results, where meshes

coarser than 10mm show increasing divergence in the value of penetration in the convex and concave parts, about the seemingly real value identified in finer meshes (5mm and 10mm).

The peak axial stress at the contact point, shown in Figure 9, shows that at 5mm and 25mm mesh sizes exhibit a higher contact stress than the 10mm, 15mm or the 20mm. This appears to be due to random alignment of nodes at different mesh discretization near the point of initial contact; as shown in Figure 10.

Figure 9. Variation of peak axial contact stress against increasing load factor, for the various mesh sizes.

While peak stresses may not be of any design importance they may cause convergence issues, specifically when using non-linear materials within the model.

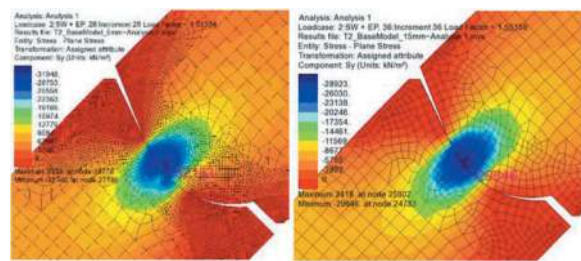

Figure 10. Axial stress at joint at load factor 1.5 in kPa; (a) 5mm mesh (b) 15mm mesh.

6.2 Contact stiffness

Naturally, when increasing the contact stiffness we see a linear increase in peak stress at contact, this conforms to Eq. (1) above.

More interestingly, increasing the contact stiffness past 1.0 does not seem to have a significant effect on increasing bursting forces observed in the crown or wall, with the highest increases occurring at the higher load factors, with a maximum increase of 8% when doubling contact stiffness at Crown-LF:3.0 in Figure 12. However, halving contact stiffness leads to a 15% reduction in bursting force in the wall, for the same case.

Figure 11. Variation of peak axial stress at contact with contact stiffness, where a load factor of 0.0 represents self-weight.

Figure 12. Variation of bursting forces in the wall and crown, with contact stiffness, where a load factor of 0.0 represents self-weight.

The unsymmetric response to altering contact stiffness can be explained by observing the change in contact width.

Figure 13 shows the inversely proportional relationship between contact stiffness and contact width, plateauing after 1.0-1.2 contact stiffness factor. This explains why reducing contact stiffness has a significant observable effect on bursting forces, while increasing them is substantially less effective.

Bursting forces increase with reducing contact width, as the gradient of stress dispersal is steeper requiring higher stabilising radial stresses to satisfy local equilibrium.

Naturally the same inverse proportionality can be observed when inspecting the penetration results.

An indirect effect of increasing the contact stiffness is increasing the shear stresses observed at the joint. Figure 15, shows shear stress increasing by 30% for LF: 2.0 when doubling the contact stiffness factor from 1.0 to 2.0. This effect is less pronounced

Figure 13. Variation of contact width with contact stiffness, where a load factor of 0.0 represents self-weight.

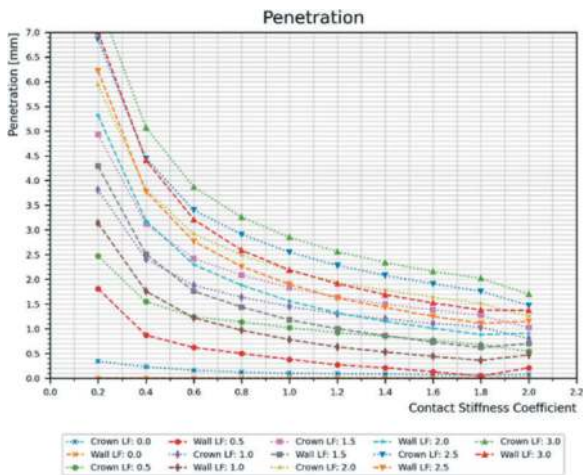

Figure 14. Variation of penetration with contact stiffness, where a load factor of 0.0 represents self-weight.

at lower load factors, with LF: 1.5 only showing a 10% increase when undergoing the same change.

Figure 15. Variation of peak shear stresses at the contact, with contact stiffness, where a load factor of 0.0 represents self-weight.

Lastly, increasing contact stiffness has been observed to slightly reduce the joint rotation, this is likely due to higher axial stresses translating to higher frictional forces, the effect is not significant.

Figure 16. Variation of joint rotation with contact stiffness, where a load factor of 0.0 represents self-weight.

6.3 Friction coefficient

One important aspect of any contact element when considering non-smooth contact, is the friction coefficient as it is the main variable affecting the tangential contact properties.

As is anticipated, increasing the coefficient of friction leads to an increase in rotational stiffness and therefore lower rotation. At 1.5 load factor the joint rotation is 8.3% lower for a 0.7 coefficient than a 0.2 coefficient.

The opposite trend can be observed in the peak shear stress near the contact where an increase in the friction coefficient leads to an increase in the peak shear stress. This trend is observed up to a load factor of 2.5x full backfill, above which lower coefficients show higher shear stresses, likely due to the higher rotation altering the stress field.

Figure 17. Variation of joint angle with coefficient of friction, where a load factor of 0.0 represents self-weight.

Figure 18. Variation of peak shear stress with coefficient of friction, where a load factor of 0.0 represents self-weight.

Similarly, the increased rotational stiffness constraining the joint rotation leads to higher peak axial stresses. Figure 19 shows an increase between 15% and 20% for most load factors.

Figure 19. Variation of peak axial stress with coefficient of friction, where a load factor of 0.0 represents self-weight.

As the joint rotation becomes more restricted with higher friction coefficients, the joint becomes less able to rotate towards a more stable configuration. A more stable configuration would be categorized as one which maximises contact width and reduces contact eccentricity by centring the line of thrust.

Figure 20 shows the reduction in contact width with increasing friction coefficients. At a load factor of 1.0 we see a reduction of 11.5% in contact width between a 0.2 and 0.7 coefficient of friction.

The penetration increases slightly but not significantly as is expected, matching the increase in peak axial stress, while the bursting forces in the wall and the crown are seemingly unaffected by the friction coefficient.

Figure 20. Variation of contact width with coefficient of friction, where a load factor of 0.0 represents self-weight.

Figure 21. Variation of bursting forces with load comparing results for the model with reinforcement modelled and the one without.

6.4 Reinforcement

Modelling reinforcement has shown no significant impact on peak stresses at contact, contact width or contact penetration; indicating that contact properties are agnostic towards the presence of reinforcement, particularly the lack of effect on axial stiffness of the contact.

However, the bursting forces and the joint rotation have shown clear effects. Figures 21 and 22 show that modelling the reinforcement has limited the tensile bursting stresses and therefore more accurately captured a lower bursting force.

Another observation is the bigger difference between the bursting force in the crown and the wall, where the model with no reinforcement shows little difference. This is due to the differing quantity of reinforcement between the crown and the wall near the joint.

Figure 23 shows another benefit of modelling reinforcement; where the model with reinforcement shows lower joint rotation, due to increased stiffness of

the wall and crown units, compared to the model without the reinforcement. This leads to more precise displacements, especially where the structure is heavily loaded (i.e. at high load factors) or heavily reinforced.

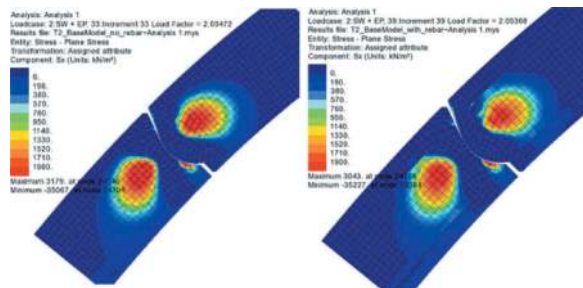

Figure 22. Radial (Bursting) tensile stresses at joint at load factor 2.0 in kPa; (a) without reinforcement (b) with reinforcement.

Figure 23. Variation of joint rotation with load comparing results for the model with reinforcement modelled and the one without.

7 VERIFICATIONS

The structural verifications of the tunnel lining were focussed on designing for the following:

1. Shear and moment transfer at the loop-to-loop connections.
2. Crushing and bursting at the knuckle joints.
3. General section capacity checks, particularly at the base of the arch walls.

Figure 24. Showing specific points of interest for design considerations.

For more detail on the design development, construction, sustainability and other challenges refer to *Smith and Psomas (2023)*. The fire design and testing were detailed in *Psomas et al. (2023)* and the calibration between finite element analysis and physical testing for joint behaviour has been covered in *Li et al. (2024)*.

8 CONCLUSIONS

This paper presented an overview of the twin-arch tunnel design used for the green tunnels on HS2, focussing on the finite element modelling aspects of the knuckle-joint and subsequent effects on the design. The particular focus was on mesh size, contact friction coefficient, contact stiffness and modelling of reinforcement.

Regarding mesh size, mesh sensitivity analysis has been shown to be crucial as mesh size will dictate the sensitivity of the contact elements, with coarser meshes over-estimating contact width, causing stress concentrations and convergence issues as well as showing disparity between stresses observed at either side of the joint.

Similarly, the stiffness of the contact elements significantly impact the local stress field at the joint by altering contact width and penetrations. It was observed that increasing the contact stiffness past that of the parent geometries has less of an effect than reducing stiffness. Primarily, the contact stiffness should be calibrated so as not to underestimate the bursting forces generated while not leading to artificially high stresses.

The friction coefficient analysis highlighted the impact on the joint articulation, with increased friction reducing joint rotation and leading to shorter contact widths and higher axial and shear stresses.

Finally, the effect of modelling reinforcement showed the significant influence the reinforcement has on constraining radial tensile stresses, leading to more accurate bursting forces, as well as increasing the stiffness of the units and reducing joint rotation observed.

ABSTRACT: When analysing the damage phenomenon (crack, seepage, et al.) of a segmental lining during tunnel construction, its movement and deformation along the longitudinal direction is a critical aspect to be studied. Since the segmental lining is assembled by segments and using connecting bolts, there are many joints in the lining, which are the weak part of the lining and have an obvious deformation under the application of construction loads. This paper focuses on the circular joint which has a great influence on the segmental lining deformation along the longitudinal direction. Firstly, the evaluation methods of the bending stiffness and shear stiffness of a circular joint are developed; and then, based on the interaction between the connecting bolt and its hole, the methods for the evaluation of the shear stiffness of a single bolt and the one of the whole circular joint are proposed; finally, the segmental lining deformation along the longitudinal direction is analysed and the main factors are discussed.

Keywords: Tunnel segmental lining, Circular joint, Shear Stiffness, Bending Stiffness, lining behaviour in the longitudinal direction, Connecting Bolts, Bolt/Bolt hole interaction, Finite Element Method (FEM), Numerical Methods

1 INTRODUCTION

Segmental lining is widely used to support the surrounding ground when the tunnel boring machines (TBM) is adopted for the tunnel construction. Since the segmental lining consists of segments and connecting bolts, there are many joints that influence its behaviour. During the construction of the tunnel, the crack and seepage can be observed inside the lining (Gong et al., 2020; Lu, 2020), and the uplift movement of the segmental lining is a common phenomenon (Zhou and Ji, 2014).

In order to understand the reasons of the crack and seepage inside the lining, the segmental lining deformations along the longitudinal direction are widely studied using numerical models and analytical solutions (Chen et al., 2018; Cheng et al., 2021). Regarding this type of analysis, the influence of the circular joints is

fundamental. Shiba et al. (1988) proposed the equation for the joint bending stiffness. Li et al. (2019) carried out a laboratory test to evaluate the joint stiffness under the application of a normal forces and moment. Cheng et al. (2021) suggested the general solution for the segmental lining deformation. Based on laboratory test, researchers (Guo et al., 2023a; Guo et al., 2023b; Liu et al., 2018) tested the bending and shear deformation of joints in the detailed; they further explained the nonlinear behaviour of the joint due to the nonlinear properties of the constituent materials.

In this paper the methods used to determine the variable joint bending and shear stiffnesses of the circular joints are introduced. Furthermore, a FEM model is developed to calculate the segmental lining deformation along the longitudinal direction and an iterative procedure is proposed in order to correctly consider the variable joint stiffness values. Using the proposed

method, deformations of rings and joints can be evaluated separately, and the nonlinear deformation of the tunnel segmental lining can be researched.

2 STIFFNESS OF THE CIRCULAR JOINT

When the tunnel segmental lining has a deformation along the longitudinal direction, the stiffness of the circular joints shows a nonlinear behaviour with the increase of the joint deformation. The methods adopted to calculate the bending and the shear stiffnesses of the circular joints are discussed in this section.

2.1 Bending stiffness

The bending stiffness of a circular joint is affected by the state of the joint, which can be described by the location of the neutral axis: it can be represented by the angle φ introduced by Shiba et al. (1988) and is determined by the existing normal force and the applied moment. There are two kinds of circular joint states: open and closed. When the joint is closed, the segments are connected each other, and the bending stiffness of the joint is the same of the lining segment. The limit moment M_{lim} of the circular joint before opening can be determined by the normal force N with the following equation:

$$M_{lim} = \frac{N \cdot I}{A \cdot R_e} \quad (1)$$

where I is the inertia moment of the ring cross-section, A and R_e are the cross-sectional area and the external radius of the ring, respectively.

When the joint is open, the bending stiffness of the joint show a nonlinear behaviour. The influence of the moment and of the normal force can be represented by a parameter λ ,

$$\lambda = \frac{N \cdot (D_e - t)}{4 \cdot M} \quad (2)$$

where D_e is the external diameter of the tunnel, t is the thickness of the lining.

The equivalent bending stiffness $(EI)_{eq}$ of the joint can be obtained by the following equation (Han et al., 2023a):

$$(EI)_{eq} = \left[K_{com} \cdot \left(\frac{\pi}{2} - \varphi - \sin \varphi \cdot \cos \varphi \right) + K_{ten} \cdot \left(\frac{\pi}{2} + \varphi + \sin \varphi \cdot \cos \varphi \right) \right] \cdot \frac{(D_e - t)^3 \cdot t}{16} \cdot L_{b,p} \quad (3)$$

where $L_{b,p}$ is the projection length of the bolt, and K_{ten} are the tensile stiffness and compression stiffness of the joint:

$$\begin{cases} K_{com} = \frac{2 \cdot E_{con}}{L_{b,p}} \\ K_{ten} = \frac{2 \cdot E_b}{l_b} \cdot \frac{n \cdot A_b}{A} \end{cases} \quad (4)$$

where E_{con} is the elastic modulus of concrete, E_b is the elastic modulus of the bolt steel, l_b is the length of the bolt, n is the number of connecting bolts in the circular joint and A_b is the cross-sectional area of the connecting bolt.

In Equation 3, when the normal force is equal to 0, the angle φ can be obtained by the following simplified equation:

$$\varphi + \cot \varphi = \pi \cdot \left(\frac{1}{2} + \frac{K_{ten}}{K_{com} - K_{ten}} \right) \quad (5)$$

When the normal force is larger than 0, the angle φ can be derived on the basis of Equation 2:

$$\lambda = \frac{2 \cdot m \cdot (\cos \varphi + \varphi \cdot \sin \varphi) - \pi \cdot \sin \varphi}{-2 \cdot m \cdot (\varphi + \cos \varphi \cdot \sin \varphi) + \pi} \quad (6)$$

where m can be determined by K_{com} and K_{ten} :

$$m = \frac{K_{com} - K_{ten}}{K_{com} + K_{ten}} \quad (7)$$

Furthermore, the equivalent bending stiffness of the joint also can be rewritten with the ratio between the equivalent bending stiffness of the joint and the one of the segmental lining ring:

$$(EI)_{eq} = \text{JBSE}_{Boltz} \cdot E_{con} \cdot I \quad (8)$$

where JBSE_{Boltz} is the joint bending stiffness efficiency based on the Boltzmann function; it is equal to the ratio of the bending stiffnesses between the joint and the ring, and it can be considered as a modifying parameter of the bending stiffness of the lining ring.

JBSE_{Boltz} is a function of the λ parameter:

$$\text{JBSE}_{Boltz} = \frac{(A_1 - A_2) \cdot \alpha}{1 + e^{(\lambda - \lambda_0)/q}} + A_2 + \Delta \quad (9)$$

where A_1 , A_2 , λ_0 and k are the basic parameters, α and Δ are the modified parameters. The detailed derivation of these parameters can be found in the reference (Han et al., 2023c):

A_1 is the lower value of the modified parameter JBSE_{Boltz} , which can be obtained by Equation 3 and Equation 4 when the normal force is equal to 0;

A_2 is the upper value of JBSE_{Boltz} which is equal to 1;

λ_0 is the specific value of λ when JBSE_{Boltz} is equal to $(A_1 + A_2)/2$, where the equivalent bending stiffness of the joint $(EI)_{eq}$ can be obtained by Equation 5, the angle φ can be derived by Equation 3, and λ_0 can be calculated by Equation 6;

q is a constant value, and can be obtained by the following equation:

$$q = \frac{A_2 - A_1}{4 \cdot \text{JBSE}} \quad (10)$$

where JBSE is the slope of the centre point ($\lambda_0, (A_1 + A_2)/2$), which can be obtained by two adjacent points with a tiny increase $\Delta\lambda$, where the ordinate value of $JBSE_{Boltz}$ can be obtained on the abscissa value and $\lambda_0 + \Delta\lambda$ based on Equation 3, Equation 5 and Equation 8;

α and Δ are the modified parameters and can be obtained by the following equations:

$$\alpha = \frac{(1 + e^{(1-\lambda_0)/k}) \cdot (1 + e^{(-\lambda_0)/k})}{e^{(1-\lambda_0)/k} - e^{(-\lambda_0)/k}} \quad (11)$$

$$\Delta = -\frac{(A_1 - A_2) \cdot \alpha}{1 + e^{(1-\lambda_0)/k}} \quad (12)$$

Based on Equation 3 and Equation 8, the equivalent bending stiffness of the joint can be calculated separately. The results are shown in Figure 1 referring to a well-known case of a shield tunnel (Zhou and Ji, 2014), and the results by the two methods show a very good consistence.

Figure 1. The trend of the joint bending stiffness based on the Equation 3 and Equation 8 calculation for a well-known case of a shield tunnel (Han et al., 2023c; Zhou and Ji, 2014).

2.2 Shear stiffness

The shear stiffness of a joint is influenced by the relative displacement of segments. Since the connecting bolts are installed along the circular joint, the inclination angle of the bolts varies with the location of the bolts on the circular joint. The shear stiffnesses of a single bolt and of the whole circular joint are here discussed separately.

2.2.1 Shear stiffness of a single connecting bolt

Based on the Timoshenko theory, the equivalent shear stiffness of a joint $(k \cdot G \cdot A)_{eq}$ is equal to the ratio between the shear force V_{total} applied on the joint and the corresponding relative displacement v_{seg} together with the projection length of the connecting bolt L_{bp} .

$$(k \cdot G \cdot A)_{eq} = \frac{V_{total}}{v_{seg}} \cdot L_{bp} \quad (13)$$

When the segments have a relative displacement along the joint Δv_{seg} , the ratio between the

increase of the applied shear force ΔV_{total} and the corresponding relative displacement can be defined as shear stiffness K_{eq} :

$$K_{eq} = \frac{\Delta V_{total}}{\Delta v_{seg}} \quad (14)$$

where the applied shear force on the joint ΔV_{total} is equal to the shear force of the bolt on the cross section along the joint.

Furthermore, considering the inclination angle of the connecting bolt, the equivalent shear stiffness of the joint is the combination of the joint-bolt tensile stiffness and the joint-bolt shear stiffness when only the bolt is considered during the shear deformation (Han et al., 2023d):

$$K_{eq} = K_{eq,Q} \cdot \cos^2(\alpha) + K_{eq,N} \cdot \sin^2(\alpha) \quad (15)$$

where $K_{eq,Q}$ is the joint-bolt shear stiffness and $K_{eq,N}$ is the joint-bolt tensile stiffness, when the bolt is perpendicular to the plane of the joint; α is an inclination angle of the connecting bolt.

Based on the relative displacement direction and the tensile state of the bolt, there are two basic models for the joint shear deformation: the tensile model and the no tensile one, because there is no constraint on the bolt head when the bolt is compressed along the axial direction.

When the joint deformation follows the no tensile model, the shear stiffness K_{eq} can be obtained by the shear stiffness of the joint:

$$K_{eq} = K_{eq,Q} \cdot \cos^2(\alpha) \quad (16)$$

Based on the results of Han et al. (2023d), the joint-bolt tensile stiffness has a constant value (the green line in Figure 2), and the joint-bolt shear stiffness has a nonlinear trend varying the relative displacement between the segments (the blue lines in the figure).

Figure 2. The joint-bolt tensile stiffness and the shear stiffness when the bolt is perpendicular to the plane of the joint (after Han et al., 2023d).

The tensile stiffness of the joint can be obtained by the following equation:

$$K_{eq,N} = \frac{1}{\frac{\coth(\rho \cdot l_{thread})}{E_b \cdot A_b \cdot \rho} + \frac{l_{shank}}{E_b \cdot A_b} + \frac{1}{K_{x,o}}} \quad (17)$$

where l_{thread} is the length of the thread part of the bolt which is installed inside a concrete bolt hole, l_{shank} is the length of the shank part of the bolt. Parameter ρ can be obtained by the following equation:

$$\rho^2 = \frac{\beta_c \cdot \pi \cdot d_b}{E_b \cdot A_b} \quad (18)$$

where β_c is the concrete foundation shear modulus, d_b is the diameter of the bolt. $K_{x,o}$ represents the compressive stiffness of the concrete surface under the application of the washer of the bolt head.

$$K_{x,o} = k_c \cdot \frac{\pi}{4} \cdot (d_{washer}^2 - d_h^2) \quad (19)$$

where d_{washer} and d_h are the diameter of the washer and the bolt hole, respectively; k_c is the concrete foundation compressive modulus. The parameters k_c and β_c can be determined by laboratory tests and are discussed in the references (Han et al., 2023b).

The shear stiffness of the joint has three parts, and also includes three key parameters: a maximum shear stiffness, locations of a starting point and of a final point. The maximum value of the shear stiffness can be obtained by the following equation:

$$K_{eq,Q,max} = 2 \cdot E_b \cdot I_b \cdot \beta^3 \cdot |\eta| \quad (20)$$

where I_b is the moment of inertia of the bolt cross-section, η and β are two parameter; β depends on the concrete foundation compression modulus:

$$\beta = \sqrt[4]{\frac{k_c \cdot d_b \cdot 1000}{4 \cdot E_b \cdot I_b}} \quad (21)$$

the η parameter depends on the bolt length and on β : the detailed derivation of them can be seen in Han et al., 2023d.

The location of the starting point can be obtained by the following equation:

$$L_{start} = \frac{d_{max,h,l} - d_b}{2} \cdot \frac{l_{shank}^3}{l_{bolt,l}^2 \cdot (3 \cdot l_{shank} - 2 \cdot l_{bolt,l})} \cdot \frac{1}{\cos(\alpha)} \quad (22)$$

The location of the final point is equal to the sum of the length of part I and part II.

$$L_{final} = L_{start} + L_{partII} \cdot \frac{1}{\cos(\alpha)} \quad (23)$$

where L_{partII} is the length of part II:

$$L_{partII} = \frac{2}{K_{eq,Q}} \cdot \frac{15 \cdot E_b \cdot I_b}{4 \cdot l_{bolt,rs}^3 + 10 \cdot E_b \cdot I_b \cdot \delta \cdot l_{bolt,rs} - 10 \cdot E_b \cdot I_b \cdot \beta \cdot l_{bolt,rs}^2} \cdot \frac{d_{max,h,r} - d_b}{2} \quad (24)$$

where $d_{max,h,l}$, $d_{max,h,r}$, $l_{bolt,l}$ and $l_{bolt,rs}$ are geometrical parameters of the bolt, δ and ω are the middle parameters which can be found in the reference (Han et al., 2023d), where the segment connected with the bolt head is the left one.

The representation of the connecting bolts in the cross section of the segmental lining rings is shown in Figure 3. The green rectangle is the first ring and the white one is the second installed segmental ring. The angle ϑ represents the location of each connecting bolt in the cross section.

The bolts have different angles with the circular joint. The equivalent inclination angle γ is used to represent the angle of the bolt axis with the displacement vector of the lining segment.

2.2.2 Shear stiffness of a circular joint

Figure 3. Different axial directions of the bolts in the cross section (after Han et al. (2023d)).

The angle γ of the considered bolt with the location ϑ can be determined by the following equation:

$$\gamma = \arcsin(\sin \alpha \cdot \cos \vartheta) \quad (25)$$

where α is the inclination angle of the bolt at point 1 as shown in Figure 3, ϑ represents the location of the considered bolt in the cross section ($\vartheta \in [0, \pi]$).

When $\gamma > 0$, the joint-bolt tensile stiffness can be ignored, and the joint-bolt shear stiffness can be obtained by Equation 16, where the angle α is replaced by γ . When $\gamma \leq 0$, the shear stiffness of the joint can be calculated using Equation 15 by replacing α with γ . Finally, the shear stiffness of the circular joint can be obtained by the summation of the shear stiffness K_{eq} of all the bolts in the lining cross section.

Table 1. The assumed material parameters.

Bolt steel Elastic modulus (GPa)	Bolt Steel Poisson's ratio	Concrete Elastic modulus (GPa)	Concrete Poisson's ratio	Concrete foundation compression modulus (MPa/mm)	Concrete foundation shear modulus (MPa/mm)
206	0.3	35.5	0.2	74.87	10.10

Table 2. The geometrical parameters of the bolting system.

Bolt diameter (m)	Diameter of gasket (m)	Inclination angle of the bolt (°)	Length of the bolt on the left segment (m)	Length of the bolt on the right segment (shank part + thread one) (m, m)	Max and min hole diameter on the left segment (mm, mm)	Max hole diameter (mm)
0.03	0.07	30	0.282	0.06 + 0.19	36, 40	60

The calculated results of the shear stiffness of each bolt are shown in Figure 4 and the one of the whole circular joint with the increase of the relative displacement is shown in Figure 5, where the joint is connected by 19 bolts. The assumed material parameters of the bolt steel and concrete are listed in Table 1 and the structural parameters are listed in Table 2.

Figure 4. The distribution of the shear stiffnesses on the joint connected by 19 bolts.

From Figure 4, the shear stiffness of all the bolts on the circular joint shows a uniform distribution: the value of the shear stiffness of the joint increases from the top to the bottom. With the increase of the relative displacements of the segments, the shear stiffness of each bolt increases correspondingly. Based on Figure 5, the shear stiffness of the circular joint shows a similar trend with the one of the single bolt, where the minimum shear stiffness of the joint is determined by the joint-bolt tensile stiffnesses of all the bolts.

Based on Equation 13, the shear stiffness of the circular joint can be determined based on the relative displacement of the segments together with the projection length.

The distribution of the shear stiffness on the circular joint is uneven as shown in Figure 4: there are different start points and final points for each bolt varying the equivalent inclination angle γ based on Equation 22, Equation 23 and Equation 25. Considering the uniform distribution of the bolts on the circular joint, a virtual bolt at the location $\vartheta = 45^\circ$ is used to represent the shear stiffness of the circular joint together with the number of bolts. Therefore, the shear stiffness can be derived by Equation 15:

$$\begin{cases} K_N & v_{seg} < L_{s,\vartheta=45^\circ} \\ K_N + K_Q \cdot \frac{v_{seg}}{L_{f,\vartheta=45^\circ}} & L_{s,\vartheta=45^\circ} \leq v_{seg} < L_{f,\vartheta=45^\circ} \\ K_N + K_Q & v_{seg} \geq L_{f,\vartheta=45^\circ} \end{cases} \quad (26)$$

where n is the number of bolts on the circular joint, $L_{s,\vartheta=45^\circ}$ and $L_{f,\vartheta=45^\circ}$ are the start point and the final point when the equivalent inclination angle is equal to $\gamma_{\vartheta=45^\circ}$ at location $\vartheta = 45^\circ$ (Equation 25):

$$\begin{cases} K_N = K_{eq,N} \cdot \sin^2(\gamma_{\vartheta=45^\circ}) \cdot \frac{n}{2} \\ K_Q = K_{eq,Q,max} \cdot \cos^2(\gamma_{\vartheta=45^\circ}) \cdot n \end{cases} \quad (27)$$

Figure 5. The shear stiffness of a circular joint connected by 19 bolts varying the relative displacements.

Based on Equation 26, the shear stiffness of the circular joint is also shown in Figure 5: a good consistence between the two curves can be seen and Equation 26 can be used to calculate the equivalent shear stiffness of a circular joint.

Based on Equation 13, the equivalent shear stiffness of the joint $(k \cdot G \cdot A)_{eq}$ can be obtained as:

$$(k \cdot G \cdot A)_{eq} = \begin{cases} K_N \cdot L_{bp} & v_{seg} < L_{s,\theta=45^\circ} \\ \frac{K_N \cdot L_{s,\theta=45^\circ} + \left(K_N + K_Q \frac{L_{s,\theta=45^\circ} + v_{seg}}{2L_{f,\theta=45^\circ}} \right) \cdot \frac{(v_{seg} - L_{s,\theta=45^\circ})}{v_{seg}} \cdot L_{bp}}{v_{seg}} & L_{s,\theta=45^\circ} \leq v_{seg} < L_{f,\theta=45^\circ} \\ \frac{K_N \cdot L_{s,\theta=45^\circ} + \left(K_N + K_Q \frac{L_{s,\theta=45^\circ} + L_{f,\theta=45^\circ}}{2L_{f,\theta=45^\circ}} \right) \cdot (L_{f,\theta=45^\circ} - L_{s,\theta=45^\circ}) + (K_N + K_Q) \cdot (v_{seg} - L_{f,\theta=45^\circ})}{v_{seg}} \cdot L_{bp} & v_{seg} \geq L_{f,\theta=45^\circ} \end{cases} \quad (28)$$

On the basis of Figure 1 and Figure 5, both of the bending stiffness and shear stiffness of a circular joint show a nonlinear behaviour with the relative displacement of the segments on the joint. Considering a nonlinear behaviour of the circular joint, the segmental lining deformation along the longitudinal direction is discussed on the next section.

3 SEGMENTAL LINING DEFORMATION

3.1 FEM model of segmental lining deformation

During the construction of a tunnel using the Tunnel Boring Machines (TBMs), the applied forces on the segmental lining can be divided into two classes: the loads along the axial direction of the tunnel, and the ones on the cross section of the tunnel, perpendicular to the axial direction. The forces on the cross section are produced by the slurry (the filling material) and the ground surrounding the tunnel; the mechanical behaviour of the slurry change over time, and the state of the slurry transforms slowly from a liquid state to solid one. When the slurry is in the liquid state, there are great buoyancy forces acting on the segmental lining; the buoyancy effect of the slurry decreases with the hardening phase (Fu et al., 2023). The slurry presence in the model is considered with a fluid zone and a solid one separately (Figure 6). Due to strong constraints by the tail brush inside the TBM tail, a fixed

constraint is applied on the first node of the model. For the forces applied along the axial direction of the tunnel, the friction between the lining and the surrounding ground is ignored, and the normal force (axial force in the longitudinal direction) acting on the segmental lining is equal to the applied normal force by the hydraulic jacks: these forces can affect the

bending stiffness of the circular joint on the basis of Figure 1.

Based on the Timoshenko theory, a FEM model is adopted to analyse the lining deformation along the longitudinal direction: it represents both the segmental lining rings and circular joints using standard elements and joint elements as shown in Figure 6. With the FEM model, the behaviours of joints and rings can be separately analysed considering the nonlinear behaviour of joints as previously introduced.

On the FEM model (Figure 6), the external forces on each node $[F]$ are equal to the global stiffness matrix $[K]$ multiplied by the corresponding nodal displacements $[S]$:

$$[K] \cdot [S] = [F] \quad (29)$$

The global stiffness matrix can be obtained by composing the local stiffness matrices on each element:

$$[K] = \begin{bmatrix} k_{1,a} & k_{1,b} & 0 & \cdots & 0 & 0 \\ k_{1,c} & k_{1,d} + k_{2,a} & k_{2,b} & \cdots & 0 & 0 \\ 0 & k_{2,c} & k_{2,d} + k_{3,a} & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & 0 & 0 \\ 0 & 0 & 0 & \cdots & k_{n-1,d} + k_{n,a} & k_{n,b} \\ 0 & 0 & 0 & \cdots & k_{n,c} & k_{n,d} \end{bmatrix} \quad (30)$$

Figure 6. The numerical elements of the segmental lining model with the applied constraints (after Han et al., 2023c).

where the terms of the stiffness matrix depend on the element stiffness matrix:

$$[k_E]_i = \begin{bmatrix} k_{i,a} & k_{i,b} \\ k_{i,c} & k_{i,d} \end{bmatrix} = \frac{EI}{l^3} \begin{bmatrix} \frac{12}{1+\Phi} & \frac{6l}{1+\Phi} & -\frac{12}{1+\Phi} & \frac{6l}{1+\Phi} \\ \frac{6l}{1+\Phi} & \frac{4+\Phi}{1+\Phi} l^2 & -\frac{6l}{1+\Phi} & \frac{2-\Phi}{1+\Phi} l^2 \\ -\frac{12}{1+\Phi} & -\frac{6l}{1+\Phi} & \frac{12}{1+\Phi} & -\frac{6l}{1+\Phi} \\ \frac{6l}{1+\Phi} & \frac{2-\Phi}{1+\Phi} l^2 & -\frac{6l}{1+\Phi} & \frac{4+\Phi}{1+\Phi} l^2 \end{bmatrix} \quad (31)$$

where Φ is the ratio between the bending stiffness (EI) and shear stiffness (kGA) of elements based on Timoshenko theory:

$$\Phi = \frac{12 \cdot (EI)}{(kGA) \cdot l^2} \quad (32)$$

For the standard element, the bending stiffness and shear stiffness depend on the material of the segmental ring (concrete), $(kGA) = (k \cdot G_{con} \cdot A)$, k is the shear coefficient based on the Timoshenko theory.

For the joint element, the bending stiffness (EI) can be determined based on Figure 1 and the shear stiffness (kGA) depends on Figure 5 with the relative displacement of segments.

Before the hardening of the slurry, the state of slurry is liquid. The length of the liquid zone is determined by the speed of the TBM excavation v and by the hardening time of slurry t_0 :

$$d = v \cdot t_0 \quad (33)$$

The buoyancy force can be quickly evaluated with the Archimedes' principle based on the specific weight of the slurry γ_{sl} and of the concrete ring γ_{con} :

$$q = \gamma_{sl} \cdot \frac{\pi}{4} \cdot D_e^2 - \gamma_{con} \cdot \frac{\pi}{4} \cdot [D_e^2 - (D_e - 2t)^2] \quad (34)$$

In the FEM model, the influence of the solid slurry and of the surrounding ground can be considered by adding a series of additional springs connected to the nodes in the global stiffness matrix $[K]$ along the main diagonal (Oreste, 2007). The additional terms can be obtained by the following equation:

$$[k_w]_{i,a} = \begin{bmatrix} k_w \cdot l_{av,i} & 0 \\ 0 & 0 \end{bmatrix} \quad (35)$$

where $l_{av,i}$ is the average length of the elements around the node i , and k_w is the spring stiffness considering the stiffness of the solid slurry and of the ground; it can be determined by the following equation (Han et al., 2023c):

$$k_w = \gamma_G \cdot (50 \cdot h_0 - 6.25\pi \cdot D_e) \quad (36)$$

where γ_G is the bulk density of the ground, h_0 is the depth of the tunnel axis from the ground surface.

Based on Equation 8 and Equation 28, the bending stiffness of the joint depends on the bending moment and on the normal force acting on the joint;

the shear stiffness of the joint depends on the relative displacement of segments on the joint. An iterative procedure needs to be adopted to analyse the deformations of the segmental lining along the longitudinal direction.

The FEM model can be calculated on the basis of the following procedure:

Step 1: calculating the moment M_0 and the relative displacement v_0 of each joint considering JBSE equal to 1 and the shear stiffness of the joint at its maximum value;

Step 2: based on Equation 8 and Equation 28, calculating the new bending stiffness and the shear stiffness of each joint, and also the new moment M_1 and the relative displacement v_1 ; furthermore, the new average value of the moment between M_0 and M_1 , and the relative displacement \bar{v}_1 can be obtained;

Step 3: calculating the new bending stiffness and new shear stiffness by Equation 8 and Equation 28, and also the moment M_i and the relative displacement v_i , where $i = 2, 3, 4 \dots$

Step 4: comparing the new moment M_i and relative displacement v_i with the corresponding average values \bar{M}_{i-1} and \bar{v}_{i-1} ; when the biggest differences of the moments and the relative displacements are larger than a specific value, the average value \bar{M}_i and \bar{v}_i can be obtained and substituted into the step 3 and so on; otherwise, finishing the iterative procedure.

3.2 The influence of the circular joint stiffnesses

Based on the developed FEM model, the segmental lining deformation along the longitudinal direction can be obtained for a real case, with an external diameter of the tunnel of 8.5m, a thickness of the lining of 0.4m and a length of the ring 1.6m. The densities of the slurry and of the segmental lining are 1938kg/m³ and 2500kg/m³, respectively; the density of the ground is 1800kg/m³ and the depth of the tunnel from ground surface is 15m. The assumed advancing speed of the TBM is 0.5m/h, and the hardening time of the slurry is 15h. The material and structural parameters of the connecting bolt and of the bolt hole is the same as Table 1 and Table 2. The JBSE and the shear stiffness of the joints along the longitudinal direction are shown in Figure 7 and Figure 8.

From Figure 7, the normal force has a significant influence on the joint bending stiffness. When the normal force is equal to 0, the joint has a low bending stiffness. With the increase of the normal force, the bending stiffness of the joint also increases. However, the distribution of the bending stiffness is not uniform, and the joints close to the fluid slurry zone have low stiffness values. When the normal force is larger than 5MN, only the first joints have a lower bending stiffness than the rings; most of the bending stiffness values of joints are close to the one of the ring.

Based on Figure 8, the shear stiffnesses decrease from the first joint within the fluid slurry zone, and the

Figure 7. The JBSE value of the joint along the longitudinal direction, for different values of normal forces.

Figure 8. The shear stiffness of the circular joint along the longitudinal direction, for different values of normal forces.

values keep as a constant in the solid slurry zone; the normal force has no effect on the shear stiffness. Therefore, the thrust force has a slight influence on the vertical displacements of the segmental lining, while influencing the bending deformation; the fluid slurry zone has a significant effect on the uplift displacement. The influence of the length of the fluid slurry zone is shown in Figure 9 and Figure 10, where the hardening times of slurry are taken 1h, 5h, 10h and 15h separately.

In Figure 9 the joints show a significant displacement than rings: it means that the uplift displacement of segmental linings is caused by the relative displacements of joints in the fluid slurry zone. In Figure 9 the hardening time of the slurry has a significant influence on the vertical displacements of segmental lining. When the hardening time of the slurry is reduced, the buoyancy phenomenon in the liquid slurry decreases (Figure 10): it causes a reduction of the relative displacement of the first joint as shown in Figure 9.

The density of the slurry is another factor affecting the buoyancy phenomenon. The vertical displacement of the segmental lining along the longitudinal direction is shown in Figure 11 with different slurry densities.

From Figure 11, the vertical displacements of the segmental lining along the longitudinal direction

Figure 9. Vertical displacements of the segmental lining for different slurry hardening times varying the distance from the TBM tail.

Figure 10. The shear forces on the segmental lining for different slurry hardening times varying the distance from the TBM tail.

decrease with the decrease of the slurry density in the fluid slurry zone. The reduction of the vertical displacement increases when the density of the slurry varies from 1600 to 1200kg/m³ and from 1200 to 800kg/m³.

Based on the results of Figure 9 and Figure 11, reducing the hardening time and the density of the slurry is a useful technique to decrease the uplift displacement of the tunnel lining.

4 CONCLUSIONS

Focusing on the nonlinear behaviour of segmental lining joints, calculation methods for the bending stiffness and shear stiffness of circular joints are discussed, and the effect of the slurry presence on the segmental lining deformation along the longitudinal direction is analysed.

1. The bending stiffness of joints is discussed, and the a calculation method is developed. The bending stiffness of joints is determined by the normal forces and the moment applied on the joint: the

Figure 11. Vertical displacements of the segmental lining with different slurry densities varying the distance from the TBM tail.

value of the bending stiffness decreases with the increase of the moment.

2. A simplified method for the evaluation of the joint shear stiffness with a single bolt is developed. Considering that the shear stiffnesses of inclined bolts are not uniform, the equation of the shear stiffness of a circular joint is proposed. Based on the calculated results of the shear stiffness, the joint shear stiffness increases with the relative displacement of the joint.
3. Considering the nonlinear behaviour of joints, a FEM model based on the Timoshenko beam theory is introduced and an iterative procedure is adopted to calculate the segmental lining deformation along the longitudinal direction. The FEM model can successfully evaluate the deformation of the rings and the joint separately.
4. Based on the calculated results, the normal force shows an obvious influence on the bending stiffness of joints, but no effect on their shear stiffness. The vertical displacements of the lining are mainly influenced by the relative displacements of the joints. Furthermore, decreasing the hardening time and the density of the slurry the vertical displacements of the segmental lining can be reduced.

ABSTRACT: In Japan, road tunnels are commonly constructed using conventional tunneling methods. For tunnel cross-sections with an internal width of approximately 10 m, the standard specification includes the application of 30 cm thick unreinforced concrete using the cast-in-place method for the permanent lining. Cast-in-place unreinforced concrete has been established as a standard specification owing to its affordability and consistent quality assurance. Recently, precast permanent linings have been considered to accelerate construction and enhance quality under specific condition. However, in terms of load-bearing performance, the effects of the joint structure, joint location, and number of joints between precast slabs on the failure mechanism and structural capacity of the lining have not been fully clarified. Accordingly, evaluating these effects at the design stage is difficult. In this study, we conducted full-scale lining loading tests using two types of precast permanent linings with different joint structures and an unreinforced concrete permanent lining. In the experiment, we considered the failure mechanism and load-bearing capacity of the precast permanent lining compared with those of the cast-in-place unreinforced concrete permanent lining.

1 INTRODUCTION

In Japan, road tunnels are commonly constructed using conventional tunneling methods. According to the Technical Standards of Road Tunnel and its Explanation (For Structure) (2003), cast-in-place unreinforced concrete with a design thickness of 30 cm is commonly applied in sections with an inner width of approximately 10 m and where no external forces other than self-weight are expected. These specifications were not determined through performance assessments but have become assumed standards for typical sections for two-lane road tunnels based on past construction records and the cost-effectiveness and consistent quality of unreinforced concrete. In tunnels in which construction satisfying the above specifications has been conducted in standard sections, instances of significant deterioration in structural stability during the operational period are extremely rare. Therefore, despite not being determined through performance assessments, specifications for conventional lining work can ensure the load-bearing capacity and other performance criteria.

Recently, precast lining work in some cases in Japan has been one of the factors considered to improve the speed of construction. However, the adoption of precast lining work in mountain tunnels in Japan is very rare, and the impact of joint structures, joint positions, and the number of joints between precast sections on the failure mechanism and structural strength of the lining has not been fully elucidated.

In this study, we conducted large-scale loading tests using two types of precast lining work with different joint structures to understand the mechanical properties of precast lining work, including load-bearing capacity and failure mechanisms, in comparison with conventional lining work.

2 OUTLINE OF THE LINING STRUCTURE

2.1 Case 1 Cast-in-place reinforced lining

Figure 1 shows an overview of the full-scale specimen as previously reported (Ishimura et al., 2017). The specimen had a plain cross-section with no joints

*Corresponding author: kikuchi-k573ck@pwri.go.jp

or changes in lining thickness. The lining thickness was 300 mm, and the outer diameter was 9700 mm. The design uniaxial compressive strength (UCS) of the concrete was 18 N/mm². A typical lining used in Japanese road tunnels was assumed in this case.

Figure 1. Overview of specimen (case1).

2.2 Case 2 precast lining consisting of two pieces

Figure 2 shows an overview of the full-scale specimen as previously reported (Fujiwara et al., 2023). It consisted of two symmetrical pieces with one joint at the crown. The lining thicknesses were 140 mm for the general section, 200 mm for the joint, and 196 mm for the foot section. The outer diameter remained constant at 9480 mm.

Figure 2. Overview of specimen (case2).

Figure 3. Joint structure (case2).

Figure 4. Reinforcement arrangement (case2).

Figure 3 shows the joint structure as previously reported (Tatsumi et al., 2023). The joints were connected to the plates and nuts using M24 bolts from the ends, whereas the right and left pieces were interlocked. The connecting hole for the bolt insertion was

fabricated from a $\phi 48.6$ mm SD345 hollow steel pipe. The tightening torque was 100 Nm and the initial state of the structure was similar to a pin with a small rotational spring value. A rubber plate 5 mm thick was placed on the contact surface of the piece.

Figure 4 shows the reinforcement arrangement. The designed UCS of the concrete was 60 N/mm². The main reinforcement consisted of eight SD345-D16 bars on the interior and exterior surfaces, and the SD345-D13 bars were placed inside the main reinforcement at a pitch of approximately 250 mm. The joints were thickened on the inside surface by approximately 85° to 95°, and the main bars on the inside were straight members without curvature. The legs were cast with a no-shrink mortar and a designed UCS of 80 N/mm² after the specimens were installed to avoid weak areas owing to differences in the UCS.

2.3 Case 3 precast lining consisting of three pieces

Figure 5 presents an overview of the full-scale specimens. It consisted of three pieces with joints at 20° and 110°. The designed lining thickness was 170 mm.

Figure 5. Overview of specimen (case3).

Figure 6. Joint structure (case3).

Figure 7. Reinforcement arrangement (case3).

Figure 6 shows a schematic of the joints. The joints were bolted together using M20 bolts at two points on the outer surface of the specimen. Each specimen was fastened with an axial force of approximately 20 kN. The contact surfaces of the frame were smooth.

Figure 7 shows the reinforcement arrangement. The designed UCS of the concrete was 40 N/mm². The main reinforcement consisted of six SD345-D19 bars on the inside and outside surfaces, and the SD345-D13 bars were placed inside the main reinforcement at

a pitch of approximately 250 mm. For the legs, a no-shrink mortar with a designed UCS of 80 N/mm² was placed after the specimens were installed to avoid weak areas owing to the UCS differences.

3 OUTLINE OF THE EXPERIMENT

3.1 Outline

Figure 8 shows a schematic of the test equipment. This full-scale equipment could load a specimen of the same size as the general section of a two-lane road tunnel in Japan. Seventeen hydraulic jacks with a loading capacity of 2000 kN were installed on the reaction wall at a 10° pitch. Each jack was capable of load, displacement, and springing control. The springing control maintained a constant spring and could simulate arbitrary ground reaction forces.

Figure 8. Overview of test equipment.

In the experiments, the loading type was designed to simulate the passive earth pressure acting on the crown under conditions in which a sufficient ground reaction force could be applied. First, as a preliminary loading, the loading jacks were loaded in stages of up to 40 kN/jack under full jack load control to ensure the stability of the equipment and specimen by maintaining close contact between the loading jacks and specimen and a constant hydraulic pressure. Each specimen was subjected to an axial force equivalent to its weight. Subsequently, the 80°, 90°, and 100° jacks were forced to displace the specimen to the inside by 0.5, 0.8, and 0.5 mm at a loading rate of 1–2 mm/min per step as the main loading. The jacks, except the loading jacks, were spring-loaded, and the spring constant was set to 400 kN/mm. According to Specifications for Highway Bridges: Part IV Substructures (2017), this provides a ground deformation coefficient of approximately 500 MN/m².

During the experiment, we measured the reaction force and stroke of each jack, circumferential strain on the interior and exterior surfaces of the specimen, circumferential strain of the main reinforcement approximately the joints, and the amount of joint opening. In addition, the cracks on the specimen surface were visually observed and recorded between loading steps.

In addition, we simultaneously prepared cylindrical test specimens while casting the full-scale test specimen. The properties of the concrete obtained through uniaxial compression tests conducted on the day of load testing are listed in Table 1. The average values for each piece of the precast lining are shown.

Table 1. Properties of concrete.

		CASE1Cast-in-place unreinforced lining	CASE2Two-piece pre-cast lining	CASE3Three-piece precast lining
UCS	(N/mm ²)	25.4	70.4	68.3
Tensile Strength	(N/mm ²)	2.0	3.9	3.9
Young's Modulus	(kN/mm ²)	19.3	36.3	36.5
Poisson's Ratio	-	0.15	0.20	0.19

3.2 Calculation method of M-θ for joints

A schematic of the measurement conditions near the joint is shown in Figure 9. The rotation angle θ of the joint was calculated using the measurement results of the gap width installed on the upper and lower surfaces of the joint according to Design Standards for Railway Structures and Commentary (Shield Tunnel) (2022).

The bending moment (M) of the joint was first calculated by determining the bending strain from the strain measurements of the inner and outer main bars near the joint, both to the left and right of the center of the joint. Subsequently, the second moment of the area of the equivalent section about the axis at the center of the section (h/2) was calculated using the Young's modulus ratio (n). These values were used to calculate M of each structural element, which was then averaged to estimate the bending moment of the joint.

However, because we did not consider the softening of the Young's modulus, the calculated bending moment may have been larger than the actual value when the nonlinear range was reached. Additionally, under the assumption of plane-stress conditions, the value became approximate when the deformation or failure of the section increased such that the assumption of plane-stress conditions no longer held. Note that both the rotation angle and bending moment were calculated using the initial values set at the initial step of the applied load.

3.3 Evaluation method for the load-bearing performance of lining

To assess the load-bearing capacity and failure mechanisms of the linings, we focused on two distinct aspects: local damage, such as tensile cracking

and compressive failure, and the ultimate limit state at which the entire lining becomes destabilized.

Regarding the local damage, we examined the variations observed on the surface of the lining, such as cracks and crushing, and focused on the applied load values at which these occurred, locations of damage initiation, and number of affected areas. For the overall structural destabilization, we defined the maximum load as the load-bearing capacity of the entire lining structure and used it to evaluate the load-bearing capacity.

4 EXPERIMENTAL RESULTS

4.1 Case 1 Cast-in-place unreinforced lining

Figure 10 shows the relationship between the applied load (the total of three load jacks) and crown displacement (post-unloading steps are omitted). As the displacement increased, the applied load increased linearly. Tensile cracking initially occurred on the inner surface at the top and then on the outer surface of the shoulder at relatively low load levels. Subsequently, compressive failure occurred in reverse order, beginning with the outer surface at the top and then the inner surface of the shoulder, reaching an overall load-bearing capacity of approximately 2400 kN.

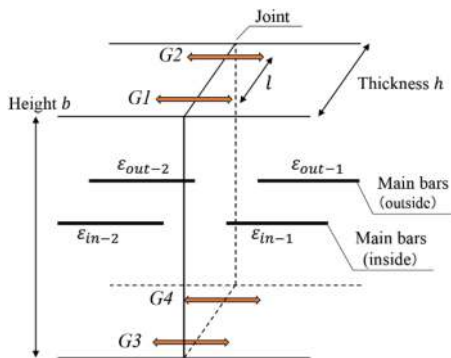

Figure 9. Schematic diagram of the measurement.

Figure 10. Load-displacement curve.

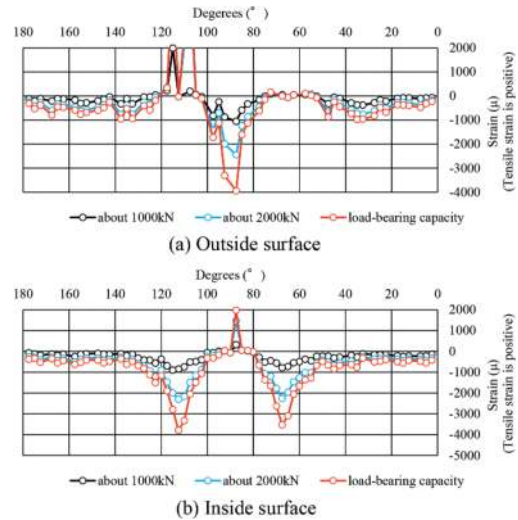

Figure 11. Strain distribution.

Figure 12. Load-displacement curve.

Figure 11 shows the circumferential strain distributions on the inner and outer surfaces when reaching approximately 1000 and 2000 kN, respectively, and the overall load-bearing capacity. At the crown, both the concrete and main reinforcement were in a state of full cross-sectional compression. On the outer surface at the crown and the inner surface of the shoulder, compressive strains of approximately -3000μ to -4000μ were observed, whereas tensile strains were observed on the opposite sides, and all other sections were in a state of full compression. Thus, we inferred that the axial forces developed uniformly and bending moments occurred at the crown and shoulder sections, leading to bending compressive failure and ultimately resulting in the attainment of the overall load-bearing capacity of the structure.

4.2 Case 2 Two-piece precast lining

Figure 12 shows the relationship between the applied load (the total of three load jacks) and crown displacement (post-unloading steps are omitted). As the displacement increased, the applied load increased linearly. Tensile cracking occurred on the outer

shoulder surface at approximately 500 kN, after which no significant damage was observed. At approximately 2400 kN, the load-bearing capacity was reached, spalling occurred near the crown surface, and the displacement gauge fell off. Shortly thereafter, cracks resembling compression were observed on the inner surface at approximately 85° – 95° , accompanied by spalling of the lining surface, resulting in a decrease in load.

Figure 13 shows the condition near the crown after unloading, and Figure 14 shows the condition of the main reinforcement. Cracks resembling compression cracks were observed on both the inner and outer surfaces near the crown, along with spalling. On the upper surface, cracks with a width of approximately 10 mm developed horizontally from the center of the steel pipe, with the concrete covering the inner side detached. When the detached concrete was removed from the inner surface of the test specimen, we confirmed that the main reinforcement near 90° – 95° had deformed inwardly into a convex shape.

Figure 15 shows the M- θ curve in the joint area. As the load increased, the stiffness approached its maximum value, and a significant increase in the slope occurred at approximately 35 mrad. This was considered to be due to the closure of the gaps between the contact surfaces at approximately 35 mrad, along with the increased transmission of axial forces and bending moments caused by the structure. After the onset of crushing and spalling near the joint, the reliability of the measured values decreased, and we considered them as reference values because of their unloading-induced behavior.

Figure 13. Condition of the failure joint.

Figure 14. Condition of the main reinforcement failure.

Figures 16 and 17 show the circumferential strain distribution in the concrete and main reinforcement at approximately 1000 and 2000 kN

Figure 15. Moment-rotation curve.

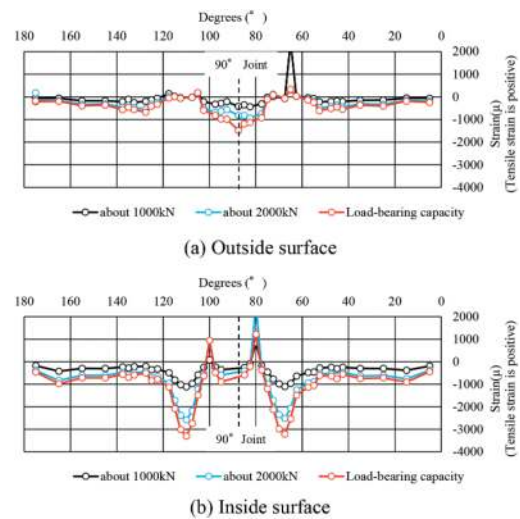

Figure 16. Strain distribution.

and the load-bearing capacity. At the crown section, both the concrete and main reinforcement were in a state of full cross-sectional compression. In the shoulder section, bending compression occurred with tensile strain on the outer surface and compressive strain on the inner surface. In sections other than the crown and shoulder, both the inner and outer surfaces exhibited small compressive strains, indicating complete compression. On the outer surface of the concrete, a significant tensile strain was measured at approximately 1000 kN. However, it decreased in subsequent steps owing to the stress relief caused by the occurrence of cracks approximately the strain gauge. Additionally, the yield strain calculated from separate tensile tests of the steel reinforcement was approximately 1900μ , suggesting that the steel reinforcement had not reached the yield point according to the strain measurements inside the test specimen.

From the above observations, we can infer that the axial compression forces developed uniformly in the test specimen with the application of load, and bending moments occurred in the shoulder section.

Near the crown, the lining remained in a state of full compression with minimal bending moments, eventually resulting in the compression failure of the concrete near the crown and spalling of the steel reinforcement owing to deformation; thus, the overall load-bearing capacity was attained. Compared with the cast-in-place unreinforced lining in Case 1, the following common points were identified:

- The load-bearing capacity was approximately similar.
- Near the shoulder section, axial forces and bending moments were generated, resulting in bending compression, whereas from the foot to the shoulder, small axial compression forces were generated, resulting in full compression.

However, differences were also noted:

- In the two-piece precast lining, the overall load-bearing capacity was reached through buckling of the main reinforcement and spalling of the covered concrete near the crown joint. However, note that the shoulder section also experienced strains close to the ultimate strain, suggesting it was in a state approaching cross-sectional failure.

4.3 Case 3 Three-piece precast lining

Figure 18 depicts the relationship between the applied load (total of three load jacks) and crown displacement. The load–displacement relationship was approximately linear but exhibited two peaks: approximately 2550 kN (the first peak) at approximately 37 mm of displacement and 2600 kN (the second peak) at approximately 46 mm of displacement. At relatively low loads, tensile cracking occurred on the inner surface of the crown and outer surface of the shoulder at 70°. From approximately 2300 kN to the first peak, cracks were observed in the concrete, indicative of compressive failure on the inner surface of the shoulder at 110° and spalling.

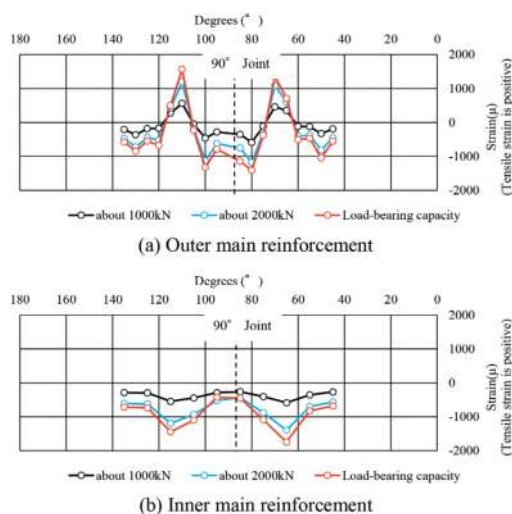

Figure 17. Strain distribution.

Near the second peak, spalling of the covered concrete on the outer surface at 110°, buckling of the main reinforcement, and spalling of the inner concrete surface occurred, resulting in a decrease in the load.

Figure 19 shows the conditions near the shoulder after unloading. The outermost main reinforcement deformed near 115° with spalling of the covered concrete. While deformation of the inner side reinforcement was not observed, spalling of the covered concrete was evident. Furthermore, cracks considered to be caused by compression were detected on the outer surface of the crown, which were not visible during the experiment because of the load plate.

Figure 20 shows the M- θ curve in the joint area. For the joint at 110°, changes in slope occurred at approximately -4 and -12 mrad. Up to approximately -4 mrad, was considered to be due to axial force introduction and the fitting of the test equipment to the test specimen. A constant negative bending moment slope was observed up to approximately -12 mrad. However, beyond this point, it remained relatively constant at approximately -20 mrad. The step at approximately -12 mrad coincided with the step in which signs of crushing were observed on the inner surface near 110°. In other words, the behavior of the joint was considered to change owing to cross-sectional failure. Beyond this point, the reliability of the measured values decreased, possibly because of the partial spalling of the bottom displacement gauge near the first peak; thus, we considered them as reference values.

For the 20° joint, the deformation was considered to be small. Compared with the 110° joint, the bending moment was approximately 1/2, the rotation angle was approximately 1/10, and the joint was under full compression.

Figures 21 and 22 show the circumferential strain distributions in the concrete and main reinforcement at approximately 1000, 2550 (first peak), and 2600 kN (second peak). Please note that, because of the positioning of strain gauges, values from certain locations that could not be accurately obtained have been omitted. The strain in the outer surface of the concrete near 110° exhibited a slight tensile strain up to the first peak but transitioned to compression at the second peak, indicating full cross-sectional compression. At 20°, both the concrete and main reinforcements were in a state of full compression. The inner surface of the concrete at 90° exhibited almost no strain, but the main reinforcement exceeded its yield point under tension. Numerous longitudinal tensile cracks on the concrete surface from the early stages suggested a decrease in strain owing to the stress relief caused by concrete surface cracking.

At 70°, both the concrete and main reinforcement were in a state of bending compression. Except for the crown and shoulder sections, all other sections exhibited full compression.

From these observations, we inferred that with the application of the load, the axial compression forces developed consistently throughout the test specimen. In the joint area near 110°, bending compression was

Figure 18. Load–displacement curve.

Figure 19. Condition of the failure joint.

Figure 20. Moment–rotation curve.

observed until the first peak, followed by full compression. Ultimately, the concrete compression failure and deformation of the steel reinforcement resulted in spalling, causing structural instability. However, deformation may have occurred in weak areas at locations where the load plate served as a fulcrum and did not provide support, which may not be the case in scenarios with the anticipated ground reactions.

Compared with the cast-in-place unreinforced lining in Case 1, the following common points were identified:

- The load-bearing capacity was approximately similar.

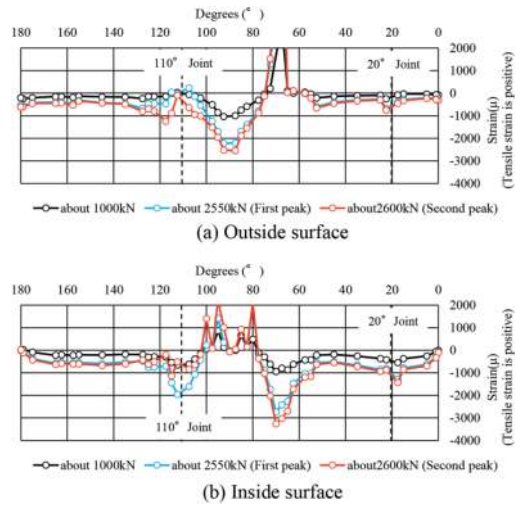

Figure 21. Strain distribution.

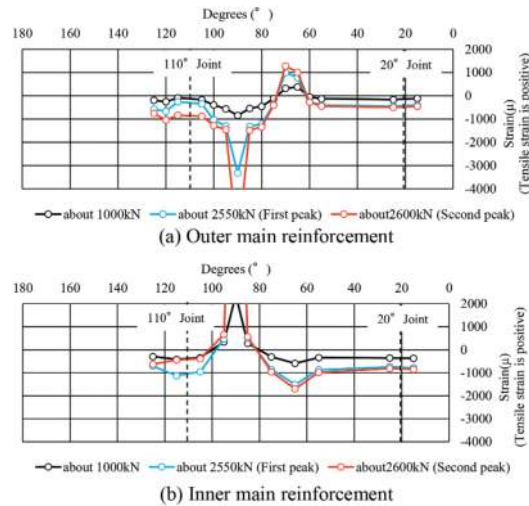

Figure 22. Strain distribution.

- Axial forces and bending moments were generated at the crown and shoulder sections until the first peak with bending compression, whereas small axial compression forces were generated from the foot to the shoulder, resulting in full compression.
- A decrease in load owing to bending compression failure occurred at the crown and shoulder sections (represented by the first peak).

However, the following differences were also noted:

- The three-piece precast lining exhibited two peaks in the load.
- The second peak was determined by the buckling of the main reinforcement and the spalling of the covered concrete near the joint area at 110°.

4.4 Consideration of the failure mechanism

In the cast-in-place unreinforced lining, under relatively small loads, tension cracks appeared on the inner surface of the crown and outer surface of the shoulder. Subsequently, section failure occurred on the outer surface of the crown and inner surface of the shoulder, ultimately affecting the overall load-bearing capacity of the structure. Both axial forces and bending moments were generated in the crown and shoulder regions, resulting in flexural-compressive failure. The final load-bearing capacity was approximately 2400 kN.

Although the presence or absence of tensile cracks in the precast lining varied depending on the joint position, it exhibited failure mechanisms similar to those of cast-in-place unreinforced linings. The final load-bearing capacity of the entire structure was approximately 2400–2600 kN, which was equivalent to that of a cast-in-place unreinforced lining. However, unlike the cast-in-place unreinforced lining, where the load decreased shortly after the flexural-compressive failure in the shoulder region of the concrete, in the precast lining near the joints, both rebar buckling and spalling of the cover concrete caused a reduction in load. The failure patterns observed in these cases closely resembled the seismic damage in reinforced concrete bridge piers (Figure 23), and we speculated that they shared a similar mechanism. Based on the Specifications for Highway Bridges: Part V Seismic Design (2017), for reinforced-concrete bridge piers, a method for investigating the failure mechanism was established by comparing the axial force exerted on the reinforcing bars with the resistance of the cover concrete, as shown in Figure 24 (Maekawa et al., 2003). We are currently exploring an investigative approach for assessing the spalling of cover concrete and buckling of reinforcing bars observed in precast linings. The following were the estimated failure mechanisms of the precast lining:

Stage 1: In both experiments, the joint structures were relatively resistant to the generation of bending moments compared with the general section of the specimen. Consequently, the influence of the axial forces became significant, resulting in a state of full cross-sectional compression.

Figure 23. Seismic damage (Hanshin Expressway Management Engineering Center et al., 2020).

Figure 24. Failure mechanism.

Stage 2-1: For the two-piece precast lining, the joint section (90°) was displaced inward as a load was applied. The main reinforcement on the inner surface of the crown, which initially had a straight configuration, gradually deformed inward owing to the influence of bending moments. This deformation resulted in the development of axial compression forces.

Stage 2-2: For the three-piece precast lining, as the load was applied, the curvature of the main reinforcement in the joint section (110°) increased. After the first peak, the lining reached a state of full compression and axial compression forces developed in the steel reinforcement.

Stage 3: The force exerted by the deformed main reinforcement on the convex side pushing against the covered concrete exceeds the resistance of the covered concrete and causes it to spall.

Stage 4: With a reduction in the effective cross-sectional area, both the buckling of the steel reinforcement and the compressive failure of the concrete on the opposite side occurred almost simultaneously.

The phenomena in Stages 3 and 4 significantly affect the overall load-bearing capacity of the structure and are considered critical for determining the limit state of the lining.

5 CONCLUSION

In this study, we conducted full-scale load tests on two types of precast concrete linings with different joint structures and compared them with the cast-in-place unreinforced lining commonly used in Japan. Thus, we assessed the mechanical performance, including the load-bearing capacity and failure mechanisms. The following are the conclusions of this study:

- Under conditions where a ground reaction force of approximately 500 MPa can be expected around the perimeter, in the assumed loading scenario considering the uplift loads, the load-bearing capacities of the two-piece precast and three-piece precast linings used in this study were approximately comparable to that of the cast-in-place unreinforced lining. Furthermore, we confirmed that the axial forces and bending moments in the crown and shoulder areas followed a failure mechanism similar to that of a cast-in-place unreinforced lining.
- The joints of the two types of precast lining exhibited different results in terms of their maximum rotational angles and $M-\theta$ slopes due to differences in their structures and positions. However, we observed that M and θ were approximately proportional, and the joint area tended to fail almost simultaneously with the load-bearing capacity of the lining.
- The bending moments of the precast lining joints were reduced, resulting in an overall state of compression. As a result, compressive forces dominated the main reinforcement with curvature, resulting in

deformation and forces that pushed out the cover concrete. This phenomenon exceeded the resistance of the cover concrete and caused spalling.

- The spalling of the cover concrete significantly affected the load-bearing capacity of the entire structure under the experimental conditions and for the targeted precast linings.

In the lining design, from a stress calculation perspective, placing the main reinforcement away from the centroid is advantageous. However, when the cover concrete is thin and compressive action occurs from the convex side to the inner side, cover concrete spalling may occur. On the side facing the ground, resistance can be expected owing to the ground; however, on the inner side, the resistance may not be reliable. Therefore, the inspection method proposed in this paper for the inner side design should be considered when setting member cross-sections.

Generally, the rotational spring constant increases with the introduction of axial compressive forces. Therefore, the $M-\theta$ curve obtained in this study may not be applicable under certain loading conditions for the same joint configuration.

Future research will involve numerical analysis to reproduce the failure mechanisms and investigate inspection methods related to the spalling of cover concrete considering axial compressive forces.

Development and application of highly adaptable lining equipment for complex tunnels with variable sections

Jinshu Liu*

China Railway Construction Heavy Industry Corporation Limited, Changsha, China

ABSTRACT: Aiming at the requirements from the complex construction scenarios and working conditions of tunnels with variable sections such as alternating large and small sections, right-angle turns and small entrances, a brand-new highly adaptable lining equipment is developed to solve the problems of existing tunnel lining equipment such as low assembly efficiency, long transition period, and high labor intensity. By studying the method for rapid assembly of trolley formwork, the mode is changed from the installation of fragmented small formwork to the overall installation of pre-assembled large modules, and auxiliary installation devices as module lifting mechanism are innovatively designed, so as to realize the automatic lifting in narrow spaces in tunnel. The equipment, in fabricated gantry structure, is equipped with automatic rail feeding device and traversing mechanism to realize automatic rail feeding in tunnels with alternation of variable sections and right-angle turns in tunnel, thus effectively shortening the transition time in tunnel. As compared with traditional construction equipment, the assembly cycle is shortened from 15 days to 7 days, and the number of constructors is decreased from 10 to 6.

Keywords: rapid assembly, lifting mechanism, automatic rail feeding, right-angle turns in tunnel

1 INTRODUCTION

In recent years, the tunnel construction in China has developed rapidly. As an important part of tunnel construction, secondary lining directly affects the stability of tunnel structure and traffic safety. The secondary lining construction has gone through the stages of manual formwork erection, manual formwork setting up, fully hydraulic lining trolley and intelligent lining trolley. The first lining trolley was introduced in China as early as 1978, and was initially applied to Dayaoshan Tunnel of Beijing-Guangzhou Railway. At present, lining trolley has been widely used in the construction of national key projects such as railways, highways and hydraulic engineering [1]~[4].

The digitalization and automation of lining is a hot topic in current study. The experts and scholars as well as benchmarking enterprises in China have carried out a large number of studies. Dong Wanlong et al [5] studied the trolley positioning technology to solve the walking problem in small-radius curved tunnels; Wang Baiquan [6] studied the control system of intelligent trolley to effectively realize automatic control and real-time monitoring of pouring process; Ji Haidong et al [7] developed a new

digital lining trolley for pressurized pouring tunnel, realizing the mold grouting, high-frequency vibration and digital control.

Aiming at the problem of obvious change in section size in the process of tunnel construction, Liu Yunzhu [8] designed a lining trolley for tunnels with variable sections to adapt to 5 different tunnel sections; Ren Wenbin [9] designed a lining trolley for variable sections of super-large section tunnels, which can meet the adaptive design of sections in 14.5 m to 25 m; Li Feng [10] studied the key elements of design and manufacture of lining trolley for variable sections, and achieved good economic benefits; Xue Jiansong et al [11] focused on the influence of formwork connection hinge points on the change of trolley sections in combination with the characteristics of variable sections of Lanzhou-Chongqing Railway.

The current research mainly focuses on the intelligent design of lining trolley for railway and highway tunnels and the adaptive design of large-section tunnels with variable sections. The existing lining trolley cannot meet the special needs in tunnel construction such as narrow spaces, varied section shapes and many right-angle turning branches. Therefore, it is urgent to design a highly adaptable lining equipment

*Corresponding author: liujinshu@crchi.com

for the lining of complex tunnels with variable sections to solve the problems existing tunnel lining equipment such as low assembly efficiency, long transition period and high labor intensity.

2 OVERALL DESIGN OF HIGHLY ADAPTABLE LINING EQUIPMENT

2.1 Structural composition and parameter design of highly adaptable lining equipment

In order to meet the needs of secondary lining operation for special tunnels with variable complex small sections, a brand-new lining equipment with high adaptability is developed, which is capable of adapting to tunnels with variable sections and has the functions of crossing small-section tunnels and right-angle turns. Its main structures include traveling system, gantry assembly, formwork assembly and auxiliary installation device, as shown in Figure 1, with the performance parameters as shown in Table 1.

Figure 1. Structure diagram of highly adaptable lining Equipment.

Table 1. Performance parameters of highly adaptable lining equipment.

S/N	Parameter	Technical Indicator
1	Adaptable section size 1	Clear span: 5.5 m; arch camber height: 4.5 m
2	Adaptable section size 2	Clear span: 6 m; arch camber height: 5 m
3	Section type	1/4 arch
3	Lining thickness	350mm
4	Single covering length	6m+6m
5	Top formwork removal stroke	200mm
6	Travel drive	Track-type traveling, gradeability $\geq 6\%$
7	Deformation of side formwork	$\leq 2\text{mm}$
8	Deformation of top formwork	$\leq 1\text{mm}$

2.2 Traveling system

The traveling system device is the power unit for movement of the whole vehicle, consisting of active traveling box, driven traveling box, traversing mechanism and track. The traveling motor realized the traveling by driving the chain to rotate the running wheel through a reducer, where a sprocket and a drum are connected outside the output shaft of the reducer. During traveling, the bottom oil cylinder jacks up the whole machine, the track is suspended, the wire rope is pulled by the drum to automatically drive the track to move forward; then the bottom oil cylinder is retracted, and the whole machine is lowered onto the track to realize the forward positioning of the whole machine. In order to meet the requirements of covering tunnel sections with different track elevations, heightening joints are set above the running box and below the traversing device in the traveling system.

2.3 Gantry assembly

The gantry assembly is the main supporting structural member of the formwork, bearing the mass of concrete and formwork during pouring. In order to ensure a rapid transition in tunnel, the gantry assembly is designed as split type and consists of two symmetrical 6 m unit modules, each of which can be separately assembled into a trolley in 6 m long. During a transition, by splitting the gantry, the trolley in 12 m long can be split into two symmetrical trolleys in 6 m long each.

In order to meet the requirements of internal traffic space, the gantry is equipped with a swing-type rotating cross brace, which realizes rapid swing and connection through the swing pin shaft and self-locking lead screw mechanism and supports stress. In the covering, the cross brace rotates to the middle position and the screw rod rotates tightly to bear the lateral pressure transmitted by the formwork on both sides to ensure the rigidity of the overall structure. After covering, it rotates to both sides to make the middle passage open to traffic. Due to the rotational structure of the cross brace, the operation load is small and safe. The section passage space is $\geq 3.3\text{m}$ wide and $\geq 4.2\text{m}$ high.

2.4 Formwork assembly

The formwork assembly is the working face of trolley, mainly consisting of dome assembly, lateral formwork and blocking system. A modular design concept is adopted for the formwork assembly, where both the side formwork and top formwork are of modular design. Different formwork module combinations can be selected during installation to meet the construction requirements of different sections, as shown in Figure 2 and Figure 3.

The dome assembly consists of 10 sets of top modules, each 1.2 m wide. In order to meet the construction requirements of the following 2 sections, as

shown in Table 2. The top formwork is designed as flexible formwork, which can be deformed according to the radian of the framework. Universal formwork

Table 2. Performance parameters of highly adaptable lining equipment.

Specification of dome	Section 1	Section 2
Span/mm	5500	6000
Radius/mm	3437	3750
Springing height/mm	4500	5000

Figure 2. Structural diagram of formwork assembly in 5.5m trolley.

Figure 3. Structural diagram of formwork assembly in 6m trolley.

units can be used for dome with different spans to realize convenient span construction.

The lateral formwork assembly consists of 10 sets of lateral formwork modules, each with a width of 1.2 m. Each set of lateral formwork is assembled by two or more pieces of lateral formwork. A single piece of lateral formwork has the height of 1.5 m, 2.5 m, 3 m etc. They are combined according to different springing heights to realize the design of 5.5m and 6m springing heights. The combination of formwork in 1.5 m and 2.5 m high can meet the springing height of 4m, and the combination of formwork in 1.5 m and 3 m high can meet the springing height of 5 m. The formwork combinations for the two sections are shown as Figures 2 and 3.

2.5 Auxiliary installation devices

In-tunnel auxiliary installation devices include top formwork lifting mechanism and lateral formwork lifting mechanism. The top formwork lifting mechanism consists of winch, pulley block, sliding track, sliding support and lifting platform. Under the action of the winch, the pulley block drives the sliding support to rise and fall on the sliding track through the steel wire rope, thus driving the lifting platform to rise and fall. The top formwork assembly can be lifted from the ground to above the gantry through this lifting mechanism; the lateral formwork lifting mechanism consists of winch, sliding support and sliding track. The sliding track is installed on the top of the gantry, while the winch is installed on the sliding support and can move forward and backward along the sliding track. When lifting the lateral formwork, the winch wire rope bypasses the pulley of the dome framework to lift the side formwork upward. They can effectively improve the automation in tunnels with narrow sections.

Figure 4. Schematic diagram of lifting in tunnel.

3 STRUCTURAL ANALYSIS OF HIGHLY ADAPTABLE LINING EQUIPMENT

3.1 Determination of boundary conditions

The trolley mainly bears the lateral pressure of concrete, the dead weight of concrete and the dead weight of structure. Of them, the top formwork bears the dead weight of concrete and structure, which is mainly directly connected to the section, and the side formwork mainly bears the lateral pressure of concrete. As shown in Figure 5.

3.2 Lateral formwork pressure

The lateral pressure of concrete acting on the formwork is increased with the pouring height of concrete. Where the pouring height reaches a certain critical value, the lateral pressure will no longer be increased. At this time, the lateral pressure is the maximum lateral pressure, as shown in Figure 6.

Figure 5. Schematic diagram of trolley stress.

Figure 6. Schematic diagram of lateral formwork pressure.

$$P_0 = \min \left\{ \begin{array}{l} 0.22\gamma_c t_0 \beta_1 \beta_2 v^{\frac{1}{2}} \\ \gamma_c H \end{array} \right. \quad (1)$$

Where

p_0 —Lateral pressure of newly poured concrete on the formwork, in KN/m²

γ_c —Gravity density of concrete, in 25KN/m³

t_0 —Initial setting time of newly poured concrete, taken as 5h

β_1 —Correction coefficient of admixture influence, taken as 1

β_2 —Influence coefficient of concrete slump, taken as 1.15

v —Concrete pouring speed, in m/h

H —Total height from the position for the calculation of lateral pressure to the top surface of newly poured concrete

A - Concrete pouring area

In consideration of the concrete impact load and the concrete pouring speed, a safety factor of 1.2 is taken, and the lateral pressure of concrete is calculated as follows:

$$P_1 = 1.2P_0 \quad (2)$$

Thus the effective head height is calculated h_c

$$h_c = \frac{P_1}{\gamma_c} \quad (3)$$

The lateral formwork load is mainly subject to the concrete pressure, as shown in Figure 6, with its load calculation formula as below:

$$F = AP \quad (4)$$

The lateral pressure of concrete at the upper section of lateral formwork is calculated first, the load on which section is variable.

For section h ,

$$F_1 = (P_1 + P_2)/2 \times (h \times w) \quad (5)$$

For section H-h, the lateral pressure is unchanged and subject to a load as below:

$$F_2 = P_1 \times (H - h) \times W \quad (6)$$

In conclusion, the total lateral formwork load is calculated as below.

$$F = F_1 + F_2 \quad (7)$$

3.3 Finite element analysis

In addition to their own gravity, the vault and lateral formwork bear uniformly distributed loads, and the bottom of the model releases the degrees of freedom in the span direction. The trolley is made of material Q345, with the material parameters as shown in Table 3.

The load of formwork is determined according to Section 3.1. In consideration of the dead weight and concrete weight, the formwork system is calculated with finite element calculation software, with the calculation results as shown in Figures 7, 8 and 9. The stress of the gantry assembly bears the reaction force of the formwork system and the dead weight of the gantry assembly. The reaction force of the formwork is extracted to analyze the stress of the gantry, with the calculation results as shown in Figures 10 and 11.

Table 3. Design of Q345 material parameters.

S/N	Parameter	Value
1	Density ρ /(t/mm ³)	7.85e-9
2	Elastic modulus E (MPa)	2.1e5
3	Poisson's ratio μ	0.3
4	Yield strength σ_s (MPa)	345
5	Allowable stress for weld: $0.8*\sigma_s$ /(MPa)	276

Figure 7. Stress nephogram for finite element analysis of formwork assembly.

Formwork Assembly

Figure 8. Displacement nephogram for finite element analysis of formwork assembly.

Figure 9. Displacement nephogram for finite element analysis of dome assembly.

The overall maximum stress of the formwork assembly model is 251 MPa, with the overall stress below 45 MPa. The local concentrated stress of the gantry assembly is 230 MPa, with the overall stress

Figure 10. Stress nephogram for finite element analysis of gantry assembly.

Figure 11. Displacement nephogram for finite element analysis of formwork assembly.

lower than 150 MPa. The maximum deformation of lateral formwork, top formwork and gantry is 1.7m, 0.9mm and 8mm respectively, meeting the design requirements.

4 RAPID INSTALLATION AND VERIFICATION OF HIGHLY ADAPTABLE LINING EQUIPMENT

4.1 Quick installation method

4.1.1 Modular installation

In order to improve the trolley installation efficiency, a method for overall installation of pre-assembled large modules is developed, wherein the top formwork is divided into 10 unit modules, and each single module is assembled on the ground to form the dome module. The dome module is lifted to the top of the gantry by the top formwork lifting mechanism, and then pulled to the set position to complete the assembly and connection of 10 top formwork modules in turn, as shown in Figure 12.

After the top formwork is installed, it is necessary to connect the lateral formwork with the shoulder of the top formwork. The top formwork unit is designed with a lateral formwork winch, which can quickly complete the connection between the lateral formwork and the shoulder of the top formwork with manual assistance, greatly improving the installation efficiency and reducing the intensity of manual operations.

Figure 12. Schematic diagram of trolley installation process.

4.1.2 Trolley formwork removal

The formwork removal process is shown in Figure 13. After the completion of pouring, the plugging, foot formwork, lead screw and bottom corner cross beam are removed to control the shrinkage of lateral formwork and shoulder formwork cylinder, so that the removal of lateral formwork is completed. The jacking oil cylinder of the gantry is controlled to shrink, and the dome is lowered, so that the formwork removal of the dome is completed. The maximum stripping stroke of lateral formwork is 200mm, and the maximum stripping stroke of top formwork is 170mm.

Figure 13. Schematic diagram of formwork removal process of trolley.

4.1.3 Small-radius right-angle turns

A trolley in 12 m long is divided into two trolleys in 6 m long each, and each single trolley can independently turn in a tunnel for walking and covering construction. Before a turning, the lifting mechanism, walking platform, block and other related components are removed. When turning, the trolley in 6 m long first travels to the middle of an intersection and turns through reverse actions of the traversing devices at both ends of the trolley, where a 90° turn is completed by about 57 actions with the single cycle turning angle of 1.6°. The second trolley in 6 m long, after completing a turn in the same way, is

Figure 14. Schematic diagram of trolley splitting.

Figure 15. Schematic diagram of a right-angle turning in tunnel by a 6m trolley.

connected with the first trolley and is combined into a trolley in 12 m for covering construction in situ. The small-radius right-angle turning process is shown as Figure 14 and Figure 15.

4.2 Engineering verification

The equipment was applied for the first time in a construction site, with good construction results achieved, and has now been popularized to many construction sites. As compared with ordinary trolley, the number of installers is decreased from 10~12 to 6~8, the installation time is shortened from 15 days to 7 days. The on-site installation of a trolley is shown as Figure 11. The installation time of each component in the 6-person team is shown as Table 4.

Figure 16. Schematic diagram of trolley installation.

Table 4. Statistics of installation time for each component.

S/ N	Component installed	Ordinary trolley	Highly adapt- able lining equipment
1	Track, traveling mechanism and lower longitudinal beam	1	0.5
2	Gantry and connecting beam	1	0.5
3	Lifting mechanism and lateral shifting mechanism	1	0.25
4	Lateral formwork cleaning and lateral formwork lead screw	4	1
5	Top formwork skeleton	5	0.5
6	Lateral formwork		
7	Adjustment of clearance and dislocation of top formwork	2	2
8	Installation of vibrating system	0	0.5
9	Action debugging and trolley positioning	1	0.5
10	Total	15	5.75

5 CONCLUSIONS

It has been verified that the highly adaptable lining equipment can effectively meet the requirements from the complex construction scenarios and working conditions of tunnels with variable sections such as alternating large and small sections, right-angle turns and small entrances.

By designing the combination of flexible formwork and modules, two different tunnel sections in 5.5 m and 6 m can be realized, which only requires replacing two sets of top formwork and one set of lateral formwork, thus ensuring the economy of lining construction.

The dome module is pre-assembled on ground and lifted to the top of the gantry in groups to realize an overall modular installation of the structure, effectively reducing the material cleaning and transportation time, and greatly improving the installation efficiency of lining equipment in narrow tunnels.

The development of automatic auxiliary installation devices effectively solves the challenge of rapid lifting in narrow spaces. Only loaders are required to assist in installing the gantry for the trolley installation in tunnel, and no other auxiliary equipment is needed, reducing the manual labor intensity, decreasing the number of installers and saving the installation time.

Aiming at the challenge of small-radius right-angle turning of complete vehicles at T-shaped and cross-shaped tunnel intersections, a trolley in 12 m long is designed into two trolleys in 6 m each that can be quickly split and merged. Each section is iteratively deflected by a traversing mechanism to quickly realize right-angle turning in narrow spaces. During a transition, there is no need to disassemble the whole machine device, and it can quickly pass through complex sections, solving the problem of long transition period of traditional lining trolley, realizing automatic track feeding and right-angle turning in tunnels with alternation of variable sections, and effectively shortening the transition time in tunnel.

China Railway Economic and Planning Research Institute Co., Ltd., Beijing, China

ABSTRACT: The maximum excavation span of the Badaling long-span tunnel on the Beijing-Zhangjiakou Railway is 32.7m. The initial support force is mainly provided by prestressed anchorage cable, prestressed anchor, and shotcrete. Combined with the anchor cable arching effect, suspension effect, confining pressure effect, and span reduction effect, the mechanism of anchor cable action in the Badaling long-span tunnel is analyzed, and the safety factor is obtained. Based on the bearing arch theory, a method for designing the supporting structure of a “one injection and double anchor” tunnel is proposed. The results show that the prestressed anchorage cable can provide effective anchoring force before the load-bearing arch is completed and reduce the displacement of the vault. The calculated displacement of the vault is 0.3mm; Under the suspension and arching action of prestressed anchorage cables, the Badaling long-span tunnel has been verified to have safety factors of 2.5, 8.83 and 4.62 respectively; Put forward the design method of “one injection and double anchor” support structure, the support effect is effectively guaranteed, and the safety reserve is high. The research method provides a reference for the design of tunnel supporting structure.

1 INTRODUCTION

Anchor rods (cables) have been widely used in tunnel engineering and have become an important component of anchor spray support. Due to the complexity of the anchor rod anchoring system medium and the diversity of anchor rod forms, there is no unified theory on the mechanism of anchor rod anchoring. At home and abroad, the mechanism of bolt action is studied from the following two aspects. The first aspect is based on the load transfer mechanism of bolt, especially the bond stress distribution and load transfer mechanism between bolt and grouting body, grouting body and surrounding rock. On the other hand, the mechanism of bolt action is studied from the reinforcement effect of anchorage body.

Starting from the engineering practice, it is not the ultimate goal to obtain the maximum anchoring force by the load transfer mechanism of the anchor rod. While ensuring the safety of the project, striving to be economical and rapid is the primary goal in engineering practice. Effective and reasonable use of anchoring force in engineering, that is, from the perspective of reinforcement effect to study the mechanism of bolt action.

Predecessors have put forward the theory of bolt suspension, composite beam and composite arch. Dong put forward and discussed the theory of loose circle support, the classification method of loose circle surrounding rock and bolt-shotcrete support. After a lot of measurement work, Freeman put forward the theory of bolt center point and expounded the concepts of pull-out section and anchorage section of full-length bonded bolt. Zou studied the

*Corresponding author: liujianyou2008@qq.com

working mechanism of bolt in different rocks and discussed the influence mechanism of mechanical parameters of different rock masses through simulated block test. Through indoor test and theoretical analysis, Hou studied the strengthening effect of bolt support on the peak strength and residual strength of rock in the anchorage range, and analyzed the control degree of anchorage body on the plastic zone and fracture zone of surrounding rock.

Based on the Badaling large-span tunnel, this paper analyzes the mechanism of prestressed anchor cable in super-large-span tunnel, and puts forward the safety factor of Badaling large-span tunnel under suspension and arching. Based on the theory of tunnel bearing arch, the design method of super large section tunnel with ‘one spray double anchor’ as the main supporting structure system is established. The research method provides a reference for the design of anchor cable support for super-large-span tunnels.

2 SUPPORTING SYSTEM OF SUPER-LARGE-SPAN TUNNEL

The ‘Code for Design of Railway Tunnels’ (TB10003-2016) defines the tunnel span classification, and defines the tunnel with an excavation span greater than 14 m as a super-large-span tunnel, but there is no classification for super-large spans. Here we define the tunnel with a span greater than 18 m as a super-large-span tunnel. In the railway industry, super-large-span tunnels are mainly used in railway tunnels or underground stations with three or more lines.

There are two main design ideas of tunnel support system:

- (1) Rigid support system based on secondary lining. This kind of support system takes the secondary lining concrete as the main bearing structure, emphasizes the bearing role of the secondary lining, and ignores the role of primary support such as shotcrete and bolt. Because the bolt is a hidden project, the construction quality is difficult to detect, and the construction effect is difficult to evaluate. Therefore, in the actual construction of tunnels in China, the designed bolt is often not implemented, resulting in most of the tunnels in China mainly relying on the support of the secondary lining.
- (2) Flexible support system based on bolting and shotcreting. This kind of support system uses shotcrete, anchor, anchor cable, grouting and other means to reinforce the surrounding rock, and forms a surrounding rock bearing arch around the tunnel to bear the main load of the tunnel. The supporting system makes full use of the self-bearing effect of surrounding rock, and emphasizes the role of anchor rod in the design and construction process.

For medium and small span tunnels, the rigid support system based on secondary lining can meet the requirements of tunnel stability. However, for super-

large-span tunnels over 18 m, the bending moment caused by the weight of the secondary lining itself is very large, and the actual bearing effect is very small. If the rigid support system based on the secondary lining is still used, the designed secondary lining structure will be very thick, resulting in huge engineering waste.

Therefore, in the super-large-span tunnel of Badaling Great Wall Station of Beijing-Zhangjiakou High-speed Railway, we propose a new support structure system for super-large-span tunnels with 32.7 m grade V surrounding rock-prestressed anchor mesh shotcrete shell self-bearing support structure. The main support measures of the support system are as follows:

- (1) Steel frame: $\Phi 22$ grid steel frame 150×160 mm, spacing 0.8m;
- (2) Shotcrete: 35cm thick;
- (3) Ordinary anchor: mortar anchor with a diameter of 25 mm and a length of 6 m, with a circumferential spacing of 2.4 m and a longitudinal spacing of 0.8 m, is used to reinforce the surface surrounding rock;
- (4) Prestressed anchor bolt: 32mm in diameter, 11m long prestressed anchor bolt, circumferential spacing of 1.2m, longitudinal spacing of 0.8m, tension design value of 100kN, used to reinforce shallow surrounding rock;
- (5) Prestressed anchor cable: anchor cable length of 25 m, ring, longitudinal spacing of 2.4 m, prestressed design value of 700kN and 1000kN, used to reinforce deep surrounding rock;
- (6) Secondary lining: 60 cm thick molded reinforced concrete lining structure, the main reinforcement is HRB500 steel bar with a diameter of 28 mm and a spacing of 20 mm, as a safety reserve.

Figure 1. Supporting system of super-large-span tunnel.

3 THE ACTION MECHANISM OF ANCHOR CABLE IN SUPER-LARGE SPAN TUNNEL

The action mechanism of anchor cable in super-long-span tunnel includes: suspension effect, span reduction effect, confining pressure effect and arching effect.

3.1 Suspension effect of anchor cable

In the super-large span tunnel, the suspension effect of the anchor cable is mainly manifested in two aspects: the suspension effect on the bearing arch of the surrounding rock and the suspension effect on the unstable block.

(1) Suspending effect on bearing arch of surrounding rock

In the super-long-span tunnel, the reinforcement effect of ordinary mortar anchor and prestressed anchor will form a bearing arch of surrounding rock around the tunnel. However, this bearing arch can only play a bearing role after the excavation of the tunnel is completed and the construction of the anchors of each arch ring is completed. This is similar to the segment of the shield tunnel. Only after the segment is completely assembled to form a closed loop, the segment can play a bearing role.

The arch rings excavated in the super-long-span tunnel are equivalent to the segments of the shield tunnel. The construction process of the ordinary anchor bolt and the prestressed anchor bolt is equivalent to the production process of the segments, and the role of the prestressed anchor cable is to suspend the arch rings before each arch ring is arched to stabilize each arch ring, as shown in Figure 1. Therefore, the prestress F_1 of the anchor cable should be greater than the weight of each arch ring, that is:

$$F_1 = \frac{G_1}{n} \quad (1)$$

Where, G_1 is the weight of arch ring; n is the number of anchor cables on the arch ring.

Figure 2. Suspension effect of prestressed anchor cable.

(2) The suspension effect on unstable blocks

The unstable block of tunnel surrounding rock is a possible sliding block formed by the cutting of structural planes such as joints and cracks in surrounding rock. The larger the span of the tunnel, the larger the scale of the unstable block that may be formed, and the smaller the stability coefficient of the block. At this time, the role of the anchor cable is to ensure that the unstable block does not slide during the tunnel excavation through the suspension effect.

Therefore, the prestress F_2 of the anchor cable can be calculated according to the following formula:

$$F_2 = \frac{G_2 - Q_2}{n_2} \quad (2)$$

Where, G_2 is the weight of unstable block; Q_2 is the frictional resistance of the structural plane to prevent the block from sliding down; n_2 is the number of anchor cables acting on unstable blocks.

3.2 Span reduction effect of anchor cable

The prestressed anchor cable is equivalent to increasing the elastic support on the tunnel surface, and the prestress of the anchor cable is equivalent to the support reaction force. Taking the surrounding rock in a certain range around the tunnel as an arch member to bear the load of surrounding rock, a series of anchor cables can be regarded as a series of supports. The span of the bearing arch of the surrounding rock of the super-long-span tunnel will be reduced from the span L_0 of the tunnel to the spacing L_1 of the adjacent anchor cables, and the stress system of the long-span tunnel will be transformed into a multi-support continuous beam. The span reduction effect of anchor cable can effectively reduce the stress and deformation of rock strata and improve the bearing capacity of surrounding rock bearing arch.

The load structure model can be used to calculate the influence of the span reduction effect of the anchor cable on the deformation and stress of the bearing arch, as shown in Figure 3. The bearing arch of surrounding rock formed by ordinary anchor bolt and prestressed anchor bolt is taken as the concentrated load of simply supported arch beam structure. Under the action of vertical load q , horizontal load kq and prestress F_3 of anchor cable, the settlement s of bearing arch vault is affected by the following parameters:

$$s = f_1(q, k, F_3, L, H, E_m) \quad (3)$$

Where, q is the vertical load; k is the horizontal load coefficient; F_3 is the anchor cable prestress; L is the tunnel span; H is the height of the tunnel; E_m is the deformation modulus of the bearing arch rock mass.

The above calculation model can also be used to calculate the anchor cable prestress F_3 required to meet the requirements of vault settlement control.

In addition, during the excavation of super-large-span tunnels, various temporary vertical and horizontal supports are often used to divide the super-large-span tunnels into several small-section tunnels for construction, such as CD, CRD, double-sided drift method and other conventional construction methods. Due to the influence of temporary support, large machinery is difficult to unfold, resulting in a significant reduction in the construction efficiency of super-large-span tunnels.

The span reduction effect of anchor cable can replace the temporary support structures such as middle partition wall and temporary cross brace of these conventional construction methods. By adopting anchor cable support and canceling temporary support, the mechanized excavation of large section of super large span tunnel can be realized, and the safety and work efficiency can be improved.

Figure 3. Span reduction effect of anchor cable in large span tunnel.

Figure 4. Computation module.

3.3 The confining pressure effect of anchor cable

The prestress of the anchor cable acts on the surface of the tunnel surrounding rock, so that the tunnel bearing arch changes from a two-way stress state to a three-way stress state. The prestress of the anchor cable provides a confining pressure for the tunnel bearing arch, thereby improving the compressive strength of the rock mass in the bearing arch and also improving the bearing capacity of the bearing arch.

The confining pressure σ_3 of the tunnel wall includes the prestress of the anchor cable F_4 , the prestress of the anchor bolt F_b , the support force p_s of the grille steel frame and the shotcrete, and the support force p_c of the secondary lining concrete.

$$\sigma_3 = \frac{F_4}{s_1 \cdot s_2} + \frac{F_b}{s_{b1} \cdot s_{b2}} + p_s + p_c \quad (4)$$

Where, F_4 is the prestress of prestressed anchor cable; s_1 and s_2 are the ring and longitudinal spacing

of the anchor cable respectively; F_b is the prestressing force of the bolt; s_{b1} and s_{b2} are the ring and longitudinal spacing of the bolt, respectively.

The compressive strength σ_m of rock mass can be calculated according to the following formula.

$$\sigma_m = \sigma_3 \left[\tan\left(\frac{\pi}{4} + \frac{\varphi_r}{2}\right) \right]^2 + 2C_r \cdot \tan\left(\frac{\pi}{4} + \frac{\varphi_r}{2}\right) \quad (5)$$

Where, σ_m is the compressive strength of the rock mass in the bearing arch; C_r is the cohesion of rock mass; φ_r is the internal friction angle of rock mass.

Figure 5. The confining pressure effect of anchor cable.

3.4 Improvement effect of anchor cable

The improvement effect of anchor cable on surrounding rock is mainly reflected in the following four aspects:

- (1) The anchor cable connects the rock blocks in the bearing arch together, which improves the integrity of the rock mass in the bearing arch.
- (2) The prestress of the anchor cable can make the joint fissure of the rock mass close, increase the normal stress on the joint surface, and improve the shear strength of the structural surface.
- (3) The grouting during the construction of the anchor cable will fill the gap of the rock mass, thus improving the cohesion and internal friction angle of the structural plane.
- (4) When the structural plane slides through the anchor cable, the anchor cable grouting body and the anchor cable steel strand need to be cut off, so as to improve the cohesion C_r and internal friction angle φ_r of the rock mass in the bearing arch, and improve the compressive strength σ_m of the rock mass in the bearing arch. As shown in (6).

$$\sigma_m = \sigma_3 \left[\tan\left(\frac{\pi}{4} + \frac{\varphi_r}{2}\right) \right]^2 + 2 \left[C_r + \frac{\sin \varphi}{s_1 s_2} f_v A_s + f_{cv} A_{cs} \right] \tan\left(\frac{\pi}{4} + \frac{\varphi_r}{2}\right) \quad (6)$$

Where, A_s is the cross-sectional area of anchor cable steel strand; A_{cs} is the cross-sectional area of anchor cable grouting body; f_v is the shear strength of steel strand; f_{cv} is the shear of grouting body; φ is the angle between anchor cable and structural plane.

Figure 6. Improvement effect of anchor cable.

3.5 Arching effect of anchor cable

After all the construction of the anchor cable is completed, the tension at both ends of the anchor cable diffuses according to the stress diffusion line of 45°, and a larger bearing arch is formed around the tunnel. The thickness d_b of the bearing arch can be calculated according to the following formula.

$$d_b = L_f - 0.5 \frac{r + L_f}{r} s_1 \quad (7)$$

Where, L_f is the length of the free section of the anchor cable; s_1 is the circumferential spacing of the anchor cable; r is the curvature radius of the tunnel wall.

Assuming that the vertical load outside the arch of the anchor cable is q , the horizontal load is kq , the tunnel span is L , and the tunnel height is H , the axial force R of the bearing arch is:

$$R = \frac{kq(H + d_b)}{2} + \frac{q(L + d_b)^2}{8(H + d_b)} \quad (8)$$

The safety factor of the bearing arch K is:

$$K = \frac{\sigma_m \cdot d_b}{R} = \frac{8\sigma_m \cdot d_b(H + d_b)}{4kq(H + d_b)^2 + q(L + d_b)^2} \quad (9)$$

According to formula (7), the bearing arch thickness d_b required to meet the safety factor K of the bearing arch can be calculated, and the length of the free section of the anchor cable can be calculated according to formula (5).

Figure 7. Arching effect of anchor cable.

4 DESIGN METHOD OF PRESTRESSED ANCHOR CABLE

The design of anchor cable mainly includes the design of anchor cable prestress, spacing, length (free section length and anchorage section length) and other parameters, as well as the design of anchor cable structure.

4.1 Design of pre-stressing force of anchor cable

According to the action mechanism of anchor cable in super-large span tunnel, the design of anchor cable tension must meet the following requirements:

In order to ensure the stability of the surrounding rock of the tunnel during the construction process, the prestress F_d of the anchor cable should be greater than the prestress F_1 and F_2 required for the suspension effect of the anchor cable, refer to formulas (1) and (2).

$$F_d > \max(F_1, F_2) \quad (10)$$

The design of prestressed anchor cable in the large span section of Badaling tunnel is based on the theory of prestressed anchor bearing arch. The thickness of bearing arch is determined by combining the three hinged arch model and the design parameters of prestressed anchor bolt. The compressive strength of rock mass in bearing arch is calculated by the method of 'one spray double anchor', and the safety

factor is used to verify the safety and reliability of supporting structure design.

4.2 Prestressed anchor cable supporting theory

The pre-stressed anchor cable support technology is developed on the basis of the pre-stressed technology. The in-depth study of the anchoring technology improves the theoretical system of the pre-stressed anchor cable support. Bolt support theory has suspension theory, bearing arch theory, surrounding rock loose circle theory, composite beam theory, etc., among which only suspension theory and bearing arch theory can provide support design parameters. The load-bearing arch theory is suitable for relatively thick layered rock strata, and the load-bearing arch with certain strength is formed within the anchorage range of the anchor cable. Therefore, the bearing arch theory of prestressed anchor cable is used as the theoretical basis for the support design of Badaling large-span transition section tunnel.

Table 1. Design parameters of prestressed anchor cable tension for large-span tunnel of Badaling underground station.

Anchor cable tension design	5 core anchor cable	7 core anchor cable	Explanation
Design reference value / kN	300	400	According to the requirements of surrounding rock stability control, the minimum tension of anchor cable needs to be provided. When it is less than this value, it is necessary to make up the anchor cable or take other alternative measures. The minimum allowable value of anchor cable monitoring.
Design tension value /kN	490	700	Locking value of anchor cable tension construction
Design target value /kN (Tension design value)	700	1000	After the excavation of the tunnel is completed, the expected target value of the anchor cable tension when the surrounding rock deformation is stable is determined according to the deformation of the surrounding rock and the stress characteristics of the anchor cable. When the anchor cable is detected, the

(Continued)

Table 1. (Continued)

Anchor cable tension design	5 core anchor cable	7 core anchor cable	Explanation
Design limit value/kN	1040	1450	detection standard is 1.2 times of the value. The ultimate tension value of the anchor cable used in the design of the anchor cable is 80 % of the anti-pulling force of the anchor cable. The maximum allowable value of anchor cable monitoring.
Pullout strength of anchor cable / kN	1302	1822	The maximum tension value provided by the anchor cable is the minimum value of the holding force between the steel strand and the grouting body, the cohesion between the grouting body and the surrounding rock, and the tensile strength of the steel strand.

Note: (1) When the anchor cable is detected, the detection standard is 1.2 times of the design target value of the anchor cable tension; (2) When anchor cable monitoring, anchor cable tension measured value should be greater than the design reference value, less than the design limit value.

4.3 Three-hinged arch model

As shown in Figure 4, it is assumed that the section of the prestressed anchor reinforced bearing arch structure is a three-hinged arch, the vertical load is q , the horizontal load is kq , and k is the ratio of horizontal stress to vertical stress. The vault O is taken as the origin, the arch height is H , the arch span is L , $P(x, y)$ is any point on the left half arch, OP is taken as the detachment body, and the bearing arch is assumed to be a reasonable arch axis. The arch side wall can be obtained, and the vault axial force is:

Figure 8. Three hinged arch stress model.

$$R_{\text{sidewall}} = \sqrt{\left(\frac{qL^2}{8H} - \frac{kqH}{2}\right)^2 + \left(\frac{qH}{2}\right)^2} \quad (11)$$

$$R_{\text{vault}} = \frac{kqH}{2} + \frac{qL^2}{8H} \quad (12)$$

4.4 The joint action of one anchor and two sprays

Under the combined action of prestressed anchor bolt, prestressed anchor cable and shotcrete, the formula of confining pressure strength is:

$$\sigma_3 = P_b + P_a + P_s \quad (13)$$

$$[\sigma_c] = \sigma_3 \cdot \tan^2\left(45^\circ + \frac{\phi_g}{2}\right) + 2C_g \cdot \tan\left(45^\circ + \frac{\phi_g}{2}\right) \quad (14)$$

Where, P_b is the pre-stressed anchor support force (kpa); P_a is the supporting force of prestressed anchor cable (kpa); P_s is the shotcrete support force (kpa).

σ_c is the compressive strength of rock mass in the bearing arch; C_g is the cohesion (kpa) of medium-hard rock or soft rock after grouting improvement; ϕ_g is the internal friction angle of medium hard rock or soft rock after grouting improvement.

According to the joint support effect of one anchor and double spray, the safety factor is checked to judge the support effect of prestressed anchor cable design parameters.

$$d_b = L_1 - 0.5 \frac{r+L_1}{r} s_1 - 0.5s_1 \quad (15)$$

$$K_{\text{sidewall}} = \frac{[\sigma_c] \cdot d_b}{R_{\text{sidewall}}} \quad (16)$$

$$K_{\text{vault}} = \frac{[\sigma_c] \cdot d_b}{R_{\text{vault}}} \quad (17)$$

Where, K_{sidewall} is the safety factor of the side wall; K_{vault} is the safety factor of the vault; d_b is the thickness of the bearing arch; L_1 is the length of the free end of the prestressed anchor; s_1 is the circumferential spacing of the anchor; r is the radius of curvature of the tunnel wall.

The safety factor of the primary support structure of the prestressed anchor cable under different stresses is shown in the following figure:

According to the settlement results, the safety factor 1.15 is taken as the critical value, that is, when the prestress of the anchor cable is attenuated to 400 kN, the safety factor of the initial support structure is 1.15, and the prestress of the anchor

Figure 9. The safety factor curve of primary support structure under different stress of anchor cable.

cable 400 kN is the minimum prestress of the anchor cable detection. Therefore, in the actual construction, when the anchor cable prestress is less than 400 kN, other engineering measures need to be taken to make up for the loss of anchor cable prestress. When the anchor cable prestress is greater than 400 kN, it can be considered that the anchor cable structure is effective, and other engineering measures are not considered. The design parameters of anchor cable prestress are shown in Table 2.

Table 2. Design parameters of anchor cable prestress.

Anchor prestress	Prestress value/kN	Safety factor
Minimum	400	1.15
Stretch locking value	700	1.19
Design value	1000	1.22

5 CONCLUSIONS

Through the analysis of the mechanism of anchor cable in Badaling large-span tunnel, the arching effect, suspension effect, span reduction effect and confining pressure effect of anchor cable on large-span tunnel are studied. Based on the bearing arch theory, a design method suitable for super-long-span tunnels with 'one spray and two anchors' as the main supporting structure system is established, and the following main conclusions are obtained:

- (1) The prestressed anchor cable can effectively provide the anchoring force, reduce the vault displacement and improve the mechanical parameters of the surrounding rock before the bearing arch is not closed. After the prestressed anchor cable is completed, the vault displacement is calculated to be 0.3mm.
- (2) The supporting effect of prestressed anchor cable in Badaling large-span tunnel is effectively guaranteed. Under the action of prestressed anchor cable suspension and arch formation, the safety factors of Badaling large-span tunnel are verified to be 2.5, 8.83 and 4.62 respectively.

- (3) Based on the bearing arch theory, the design method of “one spray double anchor” support structure is proposed. Considering the safety factor of the primary support structure, the safety and reliability of the prestressed anchor cable are proved.

ABSTRACT: High stiffness supporting structure is difficult to cope with the large deformation problem of soft surrounding rock tunnel effectively, safely, and economically. This paper presents a kind of orthogonal flexible support structure (OFSS) for soft surrounding rock tunnels, which has the advantages of low damping, large travel, and high compressibility. Field application results show that: 1) the OFSS gives full play to the role of absorbing surrounding rock deformation and releasing surrounding rock pressure; 2) The OFSS ensures the tunnel safety limit, no spalling of concrete, steel frame yield phenomenon; 3) The OFSS has obvious advantages in construction safety and economy. The research results provide a new idea and method for the treatment of large deformation of similar soft surrounding rock tunnels, which is of great engineering and theoretical value.

Keywords: Soft rock tunnel, Large deformation, Energy principle, Orthogonal flexible support structure, Case study

1 INTRODUCTION

When the tunnel passes through the high ground stress and weak surrounding rock strata in the western region of China, it is very easy to produce serious large deformation disasters, which will not only lead to the damage and intrusion of the supporting structure, increase the safety risk, but also lead to the repeated input of supporting materials, the soaring construction cost and the delay of the construction period (Wang et al., 2012; Chen et al., 2017; Yang et al., 2017; Li et al., 2018; Kang et al., 2022; Zhang et al., 2023). The new Languang railway has a total length of 492km and a tunnel length of 343km, among which the tunnels containing soft rocks such as carbonaceous slate and carbonaceous phyllite, such as the Muzaling tunnel et al., have a total length of 83km. Under the influence of high ground stress and strong geological structure, serious large deformation of weak surrounding rock occurred in tunnel construction, with the maximum radial deformation reaching meter level, resulting in

deformation and destruction of supporting structure, which greatly increased the construction safety risk, delayed construction progress, and increased construction cost (Zou et al., 2010; Sun et al., 2012; Wu et al., 2013; Zhao et al., 2014; He et al., 2014; Huang et al., 2014; Wu et al., 2014; Huang et al., 2016; Li et al., 2017). The newly built Lixiang railway is located in the fault zone formed by the collision and accumulation of the Eurasian plate and the Indian Ocean plate. The Zhongyi tunnel et al., along the line, are subjected to the intense compression action of large-scale geological structures, resulting in great tectonic stress, crushing, and metamorphism of surrounding rock and joint fissure development. During construction, large deformation of weak surrounding rock occurred continuously, with the maximum horizontal convergence deformation of 87cm on one side and the maximum uplift of the bottom plate reaching meter-level, resulting in deformation, damage, and erosion of the initial supporting structure, which required multiple disassembly and replacement, seriously affecting normal construction

*Corresponding author: liuyangtunnel@my.swjtu.edu.cn

safety and construction schedule (Li et al., 2018; Yan et al., 2019a, b; Deng et al., 2020; Gan et al., 2020; Li et al., 2021; Li et al., 2022). Therefore, large deformation of weak surrounding rock will be one of the key technical problems plaguing tunnel construction in western China (Cheng et al., 1997; Wang et al., 2008; Wang et al., 2010; Sun et al., 2015; Chang et al., 2015).

Through a large number of tunnel construction practices, we have accumulated a wealth of experience in dealing with large deformation of soft surrounding rock tunnels, but there has been no breakthrough in the study of weak surrounding rock tunnel support design theory and supporting construction methods. The problem of large deformation is encountered in the construction of soft surrounding rock tunnels, and the construction site is always difficult and slow in the process of “implementation-destruction-disassembly” of the cyclic supporting structure, resulting in a serious delay in the construction period, eventually becoming the key control problem of the whole tunnel and even the whole line. The reasons are as follows:

First, theoretical research on tunnel support design of weak surrounding rock is seriously backward. The current tunnel design specifications still regard the theory of loose pressure based on collapse arch as the guiding principle for tunnel design and construction. However, this is different from the pressure mechanism generated by the plastic deformation extrusion support structure of weak surrounding rock in large deformation tunnels. Moreover, it is inconsistent with the surrounding rock pressure distribution law obtained from the field measurements of a large number of tunnel projects with large deformation of the weak surrounding rock. In addition, the large eccentric tensile failure mode of supporting structure under loose load also runs counter to the small eccentric compressive shear failure mode shown in a large number of tunnel projects with weak surrounding rock (Qiu et al., 2017).

Second, the weak surrounding rock tunnel support design concept is backward. At present, when encountering the phenomenon of large deformation in the weak surrounding rock tunnel in China, the mainstream support design concept is “early support and strong support”.

A large number of weak surrounding rock tunnel engineering cases shows that “early support and strong support” often cannot effectively solve the problem of large deformation. The final stable state of the tunnel comes from the full release of surrounding rock pressure after repeated disassembly of damaged supporting structures. After accumulating a lot of experience in soft rock large deformation tunnels, people gradually realize the correctness and necessity of the support design concept which is different from “early support and strong support” and allows the surrounding rock to produce a certain deformation to release the surrounding rock pressure.

Based on the principle of energy, this paper carries out the design and field application of the

orthogonal limit energy dissipation support system based on the large deformation control project of a weak surrounding rock tunnel in western China. The research results will provide new ideas, new theories, and new methods for the design and construction of tunnel support with similar weak surrounding rock and large deformation, which has great engineering and theoretical significance.

2 CASE BACKGROUND

The tunnel in this paper is located in Aba County, Aba Prefecture, Sichuan Province (Figure 1), which is a one-way two-lane highway tunnel. The strike of the tunnel is 124° , the length is 5564m, and it is a very long tunnel with a maximum buried depth of 357m.

Figure 1. Tunnel site.

2.1 Geological condition

The tunnel is located in the mountainous plateau, and the mountain spreads from south to north. Geological data show that the strata of the tunnel are interbedded with strong-medium weathering metamorphic sandstone and slate, and the main mineral components are quartz, feldspar, and mica. Due to the influence of regional structure and fracture, the surrounding rock exposed by actual excavation is easily weathered and broken to form sheet rocks or cuttings, showing typical phyllite characteristics, with soft lithology, easy slime and softening in water, expansion, and creep, and extremely poor engineering geological conditions. The maximum main stress of the tunnel measured by the hydraulic fracturing method is 11.15MPa. The surrounding rock exposed by excavation is shown in Figure 2.

2.2 Large deformation status

The initial support design of the tunnel is a Z5d composite lining of V-class surrounding rock. 50m after construction, due to the serious deformation and damage of the initial support, the support design was changed to Da composite lining.

To more accurately grasp the deformation and failure status of the tunnel, this paper used the three-

Figure 2. The surrounding rock exposed by excavation.

dimensional laser scanning technology to carry out the initial support deformation monitoring for section DK75+157~DK75+167 of Da composite lining.

The monitoring results are shown in Figure 3. Cool colors mean that the deformation has not exceeded the limit, whereas warm colors mean that the deformation has exceeded the limit. As shown in Figure 3, varying degrees of invasion have been generated throughout the monitoring section. Among them, the invasion at the left waistband is the most serious, exceeding 60cm, while the invasion at the right waistband is relatively light, generally ranging from 0~30cm. The deformation of the initial support has entered a state of slow convergence.

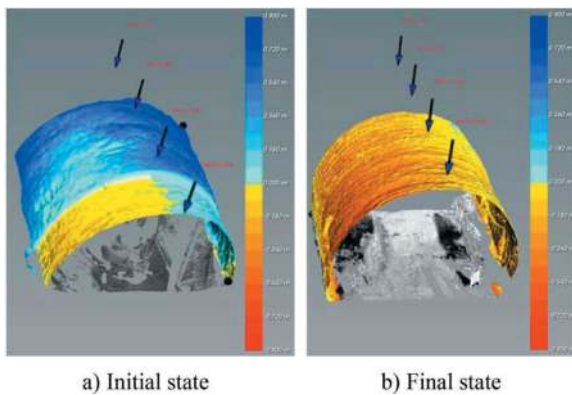

Figure 3. The deformation monitoring result.

The deformation and failure status of the initial support observed on-site is shown in Figure 4.

The deformation and failure rule of the initial support shows that the support structure has compressive shear failure under the deformation pressure of the surrounding rock.

Figure 4. The deformation and failure status of the initial support.

3 ORTHOGONAL FLEXIBLE SUPPORT SYSTEM

3.1 Energy type support principle

The energy released by a large deformation tunnel is constant from the excavation to the final stable state. The basic equation is given below:

$$W = F \times S \quad (1)$$

Where W is work, F is force and S is displacement. Eq. (1) shows that, when the W is constant, there are infinite solutions for F and S . The strength design concept uses the support structure with high-stiffness to provide strong supporting resistance. The deformation of the surrounding rock is small, and the internal force of the support structure is huge. Commonly used concrete and steel arches are high-stiffness support structures. Even if its thickness and stiffness are increased, it is difficult to suppress the deformation of surrounding rock in the high-situ stress soft rock stratum. On the contrary, the flexible support concept uses a support structure with low

stiffness and high deformability to absorb the deformation of the surrounding rock and release the pressure of the surrounding rock. Figure 5 shows the support process with two different support concepts.

Figure 5. The working process of two support concepts in dealing with the large deformation of the tunnel.

3.2 Field application

According to the results of initial support deformation monitoring in Chapter 2, the orthogonal flexible support design of a large deformation tunnel is carried out by further utilizing the deformation pressure variation characteristics of the surrounding rock, as shown in Figure 6.

Figure 6. OFSS.

The main support parameters of the OFSS are as follows:

- 1) Single-layer initial support, I22b steel frame, spacing 60cm;
- 2) The hoop flexible support components are installed at the left and right arches of the steel frame (30°), with a height of 30cm, and are connected by bolts;
- 3) The radial flexible support components are arranged between the steel frame and the surrounding rock (Arch waist to corner), with a thickness of 80cm on the left and 50cm on the right;
- 4) Using C25 shotcrete, thickness 26cm.

The on-site construction process is shown in Figure 7.

a) Hoop flexible components b) Radial flexible components

c) Left side steel frame d) Right side steel frame

e) OFSS

Figure 7. Construction process of OFSS.

Figure 8. Deformation monitoring result.

The large deformation treatment effect of the orthogonal flexible supporting structure is shown in Figure 8.

Figure 8 shows that no invasion occurs in the whole test section of the OFSS. Further, the typical section is selected to investigate the deformation convergence of each key point, the result is shown in Figure 9.

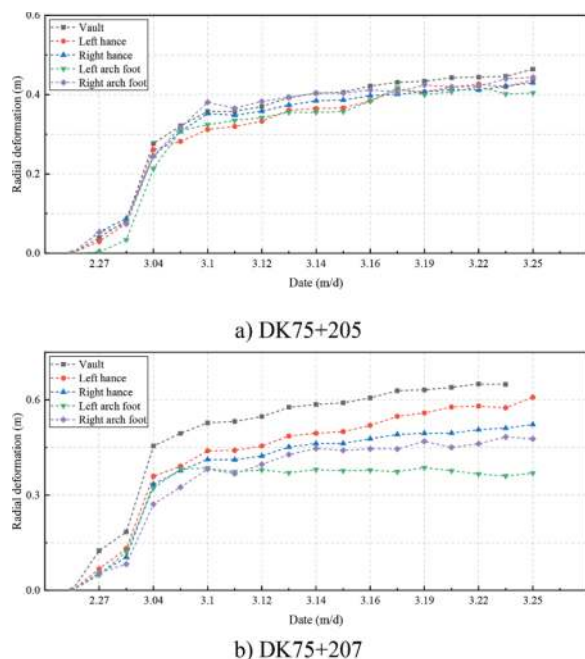

Figure 9. Deformation convergence of typical section.

Figure 10 Shows that key points of the typical section have entered a state of slow convergence.

4 CONCLUSIONS

Aiming at the difficult problem of large deformation treatment of high in-site stress and soft rock tunnels, this study proposes an OFSS based on the energy principle. The related study results are as follows:

- 1) The deformation pressure of surrounding rock acts on the initial support of the large deformation tunnel, rather than the loose load formed by the collapsing rock mass of the arch.
- 2) The OFSS which acts on both the hoop and radial direction of the tunnel is proposed.
- 3) The OFSS effectively solves the problem of large deformation support of soft rock tunnels and has important engineering and theoretical value.

Study on railway tunnel lining anti-crack surface reinforcement strengthening and design method

Zhiqiang Liu* & Xiaofei Xing

China Railway Southwest Research Institute Co., Ltd., Chengdu, China

Lun Gong

School of Civil Engineering of Southwest Jiaotong University, Chengdu, China

ABSTRACT: In order to avoid excessive reinforcement of cracks in plain concrete lining and ensure the stability after crack treatment and reinforcement, this paper proposes a reinforcement measure of protective covering rebars for tunnel lining cracks, and verifies its design method effectiveness. The main conclusions include: (1) a reinforcement measure of protective covering rebars is proposed, and the applicable environmental conditions of protective covering rebars are determined; (2) The reinforcement measure of protective covering rebars is only applicable to reinforcing crack with depth less than $0.5H$; (3) The design process and checking calculation method of reinforcement of protective covering rebars have been put forward; (4) The protective covering rebars can avoid the tensile stress concentration at the crack tip, and play a role in strengthening the structure and restraining the crack development; (5) The case shows that after reinforcement, the safety factor of lining increases from 1.23 to 4.66, and the safety factor of protective covering rebars is 29.79, indicating that the reinforcement of protective covering rebars is effective.

Keywords: Railway tunnels, Cracks, Protective covering rebar, Design method

1 INTRODUCTION

With prolonged service life of tunnels, lining cracking has become one of the major problems that impact safe operation of tunnels^[1-3]. The foreign and domestic experts have conducted research into conditioning of cracked lining.

Taking the Beijing metro project as an example and based on the theory of concrete elastic-plastic damage, Xuan Liu^[7] conducted the mechanical analysis of cracked linings. The analysis results show that the influence of vault crack is remarkable and the crack depth has the most significant impacts on the safety of lining structure.

For example, Wang Hualao et al.^[4] have calculated the lining safety factor of the Anji Tunnel under the effect of longitudinal crack, and proposed the method of plastering mortar to strengthen the cracked plain concrete whose safety factor meets the standards; for the plain concrete that does not meet the standards, I20a@550m+ reinforcing mesh + shotcrete are used for strengthening.

indicate that the W steel belt + reinforcing mesh + shotcrete will allow the safety factor of cracked structure to increase from 0.92 to 2.69, and lap rock-bolt grouting will allow the safety factor of structure to increase from 0.97 to 2.51, thus meeting the standard requirements.

In addition to the aforesaid methods, there are other common crack conditioning techniques such as concrete bushing, corrugated plate bushing, partial replacement and overall replacement^[7-11], and these techniques have been well proven. In practical strengthening design, however, some designers have raised two questions. First, for the defective crack in plain concrete lining, will bushing and replacement result in waste of resources? Second, for a crack that is repaired by plastering or grouting, if the grouting quality is poor or any environmental action causes the lining stress to change, will the crack further propagate? To address these questions, this paper proposes a surface reinforcement strengthening method and its design, to hopefully provide reference and help in improving the effectiveness of conditioning of cracked railway tunnel lining.

2 ANALYSIS OF SURFACE REINFORCEMENT STRUCTURE AND ITS APPLICATION CONDITIONS

2.1 Surface reinforcement structure

Surface reinforcement should preferably be used together with mortar cover and jointed with the lining structure by using anchor bolts, so as to create a member with consistent stress. The structural composition is shown in Figure 3.

Figure 1. Schematic diagram for surface reinforcement structure. (1 - crack; 2 - surface steel bar; 3 - side retaining structure; 4 - reinforcement anchor bolt; 5 - retaining anchor bolt hole; 6 - mortar cover; 7 - lining).

As shown in Figure 3, surface reinforcement is mainly composed of 4 parts, i.e. surface steel bar, side retaining structure, reinforcement anchor bolt and mortar cover. The surface steel bar is the main stress-bearing member and is meant to control crack opening. The side retaining structure and reinforcement anchor bolt are meant to fasten the surface reinforcing mesh, connect the surface reinforcement and lining and allow the surface reinforcement and lining to share the stress. The waterproofing mortar is mainly meant to prevent rusting and maintain durability of surface reinforcement. Surface reinforcement strengthening steps: (1) Clean the lining base surface, apply interface treating agent, and increase base surface bond strength; (2) Use reinforcement anchor bolt to fasten the surface reinforcing mesh composed of the surface steel bars; (3) Fasten and strengthen the side retaining structure; (4) Apply the surface mortar, and form the surface reinforcement structure

2.2 Analysis of application conditions of surface reinforcement

Surface reinforcement is designed to inhibit surface crack propagation and thus achieve crack conditioning. This paper mainly probes into how surface reinforcement will strengthen plain concrete lining. Therefore, surface reinforcement does not play a significant role in improving compressive strength, shear strength and permeation resistance of the structure. If the surrounding rock in the segment to be strengthened has noticeable adverse geological conditions such as flowing deformation or degradation, the stress mode of lining will significantly deviate from the “Code”, and also from the empirical perspective, the lining should be strengthened overall, so strengthening by surface reinforcement is deemed unsuitable in this condition. If strengthening by surface reinforcement is required, the ambient conditions, lining structure and crack defect of the to-be-strengthened segment must meet the following requirements: (1) The ambient strata have no flowing deformation, degradation or adverse geological phenomena; (2) The crack has no concomitant defect of water leakage; (3) Under the load pattern specified by the “Code”, the compressive strength and shear strength of the structure must meet the relevant requirements; (5) The to-be-strengthened segment has no other defects; (4) There is only a single crack that has no tendency of propagation.

2.3 Analysis of depth threshold of crack in strengthening by surface reinforcement

Based on previous experience, if the ambient environmental conditions of the tunnel do not include landslide, soft foundation base, differential settlement or goaf and the load of surrounding rock is loose load or deformation load, the lining stress is dominated by “pressure—bending”. Therefore, if the stress condition is not complex, the depth of crack shows certain pattern. For a plain concrete structure, the engineering experience indicates that the surrounding rock grade is I~IV. This paper mainly examines the pattern of lining crack depth under the load pattern of Grade III and IV surrounding rock. The lining section is from a two-line tunnel of a high-speed railway with design speed 400km/h. The height of the tunnel is 10.98m, its width 14.06m and sectional area 118.80m². The concrete strength of the lining is C35, its ultimate tensile strength 2.4MPa and its ultimate compressive strength 26.0MPa. Lining thickness is 45cm. The lateral pressure coefficient is 0 and 0.3 respectively. The calculated structural crack distribution and third principal stress (S3) are shown in Figure 2 and Figure 3 (q in the figure is the vertical surrounding rock pressure).

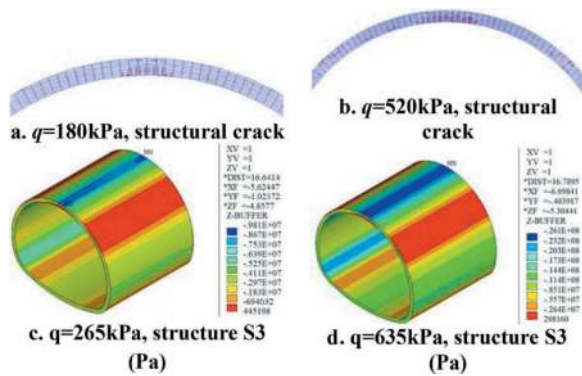

Figure 2. Lateral pressure coefficient 0, simulated and calculated lining crack.

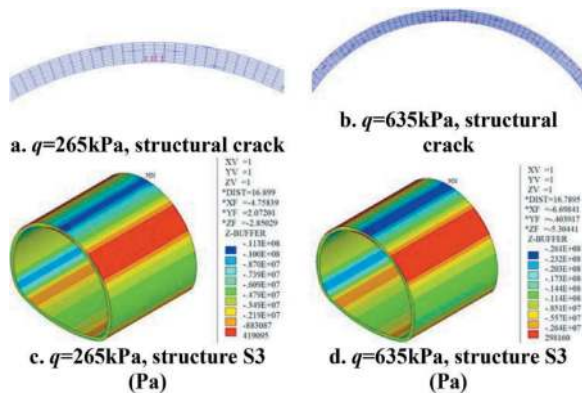

Figure 3. Lateral pressure coefficient 0.3, simulated and calculated lining crack.

As shown in Figure 2 and Figure 3, if the lateral pressure coefficient is 0 and 0.3, the crack-inducing load of the structure is 180kPa and 265kPa, the corresponding crack depth is $0.5H$ and $0.4H$, the compressive stress of the structure in this case is 9.81MPa and 11.3MPa, and the compressive safety factor is 2.65 and 2.30. The worst case deviates from Clause 2.4 of the “Code” by less than 5%, so it is deemed that the compressive strength of lining still has a certain safety margin. If the load is 520kPa and 635kPa, the minimum principal stress of the structure reaches the ultimate strength and a plastic hinge is formed at the crack, so it is deemed that the structure reaches the ultimate limit state. In this case, the crack depth is $0.6H$ and $0.5H$, and the crack depth propagation is insignificant.

Therefore, if the compressive strength of the structure meets the design requirements, the crack depth usually does not exceed $0.5H$, so surface reinforcement is only suitable for strengthening at a single crack with depth $\leq 0.5H$. (Note: H is lining thickness).

3 STUDY ON SURFACE REINFORCEMENT STRENGTHENING DESIGN METHOD

3.1 Surface reinforcement strengthening design process

Surface reinforcement strengthening design is done in 3 steps. Step 1 is to determine the application

conditions of surface reinforcement. Step 2 is to select proper surface reinforcement parameters and analyze the stress on the post-strengthening cracked lining. Step 3 is checking calculation of the post-strengthening lining strength and surface reinforcement strength. Surface reinforcement strengthening design process is shown in Figure 4.

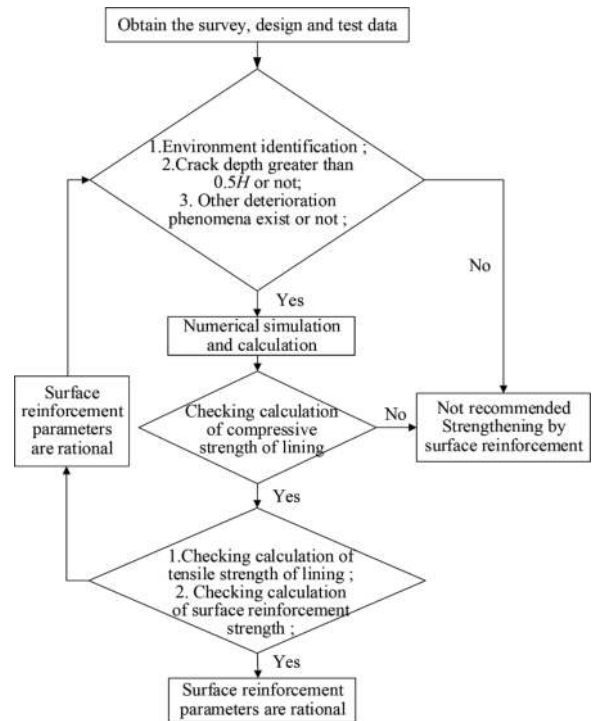

Figure 4. Surface reinforcement strengthening design process.

In the calculation, the ambient conditions of the to-be-strengthened segment must meet the requirements of 2.2. In numerical simulation and calculation, the load types of the lining must be determined based on the burial depth, surrounding rock grade and geotechnical properties of the to-be-strengthened segment. If deformation pressure is dominant, the “stratum—structure” method should be used to calculate the structural effect. If loose pressure is dominant, the “load—structure” method should be used to calculate the structural effect. Crack should be simulated by using the contact surface. With consideration of the physical properties of crack and the safety issue, it is deemed that the crack should have the following properties: (1) When exposed to axial tension, the crack is split without transferring the axial tension, and the residual tensile strength of the crack is not taken into account; (2) When exposed to axial compression, the crack is closed without transferring the axial compression, but the two interfaces of the crack do not intrude into each other; (3) Without consideration of the tangential bond strength and coefficient of friction of the crack interfaces, the interfaces are deemed to be smooth.

Surface reinforcement should preferably be used together with crack grouting to strengthen the lining, but it is hard to guarantee the effectiveness of crack grouting. For the sake of safety and easy construction, the design should take account of the following: (1) The surface reinforcement should have uniform longitudinal and circumferential spacing; (2) Checking calculation of the strengthening effectiveness of surface reinforcement can be done without considering the strengthening effect of crack grouting and mortar cover; (3) Surface reinforcement simulation can be done by using the shell element or link element, and the surface reinforcement and lining are connected at the anchor bolt and side retaining structure; (4) If surface reinforcement simulation is done by using the shell element, the equivalent thickness of the surface reinforcement model should be calculated by using the principle of equivalent axial stiffness.

3.2 Checking calculation of strengthening effectiveness of surface reinforcement

(1) Checking calculation of surface reinforcement strength To evaluate how surface reinforcement will strengthen cracked lining, it is necessary to conduct checking calculation of surface reinforcement strength and post-strengthening lining strength.

If surface reinforcement simulation is done by using the shell element, the maximum tensile stress σ_{hmj} and maximum compressive stress σ'_{hmj} of the surface reinforcement can be directly extracted. If surface reinforcement simulation is done by using the link element, the maximum axial tension N_{hmj} and axial compression N'_{hmj} of the surface reinforcement can be extracted. The axial force is divided by the surface reinforcement area A_s , to obtain the maximum tensile stress σ_{hmj} and maximum compressive stress σ'_{hmj} . The safety factor of surface reinforcement is calculated by Equation (1).

$$K_{\text{hmj}} = \min(R_s / \sigma_{\text{hmj}}, R_s / \sigma'_{\text{hmj}}) \quad (1)$$

Where: R_s is the ultimate strength of surface reinforcement. According to the *Code for Design of Railway Tunnel* ("the Code"), the safety factor of surface reinforcement is ≥ 2.0 .

(2) Checking calculation of lining strength

Checking calculation is done with the least favorable cross-section for compressive strength and tensile strength of lining. The main process: First calculate axial force N and bending moment M by using the axial stress of the nodes in the least favorable cross-section, and then calculate the tensile safety factor K and compressive safety factor K' .

The effective cross section axis of lining is used as the central axis of second moment of area of section, the axial force N_i of cross section i is calculated by Equation (2) and bending moment M_i is calculated by Equation (3).

$$N_i = \frac{1}{2} \sum_{j=1}^{n-1} [(\sigma_j^i + \sigma_{j+1}^i) \cdot S_{j,j+1}^i] \cdot l_z \quad (2)$$

$$M_i = \frac{1}{2} \sum_{j=1}^{n-1} \{[(\sigma_j^i + \sigma_{j+1}^i) \cdot S_{j,j+1}^i] \cdot l_z \cdot t_a\} \quad (3)$$

Where: n is the number of nodes in the cross section i ; j is the node j in cross section. When the cross section is at the crack, the starting point of j is at the crack tip node. When the cross section is not at the crack, the starting point of j is at the free face node of the lining. The node number increases progressively from the lining free face to the surrounding rock side. $\sigma_j^i, \sigma_{j+1}^i$ The axial stress corresponding to i cross section and j node. It is negative if pointed towards the cross section and positive if away from the cross section. $S_{j,j+1}^i$ The Euclidean space distance at j node and $j+1$ node. In the global coordinate system of the model, if the coordinate of j node is (x_j, y_j) , the coordinate of $j+1$ node is (x_{j+1}, y_{j+1}) , then

$$S_{j,j+1}^i = \sqrt{(x_{j+1} - x_j)^2 + (y_{j+1} - y_j)^2} \quad (4)$$

Where l_z is the longitudinal dimension, which is 1m in the calculation. t_a is the t axis coordinate value of the point of action of resultant force of trapezoidal load from j node to $j+1$ node, and is calculated by Equation (5), where t_j^i is the t axis coordinate value of j node.

$$t_a = \frac{S_{j,j+1}^i}{3} \cdot \frac{\sigma_j^i + 2\sigma_{j+1}^i}{\sigma_j^i + \sigma_{j+1}^i} + t_j^i \quad (5)$$

After the bending moment and axial force of the lining at the least favorable cross-section are obtained, the tensile safety factor K and compressive safety factor K'_i of the lining post strengthening are calculated by Equations (6) and (7).

$$K_i = \varphi \frac{1.75R_l b h}{\frac{6M_i}{h} - N_i} \quad (6)$$

$$K'_i = \frac{\varphi R_a b h}{N_i} \quad (7)$$

Where: R_l is the tensile strength of concrete, R_a is the compressive strength of concrete, and φ is the longitudinal bending coefficient of concrete member, which can be selected or calculated as per "the Code"; b is the breadth of section of member, and h is the effective depth of section of member. According to "the Code",

the tensile safety factor of the structure should be ≥ 3.6 and compressive safety factor ≥ 2.4 .

4 DEMONSTRATION OF SURFACE REINFORCEMENT EFFECTIVENESS AND CASE ANALYSIS

(1) Analysis of strengthening effectiveness of surface reinforcement

The tunnel section of a two-line tunnel of a high-speed railway with design speed 400km/h is used here, where the tunnel crown length is 6m and the depth of the longitudinal crack is $0.5H$. The strength grade of concrete is C35, the $\phi 12\text{mm}@50\text{mm}\times 50\text{mm}$ surface reinforcement is used for strengthening, and the steel reinforcement grade is HRB400. The surrounding rock grade in the to-be-strengthened segment is IV, and the load bearing proportion of the secondary lining is 50%; The vertical load on the structure is 77kPa and is loose load; The lateral pressure coefficient is 0.15. The finite element software is used to create the “load-structure” model for analysis, where the longitudinal dimension of the model is 12m. The physical and mechanical parameters of the material are selected according to “the Code”. The calculated first principal stress (S1) of the structure before and after strengthening is shown in Figure 5.

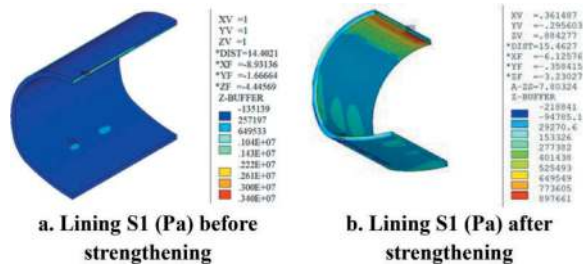

Figure 5. The calculated first principal stress of lining before and after strengthening.

Before strengthening, the maximum value of first principal stress of structure is 3.40MPa, the stress appears at the crack tip, and stress concentration happens. After strengthening, the first principal stress of structure is reduced to 0.90MPa, and it appears at the lining surface at the end of the crack in the lengthwise direction.

Therefore, surface reinforcement will reduce the tensile stress of structure, prevent tensile stress concentration at the crack tip and thus strengthen the structure and inhibit crack propagation.

(2) Checking calculation of surface reinforcement strength

The calculated first principal stress (S1) and third principal stress (S3) of surface reinforcement structure are shown in Figure 6.

As seen in Figure 6, the maximum value of first principal stress of surface reinforcement is 14.3MPa and that of third principal stress 0.024Pa. This

Figure 6. Calculated stress of surface reinforcement.

indicates that the surface reinforcement is mainly exposed to tensile stress. The design strength of HRB400 bar is $R_g=400\text{MPa}$. In calculation by Equation (1), the safety factor of surface reinforcement is $K_{\text{hmj}} = 27.97 > 2.4$, so the surface reinforcement has enough strength.

(3) Checking calculation of lining strength

The axial stress of the nodes at the least favorable cross-section before and after strengthening is extracted and calculation is done by using Eqs. (2) and (3). Before strengthening, the bending moment at the least favorable cross-section is 33.88kN·m and the axial force 138.38kN; After strengthening, the bending moment at the least favorable cross-section is 69.36kN·m and the axial force 519.75kN.

Calculation is done by using Eqs. (6) and (7). The calculated safety factor of structure before and after strengthening is shown in Table 1.

Table 1. Calculated safety factor of structure before and after strengthening.

Case	Bending moment (kN·m)	Axial force (kN)	K	K'	Strength Checking calculation
Before strengthening	33.88	276.75	1.23	284.06	Unqualified
After strengthening	69.36	519.75	4.66	11.02	Qualified

As shown in Table 1, the lining structure was dominated by tensile stress before and after strengthening. Before strengthening, the safety factor of structure is $1.23 < 3.6$, which fails to conform to “the Code”. After strengthening, the safety factor of structure is $4.66 > 3.6$, which conforms to “the Code”. Therefore, the $\phi 12\text{mm}@50\text{mm}\times 50\text{mm}$ surface reinforcement will effectively strengthen the longitudinal crack with 6m length and $0.5H$ depth at the crown.

5 CONCLUSIONS AND PROSPECTS

To prevent over-strengthening at surface crack in railway tunnel and ensure sufficient stability of crack after strengthening, this paper proposes a surface reinforcement strengthening method and its design method for the purpose of lining surface crack conditioning, and demonstrates the effectiveness of this method. Main conclusions:

- (1) A surface reinforcement strengthening method is proposed that consists of 4 parts including surface steel bar, side retaining structure, reinforcement anchor bolt and mortar cover. The environmental conditions that support application of surface reinforcement are defined.
- (2) Under the load pattern specified by “the Code”, if the compressive strength of the lining meets the design requirements, the crack depth usually does not exceed $0.5H$, so surface reinforcement is only suitable for strengthening at a single crack with depth $< 0.5H$.
- (3) The surface reinforcement strengthening design process and checking calculation method are devised. As proven, the surface reinforcement will prevent tensile stress concentration at the crack tip and thus strengthen the structure and inhibit crack propagation.
- (4) When the $\phi 12\text{mm}@50\text{mm}\times 50\text{mm}$ surface reinforcement is used to strengthen the crack with 6m length and $0.5H$ depth at the crown, the safety factor of structure increases from 1.23 to 4.66 and that of the surface reinforcement is 27.97. After strengthening, the structural strength conforms to “the Code”.

This paper has examined the strengthening effectiveness of surface reinforcement in plain concrete crack conditioning, and verifies the effectiveness of surface reinforcement in crack conditioning. For high-speed railway tunnel, however, the stability of surface reinforcement under the action of train induced wind has not been investigated, so this will be further investigated in future research.

An innovative primary support system of steel shotcrete composite structure in the tunnel

Junfu Lu & Minhao Li*

State Key Laboratory of Geohazard Prevention and Geoenvironmental Protection, Chengdu University of Technology, China

ABSTRACT: Steel arch-shotcrete support structure is widely used in tunnel primary support because of its advantages of timely support, flexible operation and superior seismic performance. However, with the development of traffic construction in China's western region, high-ground stress soft rock tunnels continue to appear during tunnel construction. Due to the complex geological structure, climatic and hydrological environment and stratigraphic and lithologic conditions, tunnels often pass through difficult geological environments such as high seismic intensity, high geological disaster risk, high tectonic stress, weak surrounding rock fracture zone and fault fracture zone. The supporting structure often bears large deformation pressure. Due to the large difference in mechanical properties between steel and shotcrete, the bonding ability between the two contact interfaces cannot resist shear stress, and relative slip occurs between steel and concrete. With the increase of relative slip, the shotcrete cracks and peels off, the steel arch is twisted, the structure loses the ability of collaborative deformation, and the overall instability of the supporting structure is destroyed. In this study, combined with theoretical analysis and numerical simulation, a steel-sprayed concrete composite structure tunnel initial support system composed of longitudinal connectors, stud shear connectors and U-shaped steel bars is proposed to improve the tunnel initial support system under external loads. The ability to resist deformation, overall bearing capacity, integrity and safety provide a reference for tunnel engineering design.

Keywords: Complex geology, Tunnel supporting, Steel and concrete, composite structure

1 INTRODUCTION

With the advantages of timely support, flexible operation and superior seismic performance, the steel arch-sprayed concrete support structure is widely used in the initial support of tunnels (Chiorean CG et al., 2017; Ding et al., 2018). Under complex geological conditions such as high ground stress, weak surrounding rock and groundwater, the supporting structure often bears large surrounding rock loads. Due to the large difference in mechanical properties between steel and shotcrete, the bonding ability between the two contact interfaces cannot resist shear stress, and relative slip occurs between steel and concrete. With the increase of relative slip, the shotcrete cracks and peels off, the arch is distorted, the overall bearing capacity of the supporting structure decreases sharply, the structure loses its synergistic deformation ability, and the surrounding rock is unstable and destroyed (Ghorbani M., 2020; Zhang et al., 2021).

Given the above-mentioned engineering difficulties, the research team in the tunnel field has proposed a variety of solutions from different perspectives.

Liu et al (2021) showed that the support method of double HK200b-type steel sets combined with large-diameter foot reinforcement bolts (FRB) and deep invert could effectively control the large deformation of the casing tunnel. Steel-concrete composite support (SCCS) was proposed by Wang et al (2021) to improve the support of loess tunnels. Based on the similarity theory, the mechanical behaviour of π -type SCCS arch under symmetric and asymmetric bias conditions without grouting was studied by a large-scale ring model test. Huang et al (2018) developed a new type of concrete-filled steel tube reinforcement support structure. This support is composed of a seamless steel tube bent to conform to the cross-section of the roadway and filled with concrete. The long-term large-scale deformation of deep roadways can be effectively controlled by using the support system of CSTS combined with

*Corresponding author: liminhao@stu.cdut.edu.cn

anchor cable. Xu et al (2017) designed a new type of grid steel frame-core tube support system. The outside of the structure is composed of flexible steel grilles and granular structural members. The inside of the structure is composed of steel core tubes. The units are connected by connecting steel plates with rubber pads. Steel core tube and steel sleeve connection A support system with square steel confined concrete (SQCC) was proposed by Wang et al (2016,2018), and the pure bending indoor test and numerical test of square steel confined concrete jointless members, flange joint members and casing joint members were carried out. Through field reference, the deformation of the surrounding rock is well controlled. Some researchers (Li et al.,2020; Liu et al.,2021) used concrete-filled steel tubular (CFST) support as a solution to the problem of large deformation of tunnels. The passive support method with high support resistance, such as concrete-filled steel tubular support and U-shaped steel, is used to form a passive support ring to assist or mobilize the surrounding rock of the roadway to exert its bearing capacity.

Although experts have proposed a variety of solutions, there are still many defects. For example, the additional materials will greatly increase the cost of the project, the complex support system will greatly extend the construction period, and the applicability of some new structures is not strong.

Based on the above challenges, a new type of initial support system for tunnel steel reinforced concrete composite structure is designed. This paper first introduces the design and function principle of the new support system. Then, the stress characteristics of traditional support and combined support are compared and analyzed by numerical simulation to verify the superiority of the new combined structure.

Through the use of this structure, the stiffness of the initial support structure of the tunnel can be increased, the cooperative deformation ability between the structures in the initial support system can be enhanced, the bearing capacity and deformation resistance of the initial support structure can be improved, to solve the problem of deformation and failure of the initial support structure due to the excessive in-situ stress in the tunnel.

2 DESIGN OF SUPPORTING SYSTEM

2.1 Introduction of supporting system

In this paper, a primary support system of tunnel shotcrete composite structure composed of three steel arches, longitudinal connection plate, stud shear connectors, U-shaped arches and shotcrete is taken as the research object, which is referred to as the primary support system of tunnel SRSC (Steel Reinforced Shotcrete) composite structure. The schematics of each structural member are shown in Figure 1.

Figure 1. Schematic of SRSC composite structure support system (1-steel arch, 2-stud, 3- longitudinal connection plate, 4- U-shaped steel, 5-Shotcrete).

Table 1. The structural functions of the primary support system of SRSC composite structure.

Structure	Function	Components
Steel arch	The section steel provides strong support resistance to withstand the pressure of surrounding rock in a short time	Section steel, bolts and flanges
Stud shear connector	The stud ensures that the steel and concrete form a whole and co-stress and coordinate the deformation of the steel mesh	Stud
Longitudinal connection plate	Strengthen the longitudinal stability of the support system	L-shaped panels, bolts, diaphragms
U-shaped steel	Reinforced support system ring stability, improves the bearing capacity	U-shaped steel, steel wire
Shotcrete	closed exposed rock surface, to prevent surface weathering	Shotcrete

Table 1 and shows the structural functions and details of the initial support system of the SRSC composite structure.

It can be seen from the table that the tunnel SRSC composite structure support system makes up for some of the functional deficiencies in the traditional support form. Firstly, the longitudinal connection is arranged between each steel arch to make the primary support structure of the tunnel have good stability along the longitudinal direction. Each steel is connected to make it a support system to jointly deform. Each steel arch improves the interaction between steel and shotcrete by arranging stud shear connectors at the web. The ability to increase the stability of the support structure in the circumferential direction and increase the bearing capacity of the support system by arranging circumferential U-shaped steel bars.

2.2 Design principle

2.2.1 Steel and shotcrete

The overall stiffness of the steel arch is large, and the small deformation under the load can better control the deformation of the surrounding rock. It can provide a large early support stiffness and can bear the main surrounding rock deformation pressure of the overall support system. The steel arch can be combined with diaphragm, stud shear, steel bar and shotcrete in time to form a combined support of composite structure so that the support structure becomes a whole with good adaptability to the section, which enhances the effectiveness of the combined support of composite structure and has good stress conditions. In the SRSC system, the spacing of steel arches and the type of steel arches should be determined according to the actual situation of the tunnel engineering site. For the convenience of erection, each steel arch is generally divided into 2~6 sections, and the joint stiffness is guaranteed. The number of sections should be adapted to the size of the section and the excavation method.

In the early stage of deformation, shotcrete plays a bonding resistance role. The bonding failure depends on the mineral composition of the surrounding rock surface and the thickness of the spray layer. The bonding resistance effect mainly depends on the quality of the surrounding rock (the mineral composition of the surrounding rock surface) and its surface cleanliness and increases with the increase of the thickness of the spray layer to a certain extent. The thickness of shotcrete should be compatible with the height of the steel arch section. The shotcrete protective layer directly between the steel frame and the surrounding rock should not be less than 40 mm, and the concrete protective layer on the free side should not be less than 20 mm.

2.2.2 Stud connection

In the tunnel SRSC composite structure support system, the stud shear members are arranged in parallel on the inner and outer sides of each steel arch web with a certain spacing, aiming to enhance the cooperative working ability with shotcrete and the bearing capacity of the structure. The design and layout of the stud shear parts in the SRSC composite support system of the tunnel are shown in Figure 2 below.

The stud shear connector is subjected to complex stresses such as tension, shear and bending of concrete and steel during the stress process. When the load is applied to the component, the component moves, and the studs also move in the same direction. The shear force is mainly transmitted to the surrounding concrete through the root of the stud. When the external load is transmitted to the root of the stud through the weld, local pressure is generated in the concrete at the root, and a large deformation is generated, so that the whole stud tends to rotate in the direction of the bending moment, and the

Figure 2. SRSC composite structure supporting system of stud shear connector layout.

rotation of the stud is constrained by the concrete at the top cap. As the load continues to increase, the studs are damaged.

2.2.3 Longitudinal connection plate and U-shaped steel bar

In the SRSC composite structure support system, the longitudinal connection plate provides lateral support. Through the diaphragm, the steel arches can be connected to form a structural system. The diaphragm can effectively enhance the lateral stiffness of the system and coordinate the overall deformation of the support structure. The diaphragm in the SRSC composite structure support system is composed of L-shaped panning, hexagonal bolts, and steel plates. The schematic diagram of each structural member is shown in Figure 3 below.

Figure 3. The composition of the longitudinal connection plate.

The role of the longitudinal connection plate and U-shaped steel bar in the tunnel SRSC composite structure support system is to strengthen the ability of cooperative work between steel arches and control the stability of the support system in the longitudinal and circumferential directions and the ability to combine with concrete. The layout of the longitudinal connection plate in the support system is shown in Figure 4

Figure 4. The layout of the longitudinal connection plate.

For the design of the steel bar in the initial support system of the SRSC composite structure, the U-shaped steel is bent. The arc of the vertical straight section of the U-shaped steel bar is roughly the same as that of the upper and lower diaphragms of the corresponding tunnel. If the U-shaped steel bar is arranged at the edge of the straight wall of the initial support of the tunnel, the bending arc is not considered. The U-shaped steel bar is shown in Figure 5.

Figure 5. U-shaped steel composition diagram.

After the diaphragm is installed between the steel arches, U-shaped steel bars are welded at a certain distance between the lower and upper parts of the diaphragm by welding, as shown in Figure 5 above.

The U-shaped steel bars are arranged along the longitudinal direction of the tunnel, as shown in Figure 6.

From Figure 6, the welded U-shaped steel bar at the lower part of the upper diaphragm intersects the straight section of the middle part of the welded U-shaped steel bar at the upper part of the lower diaphragm. The height of the upper and lower U-shaped steel bars should be the same as that of the adjacent two diaphragms. The intersection part is tied with steel wire.

Figure 6. Layout diagram of U-shaped steel in steel arch.

The role of U-shaped steel bars is to improve the stability of the support system in the ring, strengthen the bonding ability with shotcrete, and increase the bearing capacity of the support system.

3 NUMERICAL COMPARISON EXPERIMENT

In this section, the failure modes, ultimate bearing capacity, failure and stress deformation characteristics of SRSC composite structure support system and traditional support from under bending state are analysed by numerical test. To compare the failure modes and mechanical characteristics of two different tunnel support forms under a bending state, the feasibility and support effect of the SRSC composite structure support form are verified.

3.1 Modelling and parameter selection

Modelling establishment: In this paper, for the particularity and complexity of the structure, the eight-node hexahedral reduction integral element (C3D8R) in the solid element is used for the steel arch, diaphragm, stud, concrete and fixed end, and the three-dimensional truss two-node complete integral element (T3D2) is used for the steel bar element, only considering the tension or pressure.

The concrete plastic damage (CDP) model is selected for shotcrete, which can reflect the development behaviour of cracks, the change of damage degree and the process of tensile softening during the failure process of materials.

Figure 7. Numerical calculation model.

The double oblique line model is used for the constitutive model of the steel and the stud. The average bond stress-relative slip relationship between the interfaces can be simulated by the cohesive behaviour in the interaction properties. The model of the structure is shown in the Figure 7.

Regarding the interface contact of each component, the Boolean operation is used to combine each steel arch with diaphragms and studs. Secondly, the interface between the steel bar and the diaphragm is constrained by the Tie and Coupling Constraint. Steel arches (with studs), diaphragms, studs and steel bars are embedded in the concrete solid element by Embedded.

Parameter select: The support component sizes and mechanical parameters are shown in Table 2.

Table 2. Component design parameters.

Support component	Type	Size /mm
Steel arch	I16	160×88×6
Stud	Q345	63×7
Diaphragm	Q345	140×1000
Steel bar	φ20	-
Shotcrete	C30	-

The specific physical and mechanical parameters are shown in Table 3. The concrete is C30.

Table 3. Steel material performance parameters.

	Elastic modulus E / GPa	Poisson's ratio μ	Yielding Strength f_y / MPa	Ultimate strength f_b / MPa
Steel arch	205	0.3	345	510
Diaphragm	205	0.3	345	510
Stud	198	0.3	345	510
Steel bar	210	0.3	370	-

3.2 Result analysis

3.2.1 Comparative analysis of bearing capacity

Figure 8 shows the bearing capacity of the two supporting forms. It can be seen from the figure that in the initial stage of loading, the stress of the two support forms increases linearly with the load. With the increase of load, the two supporting forms of steel arch have entered the plastic stage one after another. When $q = 0.12$ MPa, the yield stress of the SRSC steel arch is 33 % higher than that of the traditional supporting arch, $q = 0.66$ MPa. The arch of the SRSC supporting system reaches the ultimate stress state, and the ultimate bearing capacity of the SRSC supporting system is 153 % higher than that of the traditional supporting system.

Figure 8. Stress load comparison curve.

Therefore, the SRSC supporting system has a greater ability to bear the load. The traditional steel arch has greater structural stress under the same load, and the structure is more likely to reach yield and ultimate load, which leads to the loss of bearing capacity of the support system. In the plastic development stage, the plastic yield development speed of the steel arch in the traditional support form is much larger than that in the SRSC support structure system. The stiffness of the SRSC support system is greater. The internal force of the steel arch under the same load also shows that the diaphragm, studs and

steel bars in the SRSC support form optimize the overall stress mode of the structure and increase the bearing capacity of the support system.

3.2.2 Comparative analysis of vertical displacement
Figure 9 describes the pattern and difference of vertical displacement change between the two support systems under different loads.

Figure 9. Load vertical displacement comparison curve.

When $q = 0.09$ MPa, the maximum displacement of the traditional support form begins to enter the plastic stage is 34.5 mm, and the maximum displacement of the SRSC support system is 21 mm. The displacement of the traditional support form increases by 1.64 times under the same load. It can be concluded that the traditional support form enters the plastic yield stage earlier than the SRSC system, and the SRSC support system has a stronger ability to resist deformation. When the support form enters the plastic yield stage, when $q = 0.12$ MPa, the SRSC support system begins to enter the plastic stage. At this time, the maximum displacement is 40mm, and the traditional support form has produced a large displacement deformation. The maximum displacement of the traditional support form is 332mm. Compared with the SRSC support system, the traditional deformation is increased by 8.3 times. When the traditional support form reaches the ultimate stress ($q = 0.26$ MPa), the maximum displacement deformation of the steel arch is 513.4mm, and the maximum displacement deformation of the SRSC support system is 289.3mm. The displacement of the traditional support form is increased by 1.77 times. Therefore, it can be seen that the stiffness of the SRSC system is larger, and the effect of restraining the deformation of the support system is more obvious. Under the same load, the displacement of the SRSC support system is smaller.

3.2.3 Comparative analysis of lateral displacement

Figure 10 shows the lateral displacement deformation of the two supporting systems under the same load.

Figure 10. Load lateral displacement comparison curve.

It can be seen from Figure 10 that under the same load, the lateral displacement deformation of the SRSC supporting system is much smaller than that of the traditional supporting structure. Before 0.09 MPa, the growth curve of load and deformation of the traditional supporting structure in the elastic stage is a straight line, and the lateral displacement is basically within 0.04 mm. With the increase in load, the traditional supporting arch reaches the yield stress and enters the plastic deformation stage. The supporting capacity and supporting effect of the supporting form begin to decrease, and the curve begins to show obvious nonlinearity. The SRSC supporting system has almost no lateral deformation before $q = 0.16$ MPa. With the increase in load, the concrete failure and the structural members in the supporting structure reach the yield stress failure, and the slope of the load-displacement curve becomes larger. When the concrete is destroyed, the load-displacement curve increases linearly. In short, the diaphragm and each component in the SRSC support system can effectively control the lateral deformation of the support form, make the lateral deformation of the support form develop more smoothly, and have better stability and deformation control ability in the lateral direction of the support system.

3.2.4 Comparative analysis of failure characteristics

Figure 11 shows the failure characteristics of the two different support systems.

Figure 11. The deformation characteristics of different support forms.

It can be seen from Figure 11 that there are some differences between the two kinds of support failure modes. The failure mode of the SRSC support system is that the three steel arches are mainly buckling along the loading direction, and the lateral steel arches have no obvious lateral torsional buckling along the out-of-plane. The failure mode of the traditional support form is that three pieces of steel are locally bent along the loading direction, and the lateral steel arch is distorted and buckled due to insufficient lateral support. It shows that the overall stability of the SRSC support system is better in the bending state, and the three steel arches can coordinate the deformation. The arch steel will not work alone due to excessive load, failing the support structure.

4 CONCLUSIONS

- (1) Compared with the traditional support form, the yield load of SRSC support is increased by 33 %, and the flexural ultimate bearing capacity is increased by 153 %. It can be seen that the SRSC support system has greater rigidity. The diaphragm, studs and steel bars in the support system optimize the overall stress mode of the structure, and the ductility is better. The SRSC support form has a greater ability to withstand loads and can provide stronger support capacity and greater bearing capacity.
- (2) The SRSC support system has smaller bending deformation in the vertical and lateral directions. When the traditional support form is destroyed, the vertical deformation and lateral deformation of the traditional support form are 1.77 times and 29.98 times that of the SRSC support system, respectively. The diaphragm and each structural member in the SRSC support system have a significant effect on the displacement deformation of the support structure, and the support system shows excellent ductility.
- (3) In the tunnel SRSC composite structure support system, the steel arch has enough lateral support, and the failure mode is mainly the overall buckling along the loading direction. The three steel arches are coordinated and deformed, and the lateral steel arch does not have obvious distortional buckling. The overall stability of the support system is better.
- (4) Through the use of this structure, the stiffness of the initial support structure of the tunnel can be increased, the cooperative deformation ability between the structures in the initial support system can be enhanced, and the bearing capacity and deformation resistance of the initial support structure can be improved, to solve the problem of deformation and failure caused by the excessive in-situ stress of the initial support structure in the tunnel.

Stress analysis of high geothermal tunnel lining structures considering different cooling measures

Mingrui Luo*, Zuobing Yuan, Lintao Fan, Liangliang Tao & Yanhua Zeng

State Key of Laboratory of Intelligent Geotechnics and Tunnelling, Chengdu, China

School of Civil Engineering, Southwest Jiaotong University, Chengdu, China

ABSTRACT: Laying insulation and ventilation are usually used as cooling measures in high geothermal tunnels, and laying cooling tubes in the lining structure part as a new cooling measure, the research on the cooling process and effect of cooling tubes on the lining structure is still lacking. Therefore, in order to study the effect of different cooling measures on the internal force of the supporting structure of high geothermal tunnel, this paper establishes an indoor test platform for the force of lining structure of high geothermal tunnel, and carries out the test of cooling measures. The results show that: ventilation and cooling pipe can effectively reduce the influence of surrounding rock on lining temperature; the cooling effect of GHEs is better than that of ventilation; in the process of cooling, the circumferential stress borne by the lining is mainly tensile stress; the coupled effect of ventilation and cooling pipe can reduce the lining temperature faster; the flow rate of the cooling pipe is in the range of 0.4m/s~0.6 m/s, and the cooling effect is better with the wind speed in the range of 1~2m/s.

Keywords: High geothermal tunnel, Laboratory test, GHEs, Ventilation, Stress

1 INTRODUCTION

In recent years, large and deep tunnels have been built, and the problem of warm and hot water in the highlands has arisen (Chen et al., 2021; Lin et al., 2022; Yan et al., 2019; Zeng et al., 2020a; Zhang et al., 2021). High ground temperatures during tunnel construction are not only hazardous to workers and reduce equipment productivity, but the long-term effects can weaken the structure of the tunnel lining, making it extremely difficult to complete the project safely (Gao et al., 2017; Liu et al., 2019; Tang et al., 2016). Therefore, research on high temperature tunnel construction has been a focus of attention.

Typically, high geothermal tunnels are cooled through ventilation (Fan et al., 2017; Tao et al., 2022a; Tao et al., 2022b; Zeng et al., 2020b; Zhou et al., 2016; Zhou et al., 2021). Tan et al. (Tan et al., 2014) investigated the effect of different wind speeds and insulation layers on the cooling effect of tunnels. Liu et al. (Liu et al., 2016) investigated the temperature stress variation characteristics of lining structures. Another cooling method is the use of the application of ground heat exchangers (GHEs). GHEs can take advantage of the high heat capacity properties of the material and are therefore widely used for geothermal energy extraction and utilization (Adam and Markiewicz, 2009; Brandl, 2006; Zhang et al., 2016a; Zhang

et al., 2014; Zhang et al., 2016b). At present, energy foundation, energy geotextile (Lee et al., 2012) and other technologies have been developed. Ventilation does not only have a significant impact on the perimeter heat transfer loop, but also on the GHEs (Bidarmaghz and Narsilio, 2018).

Currently, ventilation to lower the temperature of the surrounding rock has been intensively researched by modelling experiments, theoretical calculations, and numerical simulations. The findings of previous research indicate that GHEs concentrate stress in the lining, primarily in the circumferential direction. However, the majority of existing studies concentrate on the cooling effect of ventilation on tunnels and the thermal performance of geothermal heaters. There are few studies that take into account lining stresses under the synergistic effect of ventilation and GHEs, and even fewer studies that conduct pertinent indoor tests.

Consequently, in order to better understand how various cooling techniques affect lining stresses. In this work, a test platform was developed to investigate various GHEs flow rates and ventilation wind speeds. To analyse the impacts of various cooling measures on lining temperature and the characteristics of lining stress variations, cooling tests with only ventilation, solely GHE activation, and the coupling of the two were conducted. The results can serve as a benchmark for high-temperature geothermal tunnel projects.

2 LABORATORY TEST

Figure 1. Schematic diagram of test platform.

A stainless-steel box with measurements of 6 m by 3 m by 1.5 m serves as the model test chamber. To provide thermal and moisture insulation boundaries, the box's long sides were surrounded by 5 cm thick insulation boards made of rubber-plastic and water-repellent rock wool. The model tunnel had a cross section that was 30 cm broad, 33 cm high, and 2 cm thick. Steel wire mesh and CGM general-purpose high-strength non-shrink grout are used to line the tunnel, while rubber-plastic material serves as the thermal insulation layer. The ratio of similarity is 1:30.

PERT pipes having an outside diameter of 16 mm and a thickness of 0.015 mm are used by the GHEs. With a total pipe length of 23 m, the cooling pipes' beginning and last rings were installed at either end of the tunnel at a distance of 25 cm.

Figure 2. Schematic diagram of sensor deployment at cross section No. 6.

The thermal insulation layer was placed in front of the heat pipes, which were fitted with flow meters and throttling valves to regulate the flow rate. To guarantee that the temperature of the water entering into the test chamber is always consistent, the fluid in the heat exchanger tubes exits the test chamber and enters the circulating thermostat system. At the entrance and outlet of the heat exchange tubing lines, flow meters and type K thermocouples are attached.

Three test portions were separated by 150 cm in the test chamber. Air temperature sensors were positioned in the tunnel, and 20 K-type thermocouples were dispersed throughout the enclosure in three

different directions in each segment. Sensors in each direction are laid out at irregular spacing.

To take a peek at h different cooling measures on lining stresses. The flow rates inside the tubes of the GHEs used in this investigation were set to 0.4 m/s, 0.6 m/s, and 0.8 m/s. Full cross-section uniform ventilation was used for ventilation, with air velocities of 0, 1, 2, and 3 m/s.

3 RESULTS AND DISCUSSION

From the three kinds of working conditions, namely, ventilation only, GHEs only, GHEs and ventilation coupling effect, 1 group of working conditions is selected respectively, and the temperature field of surrounding rock and the temperature field of tunnel lining are obtained along the direction of tunnel depth when the test is carried out for 48 h. The temperature field of the surrounding rock and the temperature field of the tunnel lining are distributed according to the temperature boundary. It can be seen that the test platform can be basically divided into three sections according to the distribution of temperature field, the inlet section (L1~L3) and the outlet section (L9~L11) are more obviously affected by the temperature boundary, and the high-temperature smooth section (L3~L9) can better simulate the high geothermal

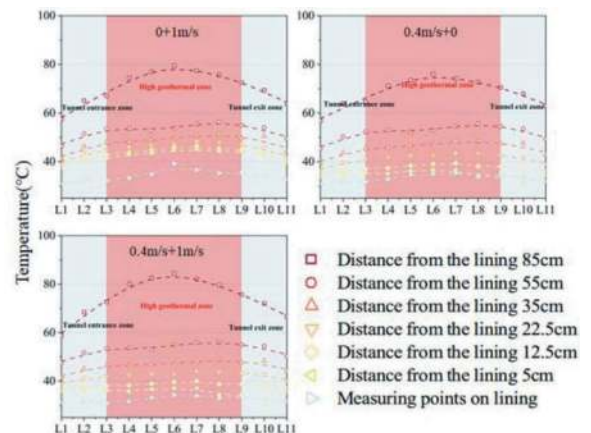

Figure 3. Temperature field distribution of the test platform along the tunnel depth direction during 48h of the test.

tunnel of the actual project. Therefore, in the subsequent analysis, the L6 section is selected for analysis.

3.1 Ventilation-only conditions

Figure 4. Diagram of temperature changes in the lined girdle, footing, and vault for ventilation-only.

Figure 4 depicts the temperature variation at various lining structure sites when just ventilation is used. With a wind speed of 1 m/s, the cooling amount at the arch's foot and vault is nearly equal—it is 80.15% of the cooling amount at the arch's waist. When the wind speed reaches 2 m/s, the temperature drop at the arch top and the arch foot varies, with the temperature reduction at the arch foot being 12.17% smaller than that at the arch top and equal to 66.85% of the temperature reduction at the arch waist. The cooling amount of the working condition with wind speed of 2 m/s increased at all places compared with the working condition with wind speed of 1 m/s. Among them, the largest increase in temperature reduction at the arch waist is 31.00%; the smallest increase in temperature reduction at the foot of the arch is 17.26%; and the increase in temperature reduction at the arch top is 29.42%. When the wind speed reaches 3 m/s, the cooling amount of the arch foot is 84.23% of the cooling amount of the arch top and 69.29% of the cooling amount of the arch waist. Comparing the results of the working conditions with wind speed of 3 m/s and wind speed of 2 m/s, the growth of temperature reduction at each position is within 0~4.35%.

It can be seen that at different wind speeds, the temperature reduction at the foot of the arch, the waist of the arch and the top of the arch increased with the test. Among them, the fastest cooling and the largest amount of cooling was observed at the arch waist, and the slowest cooling and the smallest amount of cooling was observed at the foot of the arch. This is due to the wind flow and lining surface convection heat transfer, and convection heat transfer coefficient and the shape of the heat transfer surface and other factors related to the arch waist at the heat

transfer surface is the flattest, so the fastest cooling speed, and the cooling amount is also the largest.

With the increase of wind speed, the temperature at the foot of the arch and the top of the arch gradually appeared to be different, and the cooling amount and cooling speed of each position also gradually increased, but when the wind speed exceeded 2 m/s, this change was no longer significant. And with the increase of wind speed, the fluctuation of lining temperature is also gradually significant. This is because the convective heat transfer coefficient is determined by the Nusselt number, and the Nusselt number is positively correlated with the flow rate, so the larger the wind speed, the larger the convective heat transfer coefficient and the larger the cooling rate. And the heat of the lining structure comes from the surrounding rock, and the heat replenishment capacity of the surrounding rock is limited. Therefore, when the wind speed reaches 2 m/s, the heat transfer between air-lining-surrounding rock has reached equilibrium, and continuing to increase the wind speed does not reduce the lining temperature.

As seen from Figure 5, the stress development law of the lining is basically consistent with the temperature change law. In the working condition of wind speed 1 m/s, the stress at the foot of the arch and the arch top is basically the same, which is about 59.35% of the stress at the arch waist. When the wind speed reaches 2 m/s, the stresses at the vault and the foot of the arch do not increase with the elevation of cooling, the stress at the vault is 91.98% of the stress at the vault in the case of wind speed 1 m/s, the stress at the foot of the arch is almost unchanged, and the stress at the arch waist is elevated by 10.11%. When the wind speed reaches 3 m/s, the stress at the arch is elevated by 31.29%, the stress at the arch waist is elevated by 22.56%, and the stress at the footing is elevated by 13.46%. The stresses in the lining are dominated by tensile stresses, which is due to the fact that the ventilation continuously extracts heat from the lining, leading to a decrease in the lining temperature, and thus the cold contraction of the concrete produce's stresses dominated by tensile stresses.

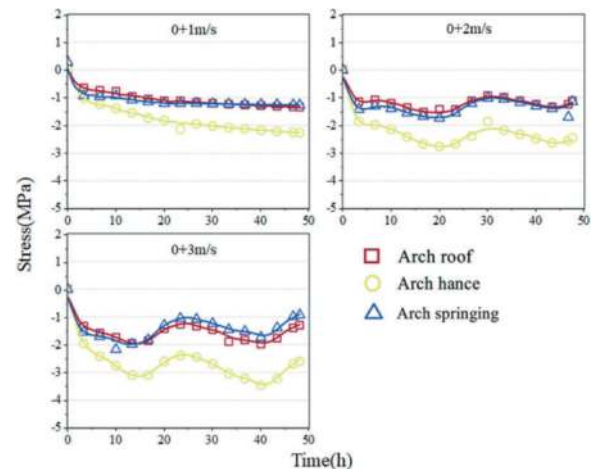

Figure 5. Diagram of stress changes in the arch waist, foot of the arch, and vault of the lining when ventilated-only.

Compared with the temperature development law, it can be seen that the stresses in the footing and vault of the lining are almost the same when the wind speed is 2m/s or less, and the growth of the stresses is less affected by the wind speed. When the wind speed reaches 3m/s, the stress at the vault is about 82.79% of the stress at the top of the arch. The stress at the arch waist has been higher than the other two locations, and the growth rate of stress increases with the increase of wind speed. This is due to the fact that the tunnel is subjected to the joint action of the surrounding rock pressure and stress, under the action of the surrounding rock pressure, the compressive stress is mainly distributed in the arch top and the foot of the arch, and the tensile stress mainly appears at the arch waist. And the results of the stresses show that at all locations of the lining, the stresses are tensile stresses. Therefore, the tensile stress at the top of the arch and the foot of the arch is relatively small compared to the stress at the arch waist.

3.2 GHEs-only conditions

As shown in Figure 6, the effect of GHEs on lining temperature is significantly greater than that of ventilation. In the case of GHEs flow rate of 0.4m/s, the cooling of the arch footing is 81.29% of the cooling of the arch waist and 66.26% of the cooling of the arch top. In the case of GHEs with a flow rate of 0.6 m/s, compared with the case with a flow rate of 0.4 m/s, there is not much change in the cooling amount of each position, and the change is basically within 12%. When the flow velocity of the GHEs increased to 0.8 m/s, the cooling amount at each position decreased, and the decrease was between 25 and 29%. This indicates that the cooling effect is basically the same when the flow velocity is within 0.4m/s to 0.6m/s. When the flow velocity is greater than 0.6m/s, the cooling effect instead decreases. This is because the cooling effect of GHEs on the lining is heat conduction, which is faster than convection heat transfer. When the flow rate in the GHEs is low, the cooling effect of the GHEs is more stable, when the flow rate is greater than 0.6m/s, the liquid in the pipe of the GHEs heats up faster, so when reaching section 6, the water temperature is already higher, and therefore the cooling effect on the lining is weakened.

From Figure 7, it can be seen that in the case of running GHEs only, the stress development pattern of the arch waist, footing and vault of the lining is basically the same as that of the ventilated-only case, but in the values are basically smaller than that at the ventilated-only case, the stresses at each position of the lining. In the case of GHEs with a flow velocity of 0.4 m/s, the difference in stress between the vault and the footing is small, and the stress at the vault is only 33.45% of that at the arch waist. When the flow velocity reaches 0.6m/s, the stress at the vault increases by 45.61%, the stress out of the arch

Figure 6. Temperature variation of the lining's arch waist, arch foot, and arch top when only GHEs are activated.

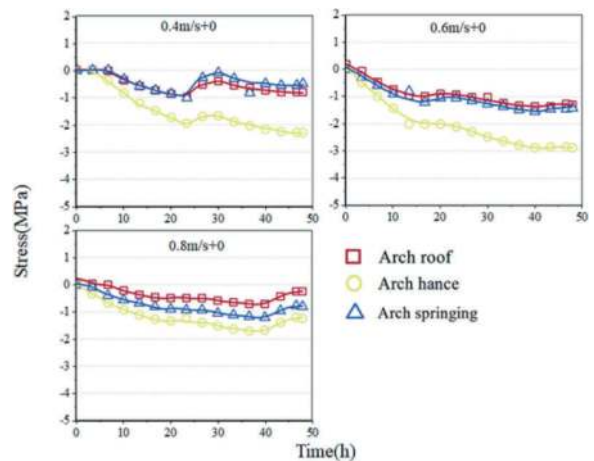

Figure 7. Diagram of stress changes in the arch waist, foot of the arch, and vault of the lining when only the GHEs are activated.

increases by 24.39%, and the stress at the arch waist increases by 68.55%. When the flow rate reaches 0.8m/s, the stresses at each place start to decrease instead, and the maximum decrease can reach 57.04%. Combined with Figure 6, it can be seen that the stress change of the lining has a highly sensitive correlation with the operating parameters of the GHEs. When the flow rate of GHEs is 0.6m/s, the stress at the arch waist can reach 2.79MPa, but it is still smaller than the stress at the arch waist in the case of wind speed of 3m/s.

3.3 Coupling of GHEs and ventilation

Figure 8 shows the temperature variation at various locations of the lining when GHEs and ventilation are coupled. It can be seen that the temperatures at the arch waist and arch top of the lining are closer. Compared with the case of ventilation only, the increase of temperature reduction in the coupled

case is from 21.63 to 51.80%; compared with the case of GHEs only, the temperature reduction in the coupled case decreases at the vault in the case of GHEs flow rate of 0.4m/s + wind speed of 1m/s, and in the rest of the cases and locations, the increase of temperature reduction in the coupled case is from 2.43 to 47.73%.

Compared with the case of GHEs flow rate of 0.4 m/s + wind speed of 1 m/s, the temperature reduction at the foot of the arch is improved by 15.28%, at the arch waist by 8.46%, and at the vault by 15.71% in the GHEs flow rate of 0.4 m/s + wind speed of 2 m/s case. When the wind speed increased to 3m/s, the cooling amount at each location of the lining basically no longer changed. This indicates that the working condition of GHEs flow rate of 0.4m/s + wind speed of 2m/s has reached the heat exchange equilibrium state of GHEs-air-surrounding rock.

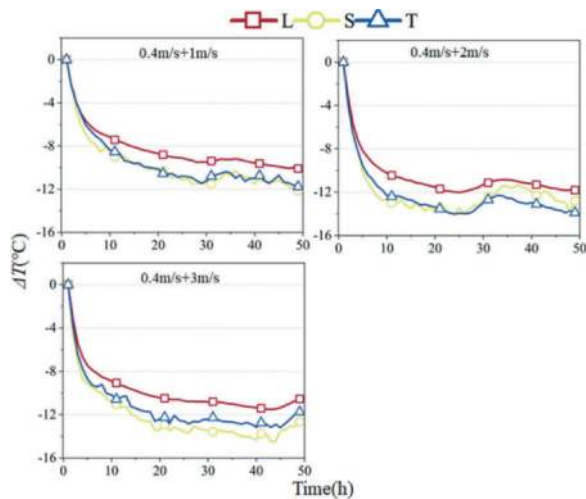

Figure 8. Temperature variations of the lining's girdle, footing, and vault when GHEs and ventilation are coupled to cool the lining.

As shown in Figure 8, in the case of GHEs flow rate of 0.4m/s + wind speed of 1m/s, compared with the case of only activating the GHEs flow rate of 0.4m/s, the stress at the soffit is reduced by 143.67%, while the stress at the soffit is elevated by 27.18%, and at the foot of the soffit is almost the same. Compared to the case of only ventilating the wind speed of 1m/s, the stress at the soffit was reduced by 28.10%, while the stress at the gable waist was elevated by 32.23%, and at the foot of the soffit was elevated by 64.20%. When the wind speed increased to 2 m/s, the stresses at all locations were elevated from 17.11% to 34.22% compared to the conditions with only ventilation or only GHEs activated. When the wind speed increases to 3m/s, the stress at each position increases and decreases at different positions compared with the conditions of ventilation only or GHEs only activation.

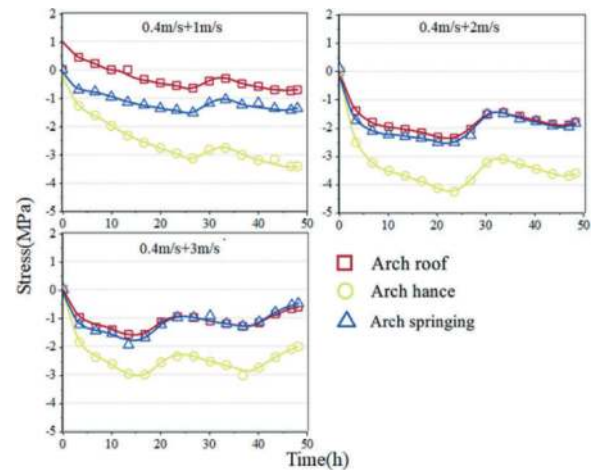

Figure 9. Stress changes in the arch waist, arch foot, and arch top of the lining for GHEs and ventilation coupled with cooling.

It can be seen that in the case of coupled cooling with GHEs and ventilation, there is a difference between the stresses at the vault and the foot of the arch when the wind speed is 1~2 m/s; after the wind speed exceeds 2 m/s, the stresses at the vault and the foot of the arch are almost the same.

Overall, the coupled cooling of ventilation and GHEs will achieve more desirable results when the purpose is cooling. The reasonable range of flow rate is 0.4~0.6m/s and wind speed are 1~2m/s. However, the ensuing stresses are also the largest, and the tensile stress at the arch waist in the GHEs flow rate of 0.4m/s + wind speed of 2m/s can be up to 3.60MPa, whereas the standard value of axial tensile strength of the standard C80 moulded concrete is only 3.11MPa. The tensile strength of the CGM concrete used in this study is more than 6MPa and therefore was not damaged. However, in the actual project, the concrete for high geothermal tunnel lining needs to be specially designed.

3.4 Comparison of lining stresses before and after cooling down

Heating of the perimeter rock and lining was required to bring them to a high ground temperature environment first before cooling measures could be carried out. The lining temperature increased from room temperature of 23°C to 45°C during this period. The lining increased in volume due to thermal expansion, but additional compressive stresses were created in the lining due to the confinement of the surrounding rock, the variation curve of which is shown in Figure 10. It can be found that the temperature stresses in the arch top, arch waist and arch footing are all 0 when they are not heated, and the lining stresses in the three places are gradually increasing with the increase of temperature. Among them, the increase of the arch waist is the largest, and its maximum value reaches 4.9 MPa; while the difference between the arch top and arch foot stress is not big, the arch top

stress is slightly smaller than the arch foot, and the two change trends are similar, and the maximum values are 1.8 MPa and 2.4 MPa, respectively.

Through the combination of heat exchanger and ventilation cooling measures, the stress on the lining is converted from relative compression to relative tension, which effectively reduces the increase of lining stress caused by high ground temperature. It can be concluded that the combination of heat exchanger and ventilation can effectively reduce the heat damage caused by high ground temperature in the actual project.

Figure 10. Graph of lining stress with increasing temperature.

4 CONCLUSIONS

- (1) Conclusions should state concisely the most important propositions of the paper as well as the author's views of the practical implications of the results.
- (2) During the implementation of the cooling measures, both the cooling process and the form of stress development in the lining were exponential. With the increase of operation time, the rate of change of temperature and the rate of change of strain both decrease gradually.
- (3) Heat exchange is a dynamic process, the lining temperature change will show certain fluctuations, and the cooling effect of ventilation is greatly influenced by the air temperature. The fluctuation of temperature will affect the lining stress.
- (4) There are differences in lining stresses at different locations. In the case of ventilation only, the cooling at the arch waist is the largest; in the case of activating GHEs only, the cooling at the arch top is the largest; and in the case of coupled cooling by GHEs and ventilation, the cooling at the arch waist and arch top is the largest.
- (5) Under the effect of different cooling measures, the stress of the lining is dominated by tensile

stress, which are all manifested as the maximum stress at the arch waist, which can reach 3.6 MPa, and the effect of this additional stress on the structural stress needs to be considered in the structural design.

- (6) The lining stress decreases with running time, while the circumferential stress at the nodes under the radial path increases with running time and eventually stabilizes.

Thrust jack loading of large diameter precast segmental tunnel lining

M.A. Mooney & H. Zheng

Department of Civil and Environmental Engineering, Lehigh University

ABSTRACT: This paper presents the results of thrust jack load testing on large diameter tunnel lining segments, and associated comparison to design procedures used worldwide to assess thrust jack bursting stresses. Large diameter tunnels constructed via shield tunnel boring machines are increasingly being adopted worldwide for roadway and metro projects. When tunnels reach such large diameters, thrust jack loading often becomes a critical governing load case. Thrust jack loading induces radial and tangential bursting stresses, as well as spalling stresses, that can damage the lining. An experimental study was performed to examine induced stresses in 13 m diameter, 45 cm thick steel fiber reinforced concrete (SFRC) and hybrid SFRC + rebar segments. From experiments, radial bursting stress governed sfrc thrust jack failure while transverse bursting stress governed hybrid failure. Transverse bursting stress occurs near mid-segment depth while radial bursting stress occurs (within SFRC) within one-half of segment thickness. The German tunneling society guidelines provide a good estimation of radial and transverse bursting stress capacity if the observed burst depth is used. Aci code simplified formulae and the iyengar approach overestimated the bursting stress of SFRC.

1 INTRODUCTION

Large diameter (13 m and greater) segmental lining systems are increasingly being adopted for highway and transit tunnels worldwide. The design of large diameter segmental lining is notably different from the far more common 6-7 m diameter segment lining systems. As detailed in Mooney et al. 2020, a number of critical aspects are quite different for large diameter lining, including segment joint rotational stiffness, slenderness ratio, and whole ring behavior with 10-12 joints compared to the 5-6 joints of most metro-size tunnels. One major difference is in the thrust jack loading imparted to segments during construction (Figure 1). TBM thrust capacity generally grows with the excavated area created by the TBM. The thrust jacks transfer the thrust through the bearing area of the lining's leading edge. While the lining bearing area for thrust force grows with tunnel diameter D , total TBM thrust grows with D^2 . As D reaches 13 m and greater, TBM thrust force can become the governing and difficult load case to design for.

With the critical thrust jack load case, many segmental lining projects have been designed with a steel fiber reinforced concrete (SFRC) and hybrid SFRC + rebar to accommodate the bursting stresses predicted by design procedures (Tiberti et al. 2015; Conforti et al. 2019). Design procedures for thrust jack loading are recommended by ACI-544.7R-16,

German Tunneling Committee (2013), and others. To evaluate segment capacity under the estimated thrust force, different design methods are available, including simplified equations (ACI 318-14, German Tunneling Committee, 2013), analytical approaches (Iyengar 1962) and computational modeling. The paper describes the results of full-scale thrust jack experiments performed to better understand the actual performance of SFRC and hybrid SFRC + RC segments subjected to thrust jack loading. A comparison of observed response with design code predicted response is made.

2 DESIGN PROCEDURES

Thrust jack force spreads over the leading edge of the liner segment, inducing radial and transverse (circumferential) tensile stresses that eventually diminish at some distance away from the load pad. The state of practice in bursting stress design analysis is summarized in ACI 544.7R-16, recommending the use of (a) ACI 318 simplified equations; (b) German tunneling committee (2014) equations; (c) Iyengar (1962) diagram analysis; and/or (d) finite element analysis. The simplified equations to estimate the bursting force T_{burst} and depth d_{burst} where T_{burst} occurs are provided by ACI 318 (Equation 1) and the German tunneling committee (Equation 2).

Figure 1. Illustration of TBM thrust jacking loads applied to ring end/bearing area of most recently installed segments. (left: Herrenknecht, 2015, right: Groeneweg 2007).

Figure 2. Bursting force estimation via simplified equations recommended by (a) ACI 318-14, and (b) the German tunneling committee.

Figure 2 illustrates the pertinent parameters wherein Figure 2a from ACI 318 conveys more of a post-tensioning beam girder application while Figure 2b from the German Tunneling committee more directly conveys thrust jack load application across a portion of the thickness of the segment.

$$\sigma_{p,r} = \frac{T_{burst}}{\phi a_l d_{burst}} \quad (3)$$

$$\sigma_{p,t} = \frac{T_{burst}}{\phi h_{anc} d_{burst}} \quad (4)$$

$$T_{burst} = 0.25F_{jack} \left(1 - \frac{h_{anc}}{h} \right); d_{burst} = 0.5(h - 2e_{enc}) \quad (1)$$

$$T_{burst} = 0.25F_{jack} \left(1 - \frac{h_{anc}}{h - 2e_{enc}} \right); d_{burst} = 0.4(h - 2e_{enc}) \quad (2)$$

Equations are provided in ACI 544.7R-16 to calculate the maximum radial (r) and transverse (t) bursting stresses based on T_{burst} and d_{burst} . The maximum bursting stress developed in the radial ($\sigma_{p,r}$) and transverse ($\sigma_{p,t}$) directions are given in Equations 3 and 4, where key terms are illustrated in Figure 3.

Figure 3. Thrust load pad geometry terms incorporated into ACI 544.7R-16 bursting stress calculations. a_l is the length of the load pad in the transverse (circumferential) direction while h_{anc} is the load pad dimension in the radial direction.

The treatment of radial bursting stress is clear from the ACI equations in that d_{burst} is defined at a depth equal to 0.4-0.5 of the segment thickness h . However, ACI uses the same d_{burst} term for transverse bursting stress, suggesting that the maximum tensile stress in the transverse direction occurs close to the load pad at

(a) Load frame and test setup

Figure 4. (a) 22 MN capacity load frame and test setup at Lehigh University; (b) steel rebar used in hybrid segment. notation used for the bars: # d where d = diameter in number of one-eighth inch increments.

a similar depth as the radial maximum bursting stress. This will be examined later in the paper based on experimental results.

Estimated bursting tensile stresses were determined using the ACI 318 and DAUB simplified method, as well as by using the Iyengar method (for radial bursting stress) using the following inputs: $l = 4.06$ m, $t = h = 450$ mm, $l_p = 1.6$ m, $t_p = 275$ mm, $e_i = 760$ mm, and $e_r = 0$. Two pairs of jacks are assembled symmetrically on one segment.

3 THRUST JACK LOAD EXPERIMENTAL TESTING

3.1 Load frame and segment setup

A cooperative experimental program was performed by Colorado School of Mines and Lehigh University to test 450 mm thick segments from a 13 m diameter tunnel project in Virginia, USA. The segments were tested in Lehigh University's Fritz Laboratory using a 22 MN (5000 kip) capacity Baldwin universal testing machine (Figure 4a). Two steel reinforcement designs were adopted: (1) SFRC and (2) hybrid SFRC + conventional rebar, i.e., SFRC + RC. The detailed design of the RC is shown in Figure 4b. The reinforcement bars have 50 mm clear cover from the segment surface. The strength of steel reinforcement bars is approximately 410 MPa.

The SFRC mix was prepared with cementitious content of 445 kg/m³ and a w/c ratio of 0.35. 4D Bekaert steel fiber was used. The fiber content was 38.5 kg/m³ with 61 mm length, 7.5 mm diameter and 80 aspect ratio for each fiber. The average 28 day compressive strength was 65 MPa. The average 28 day split tensile strength was 7.4 MPa. Crack mouth opening displacement tests were also performed according to EN 14651 procedure, and

the peak flexural strength is 1030 psi. The inverted tensile strength was estimated to be 5.44 MPa. The average elastic modulus is 30.9 GPa obtained from compressive tests on SFRC samples. Therefore, the tensile strain limit was estimated to be 180 $\mu\epsilon$.

Extensive instrumentation was used to characterize behavior during loading, including displacement transducers, strain gauges, load cells and distributed fiber optic sensors (DFOS), the detailed discussion of which is beyond the scope of this paper.

3.2 SFRC test results

Thrust jack loading of SFRC segments revealed a clear radial bursting stress failure at an approximate thrust jack load magnitude of 4400 kip (Figure 5). Long before this abrupt failure, the segment exhibited intrados and extrados cracking with crack widths summarized per load level in Figure 6. The longitudinal cracking shown in Figure 6 is caused by transverse bursting stresses. Early onset cracking due to radial bursting stress is not visible on the extrados and intrados as these cracks would run in the transverse direction. It is reasonable to assume that such cracking did also occur well before the ultimate failure at 4400 kip.

Radial and transverse strain behavior was recorded by internal strain gages embedded at multiple depths below the load pad. Measured radial strains reached the tensile strength/strain limit of 180 $\mu\epsilon$ at a depth of 9-10 in. below the load pad. This is consistent with the ACI 318 prediction of 0.5 times the segment thickness, assuming no eccentric loading. The radial strains reached the tensile strength limit at a thrust jack load level of 3500 kip, which is notably lower than the 4400 kip ultimate failure in Figure 5. Measured transverse strain reached 180 $\mu\epsilon$ at a depth of 38-40 in. below the load pad (Figure 6).

(a) Leading edge of segment (b) Side view of segment

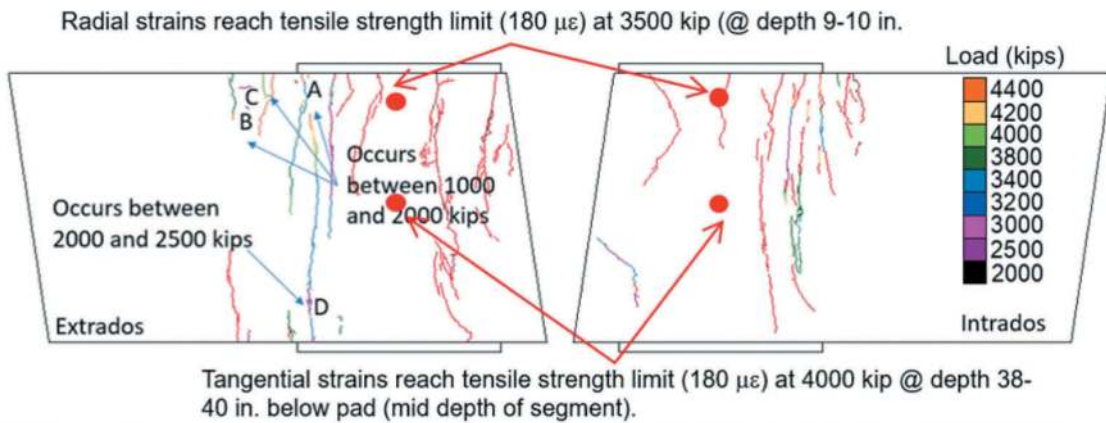

Figure 5. (a) Leading edge where radial bursting stress induced cracking is clear; (b) side of the segment where radial bursting stresses (left to right) exceeded the tensile capacity of the SFRC.

This depth d_{burst} of transverse strain is clearly different from radial d_{burst} that is not captured or conveyed in design codes. The transverse limit strain reached $180 \mu\epsilon$ at a thrust jack load of 4000 kip. This level is consistent with persistent crack widths ≥ 0.008 in, the maximum level of crack width that is typically prescribed in tunnel lining design (e.g., AASHTO 2017). Summarizing results, the SFRC segment reached radial bursting stress ultimate limit state at $d_{burst,r} = 9-10$ in. at thrust jack load of approximately 3500 kip, followed by transverse bursting stress

ultimate limit state at $d_{burst,t} = 38-40$ in. at a thrust jack load of approximately 4000 kip.

3.3 Hybrid SFRC + RC test results

The hybrid SFRC + RC segment was loaded to 5000 kip thrust jack load without the visible abrupt radial bursting stress failure that the SFRC segment experienced. The 5000 kip capacity of the test rig prevented loading the hybrid segment further. The measured internal radial strains at depths = 9-10 in. below the load pad remained at or below $180 \mu\epsilon$. The perimeter rebar in the radial direction (Figure 4b) is located in this vicinity and therefore is supporting this tensile stress. As shown in Figure 7, longitudinal cracking emerges at 4000 kip thrust jack loading. These are due to transverse bursting stresses. The measured transverse strains within the segment reach $180 \mu\epsilon$ at 4000 kip a mid depth of the segment, i.e., 40 in. In this area, there is no rebar to provide tensile capacity. This demonstrates that the ‘light’ rebar cage with perimeter reinforcement provides important radial bursting stress capacity but this essentially shifts the governing ultimate limit state to transverse bursting stress failure. Collectively, the SFRC-only transverse bursting stress capacity is not much more than the radial bursting stress capacity. Therefore, the benefit of a perimeter rebar insofar, as improving bursting stress capacity, is limited. It is worth mentioning that when a full ring of

Figure 7. Hybrid segment crack width records and locations of maximum observed bursting stresses.

segments is installed, adjacent segments provide beneficial confinement in the transverse (circumferential) direction, while there remains no confinement in the radial direction. This circumferential direction confinement likely boosts the transverse bursting stress capacity. However, there are cases, such as in continuous tunneling, where thrust jack loading is imparted to segments before the full ring is installed.

4 COMPARISON WITH DESIGN PROCEDURES

The results from SFRC testing are directly compared with design code procedures. Using the geometry of the tested SFRC segment, the reasonable assumption of no eccentricity, and the assumed SFRC tensile strength = 790 psi, ACI 318, German Tunneling Society (DAUB), and Iyengar diagram based capacities are summarized in Table 1. Radial bursting stress is the controlling bursting mode by approximately 20%. DAUB is more conservative than ACI 318, while Iyengar's estimation is less conservative. For transverse bursting stress capacity, we take the liberty to

use $d_{burst,t} = 38-40$ in. in the equations. The use of $d_{burst,r}$ would lead to much higher transverse bursting stress capacities.

The observed results from SFRC testing are summarized in Table 2. Major visible radial bursting failure occurred at 4400 kip. Per crack width criteria of 0.008 in., transverse bursting failure occurred at 3800 kip while radial bursting failure is not determinable per cracking because the resulting circumferential cracks are internal and not observable on the intrados and extrados faces. Per tensile strain limit, radial bursting occurred at a thrust jack load of 3500 kip while transverse bursting occurred at a thrust jack loading of 4000 kip.

Comparing the observed behavior with design equations, we observe that ACI 318 radial bursting matches the observed major failure and DAUB matches the results from tensile strain measurements. The Iyengar diagram seems too conservative in radial bursting stress capacity. DAUB estimation is more in line with the observed transverse bursting stress failure load based on both crack width and tensile strain limit, assuming the use of $d_{burst,t}$ in the estimation. It

Table 1. Ultimate thrust jack load capacity (no partial safety factors; SFRC tensile strength = 790 psi).

Method	Radial	Transverse	Notes
ACI 318	4500 kip	5400 kip*	Radial governs
DAUB	3700 kip	4300 kip*	Radial governs; DAUB more conservative than ACI;
Iyengar Diagrams	5300 kip	NA	Predicts highest capacity; not applicable for transverse.

*using $d_{burst,t} \gg d_{burst,r}$. Tangential capacity much higher if using $d_{burst,t} = d_{burst,r}$

Table 2. Observed radial and transverse bursting stress failure in SFRC testing.

Failure criteria	Radial	Transverse	Notes
Major (collapse) failure	4400 kip		Clear radial bursting stress failure near load pad.
Cracking/crack width	Not observable	3800 kip	Cracking due to radial bursting stress is internal and runs circumferential; not observable on intrados or extrados.
Tensile strain limit (180 $\mu\epsilon$)	3500 kip	4000 kip	Shows radial governs but tangential is significant and at mid segment depth unlike radial immediately below pad.

is worth noting that the number of experimental tests is very limited, and these results should be verified with further testing, additional diameters, etc.

5 CONCLUSIONS

Full scale thrust jack load testing on 13 m diameter SFRC and SFRC + RC segments revealed that: (a) radial bursting stress governs SFRC thrust jack failure; (b) maximum radial bursting stress occurs at a distance equal to one-half of the segment thickness; (c) maximum transverse bursting stress occurs at a distance of one-half the segment length; (d) that perimeter rebar improves radial bursting stress capacity shifting the governing condition to transverse bursting stress at mid-depth of the specimen. A comparison with multiple design methodologies shows: (a) good radial bursting stress prediction by DAUB; (b) slight overestimation of radial bursting stress capacity by ACI 318 and significant overestimation by Iyengar; and (c) good transverse bursting stress prediction by DAUB if the actual $d_{burst,t}$ of segment mid-depth is used; and (d) significant overestimation of transverse bursting stress capacity by ACI 318. All design code calculations should be clarified to differentiate between depth of maximum bursting stresses in radial vs. transverse directions. The results presented here are based on very limited testing. Further testing is warranted to both confirm findings and to further enhance understanding of this critical load case for large diameter segmental lining.

Computational approaches towards segmental linings with a reduced environmental impact

Gerrit E. Neu, Vladislav Gudžulić & Günther Meschke*

Ruhr University Bochum, Bochum, Germany

ABSTRACT: With ever-rising environmental concerns, designing more sustainable concrete structures is vital. One approach is to improve the methods of designing structures with less material consumption. Steel Fiber Reinforced Concrete (SFRC) in conjunction with smart design hybrid concepts shows great potential for material savings and improved durability of segmented tunnel linings. This paper focuses on the model-based design of SFRC structures, with the aim of analysing the effect of fibre choice and orientation on the structural behaviour and to investigate hybrid design concepts, characterized by a combination of high-performance steel fibre concrete in highly stressed zones and conventional SFRC in interior zones of the segment. The contribution presents advanced approaches for the serviceability assessment and non-linear design of SFRC segmental tunnel linings. The proposed Multi-Level FRC model is able to derive the post-cracking response of SFRC from the actual fibre properties instead of indirectly from bending tests and therefore allows for the explicit assessment of SFRC mixture parameters and fibre orientation on the structural performance. This contribution compares the performance of conventional, fibre reinforced concrete segments and hybrid designs subjected to tunnelling related loading cases and demonstrates how advanced numerical models, in conjunction with robust optimization and uncertainty models, and smart hybrid designs can be utilized to generate less vulnerable and more economical SFRC structural designs with a reduced environmental impact. Finally, a user-friendly design tool for SFRC tunnel linings, utilizing Artificial Neural Networks trained by virtual data, is presented.

1 INTRODUCTION

Concrete is one of the most used materials globally, with an estimated yearly consumption of around 30 billion tons and continuously increasing demand (Monteiro et al., 2017). The construction industry began with a range of initiatives and innovations aimed at the sustainable use of resources within the construction sector. The environmental impact of the construction can be either reduced by the usage of materials with better sustainability characteristics (e.g. reduction of the cement content, cement-free binding agents, recycled aggregates) or by improving the structural and lifetime performance of concrete (e.g. ultra- and high-performance concretes, the addition of micro and macro fibres, carbon concrete composites), thus reducing consumption.

Segmental tunnel linings as used in mechanized tunnelling are traditionally designed and constructed using pre-cast reinforced concrete (RC) lining segments.

Driven by durability considerations, recent developments in the tunnelling industry are, however, changing this paradigm, as Steel Fiber-Reinforced Concrete (SFRC) is becoming more widely used worldwide (see De la Fuente et al. (2012), grand Paris express - Metro Line 16-1, Doha Metro, etc.). Since the reinforcement scheme of SFRC segments is characterized by diffusely distributed steel fibres, they provide reinforcement in the entire segment, especially at segment extremities in which traditional reinforcement bars cannot be placed due to minimum concrete cover requirements. Furthermore, the absent minimum concrete cover requirements result in an earlier activation of the reinforcement effect in FRC and a potential slimming of the components. Steel fibres also substantially reduce concrete spalling at vulnerable locations, such as at the segment corners or in the vicinity of the jack loading platens, which results in increased robustness of the lining system (Bakshi and Nasri, 2017). Furthermore, the crack bridging capabilities of SFRC offer superior

*Corresponding author: guenther.meschke@rub.de

crack width control in comparison to RC. Another, benefit of SFRC linings is that steel fibre reinforcement can significantly contribute to reduced costs in production and transport.

A disadvantage of fibre-reinforced concrete (FRC) is the overall scatter in terms of the post-cracking behaviour due to the varying fibre orientation and distribution, which depends on the concrete casting process and the geometry of the component. This complicates the design of FRC structural members due to the need for conservative assumptions regarding the residual strength of cracked FRC.

The objective of the presented work is to develop novel fibre-reinforced segmental lining concepts to reduce the environmental impact and the costs of mechanized tunnelling projects through the use of sophisticated numerical methods for structural design. In order to do so, a simulation approach capable of predicting the structural response of segmental linings subjected to tunnelling-related loads is presented, which can as well capture the post-cracking behaviour of FRC and its scatter (Section 2). This computational model is then used to evaluate fibre-based reinforcement concepts and compare their structural performance with conventional reinforcement schemes to demonstrate their suitability for tunnel segments subjected to thrust jack loads (Section 3). Finally, the proposed modelling techniques in conjunction with optimization algorithms and uncertainty modelling are used to derive hybrid fibre-reinforced segment designs with a reduced environmental and economic impact, while the required level of safety is ensured through the probabilistic safety concept (Section 4). This highlights the potential reduction in concrete volume and steel amount by applying nonlinear FE models in conjunction with methods of optimization to the structural design procedure.

2 COMPUTATIONAL MODEL FOR RC AND SFRC

The design of FRC structures according to guideline-based approaches (e.g. fib model code 2010) is based on local verifications, for which the external stress resultants are determined by linear-elastic models and the resistance of a material point or cross-section is estimated through assumptions regarding the stress distributions in a cracked cross-section. In order to conduct a model-based analysis of a FRC structures to provide an assessment of the load-bearing capacity, the crack formation and the failure process, non-linear numerical models accounting for the post-cracking behaviour of FRC has to be used.

2.1 Multi-level FRC model

The basis of the modelling approach is discrete crack representation using zero-thickness cohesive interface elements (IEs). Zero-thickness interface elements are inserted between the solid finite elements in the part

of the domain where cracking is expected (Figure 1, top). All material nonlinearities due to cracking are modelled by the cohesive-frictional traction-separation relationship of the interface elements (Figure 1, bottom), while the bulk elements are assumed to behave as a linear elastic material. The material behaviour of the IEs is modified to account for post crack SFRC behaviour using a traction-separation law as proposed by Zhan et al. (2016). The traction-separation (t-w) law describes the post- and pre-cracking strength of SFRC as a function of crack opening and is derived using a multi-level fibre pull-out model. At the level of a single fibre, a semi-analytical model for the pull-out of steel fibres (Zhan and Meschke, 2014) is used to obtain the pull-out response of fibres with arbitrary inclinations relative to a crack surface and embedment lengths based on the concrete and fibre properties. On the crack scale, the crack bridging stress (t-w law) is obtained by homogenizing the response of multiple fibres crossing the crack, while accounting for the distributions of fibre orientations and embedment lengths. Therefore, the multi-level FRC model allows to directly assess the influence of the individual fibre type and the fibre

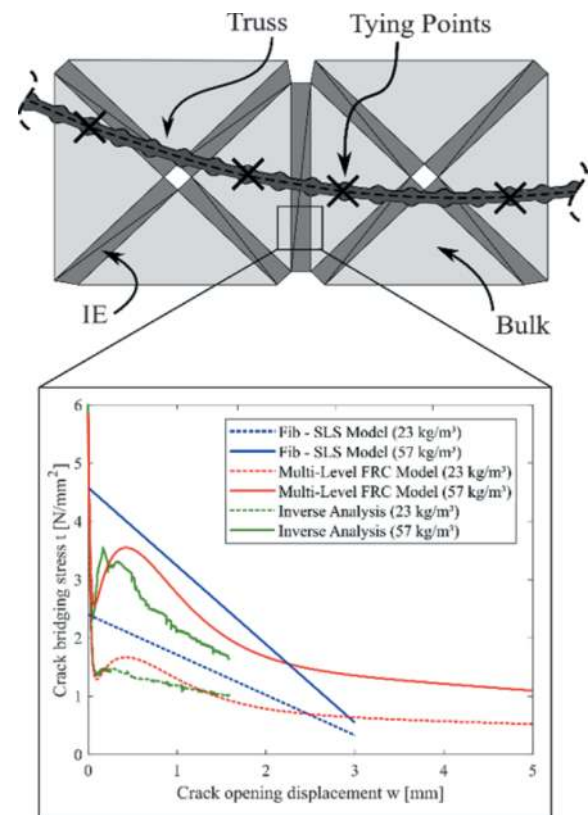

Figure 1. Top: Placement of interface elements (IE) between the regular finite elements (Bulk) and indication of the tying scheme for the consideration of rebars. Bottom: Comparison of the traction-separation laws determined by the multi-level FRC model (red) for SFRCs with 23 and 57 kg/m³ of steel fibres with stress-crack opening laws derived from bending tests by inverse analysis (green) and the fib model code 2010 (blue).

cocktail on the structural behaviour. For more details and validations see Gudžulić et al. (2020) and G.E. Neu et al. (2022). It should be noted that also arbitrary stress-crack opening relationships can be used (e.g. the stress-crack opening relationships proposed in the fib model code 2010 for modelling the tensile behaviour of SFRC at SLS and ULS).

In order to account for reinforcement bars, rebars are modelled as linear trusses and coupled with the concrete matrix using a constraint condition between control points located on the rebar elements and their respective projection points within the elements in which they are embedded (Gall, 2018). The constraint condition includes the bond-slip mechanism as provided in the fib model code 2010.

2.2 PC and SFRC material properties

In this article, the structural response of different segment designs is evaluated which can be either consists of SFRC, RC or combinations of these materials. The inputs for the material model are taken from a multi-level validation campaign (Gudžulić et al., 2020). For the concrete, a Young's modulus E_c of 39 976 N/mm², a tensile strength f_t of 6.0 N/mm² and a mode I fracture energy G_f of 0.136 N/mm was determined. The experimental campaign included fibre pull-out tests of Dramix 3D 55/60 and Dramix 3D 65/60 hooked-end steel fibres at different embedment lengths and orientations. After the successful validation of the model at the fibre level, the traction-separation laws were derived and used for numerical analyses of 3-point bending tests with different contents (23, 57 and 115 kg/m³) of Dramix 3D 65/60 fibres. The resulting stress-crack opening laws predicted by the Multi-Level FRC model are shown in Figure 1 (bottom) for a fibre content of 23 kg/m³ (red dotted line) and 57 kg/m³ Dramix 3D 65/60 fibres (red line). In addition, the linear stress-crack opening relationships for SLS calculations in accordance with the fib model code 2010 (blue lines) and based on an inverse analysis (Amin et al., 2015 - green lines) were derived from the experimental results of the bending tests and shown for comparison. For simulations on the structural scale, the traction-separation laws are incorporated in the numerical FE model using interface elements (Figure 1, top).

3 STRUCTURAL ANALYSIS OF RC AND SFRC SEGMENTS

The jack pressure applied to the segmental linings during tunnel advancement is resulting in potential critical stresses and therefore can lead to cracking between the jack pads and within the segment. In order to evaluate the suitability of different reinforcement schemes for tunnel lining segments and highlight their benefits as well as drawbacks, the structural response in terms of load-bearing capacity and serviceability performance is investigated and compared for the thrust jack loading case. For this comparison,

the properties and conditions of a reference tunnel project are used as a basis for the analysis.

3.1 Segment designs and model description

To compare a conventional and a fibre-reinforced segment, the concrete and fibre properties from the multi-level validation campaign described in Section 2.2 are used. The conventional reinforcement layout ($\Phi 10-10$ + additional rebars in high stressed regions) was derived by using conventional design procedures according to EN 1992 (2005), German tunnelling Committee DAUB (2013) & DB RIL 853 (1998) and is shown in Figure 2 (bottom).

Figure 2. Top: Segment geometry of the reference tunnel project with a inner radius of 4.8 m and a 7+0 segmentation. Bottom: The reinforcement scheme of the RC segment at the thrust jack application region.

All rebars are represented by linear truss elements with an elastic-plastic material law using the Von-Mises yield criterion and linear hardening. An elasticity modulus of 200 000 N/mm², a yield strength of 550 N/mm² and an isotropic hardening modulus of 1977.53 N/mm² for all rebars are assumed. The bond-slip behaviour is incorporated according to fib model code 1990. The SFRC segment is reinforced by 57 kg/m³ Dramix 3D 65/60 hooked-end steel fibres, which results in a similar overall steel amount per segment (SFRC \approx 258 kg/segment vs RC \approx 260 kg/segment). In addition, the concept of hybrid fibre-reinforced segment designs is adopted (Plückelmann and Breitenbücher, 2020), which is characterized by different SFRC layers placed according to the level of structural stresses. Here, the high stressed

regions around the jack pads and the longitudinal joint are reinforced by a 200 mm wide layer (ΔL) containing 57 kg/m^3 Dramix 3D 65/60 hooked-end steel fibres (Figure 2, top) while in the remaining segment a fibre content of 23 kg/m^3 is used (post-cracking behaviour according to Figure 1, bottom). The overall steel amount can therefore be reduced to 146 kg/segment , which is a reduction of around 57% when compared to the standard SFRC segment.

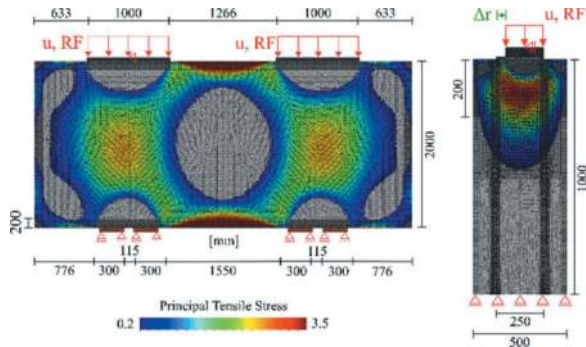

Figure 3. Geometry, boundary conditions, mesh and distribution of the principal tensile stresses of the plane segment model (left) and the partial area loading model (right).

Plane FE models analogous to the design models for the thrust jack loading case in engineering practice are used for a comparison of the investigated reinforcement schemes. The geometry, boundary conditions, mesh and the distribution of principal tensile stresses in the elastic regime are shown in Figure 3. The models represent different cuts through the segment. The partial area loading model (analogue to the strut & tie models in engineering practice - Figure 3, right) is used to analyse the bursting stress underneath the thrust jack pads, which are not covered in the plane stress model (Figure 3, left). In general, the partial area loading model (Figure 3, right) is decisive for the load-bearing capacity of a segment subjected to thrust jack loading while the plane stress segment model (Figure 3, left) is employed to check, if the derived design can prevent the occurrence of critical cracks between the thrust jack pads.

3.2 Results: Plane stress segment model

In terms of the force-displacement behaviour (Figure 4, top), the RC segment has the greatest load-bearing capacity (25.63 MN) followed by the SFRC (24.38 MN) and the hybrid segment (22.74 MN).

For an applied displacement of around 0.86 mm ($F \approx 8.95 \text{ MN}$), the first cracks (Figure 5) between the jack pads are initiated at all investigated reinforcement schemes and further propagate with increasing loading. At a displacement of around 1.5 mm ($F \approx 16 \text{ MN}$), bursting cracks in the middle of the segment are initiated and their propagation results in a further increase of the maximum separation (see plateau at

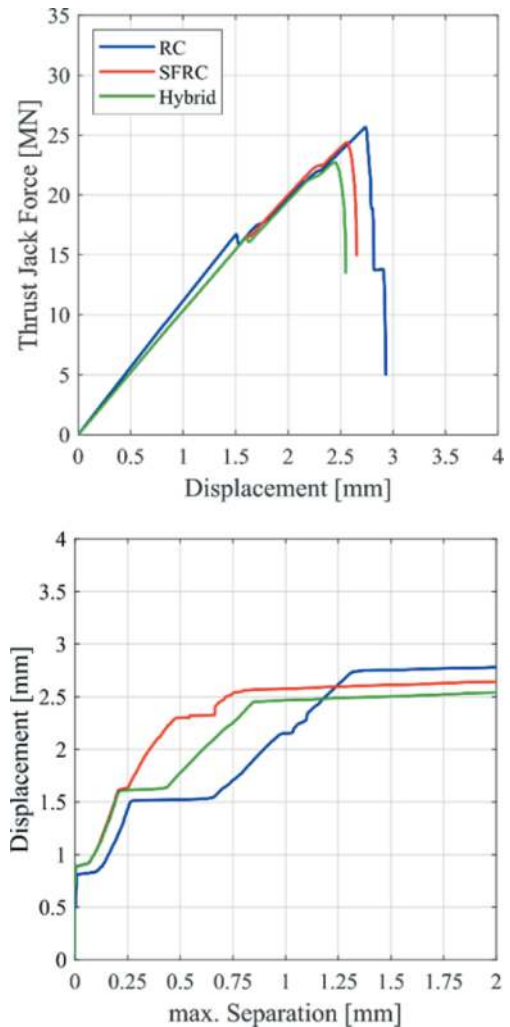

Figure 4. Plane segment model: Force-displacement curves (top) as well as the relationships between the applied displacement and the maximum crack width (bottom) for all investigated reinforcement schemes.

a displacement of 1.5 mm in Figure 4, bottom) as well as a minor drop and change in stiffness of the force-displacement curves (Figure 4, top). Failure occurs due to damages around the load and support plates (diagonal cracks & cone formation) at an applied displacement of approx. 2.5 mm, characterized by major crack openings ($> 1 \text{ mm}$) and a plateau in the displacement-separation curves (Figure 4, bottom).

The crack patterns at an applied displacement of 2.4 mm of the RC, SFRC and hybrid reinforced segments are shown in Figure 5. While the conventional reinforcement results in the formation of multiple cracks between the jack plates (Figure 5, top), the fibre-reinforced segments still provide a better crack width limitation (compare curves up to a displacement of 1.5 mm in Figure 4, bottom). In order to provide a reinforcement effect, the crack has to cross the reinforcement layer. The concrete cover restrictions delay the activation, because the crack need to propagate towards the rebar and therefore

further opens at the concrete surface. Overall, the fibre-reinforced segments provide better crack width limitation capabilities due to providing reinforcement everywhere in the segment, especially regarding the bursting cracks initiated in the middle of the segment (Figure 5). The hybrid segment performs equivalent to the full FRC segment up to a displacement of around 1.5mm ($F \approx 15\text{MN}$), because all cracks developed inside the strengthening layer. When cracks initiate and propagate towards the weaker reinforced regions of the hybrid segment at increased load, a decreased crack width control is observed (Figure 4, bottom).

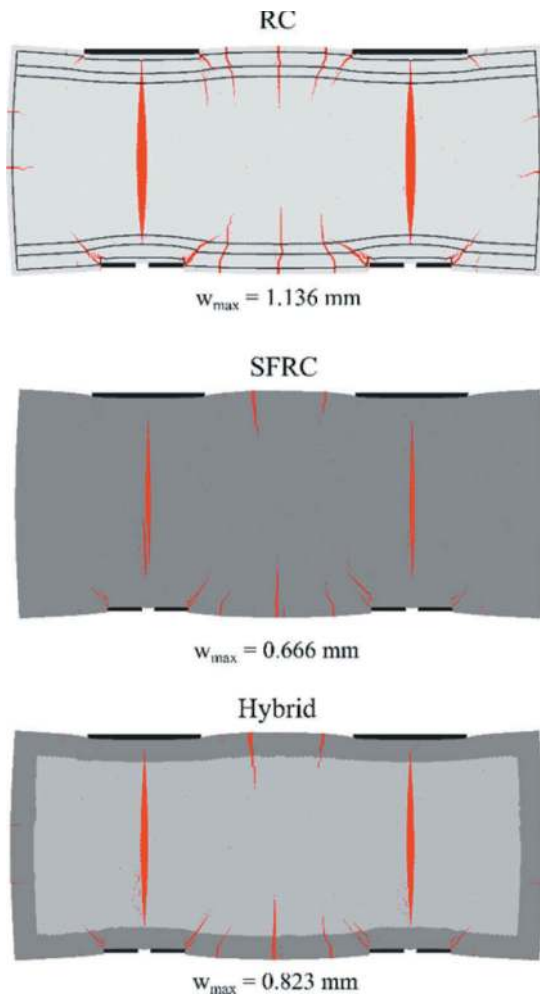

Figure 5. Plane segment model: Crack patterns of the RC, SFRC and hybrid segment and the corresponding maximum separation at an applied displacement of 2.4 mm (magnification 75x).

3.3 Results: Partial area loading model

In contrast to the plane stress segment model, an overall decreased load-bearing capacity and a superior performance of the fibre-reinforced segments can be observed (SFRC: 24.25 MN, Hybrid: 22.08 MN and RC: 19.71 MN). While the fibre-reinforced specimens fail due to the formation of

a wedge underneath the jack pad, the RC segment fail due to the propagation of the bursting crack through the whole specimen (Figure 6, bottom).

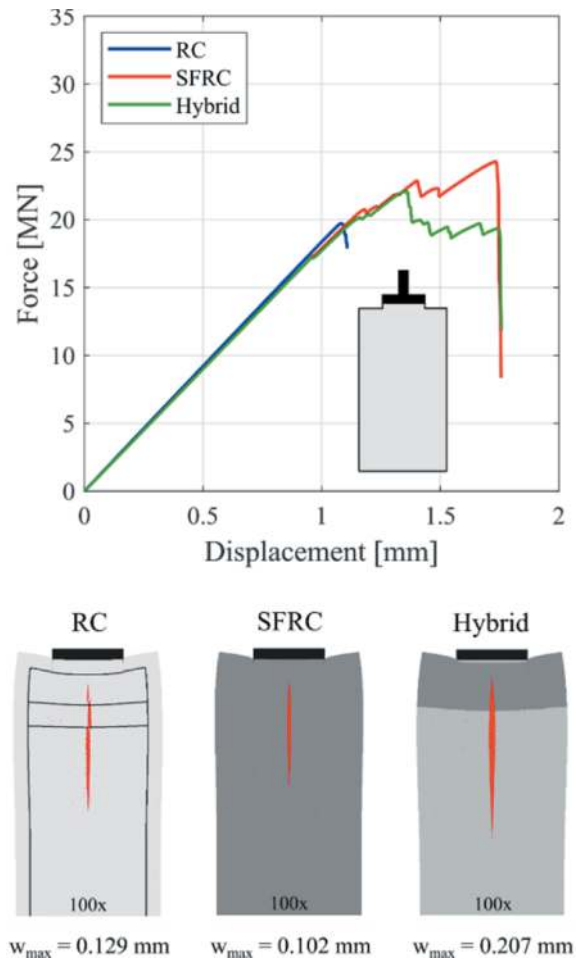

Figure 6. Top: Partial area loading model: Force-displacement curves for all investigated reinforcement schemes. Bottom: Crack patterns including the maximum separation value at an applied displacement of 1.089 mm. The RC specimen fails to a propagation of the bursting crack up to the bottom, whereas the fibre-reinforced specimen fail due to a wedge formation underneath the jack pad.

At an applied displacement of 0.94 mm ($F \approx 17\text{MN}$), the splitting crack is initiated and propagates in vertical direction (Figure 6, bottom). For the RC specimen, the splitting cracks initiate at the rebar layer and the rebars can immediately prevent a further crack opening and propagation. The rebars begin to yield at an applied displacement of 1.07 mm, which results in a propagation of the splitting crack towards the bottom of the specimen and consequently the failure of the specimen. In the fibre-reinforced specimen, the fibres provide a sufficient crack bridging resistance after a certain propagation of the splitting crack. At a displacement of 1.36 mm (Hybrid) and 1.43 mm (SFRC), the shear strength of the concrete is exceeded, and the wedge formation is initiated, which results in a drop of the force-displacement curve (Figure 6, top).

In comparison to the SFRC specimen, the hybrid fibre reinforcement provide less residual strength and therefore a softening in the structural response (Figure 6, top) in conjunction with a faster crack opening occurs (Figure 6, bottom). Figure 6 (bottom) shows the crack pattern of the RC, SFRC and a hybrid specimen at an applied displacement of 1.089 mm, which represents the structural response shortly before the yielding of the rebars in the RC specimen. The RC and SFRC specimen show a similar performance in terms of the maximum crack opening, but the bursting crack already propagated towards the bottom and therefore the fibre reinforcement will be more effective upon further loading due to the absence of rebars. In contrast to the SFRC specimen, a higher maximum crack opening can be observed for the hybrid specimen due to the propagation of the bursting crack outside the stronger reinforced layer.

4 RELIABILITY-BASED DESIGN OPTIMIZATION

For the example presented in this section, the Multi-Level FRC model, along with optimization algorithms and uncertainty models, is utilized to design a hybrid fibre reinforced tunnel lining segment subjected to thrust jack loads. The optimization-based design is carried out on the basis of the reference tunnel project presented in Section 3, for which the maximum thrust jack force of the tunnel boring machine F_{design} is specified as 5600 kN. The to-be-designed hybrid fibre reinforced segment consists of two SFRC layers (Figure 2, top), whose required thickness d as well as the fibre content c_F and width ΔL of the strengthening SFRC layer is determined by solving an optimization task under consideration of uncertainties. As reinforcement for the core zone, a FRC with a fibre content of 25 kg/m^3 is applied. In order to design the lining segment subjected to thrust jack forces, the two FE models used in Section 3 (see Figure 3) are employed in the optimization task.

4.1 Objective and input of the optimization problem

The optimization task is formulated to minimize the design variables (segment thickness d , the fibre content c_F and the width ΔL of the strengthening SFRC layer) while material uncertainties (fibre orientation λ_F , tensile concrete strength f_t and shear strength β) and imperfections (thrust jack eccentricity Δr – see Figure 3, right) are considered. It should be noted, that in this optimization problem the objective function to be minimized is specified as a weighted sum of the design variables d (80%), ΔL (10%) and c_F (10%), so that the minimum is at the constraint limit state defined by the four inequality constraints applied to both FE models. All constraints are formulated in terms of accepted failure probabilities to account for the scatter through the considered a priori uncertain parameters and therefore

providing a robust segment design (for the load bearing capacity $P_{f,ULS} = 10^{-5}$ and for the crack width control $P_{f,SLS} = 0.067$). For the failure criteria, the load bearing capacity F_{max} should be larger than the maximum thrust jack force $F_{\text{design}} = 5600 \text{ kN}$ and, in order to ensure a sufficient serviceability performance, the crack width between the thrust jack pads is restricted to 0.1 mm. Due to the computational effort involved in solving an optimization task under uncertainty, Feed-forward Artificial Neural Networks (ANNs) with two hidden layers are used as surrogate models. The ANNs for both structural models are trained with back propagation using results of 1800 FE calculations each (design of experiment generated by Latin Hypercube). A detailed description of the optimization task, uncertain variables and the probability constraints can be found in G.E. Neu et al. (2022).

4.2 Optimized segment design & constraint limit state

Due to the formulation of the optimization task, the minimum of the objective function will be on the constraint limit state (CLS), which divides the design space into feasible as well as unfeasible regions and is defined by inequality constraints. Three different strategies for optimizing a segmental lining are investigated:

- **Reference:** The optimization task as described in Section 4.1 is solved to design a hybrid SFRC segment using a conventional C40/50 concrete. The concrete tensile strength is modelled as a lognormal distributed random variable ($\mu = 1.24$, $\sigma = 0.18$). The compressive strength f_c (EN 1992, 2005), the elasticity modulus E_c (EN 1992, 2005) and the mode I fracture energy G_f (fib model code 1990) are assumed to be fully correlated with the lognormal distributed concrete tensile strength.
- **High-Performance:** This scenario should investigate how the use of a better performing concrete could further minimize the segment thickness. Therefore, the concrete tensile strength is modelled as a lognormal distributed random with the parameters $\mu = 1.51$ and $\sigma = 0.18$ (corresponds to C70/85).
- **Recycled:** In contrast, the use of a more environmentally friendly concrete (i.e. using recycled aggregates or modified cement paste) can lead to a lower concrete strength. Investigations in Kang et al. (2012) showed that the use of 50% recycled concrete aggregates lowered the measured tensile strength by 18%. This strength reduction is applied by adopting the concrete tensile strength distribution parameters $\mu = 1.04$ and $\sigma = 0.18$.

Due to the monotonic behaviour of all considered intervals, the CLS of the before-mentioned strategies are evaluated for a single realization of the intervals ($\Delta r = 40 \text{ mm}$, $\beta = 5.0$, $\lambda_F = 0.35$). More information regarding the uncertainty modelling, the parameter

ranges and different realizations can be found in G. E. Neu et al. (2022).

As can be seen in Figure 7, the segment thickness d and the fibre content c_F are dominating the shape of the constraint limit states for each case, whereas the cap width ΔL has only a minor influence. When only using the minimum fibre content of 25 kg/m^3 , a segment thickness of $d \approx 435 \text{ mm}$ ('high performance'), $d \approx 450 \text{ mm}$ ('reference') and $d \approx 465 \text{ mm}$ ('recycling') will lead to feasible designs. An increase of the fibre content up to 40 kg/m^3 enables a reduction of the segment thickness to $d \approx 400 \text{ mm}$ for the reference case. However, by further increasing the fibre content, only small reductions of the segment thickness can be achieved. The width of the SFRC cap ΔL is the least sensitive design variable. If a certain width is provided (tensile stresses occur within the strengthening SFRC layer), only small improvements with increasing cap width ΔL can be obtained (see 'reference' case at higher fibre contents c_F in Figure 7).

Figure 7. Constraint limit states in the design space for the 'reference', the 'high performance' and the 'recycling' case.

Finally, the evaluation of the objective function is performed for all cases and the optimum of each individual objective $R_{1,2,3}$ as well as the resulting design variables are summarized in Table 1.

Table 1. Design variables for each individual objective $R_{1,2,3}$ employed in the multi-objective optimization task for the investigated cases (results are rounded off).

	R1	R2	R3	d [mm]	ΔL [mm]	c_F [kg/m ³]
Reference	372	200	25	402	200	41
High Performance	358	200	25	391	200	38
Recycling	384	200	25	426	200	36

The optimization results in a 402 mm thick segment with a 200 mm wide SFRC cap containing 41 kg/m^3 of fibres for the reference case. When compared to the conventional RC segment design (Figure 2, bottom), the steel content is reduced by 59% (106 vs 260 kg/segment) and the concrete volume is reduced by 20% ($3.61 \text{ vs } 4.53 \text{ m}^3/\text{segment}$). The use of a better performing concrete can further reduce the segment thickness ($3.2 \text{ vs. } 3.61 \text{ m}^3/\text{segment}$), while a similar steel content in comparison to the reference case can be achieved ($92 \text{ vs } 106 \text{ kg/segment}$). As an alternative, the use of concrete with recycled aggregates still leads to a segment design with a lower concrete volume ($3.83 \text{ vs } 4.53 \text{ m}^3/\text{segment}$) and a reduced steel content ($108 \text{ vs. } 260 \text{ kg/segment}$) in comparison to the conventional RC design.

4.3 Design tool for SFRC and hybrid segments

As part of the model development for the design of hybrid reinforced segments using the Multi-level FRC model in combination with optimization algorithms, neural networks were derived that can predict crack width and load-bearing capacity as a function of segment thickness, fibre content, fibre orientation, and concrete strength (Section 4.1 and G.E. Neu et al. (2022)). These ANNs were implemented in a software-based design tool with a suitable graphical user interface to assist engineers in the design of fibre reinforced segment and to provide a straightforward access to the prediction models presented within this article (Figure 8).

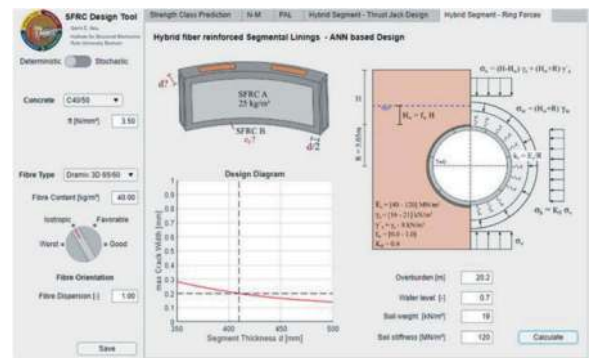

Figure 8. ANN-based design tool of hybrid fibre-reinforced segmental linings.

5 CONCLUSIONS

The results presented in this paper demonstrate the role of advanced numerical modelling approaches in the design of more sustainable fibre-reinforced concrete structures. The presented multi-level FRC model was used to compare the structural performance in terms of load-bearing capacity (ULS) and crack development (SLS) of conventional and fibre reinforced segments subjected to thrust jack loadings. It was shown that SFRC segments offer a better crack

width control and provide a comparable load-bearing capacity in comparison to RC segments with an equivalent steel content. In addition, the concept of hybrid fibre reinforced segments (placement of different SFRC layers according to the level of structural stresses) was investigated and showed to be able to reduce the overall steel content significantly.

As application case, a reliability-based optimization for the design of fibre-reinforced segmental tunnel linings subjected to thrust jack forces has been performed. A segment design is derived, consuming up to 20 % less concrete and reducing the steel content by 59 % as compared to a conventional RC design. Using high-performance concrete, a further reduction can be achieved (steel content -13 %, concrete volume -11 %), while the use of recycled concrete has been shown to be an environmentally friendly alternative (58 % less steel content and a 15% lower concrete volume in comparison to a conventional RC segment design).

ABSTRACT: This paper aims to present the design of the reinforcement required for the segmental liner of a TBM tunnel crossed by large caverns at great depth. Indeed, when a TBM tunnel is intersected by subsequent excavations, there is a significant risk of overloading the liner, especially for large excavations, in a highly stressed jointed rockmass of low/medium strength. Such situation is the case of the intersections between the Main Access Tunnel (MAT) and the two caverns of the 2200 MW pumped hydro-power Snowy 2.0 in Australia. In addition, the construction planning is characterised by multiple strict logistical constraints. To address these conditions and constraints, a combination of measures is implemented. Sliding steel ribs are employed to provide support to the precast concrete lining segments. Temporary and permanent rockbolts are also used for temporary and permanent support, and an observational approach is adopted to monitor and adapt to the changing conditions during construction. Numerical analyses are performed on discontinuous models using 3DEC and Unwedge software. On one hand, 3DEC models are used to simulate the behaviour of the jointed rock mass and the support system, enabling the evaluation of concrete segment damage evolution. Moreover, the excavation sections and planning of the cavern are adjusted so as to be aligned with the general schedule and logistical constraints while assuring MAT01 liner stability. On the other hand, Unwedge models are carried out to design definitive rockbolts based on rock block stability analysis. Some in situ measurement from the observational methods are compared with numerical results, according to the observational method.

Keywords: Concrete segment, Sliding steel rib, Discontinuous, Numerical modelling, Observational method

1 INTRODUCTION

Snowy 2.0 is a 2200 MW pumped-storage hydro-power, currently under construction, extended from the Snowy Mountain Scheme in the southeastern Australia, linking two existing reservoirs, Tantangara and Talbingo, through a 720 m depth Power Station Complex (PSC) by 27 km tunnels (Figure 1). The PSC consists of two caverns – the Machine Hall (MH) for six generation units and the Transformer Hall (TH) - connected by six busbar galleries and six draft tube tunnels.

The PSC is accessed, during the construction phase and permanently, by the Main Access Tunnel (MAT01) and the Egress, Cable and Ventilation

Tunnel (ECVT01), from which drill and blast (D&B) tunnels are realised for the construction of the caverns. MAT01 and ECVT01 are both excavated by TBM and supported with pre-cast reinforced concrete

Figure 1. Snowy 2.0 – Project location (left) and alignment (right) Ref: Snowyhydro.com.au.

*Corresponding author: xuan-phu.nguyen@tractebel.engie.com

segmental lining. During construction, MAT01 is excavated first and serves as the main access to the PSC and its surrounding tunnels. It is the only lined tunnel that crosses the two caverns.

Due to planning considerations, the circulation inside MAT01 must be maintained as long as possible, even during the excavation of the overlying upper levels of the caverns. It follows that any issue at the intersections between MAT01 and the two caverns would induce the construction of the whole PSC halted. Therefore, these intersections represent a critical point in the detailed design of the project, requiring a robust design methodology.

2 GEOLOGICAL SETTING

Figure 2. Structural model of the rockmass.

The project area is situated within the south-eastern portion of the Lachlan Orogen (Fold Belt) of New South Wales, which comprises a suite of early Palaeozoic Era (550-350 Ma) sedimentary, igneous, and metamorphic rocks that have developed during several orogenic periods. The PSC is in the Ravine Beds Formation, under 600 – 720 m depth. The formation consists of thick sequences of indurated siltstone (70%) and interbedded/interlaminated sandstone with conglomerate (30%). The joint pattern around the PSC consists of bedding and tectonic joints (Figure 2) that are classified in:

- Minor joints T1 and T2 are in-between pre-sheared joints, dominantly bedding joints, undergoing negligible tectonic displacements.
- Major joints T3 and T4 are pre-sheared joints, considered as the main weakness planes in the rockmass. Their main characteristics are presented in Table 1, and dip-direction indicated in Figure 2. One observes that both jointsets dip in the direction from TH to MH.

Rockmass geomechanical characteristics being relatively heterogeneous, a “central” case is considered for the present study:

- For an equivalent homogeneous medium: $UCS = 58$ MPa and $GSI = 72$;

Table 1. Major joint-sets T3/T4 characteristics.

Parameter	Bedding joints	Tectonic joints
Dip (°)	35	75
Dip-direction (°)	75	125
Spacing (m)	10	20
Friction angle (°)	30	
Cohesion (MPa)	0	

Figure 3. Perspective (top) and plan (bottom) views of the PSC with MAT01 highlighted in red. Orientations of horizontal principal stresses σ_h and σ_H , major bedding (green) and tectonic (orange) joint-set dip-direction are marked.

- For discontinuous medium cut by the major joints (T3/4) into blocks in which are lumped the minor joints, the rock blocks (matrix) are characterised by: $UCS = 58$ MPa and $GSI = 78$. In other words, the absence of major joints increases GSI from 72 to 78.

Vertical stresses at the PSC are practically lithostatic with a unit weight of 27 kN/m^3 , the value at the middle of the caverns being $\sigma_v = 19$ MPa.

Horizontal stresses are strongly anisotropic, the minor and major principal component ratios are respectively $K_h = 1.5$ and $K_H = 2.3$, i.e. $\sigma_h = 28.5$ and $\sigma_H = 43.7$ MPa (orientations indicated in Figure 3). Rockmass permeability being extremely low, all the calculations are carried out in total stress.

3 DESIGN METHODOLOGY

MAT01 is excavated with a single shield 11 m diameter TBM and supported by 38 cm thick pre-cast reinforced concrete segmental lining (Table 2). Generally, lined tunnel is expected to be overloaded at intersections with subsequent excavations around which stress concentration is induced by deconfinement (see §4.2), resulting in concrete segment damage due to excessive compression stresses and/or ring collapse due to ovalisation (see §4.3) and its inherent discontinuity. The larger the subsequent excavation and the higher the in situ stresses, the more important the tunnel lining overloaded.

Table 2. MAT01 main dimensions.

Parameter	Symbol	Unit	Value
Boring diameter	ϕ_{exc}	m	11.08
Annular gap	δ_{gap}	cm	21
Internal ring diameter	R_i	m	9.90
External ring diameter	R_e	m	10.66
Segment thickness	t_{ring}	m	0.38
Concrete strength	f'_{ck}	MPa	50
Ring width	L_{ring}	m	2.00

Figure 4. Lining damages zoning around MAT01 – caverns intersections. Cavern excavation benching is shown.

Accordingly, around the MAT01 - caverns intersections, lining damage was foreseen and was firstly evaluated in terms of extensions depending on the construction sequence (see §4.3). Indeed, MAT01 lining in the PSC was sub-divided into 3 zones, as sketched in Figure 4:

- Zones 1 - inside the 2 caverns: The most critical phase occurs at the excavation of the caverns crowns, giving rise to lining vertical ovalisation.
- Zones 2 - beside the caverns sidewalls: They are characterised by lining horizontal ovalisation induced by vertical stress concentration beside the caverns.

- Zones 3 - outside of zones 2: These zones are less affected by the excavation of the PSC, but the failure risks are not totally discarded.

Figure 5. Excavation and traffics in the cavern and in MAT.

Table 3. Sliding steel rib characteristics.

Parameter	Unit	Value
Grade	-	+QT630
Section	-	TH44
Density	Gg/m ³	0.00785
Young modulus	MPa	2x10 ⁵
Poisson ratio	-	0.2
Cross sectional area	m ²	5.57x10 ⁻³
Bending inertia	m ⁴	1.243x10 ⁻⁵
Elastic section modulus	m ³	1.65x10 ⁻⁴
Yield point	MPa	630
Tensile strength	MPa	790
Limit axial forces	MN	0.5
Limit axial stress	MPa	90 (15% σ_y)

Additional support along these extensions must have been installed before damage occurring. On one hand, the additional support must retain the damaged concrete segments, the overlying rock and the traffic load related to circulation inside the vaults of the caverns which are under construction (Figure 5). On the other hand, for zones 2 & 3 beside and outside the caverns, it must also be able to receive further loading induced by rockmass convergences during the excavation of the lower parts of the PSC. Thus, additional support must follow the “yielding principle”, while assuring enough resistance. Considering the multiple logistic constraints, sliding steel ribs were chosen as the main additional support. These are made of top-hat cross-section steel profiles (Thyssen-Heintzmann - TH) with friction connecting loops that allow the ring of ribs to accommodate larger displacements with limited sliding resistance. The sliding limit force and the spacing were designed according to the “resistance principle”, capable to withstand the weight of the

overlying rocks and the traffic load in the cavern. They are estimated with a local continuous model, using FLAC3D software, in which the rock is represented with residual properties. The sliding limit force being estimated at 500 kN/m, the section TH44 was chosen, the spacing is 1 m, allowing to have 2 ribs per each lining ring (2 m long).

After the PSC construction, all the steel ribs must be dismantled so as MAT01 space-proofing can be satisfied. Damaged lining rings, expected in zones 2 and maybe part of zones 3, must also be dismantled. The final extensions of liner dismantling will be decided based on monitoring data, according to the observational method. Special attention was given to the lining dismantling procedure (see §5) as they are expected to be strongly stressed.

After damaged liner dismantling, a definitive support system, consisting of rockbolts and shotcrete, will be realised. These elements are designed based on the stability of local rock blocks/wedges formed from geological joints and excavation surfaces. This design is carried out using Unwedge software.

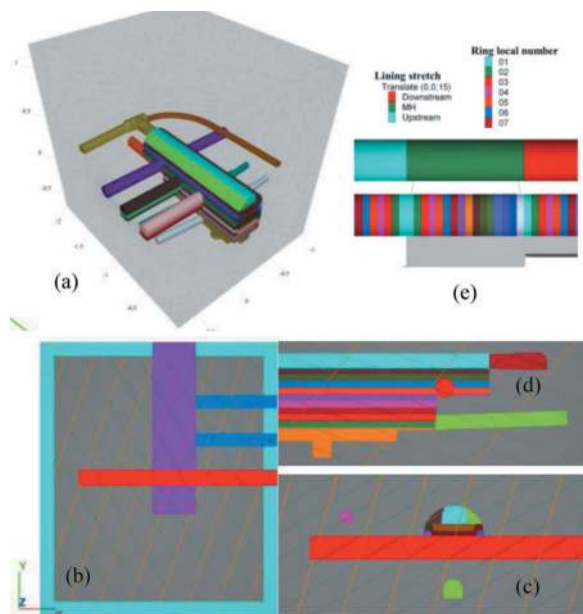

Figure 6. 3DEC model for MAT01-MH intersection: a) model limits (unit of 100m); b) horizontal cut-plane at MAT01 axis level; c) and d) vertical cut-planes along MAT01 and MH axes; e) lining ring enumeration.

4 STRUCTURAL INTEGRITY OF THE SEGMENTAL LINING AND SLIDING STEEL RIBS

4.1 Numerical models

Discontinuous models are built using 3DEC software where major bedding and tectonic joint sets (see §2) are explicitly represented. Figure 6 shows the extension of a local model focused on the MAT01-MH intersection, with all the excavation divisions following the initial phasing. Bedding joints are shown to

be more horizontal than tectonic joints, and thus expected to have larger impact on MAT01 lining. Moreover, as both joint sets dip towards the upstream (TH towards MH), overload on MAT01 lining is expected to be more pronounced on the upstream side than on the downstream side of MH.

Rock blocks are represented by an elastic perfectly plastic model with a bi-linear Mohr-Coulomb criteria fitted to the Hoek-Brown criterion. Similar models fitting the Barton-Bandis failure criterion are adopted for joints. Main characteristics of rock blocks and joints are shown in §2.

MAT01 lining is represented by shell-type structural elements called “liner” in 3DEC, which are linearly elastic (without failure) and resist to membrane and bending actions. Liner and rock excavation surface interaction is modelled using interface elements whose parameters are estimated from annular gap backfill material properties: Young’s modulus $E_{bf} = 1$ GPa, uniaxial compression strength $UCS_{bf} = 2$ MPa, and thickness $t_{bf} = 21.5$ cm. The interface normal stiffness can be estimated as $k_n = E_{bf}/t_{bf} = 1/0.215 = 4.65$ GPa/m. The interface normal tensile resistance is null and compressive resistance is infinite, meaning that liner nodes can be detached from the rock excavation surface but cannot penetrate into the rockmass. In the shear direction, without data, we assume that the interface shear stiffness is equal to the normal stiffness $k_s = k_n$. Assuming a friction angle of $\phi_{bf} = 30^\circ$, the corresponding cohesion is $c_{bf} = 0.58$ MPa. In fact, the numerical interface between liner and rock excavation surface represents the backfill material and its two interfaces with the rock excavation surface and the concrete lining extrados. As the concrete lining surface is relatively smooth, the liner – rock excavation surface shear resistance in the model would be smaller than the annular backfill shear resistance. As a friction angle of 30° is already relatively small, for the numerical liner-rock interface, we consider a friction angle of 30° and a null cohesion as the reference parameters. A liner-rock interface shear-directional cohesion of 0.58 MPa has also been considered for parametric study.

Figure 7. Vertical σ_{zz} (a) and horizontal σ_{yy} (b) stress contours after MAT01 (1) and caverns crown (2) excavations.

Effect of longitudinal joints between segments in each lining ring on its bending inertia is accounted for using Muir Wood (1975)’s formulae. In the MAT01 axis, separation between rings is explicitly represented,

with enumeration shown in Figure 6e. However, no direct interaction between adjacent rings is modelled.

4.2 Rockmass behaviour

Figure 7 exhibits stress concentrations after excavations of MAT01 (1) and after MH stage-1 (2): vertical stresses are concentrated by the excavation sides, horizontal stresses, above and below. The rock slab in-between MH stage-1 and MAT01 experiences significant stress releases: from 15-30 MPa to 0-5 MPa in the vertical direction (figures a), and from over 30 MPa to 0-10 MPa in horizontal plan (figure b). These rock blocks are totally plasticised. That's why we used rockmass residual properties when estimating necessary sliding limit force (see §3).

Figure 8. Rock displacement around MH-MAT01 intersection after CHT (a) and complete PSC (b) excavations.

In presence of a bedding joint intersecting the zone in-between MAT01 and the stage-1 of the cavern, convergences towards the cavern excavation enhance shear displacement on this joint (Figure 8a), giving rise to local overload concentration on MAT01 lining due to subsidence of the lower rock block. At the end of all the PSC excavations (Figure 8b), displacements on the cavern wall are about 10 cm, rock bedding layers clearly bend towards the caverns, and MAT01 lining rings in zones 2 (beside the caverns) horizontally ovalised. This excavation induced displacement fashion is typical for anisotropic rock masses and largely reported in literature (Sainsbury and Sainsbury, 2017).

Figure 9. Evolutions of MAT01 convergences at sections inside (a) and outside (b) MH. Negative values indicate extensions.

MAT01 ovalisation can also be observed with convergences at different sections (Figure 9). Note that negative values indicate divergences. Outside the caverns (Figure 9b), lining ring ovalisation is horizontal and diminishes with increasing distance from the caverns sidewalls. In zones 3 which are relatively far from the caverns, some convergences are still considerable, larger than 1% of the tunnel

diameter. Inside the cavern (Figure 9a), ovalisation is mainly vertical and varies depending on the relative position of the considered section to bedding joints and to the overlying excavation in the caverns.

4.3 Lining integrity evaluation

By “damage” we refer to the state of efforts at a point on the liner that does not verify ULS following AS5100.5:2017. Figure 10a presents the lining effort verification against the strength envelope on $M-N$ diagram for the stretch on MH downstream. The first five rings exhibit significant effort exceedance from the envelope. To visualise the location of the exceeding points, we introduce the strength ratio which is the ratio between the distance E_{ed} from the centre of the strength envelope to a given effort point and the corresponding distance E_{lim} from the centre to the envelope: $SR = E_{ed}/E_{lim}$. Accordingly, $SR \geq 1$ indicates that the efforts exceed the resistance envelope, while $SR < 1$, the efforts are inside the resistance envelope. Based on lining SR (Figure 10b), and its evolution with the excavation of the PSC, extensions of zones 2 are delimited for each excavation phase. Accordingly, deadlines for sliding steel ribs installation and excavation sections in the caverns can be adjusted vs logistic constraints. Besides, the SR contour shows that MAT01 lining damage on the upstream side is farther than in the downstream side, which confirms the expected effect of bedding joint orientation (see §2).

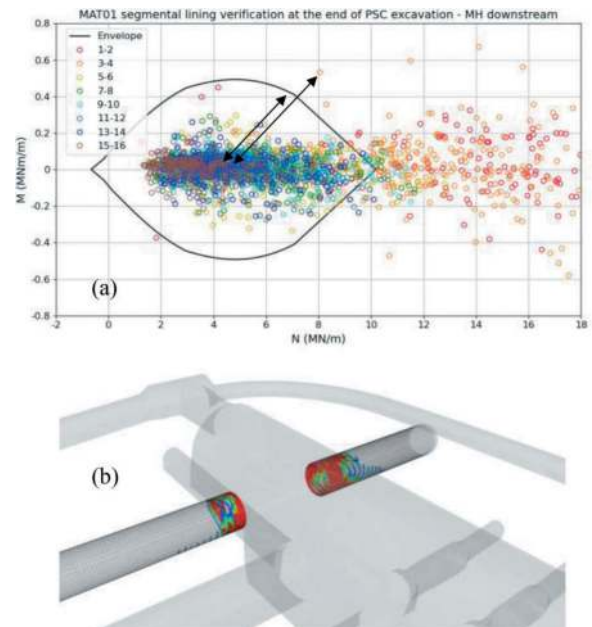

Figure 10. Lining verification after MH excavation: (a) effort points coloured following ring enumeration vs ULS envelope, and (b) strength ratio $SR > 1$ contour.

In zones 3, some slight and local exceedances of the strength envelope can be observed. In addition, in the case of higher cohesion $c_{bf} = 0.58$ MPa between the liner and the surrounding rockmass (see §4.1),

some tensile forces appear in crown and invert of the liner. As MAT01 is situated near the border of the PSC (see Figure 2), the PSC excavation induced rock displacement is not symmetric around MAT01, but toward the PSC centre. Figure 11 shows that, with higher shear strength on the rock-liner interface, this rock displacement pattern generates tensile axial forces on the crown and the invert of the liner. Note that in the numerical model, the lining rings are represented by continuous and elastic shell-type structural elements, while they are made up from discrete segments. Calculated tensile forces in a lining ring mean that the ring presents the risk of instability due to loosing contacts between segments on longitudinal joints. Thus, concrete segments in zones 3 are supported with rockbolts (two CT26WR $L = 6$ m per segment). In zones 1, due to delayed sliding steel rib installation for logistic constraints, similar rockbolt support applies prior to excavation of the Central Heading Tunnel (CHT) in the crown of the caverns (see Figure 13).

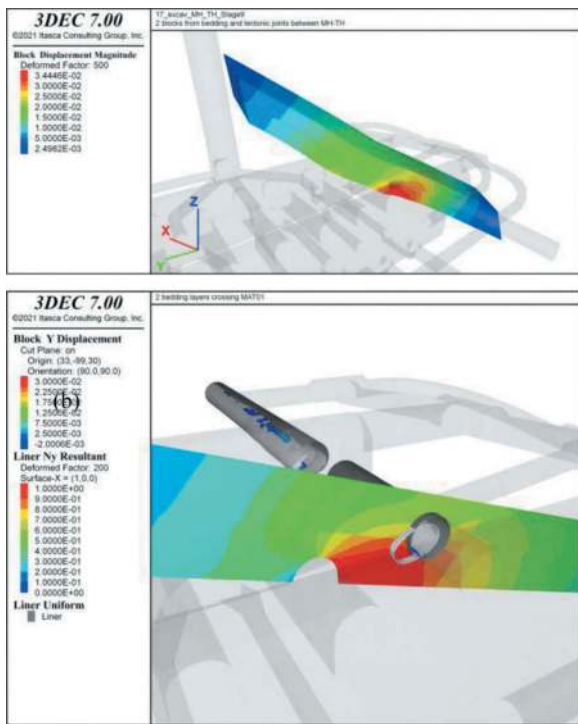

Figure 11. Interaction between two rock blocks crossing MAT01 in zone 3, between the two caverns and beside IPB-1, cut by three bedding joints and two tectonic joints, and the liner. (a) Perspective view of the blocks total displacement. (b) Blocks horizontal displacement on a cross-section, liner tensile force contour in exaggerated deformation and its initial geometry.

4.4 Sliding steel ribs verification

Steel ribs are verified for material resistance on cross-section according to AS4100:1998. As steel ribs are fixed in the tunnel axis direction on concrete lining intrados, or braced between each other by longitudinal strutting tubes, steel

structure stability, such as buckling, are not verified. For material resistance verification, the most critical measure for each cross-section is the von Mises equivalent stress σ_g resulting from combined bending moment M , axial N and shear V forces (Hirt and Bez, 1994). We introduce the strength ratio for each cross-section as the ratio between design values of the maximal equivalent and yield stresses $SR = \sigma_{gd}/f_{yd}$. Without bending moment and shear force, the sliding limit force only corresponds to a $SR = 20\%$.

Figure 12. Steel rib axial force just before breakthrough into MAT01 (a) and strength ratio SR at the end of all PSC excavations (b).

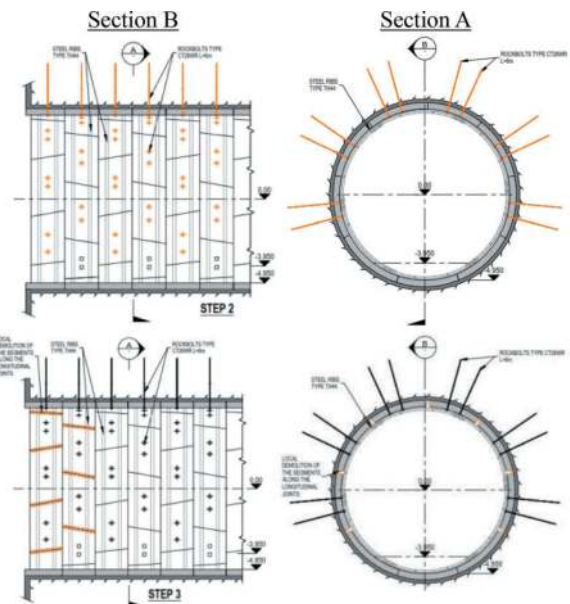

Figure 13. Concrete segment stabilisation with rockbolts (STEP 2) and ring stress release by local demolition along longitudinal joints (STEP 3).

Figure 12a shows steel rib axial forces just before the breakthrough into MAT01. One observes that the sliding limit force is reached in sections below the cavern excavation sidewall, while outside the cavern and in the middle of the stretch inside the cavern, they are far below. All strength ratios $SR < 1$. At the end of PSC excavation, steel ribs slide on over 10 m from the sidewalls of the caverns, but strength ratios are mainly below 1, except for some closest ribs that are intersected by bedding joints (Figure 12b).

5 LINER DISMANTLING AND DEFINITIVE SUPPORT

As shown in §4.3, concrete segments in zones 2 are expected to be significantly damaged, and shall be dismantled, allowing the definitive rock support based on rockbolts and shotcrete to be installed. Nevertheless, due to logistic constraints, the dismantling of the segments in zones 2 will be postponed after the completion of the caverns excavation, during which they will be temporarily supported by provisional sliding steel ribs. The final effective dismantling extension will be decided based on monitoring data.

Figure 14. Definitive support replacing damaged concrete segments.

Figure 15. Unwedge model for a rock block situated on the MAT01 crown and adjacent to a cavern side wall with definitive support.

The most critical point upon dismantling concrete segments in zones 2 at the end of the PSC excavation is that they have been significantly stressed due to rockmass convergence. Thus, to ensure maximal safety, the following principles applies:

- Stabilisation of each segment to be dismantled with two rockbolts type CT26WR, $L = 6$ m (Figure 13 – STEP 2).
- De-stressing of the ring by punctual demolition of the segments before the removal of the temporary steel ribs (Figure 13 – STEP 3). The concrete

segment and the retained rock wedges by the rockbolts are verified using Unwedge software.

- Dismantling is to be carried out in small areas, maximum at a time two rings (4 m round length) and in an angular opening $< 90^\circ$ (1/4 circle). During the transient between segments removal and permanent rockbolt installation, the rockmass stability will be assured by a primary 100 mm shotcrete having $f'_c > 1$ MPa and the two rockbolts on each segment deprived of the plate. Rock wedge stability is accordingly verified using Unwedge software.

Definitive support consists of another 100 mm secondary shotcrete (200 mm in total) and rockbolts CT26WR with $L = 6$ m, @1.5mx1.5m (Figure 14). Rock wedge stability is verified with these support elements using Unwedge software (Figure 15). For this analysis, all the jointsets (see Figure 2) are considered in different combination. In addition to the weight of the wedges, ground water pressure and seismic loading are also considered. All the safety factors are larger than unity, indicating that rock wedge stability verification is attainable.

Figure 16. Markers for steel ribs sliding measurement (a); DMP and strain gauges measured sections (b).

Figure 17. Central Heading Tunnel excavated in MH (a); Sliding steel rib installation in MAT01 (b).

The MAT01 stretch in the PSC, as identified in Figures 3 and 4, must be extensively monitored during construction. In addition to geological mapping, the monitoring system consists in:

- concrete lining rings: displacement/convergences using DMP (Displacement monitoring point) and stresses using strain gauges on steel rebars;
- sliding steel ribs: stresses using strain gauges and relative sliding displacement (Figure 16a);
- temporary rockbolts: axial force using load cells;
- joint shear displacement: video inspection via borescope camera.

Currently, MAT01 as well as surrounding construction tunnels for the PSC have been finished. The excavation of the PSC has been started with the CHT in both caverns (Figure 17a). The lower part of all the sliding steel rib has been installed in MAT01 (Figure 17b).

Some preliminary monitoring data, mainly in terms of lining rings DMP displacements and stress is provided. The allocations of the measured sections and the DMP positions on each section are shown in Figure 16b. For each measured section/ring, convergences following six directions (“string”) as shown in the figure are provided. Also, a lining ring being composed of nine segments, each segment is measured with a couple of strain gauges installed on its intrados and extrados rebars (Figure 18).

Figure 18. Implementation of strain gauges on a concrete segmental ring and example of corresponding numerical results.

Figure 19a exhibits DMP convergence on the lining ring at chainage 2+593 (marked in Figure 17) on zone 2 next the MH downstream sidewall. The current phase, namely “04_1_MH_01_C” for CHT of MH excavation stage-1, is marked by blue line. Corresponding monitored data is plotted in Figure 19b as temporal evolution. The period during which the CHT excavation front is above MAT01 is marked with blue rectangle. Both numerical and monitored results indicated small displacement by the current phase.

Similar presentation for stresses on the same lining ring is exhibited in Figure 20. Again, both numerical and monitored results indicate relatively small stress by the current phase. More significant values for DMP convergences and stress are expected after caverns crown side slashing from the CHTs which is planned for the next couple of months.

Support design for the intersections between the Main Access Tunnel MAT01 and the two caverns of the Australian Snowy 2.0 pumped-storage hydro-power, as part of the Power Station Complex (PSC) detail design, has been described. It consists in a principal access to the whole PSC during construction as well as in the service phase. Excavated by TBM and lined with pre-cast concrete segments, MAT01 directly crosses the two caverns of large dimensions, and surrounded by several construction tunnels and galleries, at some 700 m depth in a medium strength and jointed rockmass. To accommodate these significant excavation volumes and to meet multiple construction planning and organisation constraints, sliding steel ribs and rockbolts are used to support damaged concrete segments during construction, coupled with an observation method. At the end of the PSC excavation, sliding steel ribs and damaged lining rings will be dismantled and replaced by a definitive support composed of shotcrete and rockbolts.

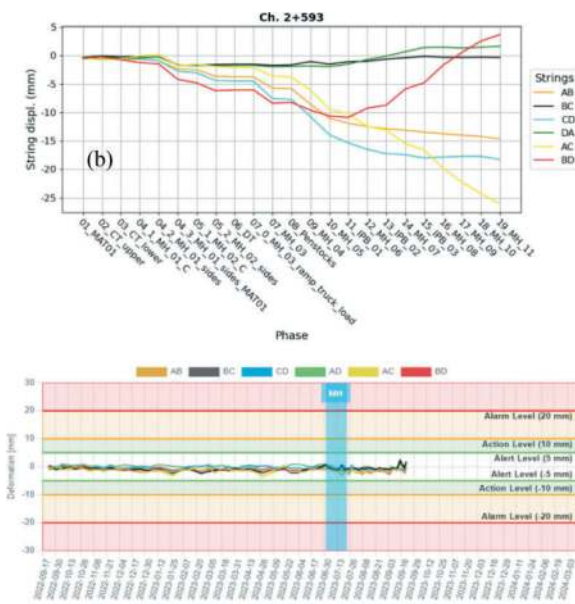

Figure 19. Numerical (a) and monitored (b) DMP displacements at ch. 2+593.

Numerical analyses have been performed on discontinuous models where major tectonic and bedding joints are explicitly represented. The results showed considerable and anisotropic rock convergences toward the two caverns, accompanied by joint shear displacements, and bending of rock bedding layers. Based on these results, MAT01 lining in the PSC was sub-divided into 3 zones – inside the cavern, adjacent to the caverns sidewalls and farther, called zones 1, 2 and 3 respectively – of different rock mass – liner interactions, logistic constraints, thus support method and planning. The extensions of these stretches depend on their positions relative to the caverns and

the bedding joint dip-direction: longer extension for the upstream side (toward which bedding layer dips) and for the larger cavern (MH). The results also showed that sliding steel ribs are effective in accommodating large tunnel convergences in a highly stressed rockmass. Only a few ribs next to the cavern sidewalls fail at intersection with bedding joints experiencing large shear displacements. Definitive support replacing dismantled lining rings is also satisfactorily verified based on rock wedge stability.

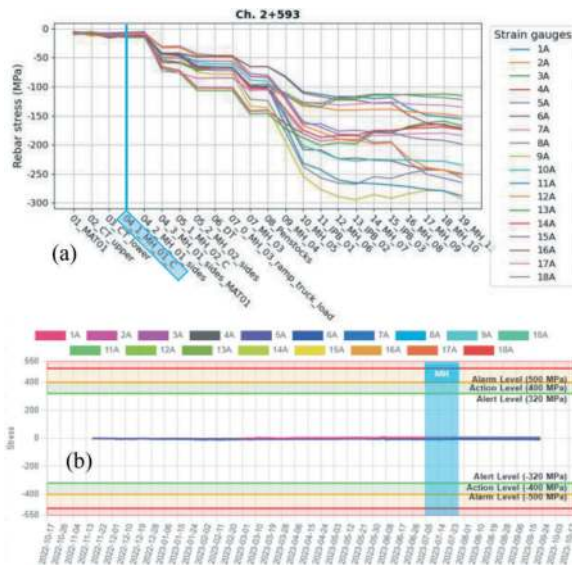

Figure 20. Numerical (a) and monitored (b) stresses on steel rebars at ch.2+593.

The excavation of the PSC has been started and currently at the excavation of the Central Heading Tunnels (CHTs) in the caverns crown. Numerical and monitored results are in good agreement so far, both indicating negligible convergences and stresses in the liner. However, larger values are expected just after the side slashing from the CHTs, and naturally during the excavation of the lower part in the caverns.

ABSTRACT: In this study, cores were sampled from several locations in the arches of the lining concrete of a road tunnel that was no longer in use to confirm the state of cracking damage at the casting end and to confirm the decline in concrete quality at the casting end by focusing on the distribution of the coarse aggregate. In this project, we conducted a series of fundamental experiments to investigate the feasibility of using volcanic glass powder, a pozzolanic material, as a concrete admixture to increase the resistance to material separation during casting and to moisture and salt penetration after curing, thereby realizing high-quality, highly durable lining concrete. The lining concrete using volcanic glass powder has been put to practical use through experiments from basic testing to construction.

Keywords: lining concrete, long-term quality, casting, volcanic glass powder, deterioration, admixture

1 INTRODUCTION

Concrete lining of road tunnels was constructed using slide arch-centres, and until the 1970s, concrete was placed by conveyor feeding or by pulling out pipes at the arch crown. Since the 1970s, however, the standard method has been to use a concrete pump to press-in concrete through a single spout per span.

The characteristic feature of this concrete placing method is that the concrete flows from the top of the arch-centre to the shoulder and fills the arch-centre. Fresh concrete flowing over a typical arch-centre length of $L=10.5$ m is prone to material separation and bleeding due to the prior flow of cement paste in addition to the settling of coarse aggregate.

In this study, one of the causes of the failure is considered to be the method of placing concrete in the arch crown. As a method to improve it from the material aspect, we devised the use of volcanic glass powder as an admixture to increase the resistance to material separation.

2 PROBLEMS WITH TUNNELS IN JAPAN

Japan has approximately 11,000 road tunnels, 5,000 railway tunnels and 44 pumped storage power plants, over 4,700km hydro tunnels in Japan. Most railway tunnels were constructed in 1920-1990, and most road tunnels were constructed after 1960 as Figure 1.

The average age of railway tunnels is 66 years, and over 100 years are 12% of the total. Furthermore, many road tunnels reaching 30-50 years of in-service are increasing.

2.1 *Increased maintenance due to aging road tunnels*

Road administrators in Japan have inspected and repaired underground structures including tunnels under their responsibility in accordance with the related laws and standards. However, their maintenance cost has been increasing as they are after construction.

*Corresponding author: nomura.mitsugu@ctii.co.jp

To improve this situation, institutionalization requires the development of long-term repair plans for all road assets as a maintenance management program based on appropriate asset management theory, and to ensure efficient budget execution.

On the other hand, many new road tunnels are being constructed to improve regional networks and reduce disaster risks. Efforts are required to reduce the future maintenance costs of these new road tunnels.

Figure 1. Number of constructed tunnels of road (MLIT annual report). MLIT; Ministry of Land, Infrastructure Transport and Tourism

2.2 Initiatives in the infrastructure sector efforts toward carbon neutrality

Japan's greenhouse gas (GHG) emissions from the infrastructure sector, including both direct and indirect emissions by the industry, account for about 0.7% of total emissions. In contrast, GHG emissions from construction sites, including the supply chain for construction materials and construction-related cargo, account for about 10% of total emissions. Steel and cement emit a large amount of construction materials during production, and the cement industry accounts for 8% of the world's CO₂ emissions.

The tunnel is shotcrete and concrete lined, and the TBM makes extensive use of cement in the segments, so there is a strong need to reduce GHG emissions during the construction phase.

3 CHARACTERISTICS AND EXPECTED EFFECTS OF VOLCANIC GLASS POWDER

Concrete using industrial by-products such as coal ash (fly ash) and blast furnace slag powder has so far been put to practical use. In October 2020, the Japanese government announced the "2050 Carbon Neutral Declaration," setting a concrete goal to realize a decarbonized society and reduce greenhouse gas emissions to virtually zero by 2050. In line with this, the Japanese government has set a specific goal of achieving a decarbonized society and virtually eliminating greenhouse gas emissions by 2050. In line with this, the future of coal-fired power plants for a decarbonized society is still being determined globally and there is concern that there will not be a stable supply of those industrial by-products.

3.1 Volcanic glass powder

In Japan, a volcanic country, volcanic sediments (natural pozzolanic materials) are distributed and buried, and their utilization is expected, and JIS A6209 (Volcanic glass powder for concrete) was established in 2020. Regarding volcanic glass powder concrete, Tomoyose et al. studied the effects of powder degree and replacement ratio on strength development, and the proponents improving durability and strength properties.

After the volcanic ash is mined, it is crushed using a roll crusher, classified using a cyclone, and the particle size is adjusted to produce the product. Volcanic

glass powder with a large specific surface area has good reactivity and strength development. As for the use of volcanic sediments as construction materials, there have been several reports on the use of Shirasu from Kagoshima Prefecture and volcanic sediments from Hokkaido as concrete admixtures, but the advanced use and diffusion of volcanic sediments existing in various regions of Japan are still far from progressing.

3.2 Basic properties of volcanic glass powder

First, it is necessary to understand that volcanic glass powder is derived from volcanoes near the mining area, and that its properties and characteristics vary depending on the place of origin. This study uses commercialized volcanic glass powder from Fukushima Prefecture, Japan.

Two types of BET specific surface areas, 186 020 cm²/g and 430 310 cm²/g, which are equivalent to JIS Category I as Table I, are available for this product. The strength and durability of both types were checked to determine the difference in effect due to the difference in specific surface area.

Araki et al. shows Figures 2 as the results of the water penetration test for the N-50 and BB-formulations and shows the moisture penetration rate coefficients obtained from the moisture penetration tests.

The addition of volcanic glass powder suppressed moisture penetration in both the N and BB formulations.

The comparison of moisture penetration rate coefficients shows that N50-B suppresses moisture penetration more than N50-A. This indicates the pozzolanic reaction of the volcanic glass powder formed the dense microstructure.

Here, the durability of lining concrete, which is not a load-bearing structure, is discussed. Deterioration of reinforced concrete is generally understood to be corrosion of the reinforcing steel or loss of integrity with the concrete as neutralization progresses from the surface due to water or gas penetration and reaches the reinforcing steel.

Although there is some evidence that the development of neutralization does not affect the strength of concrete, the risk of debonding should be increased because the material bond in the concrete is considered

Table 2. Efficiency of volcanic glass powder.

Item	Physical properties confirmed
Bleeding test	In the case of ordinary Portland cement blends, the amount of bleeding in concrete with volcanic glass powder is about half that without, regardless of the difference in BET specific surface area.
Compression strength test	An increase in strength was observed from the 7days curing compared to the no-additive blend.
surface permeability test	Torrent's proposed method and criteria were used to evaluate the denseness of the concrete surface layer. The permeability of the concrete specimens was evaluated using a five-level grading system, and no data corresponding to the "extremely poor" and "poor" categories were identified. This indicates that the addition of volcanic glass powder reduces the air permeability and increases the denseness of the concrete.
moisture penetration test	The addition of volcanic glass powder suppressed water penetration, and the effect of suppression of water penetration was remarkable in the N blend.
Salt barrier test	The effect of the addition of volcanic glass powder was confirmed, and the effect was remarkable.

to have decreased. Based on this hypothesis, suppressing surface penetration of water and gases in unreinforced concrete lining should improve durability and a longer service life.

The results of bleeding tests were also improved by mixing the volcanic glass powder, and it was considered that the concrete placing method to tunnel arches suppressed quality deterioration due to material separation.

3.3 Example of application of volcanic glass powder

Since volcanic glass powder has already been commercialized as a concrete admixture, the types of structures used here will be summarized.

3.3.1 Design architecture and water pool

In Japan, design architecture that makes the most of the texture of materials is widespread, and concrete is often used as a finish. Volcanic glass powder has been used for more than 20 years because it improves the workability of fresh concrete, resulting in a beautiful finish without uneven colour. Currently, most of the volcanic glass powder commercialized in Japan is consumed in this field.

Its use in the water pool has been empirically used to improve the waterproofing quality of the frame before waterproofing coating is applied by taking advantage of the reduced permeability of the cast-in-place concrete.

Figure 3. Application examples for public buildings.

3.3.2 Port structures and structures subject to salt damage

Concrete structures that are washed by salty seawater or exposed to flying salt accelerate neutralization and are prone to deterioration from the surface. Concrete structures placed in the sea have no coating or other means to block salt penetration, so volcanic glass powder, which is dense and highly effective in inhibiting salt penetration, is often mixed into the concrete.

In the case of the Abashiri Port facility in Hokkaido, the use of volcanic glass powder in some parts of the facility was contrasted with the non-use case.

It was reported that after 30 years of construction, surface deterioration became apparent in the unused portions, but the dense surface quality was maintained in the portions where volcanic glass powder was applied.

Figure 4. Application examples for port structure and tide embankment.

3.3.3 Tunnel lining and underground structures

Tunnel linings are cast in arches using a blow-up method, which often causes filling problems when

using reinforced concrete structures, so volcanic glass powder is sometimes mixed in to ensure fluidity in the formwork and resistance to material separation.

In addition, when a tunnel lining is planned with a water-tight structure to prevent groundwater infiltration after completion, volcanic glass powder is sometimes mixed as an elemental structure of the water barrier to improve water penetration resistance.

In addition, there are other cases of application to concrete segments of TBMs. Concrete segments are subjected to uneven pressure during assembly and excavation, which can cause cracks and chips in the concrete. In addition, the influence of neighboring structures may cause new stresses in the segment structure after completion. Particularly in road projects, TBMs with large cross-sections are often installed in parallel, and the concrete segments of the preceding TBM are subjected to partial stress overload due to the proximity of the following TBM, which can cause cracking and other problems. Volcanic glass powder may be mixed into the concrete to densify the material voids in the concrete and prevent cracking.

Figure 5. Application examples for tunnel structure, waterproof section.

Figure 6. Application examples for tunnel structure, RC concrete entrance.

Figure 7. Concrete segment for road tunnel TBM.

4 APPLICABILITY TEST OF VOLCANIC GLASS POWDER TO TUNNEL LINING CONCRETE

Nomura et al. studied the terms of the performance requirements for road tunnels, it has been determined that the concrete lining should not cause damage to users due to scouring or spalling, that it should minimize user disturbance due to repair or inspection restrictions, that is, it should resist deterioration, and that there should be no leakage or cracking that would cause discomfort or uneasiness to users. It is also desirable that there be no leakage or cracking that would cause discomfort or uneasiness to users, and that there be no large repair scars or other damage inside the tunnel.

To improve the durability of lining concrete, it is necessary to improve the homogeneity of the concrete at the casting stage to prevent defects at the gable end, which is considered to be one of the causes of scour and spalling, and to improve the surface quality to prevent deterioration factors from penetrating the surface of the concrete. The surface quality of the concrete should be improved to prevent deterioration factors from penetrating through the surface of the concrete.

Therefore, in this study, we confirmed the existence of the hypothesized damage condition at the edge of the lining and confirmed the improvement effect of the homogeneity and surface property of concrete using volcanic glass powder by simulation tests using a mock-up formwork and construction tests in an actual tunnel.

4.1 Potential defects in lining concrete

When tunnel lining concrete is soundly inspected, anomalies such as a muddy sound can be detected when the concrete seems to sound visually on the surface but has latent structural defects such as swelling or internal cracks.

In this study, based on past inspection records and field investigations, we attempted to identify areas where deformation had occurred in the gable ends of road tunnels that were no longer in service, and to remove concrete from the deformed areas to observe potential defects.

4.1.1 Sampling test results

The sampling was conducted at a section where there was no evidence of deformation due to external

forces and little leakage. In this span, longitudinal cracks of 0.4 mm to 0.6 mm and several transverse cracks were observed, as shown in Figure 8, which were probably caused by drying shrinkage. No surface cracks were observed at the sampling points.

As shown in Figure 9, the deformation is characterized by shallow layered internal cracks at 2 cm to 5 cm in depth. The crack edges have not reached the surface and have barely fallen off. The reasons for the occurrence of such cracks include tension caused by the adhesion of gable and lap formwork during resetting, and compression caused by formwork torsion due to uneven jacking down. In addition, the authors believe that because concrete flows and is cast in the gable end far from the concrete spout, the concrete becomes brittle due to material separation. If insufficient compaction occurs, this may lead to cracking on the surface and interior due to age-related deterioration.

Figure 8. Condition of sampling test point.

4.1.2 Homogeneity degradation due to concrete placement method

Since the 1970s, the standard method of lining road tunnels has been to press-fit concrete into the arch crown using a concrete pump at one spout per span. With this method, it is possible to compact the concrete up to the shoulder section by using a vibrator

Figure 9. Damage condition of the turbine by percussion inspection.

through an inspection window installed in the slide centre. However, compacting the arch crown section was difficult because the concrete had to be left to flow and fill up to the gable section. Although improved compaction methods such as formwork vibrators and pull-out vibrators are used nowadays, the method of placing arch crowns has not essentially changed.

Figure 10 shows the construction status of the gable end of the sidewall. The cement paste and bleeding water that have separated from the material can be observed, and the same phenomenon is thought to be occurring at the arch crown where the compaction status cannot be confirmed.

Figure 11 shows the construction status of the gable end of the sidewall. The cement paste and bleeding water that have separated from the material can be observed, and the same phenomenon is thought to be occurring at the arch crown where the compaction status cannot be confirmed.

Therefore, it is possible that coarse aggregate does not reach the gable end far from the casting entrance due to material separation, that the quality of the concrete may not be ensured, and that the bleeding water may not be discharged sufficiently. Although concrete is placed continuously, placement interruptions will inevitably occur due to the change-over of concrete mixer trucks and piping setups. In such cases, the rod vibrator cannot be used to compact the area where the placing is resumed, which may result in a layered boundary surface. Although

those in charge of construction have long recognized this problem, there have been few cases in which actual tunnels have been sampled and verified. In this study, core samples were obtained from the shoulders, and observations focused on the distribution of coarse aggregate.

Figure 10. Situation inside the tunnel centre during placement of concrete for tunnel lining.

Figures 11 shows observations focusing on the coarse aggregate distribution of cores taken from the area sampled in this tunnel (span number S5) and from an area within the same span that was determined to be sound by scrutiny and sounding. The coarse aggregate density in the gable end was lower than that in the centre of the span, confirming that material separation had occurred during concrete placement, as observed by the core appearance.

Figure 11. Core condition of end of span area and centre area.

4.2 Simulated construction test

In order to determine the mix design of concrete to be used for the construction test, test mixing was conducted on actual equipment and a simulated construction test was conducted using a mock-up formwork. The reason for observing changes in fresh performance over time here is that Tomoyose et al.

reported that the addition of volcanic glass fine powder, which has a large specific surface area after pulverization, to concrete can significantly reduce mortar flow.

4.2.1 Factory slump test

Figure 12 shows the change over time of the slump test (JIS A1101:2020) after 45 minutes and 90 minutes of mixing of the determined formulation in the actual test mixing. The slump volume, which was 23 cm immediately after mixing, became 20 cm at 45 minutes and 16 cm at 90 minutes after the slump test. Since it was confirmed that the amount of slump decreased in a relatively short time, it was decided to confirm whether workability could be ensured in the execution by a flowability test using a mock-up formwork.

a) 23 cm immediately after mixing

b) 20 cm 45 minutes after mixing

c) 16 cm 90 minutes after mixing

Figure 12. Factory slump test (JIS A1101:2020).

4.2.2 Flowability test

Figure 13 shows the dimensions and structure of the mock-up formwork. The front surface is an acrylic panel to observe concrete flow, and the pipe length for concrete pumping is 30 m, the same as that in the tunnel pit. The method of placing the concrete into the formwork was free-fall from a height of 1.5 m above the edge of the formwork.

First, pumping was interrupted when concrete was placed to a height of 1.0 m at the placement position, and the flow condition was recorded. Then, a rod vibrator was inserted at 1.5 m intervals for 10 s to compact the concrete, and the flow was recorded. The same procedure was repeated every 50 cm, and the top edge was finished and cured at the end.

Figure 13. Flowability test (Field).

4.3 Practice tests

After evaluation of the simulated test, it was determined that there were no problems with flowability in the formwork and material separation resistance. The test was conducted as part of the normal construction process, and except for a change in the concrete, the construction was carried out as usual.

4.3.1 Applicable formulations for implementation testing

(1) 24-15-40N in Table 3 is the mix used in the specifications at the time of ordering the lining concrete for the subject works ($\sigma_{28}=18\text{N/mm}^2$ or more, minimum unit cement content 270kg/m^3). (2) 27-18-20N is the current mix used by the contractor for the actual lining to improve workability and surface quality. (3) 27-18-20N (VGP) is an improved mix with volcanic glass powder. The volcanic glass powder used in Formulation (3) is Type B (BET specific surface area: $430\ 310\ \text{cm}^2/\text{g}$) as shown in Table 1 as a result of laboratory test mixing as described.

4.3.2 Placing of concrete

Concrete was placed using a concrete pump with a pipe length of $L=30\ \text{m}$, as in the case of placing concrete for a normal span. Practice tests were conducted for three spans using the 27-18-20N (VGP) mix (3), and no problems were observed in any of them.

In parallel with the concrete placement, concrete flowing through the arch at the end was sampled to confirm the amount of coarse aggregate by quantitative sampling, and it was confirmed that the coarse aggregate was sufficiently transported to the gable end in the construction test.

Table 3. Applicable formulations of volcanic glass powder concrete for lining.

B						
	W/B (%)	s/a (%)	C	VGP	1) AE water reducer	2)AE water reducer
(1)24-15-40N	56.7	47.5	279		2.79

1) AE water reducer(Standard), 2)AE water reducer(High performance)

Figure 14. Practice test (construction site).

4.4 Surface quality of lining concrete after improvement

4.4.1 Evaluation of surface quality

The surface quality was evaluated approximately two months after construction. Surface water absorption tests were conducted using the SWAT (Surface Water Absorption Test) method at the three locations shown in Figure 15 on the existing concrete side.

The average values of three tests conducted using (3) were collected and compared with (2) on Figure 16.

In both formulations, the surface water absorption rate coefficient was considered good at some of the gable ends, but all other areas were evaluated as general.

In the case of (2), the surface water absorption coefficient tended to be higher on the existing side, while in (3), the coefficient tended to be higher in the gable section.

Figure 17 shows the surface air permeability at each measurement point as a result of the surface air permeability test. In this test, the results showed that

(2) was evaluated as inferior and (3) was evaluated as general, and that the addition of the volcanic glass powder slightly improved the results.

Figure 15. Location of surface water absorption test and surface air permeability measurement.

4.4.2 Quality surface water absorption speed

Surface water absorption tests were conducted using the SWAT method. The test result of (2), which does not include volcanic glass powder, is poor at the Joint and tends to improve toward the End of Span, while the test result of (3) is stable throughout the entire Span length. In particular, it is important to note that the surface quality of the Shoulder, which is prone to problems, is stable.

Figure 16. Surface water absorption test results (SWAT test).

Figure 17. Surface air permeability test results (TORRENT test).

4.4.3 Surface air permeability

Surface air permeability tests were conducted using the TORRENT Test Method. The TORRENT Test is considered to represent the resistance to carbon dioxide gas infiltration from the concrete surface, and therefore, (3) is considered to be the most effective method for improving the surface quality of concrete. (3) may also increase the long-term resistance to neutralization compared to (2).

5 CONCLUSION

The effects of adding fine powder materials on concrete to improve workability and durability have been known, but it was confirmed that similar effects can be expected for volcanic glass powder and that it can be applied to tunnel lining concrete.

The addition of volcanic glass powder to the concrete lining increased the resistance to material separation and, with sufficient curing, contributed to the improvement of surface quality such as densification. In the mock-up construction tests, the addition of volcanic glass powder to the concrete lining increased the resistance to material separation and, with sufficient curing, contributed to the improvement of surface quality such as densification. In addition, in the execution test, it was confirmed that the coarse aggregate could be transported to the gable end and the homogeneity of the concrete was improved.

Achieving high load-bearing capacity linings in sprayed concrete and segmental linings with high-performance steel fibres

David Oliveira*

Aurecon, Brisbane, Australia

University of Wollongong, Wollongong, Australia

ABSTRACT: The design of fibre-reinforced concrete structures must follow the design principles concerning limit state similar to those adopted for conventionally reinforced concrete. However, the use of linear elastic analysis or conventional yield line theory may, in many cases, underestimate the benefits of the fibres to provide greater load-bearing capacity, particularly when high-performance steel fibres are adopted. This paper will present two case studies of real tunnel projects where the use of non-linear modelling of steel fibre-reinforced concrete elements coupled with physical testing provided significant benefits in the design and construction of tunnel lining. The first case focuses on the design of thin tunnelling linings using rock-bolted shotcrete linings. In this case, the non-linear modelling coupled with full-scale field tests demonstrated load-bearing capacities up to 3-5x greater than conventional design methods. The second case presents the design of a segment lining and the effects of fibre reinforcement on longitudinal joints' bursting and splitting capacity under rotation. In this case, non-linear modelling coupled with laboratory testing on large-scale segment joint samples demonstrated that conventional reinforcement would be unnecessary, whereas analysis with linear-elastic theory indicated otherwise..

Keywords: high capacity fibre reinforcement, sprayed concrete lining, TBM segments, non-linear stress

1 INTRODUCTION

Concrete is a material that is strong in compression but weak in tension and with a brittle behaviour under typical unconfined applications. As a result, steel reinforcement bars are traditionally used to enhance these two weaknesses by carrying the tensile forces after the concrete has cracked in structural applications, consequently providing ductility to the system. In conventionally reinforced concrete, the tensile strain of the concrete at cracking is much lower than the yield strain of the steel bars, which results in concrete cracking before any significant load is transferred to the steel. As a result, steel reinforcement also needs to limit the crack widths under specified levels for serviceability and aesthetic purposes but, most importantly, durability.

The use of fibres in concrete aims to achieve the same principles, i.e. to provide post-crack tensile and flexural capacity and crack-width control. However, unlike reinforcing bars, fibres are distributed in the volume of concrete. Hence, the distance between fibres is much smaller than the spacing between conventional

bars, and the result is no longer a system with two materials but one composite material. Such understanding is essential as it has implications for design. Conventional design methods of reinforced concrete may not always capture the full benefits of fibre-reinforced concrete (FRC), as will be discussed in this paper.

A key advantage of using FRC is reducing construction time compared to the traditional single or double layers of conventional reinforcing bars or welded wire mesh. Heavy construction equipment for lifting and placing reinforcing bar cages is eliminated since the FRC can be directly pumped or sprayed. As a result, large-scale tunnel projects may save several weeks. Jobsite simplifications also improve safety as reducing labour-intensive tasks reduces the personnel involved and their exposure to working at heights.

However, due to concrete workability requirements whilst fresh and adequate distribution of fibres during mixing, it is vital to understand that there are practical limits to the amount of steel that can be included in a concrete mix. Therefore, the structural capacity is unlikely the same as that achieved with

*Corresponding author: david.a.oliveira@aurecongroup.com

conventionally reinforced concrete. In contrast to the capacity limit, contractors and designers are always looking for savings associated with member sizes (thickness of linings), thus concrete volume, which higher capacities can facilitate. Reduced concrete volumes will also directly impact formwork costs of cast-in-situ linings, time of concreting and cost and risks associated with transporting TBM segments.

Therefore, reducing tunnel lining thicknesses provides significant cost-savings and sustainability benefits, and to meet the market demands, suppliers have developed high-performance fibres engineered to achieve higher strength, stiffness, and heat or chemical resistance in particular applications.

Figure 1. Example of figure and figure caption.

High-performance fibres aim to address two fibre-reinforcement mechanisms: fibre pull-out and fibre yielding/rupture (Figure 1). A good fibre-concrete bond is essential for developing post-cracking tensile capacity across the crack. High ductility FRC is obtained when fibres are pulled out across cracks in a controlled manner without significant yield or rupture.

However, it is essential to understand the difference between ductility and toughness. Ductility is the ability of the material to develop relatively large deformations before rupturing. Conversely, toughness is the material's resistance to these large deformations, which combines ductility and capacity. In most design cases, high toughness is the target, and the fibre yield capacity must be compatible with the pull-out capacity to achieve high toughness. For this reason, developing high-performance fibres involves improvements in both pull-out and yield strength.

Figure 2 presents two examples of steel fibres used in shotcrete applications in Australia. The left-hand side is a traditional end-hooked steel fibre commonly used in tunnelling applications. The right-hand side is a high-performance version with “double” end hooks for better development of strength, particularly at low deformation and smaller crack widths (≤ 0.5 mm). As seen, the improvement in pull-out capacity is followed by an increase in tensile strength from 1345 MPa to 1850 MPa. The high-performance steel fibre presented in Figure 2 is an improvement of an older but similar double-end hooked fibre version of the same supplier with a different aspect ratio and length (Dramix 4D 65/60BG). An increase in tensile strength from 1500 MPa to 1850 MPa was necessary to reduce

the yielding of the fibres and achieve higher “toughness” values at crack widths exceeding 3 mm, i.e. at ultimate limit state, and when the smaller diameter version (65/35) was used with concretes with average compressive strengths, f_{cm} , greater than 50 MPa.

Figure 2. Examples of end-hooked steel fibres: (a) more traditional fibre on the left-hand side; (b) high-performance “double-end-hooked” fibre on the right-hand side.

With high-capacity steel fibres in the market, there is a natural desire to take advantage of their availability in design by potentially reducing tunnel lining thickness or replacing conventional steel bar reinforcement where possible due to the abovementioned advantages. Such a design reduces construction costs and can provide more sustainable solutions with a lower carbon footprint by reducing the volume of concrete used and the quantity of steel.

This paper presents two case studies of tunnel projects in Australia where high-performance steel fibres were adopted in design and verified by testing with significant project benefits. The first case refers to a shotcrete application, whilst the second is a pre-cast segmental lining design.

2 SPRAYED CONCRETE APPLICATION

At the start of construction of the Westconnex motorway project in Sydney, the New M4 and M8 tunnels included in their shotcrete specification an intention to achieve a high-performance Fibre-Reinforced Shotcrete (FRS). This intention was expressed via the specification of relatively high design values for residual flexural strengths at SLS and ULS, respectively, $fr_1 = 3.5$ MPa and $fr_4 = 3.0$ MPa following BS 14651. These values could be considered relatively common practice in cast-in-situ applications at the time of construction of these projects using longer and larger diameter fibres but, to the author's knowledge, less common in sprayed concrete, i.e., shotcrete, where shorter fibres with smaller diameters are generally preferred due to workability.

These projects adopted the steel fibre shown on the left-hand side of Figure 2 in their mix design with a fibre count of 40–45 kg/m³ and a 40 MPa concrete strength. The performance during production indicated that the specified values of $fr_1 = 3.5$ MPa and $fr_4 = 3.0$ MPa were achieved only in terms of average values, i.e. not as 95% characteristic, and resulted in approximately 50% of non-conformances that had to be addressed via the project's NCR process.

The M4-M8 Link Tunnels were the next project to be constructed as part of the Westconnex motorway. Despite the unsuccessful previous attempt, this project took on the challenge of achieving the above high performance since the residual flexural strength values of the New M4 and M8 tunnels were incorporated into the project's Scope of Works and Technical Criteria (SWTC).

The design team then recommended using the high-performance fibre shown on the right-hand side of Figure 2 as the world's first shotcrete application with such fibres, which was taken forward by construction and procurement teams, resulting in a shotcrete mix design that performed as intended during construction, i.e. with characteristic values of $f_{rk} = 3.5 \text{ MPa}$ and $f_{rk} = 3.0 \text{ MPa}$ and a minimal number of non-conformances. Following the successful mix design, the next question was: how to leverage such a high-performance steel fibre-reinforced shotcrete (SFRS) in tunnel lining design?

An investigation on how to push the boundaries of the flexural capacity of thin, rock-bolted shotcrete linings led the design team to consider compressive membrane action (CMA) in the structural performance of the tunnel linings. Non-linear stress analysis investigations during the detailed design stage provided confidence that such an approach could provide linings with a capacity many times greater than conventionally predicted in the past with either deterministic methods, such as Barret and McCreath (1995) or yield line theory.

Figure 3. Schematic of large-scale field testing on shotcrete lining.

The design team proposed large-scale field tests of the as-constructed shotcrete linings with a 90 mm thickness to confirm such significant benefits following a verification assisted by testing (fib, 2013). A schematic of the test, using hydraulic bags to load the shotcrete lining to failure, is depicted in Figure 3, with some shown photos in Figure 4. Further details are presented in Bernard et al. (2022).

The test results are presented in Figure 5 against the predictions of a numerical back-analysis conducted after the tests. The back analysis followed the same methodology described in Bernard et al. (2022) but now has the actual rock bolt plate geometry embedded into the shotcrete, modelled as presented by Oliveira and Kozak (2021).

Figure 4. Photos of the large-scale field testing on shotcrete lining.

Figure 5. Large-scale field test results with numerical back-analysis.

All four test panels indicated load capacity approximately 4-5 times greater than that predicted by conventional methods used in previous projects, about 65 kN for a 90 mm thick lining. In addition, visual inspections of the failed panels during testing and the numerical back-analysis model confirmed that the capacity of the 90 mm thick lining was mainly limited by the pull-out capacity or punching shear failure of the rock bolts, as shown in Figure 6, also highlighted by the yielding of the handlebars. Once the four rockbolts plates forming the shotcrete panel failed (pulled out), the shotcrete lining would span further to the neighbouring rockbolts. As a result, the ductility seen in Figure 5 post-peak results from the enhanced flexural capacity provided by the high-performance steel fibres, tolerating the significant increase in the span for the lining panels. In contrast, the numerical back-analysis model shows a brittle failure upon rockbolt pull-out as the model only considers one-quarter of the geometry with planes of symmetry assumed at the four sides of the model, meaning that all neighbouring bolts also fail. Nevertheless, the numerical back-analysis confirmed that lining capacity was limited by the punching shear of the bolts rather than a flexural failure of the lining.

Figure 6. Numerical back-analysis of one-quarter of the panel.

The above application of high-performance steel fibres in shotcrete allowed a reduction of approximately 15% in tunnel lining thickness.

The second case study presented in this paper refers to the design of TBM segment joints for a metro project in Sydney, as discussed below.

3 BURSTING/SPLITTING CAPACITY FOR TBM SEGMENTS

The design action effects, essentially bending moments and axial forces, acting on segmental lining need to be transferred between segments in a ring via the performance of their joints, particularly the longitudinal or radial joints. These actions are transferred by simple compression, where the applicable eccentricity induces a joint rotation due to the bending moments acting in the segment bodies or any additional distortions from geometrical ring build imperfections.

The immediate failure mechanism associated with joint compression is a simple bearing crushing failure. However, this simple compression and its associated deformed shape generates tension at a certain depth.

The typical design of longitudinal joints often involves analysing the applicable elastic stresses acting in the potential bursting zone within the disturbed region (D-region) either with numerical analysis or based on an approximate solution proposed by Iyengar (1962). Suppose the maximum tensile stress in the D-region is estimated to be lower than the design splitting strength of the FRC segment, which is the peak tensile splitting strength reduced by a safety factor. In that case, the design is deemed satisfactory without further reinforcement requirements based on the assumption that the risk of cracking initiation parallel to the applied load is mitigated and that the fibre reinforcement controls any minor preexisting cracking. On the other hand, if the maximum tensile strength is exceeded, additional checks assuming the residual tensile strength of the FRC are required or that extra conventional bar reinforcement is added.

If the residual tensile capacity of the FRC is to be used in the design without bar reinforcement, analysis of joints with concentrated loads will often follow the classic strut-and-tie model proposed by Leonhardt and Mönning (1973). The diffusion of transverse stresses is assumed to develop within the D-region, which is assumed to be limited to the segment thickness (h) or the effective thickness ($'h-2e'$). The tensile transverse

stresses are uniformly distributed over a length of $0.8h$, while compression is distributed along $0.2h$, as depicted in Figure 7.

Figure 7. Strut and tie model to design partially loaded areas (DafStb, 2010).

Design analysis for a section of the Sydney Metro approaching depths of 90 m and with high groundwater pressures indicated that the longitudinal joints of the 260 mm thick segments (with a joint length of 130 mm) could experience axial forces of up to 4000 kN/m at ULS, i.e. already factored up, with an eccentricity of up to 30 mm (Figure 8) including geometrical ring build imperfections. This load can be applied as an equivalent rectangular stress block with a length of 50 mm.

Figure 8. Critical joint load case for segmental lining design.

A tie force $T = 750$ kN/m can be estimated based on the equation presented in Figure 8, taking $F_d = 4000$ kN/m, $h_1 = 50$ mm, $h = 260$ mm and $e = 30$ mm. The design capacity, R , to resist such tensile force is estimated by multiplying the tensile residual strength of the FRC over the length of $0.8(h-2e)$ and factored down by a typical reduction factor of 0.6. The design capacity was estimated as $R = 151$ kN/m based on a typical residual tensile strength of 1.575 Mpa for an associated $f_{r1} = 3.5$ MPa for FRC mixes using the Dramix 4D 80/60 BG fibre (tensile strength of 1800 MPa).

The above-estimated design capacity is significantly below the design tie force, indicating a splitting failure that would, in principle, require extra bar reinforcement. However, there is a significant drawback in the assumption presented above. The assumed D-region is based on elastic solutions that ignore the beneficial effects of fibre reinforcement in allowing the development of crack propagation in a controlled manner, thus likely significantly increasing the depth of the D-region. As a result, the design team adopted the following steps to investigate the actual capacity of an FRC segment:

- Increase the residual tensile capacity of segments by using high-performance steel fibres. The

previously used Dramix 4D 80/60 BG fibre, with a tensile strength of 1800 MPa, was replaced by the newer Dramix 4D 80/60 BGP with a tensile strength of 2200 MPa. The concrete mix design targeted an $f_{ck} = 66$ MPa with $fr1 > 4$ MPa and $fr4 > 4$ MPa, achieved without any increase in fibre count compared to the previous fibre type.

- The design would be based on non-linear stress analysis to more accurately estimate crack propagation and strength development resulting from fibre reinforcement. It is important to note that the Model Code 2010 (fib, 2013), Sections 7.2.2.4.4 and 7.11, and the AS 5100.5, Section 2.3.6, recommend that the mean values of the material characteristics be considered in such analysis.
- The design would also follow the verification assisted by testing principles described in section 7.12 of the Model Code 2010 (fib, 2013) based on a combination with the non-linear model previously described. Verification assisted by testing is the procedure where loading tests on a limited series of representative specimens are used to determine the response of structural members or systems. The verification assisted by testing aims to obtain design values for the parameters governing the response of structural members and systems under specified load conditions for a certain limit state, in this case, splitting/bursting failure.

3.1 Non-linear stress analysis

A smeared crack constitutive model was adopted in the commercial software ATENA to model both the splitting and crushing of concrete. The plasticity model for crushing is based on the triaxial failure surface of Menetrey and Willam (1995).

The entire model can also be described with respect to the equivalent uniaxial stress-strain law as depicted in Figure 9a with the compression behaviour before the peak following the Model Code Clause 7.2.3.1.3 (fib, 2013).

Figure 9. Concrete model: (a) Uniaxial stress-strain law (fib, 2013); (b) Biaxial failure function (after Kupfer, 1969).

The effects of biaxial enhancement are considered based on the relationship presented by Kupfer et al. (1969), illustrated in Figure 9b.

The above model was adjusted in the tensile zone to follow the constitutive tensile law proposed by the Model Code 2010 (fib, 2013), as shown in Figure 10.

Figure 10. (a) Tensile constitutive law from Model Code 2010 (fib, 2013); (b) corresponding crack width definitions.

The mix design pre-production testing indicated a value of $f_{cm} = 75$ MPa for the proposed $f_{ck} = 66$ MPa, also confirmed during production testing. The residual flexural tensile strengths previously discussed were converted to equivalent residual uniaxial tensile strength by the equivalent stress block factors of 0.45 and 0.37, respectively. The peak uniaxial tensile strength was adopted based on the targeted characteristic value estimated by equations provided by the Model Code 2010, resulting in a value of $f_{ctk} = 3.2$ MPa, noting that this underestimates the actual tensile strength considering a specified tensile splitting strength of 5 MPa for the mix. The Young Modulus was adopted as $E = 37800$ MPa.

Two partial segments with 750 mm length each were modelled to represent the combined bending effects of the segments and the joint. The joint includes the guide rod pocket of 32 mm diameter and gasket and caulking grooves of 65 mm length each. Considering that the segment depth is 260 mm, the contact length left for the longitudinal joints is 130 mm, of which 32 mm is the guide rod diameter/pocket. Contact elements were used between the segments with applied zero bond, i.e. zero tensile strength.

To achieve failure, i.e. collapse, the load is applied at an eccentricity of 30 mm on one side of the model, employing an applied displacement that is incrementally increased to induce joint rotation.

Figure 11 presents the minor principal stresses, i.e. compressive stresses, developed at a joint rotation of 11.57 mrad. As observed, the stresses are distributed over the entire contact length on one side of the guide rod and approximately 15 mm on the other side, which, if converted to an equivalent uniformly distributed load, could be conservatively assumed to act only on one side of the rod, i.e. with $a = 50$ mm. The maximum crack width observed was approximately 0.6 mm with no signs of a wedge failure formation, i.e. punching shear of the stress block.

Figure 11. Minor principal stress (compression) distribution at peak capacity with a maximum observed crack width of approximately 0.5 mm.

Figure 12. Model results for load-rotation performance.

Figure 12 shows the load rotation behaviour of the FRC joint with a peak resistance of approximately 6250 kN/m. A design resistance of 3810 kN/m is estimated if a reduction factor of 0.6 is applied to the predicted peak resistance. Considering that it is only approximately 6% lower than the ULS load, i.e. already factored up, this capacity can be deemed acceptable if verified by testing due to increased confidence in the predictions.

3.2 Verification assisted by testing

Three specimens representative of the segment joints were tested for failure under concentrated loads to verify the above predictions of bursting and splitting. The joint samples were square columns with 260 mm x 260 mm x 650 mm dimensions and cast with the same concrete mix design adopted for the segments. The top section of the columns was formed to have the same geometry as the segment longitudinal joints. The layout of the tests is depicted in Figure 13.

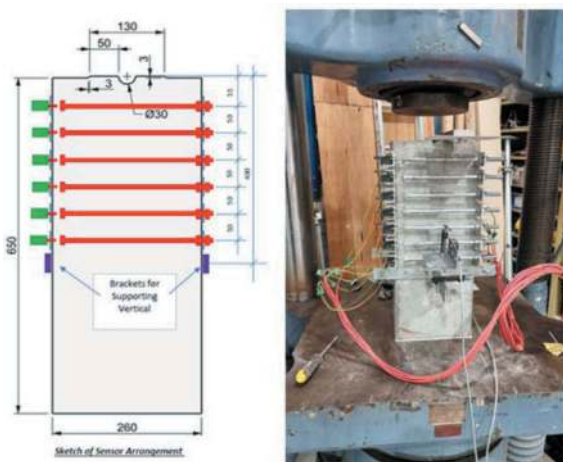

Figure 13. Testing configuration.

LVDT sensors were connected to one side of the samples and positioned against reference arms glued to the other side of the specimen (Figure 13 LHS) at

several depths to monitor the lateral expansion and, consequently, the crack widths.

The specimens were loaded over the entire available joint area on one side of the guide rod, over a length of 50 mm (Figure 14). This configuration represents an eccentricity of 40 mm, which is more severe than the case previously discussed and, therefore, considered conservative for verification purposes.

Figure 14 presents the test results against a numerical back-analysis of the tests to calibrate the FRC parameters. Unfortunately, the compression machine used in the testing was not servo-displacement controlled, and, therefore, it could not capture the post-peak behaviour accurately, as the testing increments were based on loads and not displacement. Nevertheless, the most relevant phase of the tests up to peak resistance was adequately captured and could be used compared against model predictions. Post-peak performance could also be qualitatively assessed by comparing the cracking patterns observed in the samples and those observed in the numerical model (Figure 14 RHS).

Figure 14. Experimental testing results versus numerical back-analysis: (LHS) load versus crack width curves; (RHS) comparison of cracking pattern between physical samples and numerical model.

As observed above, the back-analysis model represented the experimental results with a high degree of agreement regarding loads, crack widths and length. It should be noted, however, that the model stopped at a crack width of 1.9 mm while the tests had crack widths up to 7 mm. An important observation of the verification tests is the cracks' development length and, therefore, the D-region depth. In all tests, the average length corresponded to approximately 2 to 2.7 times the effective thickness of 180 mm (i.e. $260-2 \times 40$). This observation confirmed the previous hypotheses that a D-region limited to $0.8(h-2e)$ is over-conservative and cannot adequately capture the benefit of the fibres.

Based on the test results alone, it could be estimated that a 1 m joint length would provide an ultimate capacity of $1600 \text{ kN} \times 1000 \text{ mm} / 260 \text{ mm} = 6150 \text{ kN/m}$. However, as highlighted above, these tests imposed a higher eccentricity and are therefore conservative as the joint experiences more significant rotations.

The material parameters adopted in the segment joint design analyses were recalibrated based on the

current numerical back-analysis results as a final design check. The analysis discussed in the previous section was then re-run. Figure 13 presented the experimentally recalibrated curve with marginally higher predicted capacity, i.e. 6350 kN/m instead of the previous 6250 kN/m, indicating a good quality Class-A prediction during the design phase.

Based on the above, enough confidence was gained with the non-linear analysis and verification assisted by testing to confirm that extra bar reinforcement was not required. This result provided reasonable savings in costs and carbon footprint and benefits to the pre-cast yard not having to deal with joint ladder reinforcement, thus slightly improving the casting program.

4 CONCLUSIONS

With high-performance steel fibres available in the market, there are significant opportunities for designers to provide cost-effective solutions by reducing tunnel lining thickness and/or replacing conventional steel bar reinforcement where possible. FRC solutions can reduce construction costs and provide more sustainable solutions due to a lower carbon footprint associated with the reduced volume of concrete and the quantity of steel. In addition, large-scale tunnel projects may save several weeks in their program by removing the tasks associated with lifting and placing reinforcement cages, as the FRC can be directly pumped or sprayed. Jobsite simplifications also improve safety as reducing labour-intensive tasks reduces the personnel involved and their exposure to working at heights.

However, conventional design methods may not always fully or adequately represent the behaviour of FRC, limiting the benefits of such a solution. Non-linear stress modelling coupled with verification assisted by testing via large-scale field tests or large-scale laboratory tests may provide a valuable method to understand the problems at hand better and achieve the desired cost-effective solutions, as illustrated by the two case studies presented in this paper.

EN 14488-3 notched panel versus EN 14651 notched beam testing for pre-construction trial conformance testing of Sprayed Concrete Linings (SCL)

Chris Peaston

Peaston Concrete Consultancy, Nottingham, UK

Benoit De Rivaz*

NV Bekaert SA, Zwevegem, Belgium

ABSTRACT: In 2011 EFNARC introduced a notched panel test as a potentially equivalent alternative to the EN 14651 notched beam method of deriving flexural strength parameters consistent with limit state design to fib MC 2010. In 2022 EN 14487 and EN 14488-5, the relevant European Standards for Sprayed Concrete, were updated to reference the alternate methodologies. This paper applies Analysis of Variance methods to the results of prior laboratory-based investigations of cast and sprayed concrete undertaken to support the equivalence the alternate methodologies. This shows statistically significant differences in the alternate flexural strength parameters, contrary to the prerequisite requirement for consistent MC2010 performance classification. Full-scale sprayed concrete pre-construction trials were conducted using three different Bekaert Dramix® steel fibres and a macro synthetic fibre in both a contemporary CEM I and a CEM III B basic mix, which is being developed for potential use on the UK's HS2 project and achieves an embodied carbon reduction of 60%. In notched panel tests the steel fibres achieved a minimum MC2010 2c performance classification with the macro synthetic fibre achieving 1c classification. In the case of the commonly used Dramix® 4D 65/35BG fibre, alternate notched panel and beam tests showed the anticipated higher beam f_L strengths to have a statistically significant difference. Nonetheless residual flexural tensile strength parameters were statistically identical and led to consistent MC2020 ductility classification. In any event notched panel f_L determination is likely to be conservative and, given the less brittle failure, MC2010 crack control classification is likely to better represent the in-situ material performance. The improved consistency in a full-scale trial supports the adoption of the alternate notched panel methodology, confirms the potential to achieve the MC2010 3c performance classification with high performance steel fibres, and has the potential for more efficient fibre proportioning leading to further carbon savings.

1 INTRODUCTION

EN 14487-1:2022, the European Standard for sprayed concrete, prescribes differing ways of specifying and measuring the ductility of sprayed fibre reinforced concrete (SFRC). These include an EN 14488-5 energy absorption test, used in empirical design methodologies, and an EN 14488-3 flexural tensile strength test, in which residual strengths are determined using notched beam specimens in accordance with EN 14651 consistent with limit state design to fib MC 2010.

In 2011 EFNARC introduced a notched panel test, based on the EN 14488-5 energy absorption test specimen, as a geometrically analogous alternative to the EN 14651 notched beam methodology, thereby

potentially providing equivalent residual flexural tensile strengths. It was suggested that the notched panel test had several advantages, including using a test specimen that better represents the material in the real structure, with potentially reduced variability. This is particularly relevant to sprayed concretes where the production of suitable test specimens otherwise typically involves sawing beams from a larger test panel.

In 2022 EN 14488-3 was updated to include a residual flexural tensile strength test based on the original EFNARC (2011) proposal and EN 14487-1 was amended to include reference to the alternate notched specimen methodologies for residual flexural tensile strength determination.

This paper reports the results of a series of spraying trials using combinations of two different basic

*Corresponding author: Benoit.DeRivaz@bekaert.com

mixes and four fibres in which notched panel and beam test derived flexural tensile strength parameters were compared to examine the equivalence of the alternate tests, consider the difference in their variability, and determine the consequences for pre-construction trial conformance.

SFRC for tunnelling works are typically CEM I rich mixes with consequent relatively high embodied carbon. The spraying trials were undertaken alongside an ongoing project successfully demonstrating the potential to deliver a sprayed concrete using a CEM IIIB cement (Goodier et al., 2022), with a 60% reduction in embodied carbon, and the opportunity was taken to spray a range of fibres in a typical contemporary CEM I and alternate CEM IIIB basic mixes.

2 BACKGROUND

The equivalence of the notched panel and beam methodologies was supported by investigations comparing the results of specimens cast from the same concrete in the respective standard tests, originally coordinated by Meda (2018), and published by De Rivaz et al. (2019). In this investigation a total of six different mixes was compared by considering the ratios of the limit of proportionality (LOP) strength (f_L) and the four residual flexural tensile strengths (f_{R1}, f_{R2}, f_{R3} and f_{R4}) determined using the alternate test methods. The means of the ratios of each parameter across the six mixes were found to be close to unity.

These observations were particularly valid for three of the six mixes using the same Bekaert “Dramix®” 4D 65/35BG fibre type and dosage, which at 25 kg/m³ was said to be typical of a SFRC, with the typically higher values returned in the panel test being attributed to the larger fracture surface. A comparison of coefficients of variation (CoV) also showed that those for the panel tests were typically markedly lower. This led to the conclusion that the panel test appeared to be suitable for characterising SFRC.

Similar investigations comparing specimens prepared from individual sprayed concrete mixes have also been undertaken (Gagnon and Jolin, 2019). In this case the Dramix® 4D 65/35BG fibre type was used at dosages of 30 and 50 kg/m³ in C30/37 and C50/60 strength basic mixes to give a total of four combinations of fibre and concrete mix type.

In-situ fibre contents were not determined, although a subsequent investigation (Darveau and Jolin, 2021) repeated the 30 kg/m³ C50/60 combination in a nominally identical basic mix and measured the in-situ fibre content as 22.9 kg/m³. This represents fibre losses of 24% and leads to a similar in-situ fibre content to the 25 kg/m³ used in the previous investigation using cast fibre concretes. The Darveau and Jolin (2021) investigation confirmed that in cast and sprayed concretes with nominally identical in-situ fibre contents, SFRC performance is improved due to preferential fibre alignment.

A Gagnon and Jolin (2019) comparison of the ratios of the five individual flexural tensile strength parameters showed the panel test generally returning higher values than the beam test, consistent with the observations of the previous investigation on cast concretes, with ratios close to unity for f_L , highest at low crack widths and reducing with increasing crack width to near to unity at f_{R4} . A comparison of coefficients of variation once again showed typically lower variability in the panel test determined parameters.

These observations were also explained by the larger fracture surface, in combination with better load distribution across the fracture area, leading to the conclusion that the slightly higher strengths returned in the panel tests were not problematic and the test had the potential to be an appropriate alternative for the evaluation of SFRC.

In the knowledge of the investigations outlined above, the forthcoming amendments to the relevant European standards, and to encourage innovation with the potential for more efficient design, the first Author had previously written the alternate notched panel methodology into the construction specification for pre-construction trial qualification of sprayed concrete for the linings (SCL) in the southern section (S1/S2) of the UK’s High Speed Two (HS2) project (HS2, 2020).

A prerequisite requirement of the HS2 S1/S2 SCL specification was an appropriate pre-construction trial correlation of notched panel with notched beam test parameters although, on closer examination, and despite the contemporaneous supporting evidence summarised above, the prior investigations lack the necessary equivalence to ensure the consistent application of MC2010 based FRC performance classification criteria when assessing conformance.

The present investigation started by applying analysis of variance (ANOVA) techniques, which compare the respective within group and inter group variance, to pairs of equivalent panel and beam test derived flexural tensile strength parameters in the prior Gagnon and Jolin (2019) investigation. There are five such parameters for each test and four combinations of basic mix and fibre type giving twenty pairs of data. Of these data pairs only eight, five of which came from the same mix, were found to come from the same populations with less than a 5% chance of an incorrect judgement.

In one of the four mixes none of the five pairs of flexural tensile strength data from the two notched test types were found to come from the same population and, while the “c” class performance for the ratio f_{R3k}/f_{R1k} , i.e. $0.9 < f_{R3k}/f_{R1k} < 1.1$, in which the “c” relates to the ductility of the FRC, was consistently achieved for both panels and beams from each of the four mixes, the MC2010 classification of FRC performance was only consistent between panels and beams in one instance.

In Figures 1 and 2 the results for the two mixes using a 30.0 kg/m³ fibre dosage are respectively presented and show the mean values for each of the

flexural tensile strength parameters, along with standard deviation error bars, and their characteristic values calculated using a log normal distribution appropriate to EN 1990 procedures for an unknown population mean.

Figure 1. Gagnon And Jolin (2019) 30.0 kg/m³ C30/37 mix beam and panel mean and characteristic flexural tensile strengths.

In the 30.0 kg/m³ C30/37 mix (Figure 1) only the f_L values were demonstrated to come from the same population and performance classification in accordance with MC2010 was respectively 2.5c for panels and 1c for beams. The higher variability and relative brittleness in the beam failure is illustrated by the respective f_{R1k}/f_{Lk} values, which relate to crack control performance, of 0.90 and 0.62.

On the other hand, in the 30.0 kg/m³ C50/60 mix (Figure 2) all five pairs of flexural tensile strength parameters were shown to come from the same respective populations and, in combination with the higher strength matrix, lead to a consistent 3c MC2010 classification. In this case the respective

Figure 2. Gagnon And Jolin (2019) 30.0 kg/m³ C50/60 mix beam and panel mean and characteristic flexural tensile strengths.

panel and beam f_{R1k}/f_{Lk} values were 0.82 and 0.74 and are much as might be anticipated with the beam test expected to yield higher f_L , given the smaller fracture surface, and panel test expected to yield higher residual flexural tensile strengths given the more even load distribution over a larger fracture surface.

Nonetheless the results for the 50.0 kg/m³ fibre dosage, which might have been expected to give more similar performance given the typically more ductile failure at higher fibre dosage, were also inconsistent. Overall these results failed to achieve the prerequisite requirement that panel test results should lead to comparable or correlative MC2010, or indeed EN 14487-1(2022), performance classification as the equivalent beam tests and suggest, either that the assumption of equivalence is flawed, or that there was a significant difference in either the preparation and/or testing of the respective panel and beam test specimens in the proceeding work.

Against this background the opportunity was taken to conduct further trials using the two different basic mixes identified in Section 1 above and four fibre types, including the Dramix® 4D 65/35BG fibre which was the subject of the previous work, in the equivalent of a full-scale pre-construction trial.

3 SPRAYING TRIALS

The principal aim of the spraying trial was to obtain data for the notched panel test and for this reason 6 No. 600 mm x 600 mm by 100 mm non-absorbent plywood backed test sample panels were sprayed for each of the total of eight combinations of fibre type and basic mix.

The first of the two sprayed concrete mixes trialled was based on a contemporary liquid accelerated CEM I mix design and the second was based on a powder accelerated 70% ground granulated blast furnace slag (GGBS) mix (CEM III B) being developed for potential use on the HS2 project. Mix details are given in Table 1 and show that the mixes were nominally identical except for the cement type and admixture combination.

Table 1. CEM I and CEM III B mix designs.

	CEM I (kg/m ³)	CEM III B (kg/m ³)
CEM I	480	144
GGBS	0	336
4/10 aggregate	510	510
0/4 aggregate	1160	1160
Steel Fibres	40	40

Superplasticiser	4.50	3.50
Viscosity	1.0	1.50
Water	192	192

The spraying trials took place in the period April to June 2023 and were conducted at the premises of Shotcrete Services Ltd (SSL) in a purpose-built, although unheated, mock tunnel section. Sprayed concrete basic mix batching, including fibre addition, was undertaken at the adjacent third-party quality assurance accredited premises of SSL sister company Wealden Concrete. The batching and spraying work was therefore entirely under the control of one organisation.

The CEM I mixes were sprayed using a Meyco Suprema sprayed concrete pump with integral accelerating admixture dosing and an Oruga spraying manipulator. The CEM III B mixes were sprayed using a Turbosol TB30 sprayed concrete pump, powder accelerator dosing equipment and the same manipulator. Typically, 2 m³ of material was batched for each trial, with fibres manually weighed and dosed directly into the truck mixer hopper.

Dramix® 4D 65/35BG, 3D 80/30BGP and 4D 90/50BG hooked end drawn wire steel fibres were sprayed at a dosage of 40 kg/m³ along with a Synmix HP35 macro synthetic fibre at a dosage of 7 kg/m³. In the case of each of the two mixes sprayed with the commonly used Dramix® 4D 65/35BG fibre, two additional test panels were sprayed. These were respectively 1200 mm x 1200 mm x 150 mm, from which notched beam specimens were cut to allow a comparison with the notched panel test data, and 1200 mm x 600 mm x 150 mm, from which cores were taken for compressive strength and in-situ fibre content determination. In these cases the basic mix was also sampled for cube compression testing and flow tests were conducted. All test panels were screeded flat to aid test specimen preparation.

Pumping delivery rates and accelerating admixture dosages were recorded, along with concrete basic mix and ambient temperatures. The hardened panels were covered in wet hessian, left to cure in the mock tunnel overnight and were either cored or rough sawn in the following days to produce the required test sample pieces.

Cube specimens were cured at the batch plant in accordance with standard quality procedures and the relevant panels were cored by SSL to produce the necessary core test sample pieces prior to shipping to Loughborough University where the compressive strength testing and fibre content determination work was conducted in its Civil Engineering laboratory. All core compression testing was undertaken at the university except for the 24 hr cores, which for logistical reasons were tested by an SSL appointed test house. The 1 and 3-day cores were tested in the as received condition with subsequent cores tested in the saturated condition.

The bending test sample panels were shipped to Bekaert's laboratory in Belgium where 28-day notched panel and beam testing, including the preparation of the specimens, was undertaken with the samples air cured in ambient laboratory conditions. 28-day sawn cube compression testing was also

undertaken by Bekaert on samples of the two mixes sprayed with the Dramix® 4D 35/65BG fibre. These were cut from the notched beam test specimens immediately after testing.

4 STRENGTH DEVELOPMENT

The basic mix cubes were tested in groups of three at 7 and 28 days and returned respective means of 35.3 MPa and 34.9 MPa for the CEM I mix and 30.3 MPa and 35.7 MPa for the CEM III B mix.

The principal method of assessing the strength development of the sprayed material was by core compression testing in accordance with BS EN 12390-3. 6 No. cores were tested at 1, 3, 7 and 28 days, with 3 No. cores cut both parallel and perpendicular to the direction of spraying. In the case of the CEM III B mix it was not possible to test the 1-day cores and testing was delayed by several days.

All cores were ground to achieve the specified 1:1 length:diameter ratio and density tests were also undertaken in accordance with BS EN 12390-7. The 1 and 3-day densities were determined in the as-received condition, with all other cores being stored under water after receipt and prior to testing, and density determined in the saturated condition. Nonetheless the 3 and 7-day specimens were received at the laboratory just in time and the prior temperature control was not recorded. All core volumes were determined from the measured dimensions rather than by water displacement.

Apart from the CEM I mix 1-day strengths, there was little difference in the mean of the two subgroups of cores at each age. The statistical significance of the difference between the CEM I 1-day parallel and perpendicular cores was examined by ANOVA. This led to the conclusion that, with less than a 1% probability of being incorrect, the groups of core results came from different populations.

Nonetheless, by inspection confirmed by further ANOVA, there was no significant difference in the means of any of the other subgroups of cores at each age for either basic mix, which were therefore subsequently treated as belonging to the same populations. The data presented in the results below, is therefore based on a statistical analysis of all 6 No. cores tested at each age.

The 28-day sawn cube tests returned respective mean results of 31.3 MPa and 31.8 MPa for the CEM I and CEM III B mixes, corroborating the respective 28-day mean core strengths of 30.1 MPa and 33.1 MPa. In Figure 3 the core compression strength development with age is plotted and shows that the CEM III B core strength was consistently greater than the CEM I core strength with the 28-day cube strength consistent with the core strength in each case.

The compressive strengths were all lower than expected and the basic mix cubes failed to meet the anticipated C32/40 strength class suggesting that the concrete was of a slightly lower strength. There were

Figure 3. Core compressive strength development.

some anomalies in the 24-hour and 7-day strength development, which might be explained by the varying and uncontrolled curing regimes, although by 28-days the in-situ cores and cubes strengths were consistent albeit slightly lower than the base mix cube strengths.

5 FIBRE CONTENT AND REBOUND

Fibre contents were determined for all 6 No. cubes and 18 No. core specimens tested at Loughborough University from the Dramix® 4D 65/35BG fibre CEM I mix and from 3 No. cubes and 9 No. cores for the corresponding CEM III B mix. These returned respective mean values of 35.1 kg/m³ and 24.4 kg/m³ for the CEM I mix and 37.8 kg/m³ and 22.4 kg/m³ for the CEM III B mix. An ANOVA on the in-situ fibre content samples indicated a statistically significant difference in the in-situ fibre contents with a 5% chance of an incorrect judgement.

The basic mix cube fibre contents were a little lower than the 40 kg/m³ dosage rate, which was attributed to the relatively small sample size and inevitable losses during the fibre extraction process. The in-situ fibre content determinations may be subject to similar errors, although indicate respective fibre rebound losses of up to 39% and 44%. These are high in comparison with the 24% determined in Section 2 from the Darveau and Jolin (2021) investigation and are at the high end of the range reported elsewhere (Kaufman et al., 2013), although led to broadly comparable in-situ fibre contents.

6 FLEXURAL TENSILE STRENGTH

Notched panel tests were conducted in groups of six from each of the eight mix combinations. The result of one test on a Dramix® 3D 80/30BGP fibre CEM I panel was discarded due to an unusual crack pattern. Seven notched beam test specimens were

prepared from each of the relevant test panels for the two Dramix® 4D 65/35BG fibre mixes.

The mean, sample standard deviation and CoV were calculated for each group of test results. Characteristic values for flexural tensile strength parameters were also calculated using a log normal distribution and performance classified in accordance with MC2010 consistent with the treatment of the Darveau and Jolin (2021) data in Section 2. The mean and characteristic values for the CEM I and CEM III B mixes are respectively shown in Figures 4 - 7.

Figure 4. CEM I mix mean flexural tensile strengths.

Figure 5. CEM I mix characteristic flexural tensile strengths.

For the notched panel tests this showed that all the Dramix® steel fibres used in this investigation achieved at least a minimum 2b performance class ($0.7 < f_{R3k}/f_{R1k} < 0.9$), and a minimum f_{R1k}/f_{Lk} value of 0.9.

In the CEM I mixes some of the better performing fibres achieved the 2c classification and, despite the statistically significant lower in-situ fibre content, in the slightly stronger CEM III B mixes, the Dramix® 3D 80/30BGP fibre achieved the 3c classification.

Figure 6. CEM III B mix mean flexural tensile strengths.

Figure 7. CEM III B mix characteristic flexural tensile strengths.

Steel fibre performance classified in this way, which accounts for the variability of individual groups of results, was therefore broadly similar in the two mixes.

In the CEM I series CoV for f_L were in the range 11 – 27% and were significantly higher than those for the residual flexural tensile strength parameters, which had a maximum value of 11%. In the CEM III B series the f_L CoV was in the range 13 – 18% and the variability of the residual strength parameters was typically greater than for the CEM I mixes, with CoVs in the range 6 - 21%.

The two macro synthetic fibre mixes had similar mean f_L and f_L variability to the steel fibres mixes in the respective basic mix series, which is as expected since the fibres have little effect on the matrix tensile cracking strength. Nonetheless a significantly more brittle failure is illustrated by the respective CEM I and CEM III B mix f_{L1k}/f_{Lk} values which were 0.43 and 0.5. The variability of the residual strengths was also comparable to that of the steel fibres mixes and the ductility ratio also respectively achieved the “b” and “c” classification. Nonetheless, this is at

a significantly reduced overall performance level compared with the steel fibres, with the brittle failure leading to relatively low f_{R1k} values and a maximum 1c performance class.

Figures 8 and 9 respectively show the mean and characteristic flexural strength parameters for the CEM I and CEM III B mixes. ANOVA testing of f_L and residual strength parameters for the two Dramix® 4D 65/35BG fibre mixes shows that there was a statistically significant difference between f_L strength in panel and beam tests in both mixes. The beam f_L was higher and can be explained by the smaller fracture surface. Except for f_{R4} in the CEM III B mix, the residual flexural strengths showed no statistically significant difference, which is helpful since these are being used to classify performance according to MC2010.

Figure 8. CEM I mix mean and characteristic flexural tensile strengths.

The higher f_L strength and more brittle drop from f_L to f_{R1} in the beam tests, which can also be explained by the smaller fracture surface, was reflected in the lower f_{R1k}/f_{Lk} ratio, which in some cases only just exceeded the minimum 0.4 requirement. In the CEM I series the 2b classification was unaffected, although the greater variability of the CEM III B series led to a 1.5c classification. Some care is therefore required in interpreting the results, although this may be a result of greater variability in the lower embodied carbon CEM III B production process, which was still being developed and used prototype equipment.

The results in this relatively small comparison were therefore as might be anticipated. The smaller fracture surface explains the higher beam f_L strength, and a less brittle fracture resulting from the improved load distribution in the larger panel fracture surface leading to nominally identical residual flexural strength performance and MC2010 ductility classification. The difference in panel and beam f_L was statically significant, although suggests that a panel test derived result is conservative while the

classification of crack control and ductility in the larger specimen is more representative of likely in-situ performance.

The prior Darveau and Jolin (2021) investigation indicated the potential to achieve MC2012 3c performance in a C30/37 concrete, albeit that the panel and beam test results were inconsistent. The current testing programme suggests improved consistency in a full-scale pre-construction trial and will be continued to confirm the potential to achieve equivalent and consistent panel and beam MC2010 performance of a minimum 3c classification using high performance steel fibres.

Figure 9. CEM III B mix mean and characteristic flexural tensile strengths.

7 CONCLUSIONS

Analysis of variance (ANOVA) examination of prior laboratory-based investigations supporting the equivalence of the EN 14651 notched beam and EN 14488-3 notched panel tests showed statistically significant differences in flexural strength parameters leading to inconsistent MC2010 performance classification.

A full-scale pre-construction trial in which Dramix® 4D 65/35BG, 3D 80/30BGP and 4D 90/50BG hooked end drawn wire steel fibres, and a Synmix HP35 fibre were each sprayed in two different basic mixes, achieved a minimum MC2010 2c performance classification for the steel fibres, although the more brittle macro synthetic sprayed fibre reinforced concrete (SFRC) performance led to a 1c classification.

Notched panel and beam tests in the two 4D 65/35BG mixes showed statistically significant differences in f_L strengths, although residual flexural tensile strength parameters were statistically identical and led to consistent MC2020 ductility classification. Notched panel f_L determination is likely to be conservative and, given the less brittle failure, MC2010 crack control classification is likely to better represent the in-situ material performance.

Reduced notched panel test residual flexural tensile strength variability leads to smaller margins when conformance is based on characteristic strengths consistent with limit state design. This may lead to more efficient sprayed concrete mix design, including a reduction in the fibre volume required to achieve conformance. Pre-construction trial costs are likely to be increased although, depending on the size of the project, subsequent savings in the material costs may lead to overall savings.

In any event the improved design efficiency leads to a reduction in embodied carbon in a conformant Sprayed Concrete Lining (SCL) and, once the increasing and frequently mandatory costs of carbon offsetting are included, overall cost savings may be realised.

ABSTRACT: Two mutually exclusive approaches - one that adheres to the requirements of the Eurocode system and the requirements for concrete reinforced concrete structures (with reinforcement bars, wire meshes, lattice girders, etc.) and the other that is also applicable with the Eurocode system - will be presented for designing tunnel rock support - an observational technique using fibre-reinforced shotcrete and rock anchors to apply flexible rock support in hard rock.

An underground section with exceptionally large cross-section dimensions is used as a case study. The width and height are 45 m and 15 m, respectively, with a net cross-section of more than 500 square meters.

Tunnel is built in hard rock conditions with three major discontinuities systems (joint systems). Geological conditions are rated from Poor to Fair - Q index 1 to 4.

Along with the outcomes of observations made during execution and predictions made using potential ways to estimate and forecast the behaviour, a comparison of rock reinforcement solutions obtained using the various methods will also be provided.

Using empirical analysis, the NGI Q system will be used to calculate the necessary rock support measures.

According to theoretical models that take into account the elastic behaviour of concrete with the limit stress approach, analysis is being done to calculate the thickness of steel fibre-reinforced shotcrete and the capacity of the lining to absorb bending moments in combination with rock anchors.

Using the distinct element approach, numerical analysis was performed to determine the displacements in characteristic spots and to determine the stability of the rock mass and rock reinforcement (rock anchors).

Limit equilibrium method local block/wedge analysis for rock block stability.

Calculating the limit values for the displacements using a software for tracking the displacements, their convergence, and their attenuation.

A proposal for the development of the topic will be given.

Keywords: Rock support, Fibre reinforced tunnel lining, Observation method

1 INTRODUCTION

The application of sprayed concrete (shotcrete) tunnel linings with reinforcement (bars or fibre) and rock bolts is the most common method of reinforcing an underground structure - tunnels and caverns. In parallel with the development of sprayed concrete

applications, tunnelling has evolved and tunnels are constructed in a wide range of geotechnical conditions, from soft soils to hard rock. Despite the strong development of technologies, materials and methods for tunnel performance, some questions regarding the theoretical basis of the applied design methods are still insufficiently substantiated.

2 REGULATORY REQUIREMENTS

Structures, such as buildings, must adhere to the European System for the Design of Structures - Eurocode. This requires meeting the guidelines outlined in EN 1990 to 1999 and their associated national annexes and parameters. Precision in adherence to these standards is essential for designing sound structures. In the Eurocode system, the limit state method with partial safety factors and two boundary conditions is specified, including safety (load carrying capacity) and serviceability control (deformation). The safety of building structures is controlled by the computed values of the actions. Eurocode 7: Geotechnical Design stipulates the need to verify that boundary conditions for the geotechnical aspect of the structure are not surpassed.

Alongside the application of Eurocodes in tunnel practice, numerous other methodologies and models are available for the design of tunnel linings. These alternatives differ significantly from the requirements of EN 1992-1-1:2004. Eurocode 2: Design of concrete structures - Part 1-1: General rules and rules for buildings and EN 1992-2:2005. Eurocode 2: Design of concrete structures - Part 2: Concrete bridges - Design and detailing rules in terms of design principles. However, they are founded on observation and analysis, i.e. the observation method, of previously constructed tunnels. The NGI Q system (Barton N. Using the Q-system. Rock mass classification and support design. Handbook.) serves as an example of one such method. The methodology was developed between 1971 and 1974 and has since undergone numerous updates in line with advancements in technology and materials for tunnel construction. Drawing on the extensive experience gained from over 2000 tunnel construction examples, the methodology has been refined to ensure its effectiveness and efficiency. The approach is employed for rocky soil masses and is founded on the principle of comparable experience - definite established data for a particular soil base and structure predicted to exhibit similar geotechnical behaviour to previously constructed structures.

3 JUSTIFICATION FOR APPLYING A DESIGN SOLUTION

As per Section 2 of EN1997-1:2004. Eurocode 7: Geotechnical design, limit states may be verified using one or several methods including: calculation - analytical method; numerical modelling, failure criteria; adoption of prescribed measures - empirical method, classification system, experience; experimental models and testing; observation methods used in this study include in-situ monitoring and special geological observations. Construction measures employed consisted of exploration, pre-injection procedures, and special excavation procedures.

It is noteworthy that the aforementioned methods are permissible for geotechnical structures and

design, but they are not delineated for reinforced concrete structures.

Hoek, E. et al. (1999) outlines a methodology for assessing rock mass behaviour and design. It summarises the potential problems related to discontinuities in the rock mass, which include loosening, rock wedge/block failure, spalling, and collapse. Empirical and analytical approaches are suitable to design tunnel reinforcement that is adapted to the conditions. The predictability of low rock mass strength versus rock mass stresses involving overloading and subsequent occurrences of buckling, rupture, defoliation, cracking, plastic deformation or swelling of the rock array, can be achieved through analytical or empirical methods, or through observation of the rock mass condition. Analytical methods and design measures are applicable in adverse conditions such as weathering, swelling, alteration zones, fracturing, or significant water pressure.

4 DESCRIPTION OF THE CASE

The examined tunnel is a part of the Gothenburg-based Underground Railway Station. Its cross section widens in a cone-like shape, gradually increasing from 30.15 m at the eastern end to 44.77 m. Alongside this, the height of the cross-section also increases from 11.20 m to 15.00 m due to the widening of its profile. In the centre of the cross-section, there are vertical, monolithic reinforced concrete columns and a longitudinal reinforced concrete beam which serve to partially take the rock pressure.

Initially, a tunnel lining solution was proposed that included shotcrete with a thickness of over 250 mm, four-bars lattice girder at spacing of 1.5 m, a double welded reinforcing steel mesh, and system rock bolts. Owing to the considerable cross-sectional dimensions, a staged approach is necessary, beginning with the excavation of three pilot tunnels (as shown by number 1 on Figure 2), followed by the application of the first layer of sprayed concrete, the construction of reinforced concrete structures, including columns and longitudinal central beam (as shown by 3 on Figure 2), before finally fully excavating the profile and removing the temporary rock columns (as indicated by 4 on Figure 2).

Figure 1. Layout of East Station.

The sprayed concrete and the longitudinal cast in place beam are rigidly connected to transfer axial and shear forces, as well as bending moments, from the tunnel lining to the monolithic beam.

In this section, the rock cover varies in size, but it is never less than 12.5 m, which is more than half the width of the cross-section from the wall to the colonnade.

Figure 2. Layout of East Station.

Structural forces within the tunnel lining were calculated via a spatial Finite Element Method, continue model built using geotechnical design software.

Figure 3. Continuous FEM model of East Station.

The rock mass in the model was defined as continuous and follows parameters based on Mohr-Coloumb theory, with a cohesion of $c=1.80$ MPa, an internal friction angle of 50° , a modulus of elasticity of 23.7 GPa, a Poisson's ratio of 0.25, and a tensile strength of 0.62 MPa.

FEM analyses were conducted for various stress state cases of the rock mass, and the results were summarized. Using the limit state method as per Eurocode 2 requirements, dimensional checks were carried out. The dimensional checks conducted on the tunnel structure in 10.0 m lengthwise strips revealed that sections reinforced with Q335 type welded mesh and four-bars steel lattice girder, consisting of 8 mm diameter bars spaced at 150 mm centres, have the requisite capacity for shear forces in the radial direction. However, application of

transverse shear reinforcement (stirrups) is also necessary for larger sections.

An unforeseen and irrational outcome of the numerical model is the discovery of significant tensile forces, as well as numerous local concentrations, in the longitudinal direction of the structure that are greater than those in the radial direction. High shear forces are also present. The large tensile and longitudinal forces in the tunnel lining, which can exceed 2.0 MN of tension, necessitated a significant amount of longitudinal reinforcement. For instance, 32 mm diameter bars were laid over a 100 mm distance since it was not feasible to apply welded steel mesh. Additionally, in the area of the rock mass that is weak, there are further peaks of shear forces which amplify the results. As a result, there is a need for an increased cross section.

The findings were assessed according to previous experiences at comparable locations, with the Gjøvik Olympic Cavern Hall, Norway serving as the reference site, in comparison to the data outlined in Barton et al. (2015). Following the comparative analysis, it was discovered that the Gjøvik Olympic Cavern Hall project implemented significantly fewer rock anchors and steel fibre reinforced sprayed concrete, with larger cross-section dimensions, under nearly identical conditions and devoid of a colonnade in the middle of the vault. After over 30 years of successful operation at the analogue site, this conclusion indicates a need to reassess the design method used and seek a more appropriate solution. However, it is important to ensure that the solution satisfies safety and serviceability requirements.

5 NEW DESIGN SOLUTION

The basis of the new design solution involves evaluating potential failure mechanisms and redefining the primary load-bearing element. The design solution recognises the rock mass and its characteristic of dilation surrounding the openings, which produces compressive arches throughout the tunnel section, as the principal load-bearing element. Its capacity further increases with the substantial horizontal compressive stresses that are typical for this section. After concluding that the rock mass (geotechnical structure) was the principal load-bearing element, plans were made to reinforce it, rather than reinforcing the concrete. The core of the proposed approach is 'rock mass reinforcement'. It was predicted that a failure mechanism could arise from the creation of one or more wedges in the tunnel arch caused by gravity in the newly proposed design. In order to obtain stable and durable tunnel strengthening, decide on alarm levels for the displacements, and determine initial response measures if the behaviour of the array differs significantly from that predicted, necessary analyses and controls have been determined for this mechanism. To demonstrate that the composite set of tunnel bracing measures can achieve rock mass stability, the following analyses were conducted:

An empirical analysis was conducted to determine the required rock bolting measures. The analysis was conducted in adherence with NGI Q-system guidelines. Numerical modelling was implemented to determine the thickness of reinforced steel structural fibre sprayed concrete, as well as to assess rock mass stability, rock reinforcement with rock anchors, and displacement at characteristic points for alarm/critical levels. Stability of rock blocks was assessed through local block analysis using the limit equilibrium method.

5.1 Empirical analysis

Based on implementation experience, it is worth noting that the use of the NGI Q-system results in solutions that are more conservative than those obtained through analytical methods. This means that the NGI Q-system inherently incorporates certainty, for instance, in accounting for variations in performance quality.

The vertical red lines depicted in Figure 4 demonstrate the anticipated rock conditions range, with the red horizontal line displaying the planned tunnel width of 22.5 m. This width represents only 50% of the actual tunnel width, as a central colonnade of monolithic reinforced concrete columns has been included specifically to withstand mountain pressures. When the blue line is crossed, the system is suggested to be paired with another analysis method, such as a numerical model. Notably, the sprayed concrete thicknesses of $t \leq 120$ mm are considerably smaller than the original solution of $t = 250$ mm, while maintaining the same length and rock anchor distribution.

At $Q=1$ conditions, it is necessary to add 400 mm thick sprayed concrete ribs consisting of two rows, each with six reinforcing bars of 16 and 20 mm in diameter. The ribs must be installed over a distance of 4.0 m.

Figure 4. Empirical diagram for rock support/ reinforcement with intervals based on anticipated rock conditions, NGI Q system.

Due to technological constraints, a revised solution was developed for a rock revetment that can be applied across a range of expected rock conditions. The new solution was designed with conservative

specifications to ensure its effectiveness. Verification of the fastening according to the revised solution was conducted through further analysis to confirm its sufficiency. Further analysis is also necessary as the connection with the colonnade in the middle of the tunnel is complex, and there is a need to consider load absorption and transfer from mountain rock compression on the monolithic columns, which is crucial for ensuring safety and stability.

5.2 Analysis of fibre reinforced sprayed concrete

According to Barrett and McCreath, et. al. (1995), there exist six probable failure modes of shotcrete when employed for tunnel strengthening in robust rock mass having block cracks. These modes include adhesion, flexure, shear, punching, compression, and tension. The distinct models are displayed in Figure 5. There may be other failure patterns and combinations apart from the listed six; however, observations on accomplished processes indicates that the aforementioned six are responsible for over 90% of the failures.

Figure 5. Fracture models of sprayed concrete have been studied. Observations of falling rock wedges indicate that failure in shotcrete is caused by inadequate adhesion (a), bending (b), shear (c), punching (d), compression (e), and tension (f).

The empirical analyses conducted verify that the proposed method, involving a system anchorage applied at a distance of 1.5 m in both directions, along with fiber reinforced sprayed concrete of a 15 cm thickness, effectively prevents the formation of secondary wedges between the rock anchors. A four-step analytical analysis procedure was carried out, in line with the recommended guidelines of Swedish Road authority regulation: Projektering av bergkonstruktioner.

Verification of the adequacy of adhesion between the fiber reinforced shotcrete and the rock mass is a crucial aspect. The wedge is unconstrained by the anchors, and its adhesion to the shotcrete is examined thoroughly. In this study, a pyramidal rock wedge is formed between two rock anchors, as shown in Figure 6.

Figure 6. A rock wedge forms between rock anchors as part of the system anchorage, which helps disperse loading and reinforces shotcrete.

Assuming good adhesion between the dispersed reinforced sprayed concrete and the rock mass, it is recommended to use the following equation:

$$W_d \leq \frac{\sigma_{adk} \cdot \delta_m \cdot O_m}{\gamma_C} \rightarrow \sigma_{adk} = \frac{W_d \cdot \gamma_C}{\delta_m \cdot O_m} \quad (1)$$

$$W_k = m \cdot g \quad (2)$$

$$W_d = W_k \cdot \gamma_d \cdot \gamma_{G;dst} \quad (3)$$

Where, W_d is Design dead weight of the rock wedge, W_k is characteristic dead weight of the rock wedge, σ_{adk} is the characteristic value for adhesion between rock wedge and shotcrete, δ_m is the load bearing height of shotcrete, O_m is the rock wedge/ shotcrete load bearing perimeter, γ_C is partial factor for shotcrete, γ_d is the factor of safety, m is the mass of rock wedge, g is the gravity acceleration.

The analysis is conducted based on prerequisites related to the bond strength (adhesion), load magnitude, and anchor from the system rock reinforcement spacing. The size and weight of the rock wedge are determined for varying distances between the anchors at 30 and 45 degrees inclination within the rock mass. The required adhesion value is then calculated, and a bond strength exceeding 0.5 MPa (for solid rock mass) is deemed satisfactory.

The second check is conducted for cases where there is poor bond or high rock mass cracking. In such situations, it is assumed that dispersed reinforced concrete absorbs the actions by bending and absorbing

bending moments, and that shotcrete is anchored with rock anchors. The flexural tensile strength determines the bending moment capacity of the dispersed reinforced sprayed concrete. For a reinforced concrete section that has not yet experienced cracks, this stress value represents its tensile strength.

The bending moment capacity of dispersed reinforced sprayed concrete can be determined by assuming that it is greater than or equal to the characteristic maximum bending moment capacity of the material.

$$M_d \leq \frac{f_{flcrk} \cdot t_c^2}{\gamma_C \cdot 6} \rightarrow t_c = \sqrt{\frac{M_d \cdot \gamma_C \cdot 6}{f_{flcrk}}} \quad (4)$$

$$M_d = M_k \cdot \gamma_d \cdot \gamma_{G;dst} \quad (5)$$

Where, f_{flcrk} is characteristic value of the tensile strength of concrete until the formation of a first crack, t_c is thickness of dispersed reinforced sprayed concrete, M_d design bending moment.

The maximum design bending moment's magnitude is reliant on the slack zone's size that loads the liner between the anchors. The maximum moment can occur either in the middle of the zone/field under consideration or at the attachment points - such as rock bolts and, more specifically, steel plates of anchors. Beam or plate theory can be useful in determining the potential moment.

The analysis involved calculating the characteristic value of the bending moment at varying distances between the rock anchors, as well as determining the size of the loosened zone, at two angles - 30 and 45 degrees. Following the analysis, the results were charted, and the required thickness of the lining and characteristic value of the maximum bending moment were computed.

The adequacy of the section to resist buckling of a pyramid-shaped rock wedge that forms between rock anchors must be evaluated.

$$W_d \leq \frac{\tau_{bk} \cdot t_c \cdot O_m}{\gamma_C} \rightarrow t_c = \frac{W_d \cdot \gamma_C}{\tau_{bk} \cdot O_m} \quad (6)$$

$$W_d = W_k \cdot \gamma_d \cdot \gamma_{G;dst} \quad (7)$$

Where, τ_{bk} is characteristic shear strength of shotcrete.

The ultimate assessment is to determine the extent of penetration through the anchor support plates, given the presence of low adhesion situations.

$$W_d \leq \frac{\tau_{bk} \cdot \pi \cdot t_c \cdot (2b + t_c)}{\gamma_C} \quad (8)$$

For verification purposes, a graph is formulated demonstrating the necessary thickness of shotcrete, in

Figure 7. Load on anchor plate.

relation to varying distances between rock anchors, under the influence of loads caused by a rock wedge created at either a 30 or 45-degree angle.

5.3 Check for a gravity-loaded arch

In cases of insufficient rock coverage, where the rock mass is unable to withstand the pressures and arches generated during tunnel construction, or

when the rock mass has low strength, it becomes essential to use dispersed reinforced sprayed concrete to fully absorb the mountain pressures. In this instance, the geometry of the tunnel roof is analysed to ensure that only compressive stresses arise in the section and that they are transmitted to the surrounding walls. The equations stated by Holmgren, J. et al. (1992) and Stille, H., Holmberg, M., Nord, G., et al (1989), can be utilised to initially calculate the necessary thickness of the sprayed concrete.

$$t_c = \frac{2 \cdot B \cdot W_k \cdot \gamma_d \cdot \gamma_{G,dst}}{6.3 \cdot \left(\frac{f_{ck}}{\gamma_k} \cdot \alpha_{cc} \right)} \cdot \sqrt{1 + \frac{B^2}{10 \cdot f^2}} \quad (9)$$

$$t_c = \frac{B \cdot W_k \cdot \gamma_d \cdot \gamma_{G,dst}}{2 \cdot \left(\frac{f_{ck}}{\gamma_k} \cdot \alpha_{cc} \right)} \cdot \sqrt{1 + \left(\frac{B}{4 \cdot f} \right)^2} \quad (10)$$

$$t_c = \frac{B \cdot q}{2 \cdot f_{cd}} \cdot \sqrt{1 + \left(\frac{B}{4 \cdot f} \right)^2} \quad (11)$$

$$f = \frac{B}{2} \cdot \text{tg} \left(45 - \frac{\varphi}{2} \right) \quad (12)$$

$$f = B \cdot \sqrt{\frac{q_v}{8 \cdot q_h}} \quad (13)$$

Where, t_c is thickness of shotcrete, f is collapse arch height determined according to equation 12 and 13, f_{cd} is design compression strength of shotcrete, f_{ck} is characteristic compression strength of shotcrete, B is the width of tunnel section, W_k is characteristic value of rock mass action, q_v , q_h is the value of vertical or horizontal rock mass load, perpendicular to tunnel axis.

5.4 Numerical analysis

Numerical analysis is performed using the UDEC/Itasca software to assess the effectiveness of rock support and the stability of the tunnel. The analysis is conducted in two typical locations - the standard section and at the lowest point of rock coverage (12.5 m).

The discrete element method (DEM) is based on the laws of motion that govern solid bodies and the interaction between them. It relies on dividing the time period during which solid bodies move into a certain number of computational intervals. The technique is valuable in simulating the disintegration of cohesive forms, e.g. a solid rock formation, comprised of distinct parts (i.e. the separate rock segments defined by the main fissure systems in the mountain), as it allows for the portrayal of the behaviour of the fragmented rock masses in the vicinity of the tunnel and the acquisition of the estimates for potential movements.

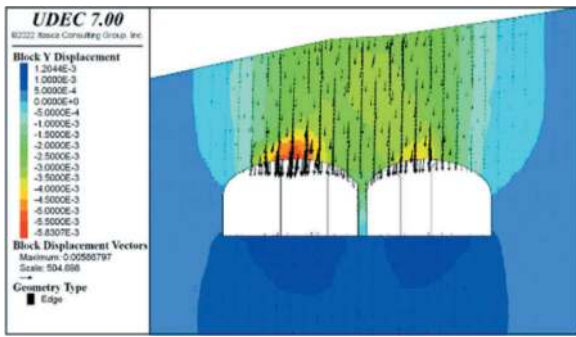

Figure 8. Analysis results for section A-A. Vertical displacements in the rock mass under gravitational stress.

Figure 9. Analysis results for section A-A. Vertical displacements in the rock mass under high horizontal stress.

The analysis revealed a displacement of 9.3 mm in the tunnel profile's arch. The forces in the rock anchors did not surpass 130 kN and remain within the allowable limits for the chosen anchor type – rock bolt, featuring an anchor and epoxy anti-corrosion coating (PC bolt M27) at 214 kN. Furthermore, the study included an examination of the rock mass displacements, sliding, and crack opening. The maximum displacements observed are slips up to 5mm, and the maximum opening value of cracks is up to 2.7mm. Both phenomena were realized in different, localized sections around the tunnel.

Based on the analyses conducted and the results obtained using the Discrete Element Method, it can be concluded that both sections are stable, even without dispersed reinforced lining. Furthermore, the selected number, distribution, and length of rock anchors are adequate for achieving a new equilibrium state in the array.

It is essential to establish a solid connection between the rock mass and the concrete columns to restrict rock mass displacements during final excavation phases, i.e. removal of temporary rock columns. A comparison of results was conducted based on the initial stressed state of the massif, i.e. gravitational and high horizontal. It can be inferred that the gravity condition plays a crucial role in determining the required rock anchorage. The initial horizontal stresses within the massif positively impact the stability of the rock formation surrounding the tunnel profile by creating arcs of compressed rock.

5.6 Block analysis

To identify the largest single block resulting from the mutual intersection of main fracture systems and determine the corresponding geotechnical indicators describing the state of the cracks, rock wedge block analysis was performed using the limit equilibrium method. This analysis aims to trace the failure mechanism arising from rock wedge formation in the tunnel arch. The geotechnical indicators were determined during mapping of completed works and geological surveys. The analysis assumes zero cohesion in the cracks and only rock anchors for rock anchorage. Dispersed reinforced shotcrete is not considered due to increased safety factors. The rock mass is assumed to be drained and not affected by underground water pressure.

Rocscience UnWedge software was used to analyse excavations of underground tunnels intersected with fracture systems. The stability has been assessed by calculating the safety factor of tetrahedral rock wedges formed around the perimeter of the block and the contour of the tunnel.

To analyze the tunnel profile, three distinct models have been employed: the Left Tunnel, which refers to the part located to the left of the colonnade; the Right Tunnel, which pertains to the section located on the right side of the colonnade; and a full profile, with the colonnade excluded from the center. The complete profile model outlines the scenario in which the monolithic strengthened concrete columns and the rock mass fail to establish a close connection.

The design tensile and shear capacity of rock reinforcement, specifically rock anchors, are incorporated in the model.

Figure 10. Block analysis results for full profile, without concrete pillars.

6 SUMMARY OF RESULTS

Since the inception of the new project solution, the following outcomes have been realized:

- A. The structural thickness of the fiber-reinforced lining, composed of sprayed concrete with steel

fibers, has been successfully reduced by more than 50%.

- B. The necessity for the application of bar reinforcement, steel reinforcing lattice girders, or welded steel reinforcing meshes has been entirely obviated. Except the quantities benefits this also leads to streamlined technological and cyclical operations for the excavation of the tunnel, presenting a significant advantage over the initial solution.
- C. The absence of steel rebars eliminates the need to fill over excavated material during the blasting process, as there is no requirement for strict adherence to the tunnel contour based on the theoretical profile dictated by steel rebars. This is halving the volume of shotcrete.
- D. This method enables a prompt implementation process and improves site safety.
- E. This is a sustainable solution from an environmental perspective.

7 CONCLUDING REMARKS AND FINDINGS

When formulating designs for underground infrastructures, the analysis must initiate by identifying potential failure and accident mechanisms. This scrutiny, necessitate supplementary checks or using of alternative methodologies compared to widely accepted practices.

Designing tunnels in hard rock conditions based solely on normative requirements for conventional buildings and bridges is not practicable. Aspects, such as the interaction between the rock mass and the structure, together with other factors not encompassed in the initial sections of Eurocode, must be taken into consideration.

Advisable is to employ normative documents, such as Eurocode 1992, only subsequent to a thorough evaluation of the resultant solution, especially in the context of hard rock formations. Basing the design on Eurocode system results in significant alteration to the reinforced concrete elements and a concomitant underestimation of the geotechnical conditions and associated dangers. For instance, the creation of rock wedges can go unnoticed in models of a continuous environment, causing a lack of appropriate systemic measures.

Essential is to identify and address such phenomena in order to implement effective solutions. The regulation and assessment of a diverse range of software products should be based on the specific assignment and geotechnical circumstances. The standard protocol entails calibration of the model after conducting a risk analysis and allowing specialists, experienced in similar projects, to handle the process.

Results should be subjected to diligent examination, ensuring their dependability and validity through alternative available approaches if deemed necessary. The assumed modeling technique, models of the soil array,

and the consideration of “disturbances in the array” have the potential to yield nonsensical outcomes that can substantially over or underestimate specific parameters. For instance, deformations may arise as a result of such occurrences.

In high-stiffness models, incorporating rigid constructions results in significant oversizing of tunnel linings, rendering them unsafe, impractical, or uneconomical. This is due to the intricate technological processes and work operations involved in hazardous environments, such as unreinforced arrays and work at height.

Hence, a comprehensive appraisal of the necessity and repercussions of utilising reinforced concrete structures for tunnel linings is fundamental before initiating the implementation process.

To ensure the successful implementation of the dispersion-reinforced tunnel lining method, it is crucial to position the anchor plates on the last bearing layer of sprayed concrete. This is a vital requirement, often overlooked during execution.

It is necessary to carry out frequent displacement monitoring and periodic assessments of them to ensure adherence to the anticipated values specified in the project.

ACKNOWLEDGMENTS

We would like to express our heartfelt gratitude to Swedish Traffic organization (Trafikverket) that allowed result and findings to be published and shared with readers.

ABSTRACT: Extensive record of tunnels excavated according with the SEM approach in swelling ground exists for both clayey soils and rocks and sulphated rock masses. However, there is less experience in shield tunnels bored under pressurized conditions (E.P.B. and slurry shields) where the impact is supposed to be lower due to the limited stress relief and navigation under saturated conditions. This paper includes the studies conducted for the risk assessment done for a large diameter TBM tunnel designed under complex geological environment which comprised mixed ground and face conditions including swelling soils and clayey soft rocks. The study also describes the approach adopted and impact on the design of the segmental lining of the tunnel planned also in a context of high regional seismicity. The design of this lining included a detailed parametric study performed to handle the existing uncertainties related with ground characterization, potential deconfinement and complex geological configurations.

Keywords: Tunnelling, TBM, Swelling, Shield, Volcanics and sedimentary rocks, Segmental lining

1 INTRODUCTION

During the detailed design of the segmental lining of a large TBM tunnel in Central America, large swelling potential of residual soils and soft sedimentary rocks was confirmed in formations which also included volcanic units.

Although the swelling phenomenon was detected and expected to be significant, difficulties during site investigation made it particularly challenging to characterize the swelling behaviour to the level needed for design. This combined with the complexity of swelling behaviour around pressurized TBMs, and the fact that no previous underground structures have been built in the rock formations under analysis, led the designers to adopt a risk based design approach.

In addition to site and laboratory testing, an analysis of state of the art of swelling analyses for similar lithologies and pressurized TBM tunnels was conducted.

This paper summarizes the risk analyses carried out as well as the final design approach for lining subjected to both significant swelling and earthquake loads combined.

2 A LITERATURE REVIEW ON SWELLING IN TUNNELLING PROJECTS

There is a large number of references for swelling in tunnels, due to its potential for considerable cost overruns and damage to the lining. For example, problems associated with swelling in the tunnels crossing the Jura Mountains and Baden-Württemberg region in Central Europe have been studied, due to the presence of sulphate-clay rocks with the presence of gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) and anhydrite (CaSO_4), often associated with the presence of Keuper facies (Bustcher et al., 2016)

*Corresponding author: sergio.sanchez@aecom.com

Recently Ramon (2014), developed a thesis for analysing and describing the swelling mechanisms of Tertiary sulphated claystones in Spain based on observations from well-known tunnels, bridges and embankments where heave induced by gypsum crystal growth in rocks and compacted soils containing sulphates.

However, there are fewer cases involving tunnels in volcanic rocks or pressurized TBMs. Carter et al. (2010) compiled a number of cases of hydroelectric tunnels excavated in the Andean formations of central Chile, where volcanic-sedimentary rocks are prevalent. The study performed analyses on the evolution of swelling behaviour of rocks containing clay minerals (specifically the smectite group -e.g., montmorillonite, nontronite, rectorite etc.) backed by a robust laboratory campaign consisting of free swell, confined Huder Amberg, null tests (on intact rock samples and on powder samples), scanning electron microscopy (SEM) detailed petrography, and X-ray diffraction. Carter et al. (2010) generally identified Oligocene-Miocene age rocks composed of andesitic/dacitic lava flows, volcanoclastic andesitic breccias, and sedimentary epiclastic rocks related with the Coya Machali formation as the most problematic rock types with respect to swelling.

However despite the extensive work carried out, exact swell-mineralogy relationships are still not clear. A meaningful guide for the development of sampling and lab testing was nevertheless established and contributes towards a better understanding of the mechanisms that may impact lining design.

Similar lab tests were carried out by Piaggio (2017) and supplemented by cyclic and triaxial testing, again on Andean volcanic rocks containing clay minerals. Swelling pressure tests with powdered rock show that swelling tended to be very dependent on the initial conditions like compaction load. Triaxial tests proved to be helpful in order to set up an analytical relationship to apply in a numerical model regarding the volumetric strains due to swelling.

The difficulty of obtaining representative samples of the rock mass, as well as the importance of the preparation of the samples to be tested and its influence on the results obtained in the laboratory tests is analyzed by Nielsen (2021). The tested samples taken from tunnels with expansivity problems related to fault zones in granites and metasediments, with presence of swelling clay minerals.

It is clear that the swelling mechanism in fault zones and in volcanics/volcano-sedimentary rocks is complex and not yet fully understood. Therefore, consideration of the order of magnitude of the swelling pressures observed in other projects around the world and in a variety of geological environments is necessary to understand whether analytical models reflect reality. Several cases of swelling in tunneling projects have been summarized in Figure 1.

Notably few examples of swelling exist for TBM tunnels. Some examples of TBM projects in Jurassic formations of Central Europe have been reported by

Kovari, (2014); Wittke et al, (2017) & Grossauer et al (2019), although most cases treat open face TBMs rather than closed face pressurized TBMs. Of particular interest is the Third Belchen tunnel tube for which Ziegler et al. (2022) provided a detailed discussion to understand swelling behavior based on instrumented sections records.

Figure 1. Swelling pressure of swelling rocks and soils at tunnelling projects.

Interesting experience has been recorded in the non sulphated Ontario Shale. Several references of smaller diameter TBMs are available (Lo et al. 2005, Cushing et al. 2016, Dimillo et al. 2016). However these again only treat open faced rock TBMs and the studies mostly focus on the time-dependency of the loads. This experience has also been applied to Sydney's shale bedrock (Dadfar et al. 2023) for the design of segmental linings.

Only a few references are available for closed faced pressurized TBMs. Ashraf (2006) described the use of 2D numerical models for the design of the segmental lining for the El Cairo Metro Line 2 tunnel which excavated soils with clay minerals. More detailed analysis, also for El Cairo Metro, is provided by Lecomte et al. (2014), who described the characterization work done to obtain representative parameters of the hard and high plasticity clay affected by Line 3 Phase 2. Swelling was expected to be triggered by changes in pore pressures due to the stress release generated by tunnel excavation.

The Slender West Lake tunnel in China (Wang et al. 2016) is another case of closed face TBM in swelling clay where instrumented sections with pressure cells and strain gauges were installed to investigate the distribution and magnitude of swelling loads.

3 SWELLING MECHANISM AND ITS SIMULATION

In clayey rocks, the swelling mechanism can a combination of osmotic flow between clay

minerals resulting on an increase in the distance between them, and the hydration with/ incorporation of water between the silicate layers of the mineral.

For the initiation of this mechanism, different conditions must be accomplished (Lo, 2005):

- A stress release and corresponding change in pore pressure;
- The presence of water;
- and a salt concentration gradient between the soil/ rock pores and the ambient fluid

For both sulphated rocks and clays, Grob's swelling law which considers logarithmic relationship between swelling strains and axial stress in the direction of swelling is generally accepted. This is consistent with the reduction of swelling deformations when a confining pressure is imposed, and the reduction of the swelling pressures when the swell deformation is allowed:

$$\varepsilon_i^{q(t=\infty)} = -k_{qi} \cdot \log_{10} \left(\frac{\sigma_i}{\sigma_{q0i}} \right) \quad (1)$$

Where $\varepsilon_i^{q(t=\infty)}$ is the final swelling strain, k_{qi} is the swelling parameter, σ_i the axial stress and σ_{q0i} the maximum swelling pressure.

This relationship was subsequently developed as to 2D and 3D for numerical analyses (Anagnostou, 1993, Wittke et al, 1998), which later incorporated the effect of seepage flow (Anagnostou 1992, 1993; Wittke, 2003) and the possibility of simulating the swelling rate over the time (Wahlen et al, 2009).

In sulphated rocks, further developments allowed for the chemical coupling and temperature effects for the simulation of gypsum crystal growth (Alonso et al, 2008; Ramon, 2014).

A specific constitutive model was developed for the commercial software PLAXIS which was developed by Benz (2010) and Schädlich (2013) and it is based in the previous work developed by Wittke and Anagnostou. This model is used for the swelling calculations presented later in this paper.

4 EXAMPLE OF SEGMENTAL LINING DESIGN IN SWELLING ROCK

4.1 Complex geological conditions

During the design of Ø12m ID TBM tunnel in Central America, high swelling potential was detected in both the soft residual overburden soils and tertiary rocks (siltstone, mudstone & carbonaceous mudstone) which would eventually host the tunnel. Swelling was determined as a governing load case for 2.3 km of the alignment and initial laboratory test suggested swelling pressures significantly higher than anything the design team could find in the available literature. Further, the project is located in

a region of very high seismicity. The initial attempts to design the segmental lining for the combined effects of a worst-case swelling scenario and high seismic forces proved cost prohibitive. This triggered the need a risk-based approach to determining the impact of swelling on the lining design. The following provides some context to the subsurface conditions of this design example.

Table 1. Index and mechanical parameters of the swelling potential soils.

	γ_{ap} (kN/m ³)	Fines (%)	P.I.	Su (kPa)	E' (MPa)
Silty mud	16.0	70	29	11	2
Residual soil	19.0-19.5	50-75	30	65-170	13-30

Table 2. Index and mechanical parameters of the swelling potential soils.

	γ (kN/m ³)	σ_{ci} (MPa)	E _m (MPa)
Mudstone	21.5	1.6	200
Siltstone	22.0	3.0	80-575

The potential for swelling was first detected by weathering potential characterized by Slake Durability Index. Figure 2 shows the SDI compared the content of phyllosilicates in the swelling prone rock units.

Figure 2. Mineralogy, clay content and SDI.

The swelling prone rock units contain clay in the range of 30 to 65%; with smectite contents in the range 40 to 80%. Some samples had smectite reaching as high as 90%.

For the specific characterization of swelling behavior, null pressure and free swelling tests were performed in accordance with ASTM D 4546-08 & ASTM D 3877. Huder-Amberg tests were also performed and yielded results

which suggested swell pressure far in excess of the ASTM test results and significantly higher than anything the design team could find in the literature. This made it much more difficult to accurately characterize the swelling behavior from a design standpoint.

After consideration of all testing results and a thorough review of the literature, it was determined that the Huder-Amberg tests were yielding erroneous results, likely resulting from poor sample handling and preservation and, possibly, due to the stress path typical of this test and maybe inappropriate for these soft rocks. Ultimately, a free swelling of a 3% and a null pressure close to 500 kPa were accepted as the probable maximum limits based on ASTM testing.

4.2 Swelling loads in codes and standards

Swelling is identified in many design codes as a geological hazard and/or load case that must be incorporated into the design. However, guidance on how to do so is notably light. AASHTO LRFDTUN (2017) for example defines swelling as something that needs to be evaluated but it don't provide load factors nor does it clearly state in which load combinations it should be featured.

FHWA-NHI-10-034 (2009) (Technical Manual for Design and Construction of Road Tunnels — Civil Elements. 2009) and FHWA-HIF-20-035 (2020) (Precast concrete segmental liners for large diameter road tunnels) both similarly treat swelling in the same way as other particular ground loading cases (such as squeezing ground, rock wedge load, creeping ground, etc.), that is as a specific type of ground classification which generates earth pressure. The former appears to suggest that swelling be treated as a ground load and thus subject to standard earth pressure load factors, however the latter identifies swelling as a “transient load” suggesting it have some other undefined load factor.

Other internationally recognized design guides such as the British tunnelling Society's (BTS) “Tunnel design guide” which explicitly states “Where swelling is unavoidable, the linings should be designed specifically for the stress-dependent portion of volume change”.

Therefore it is interpreted by the authors that the code intent is generally to treat swelling as an earth pressure (in other words a pressure on the lining exerted by earth – regardless of the mechanism generating it). Thus, a load factor of 1.35 as defined for earth pressures in the AASHTO (2017) is assumed to be the appropriate way to handle swelling in the LRFD context.

4.3 Design approach used for the segmental lining

In theory, the use of pressurized slurry TBM excavation should mitigate the degree of swelling compared to typical open face TBM or conventionally mined excavation. The pressure in the excavation chamber

maintains some degree of confinement around the excavation perimeter which limits the changes in stress which trigger swelling. Further, the slurry (or conditioned muck) in the excavation chamber preserves the saturated state of the ground, limiting the change in moisture content of the ground during excavation.

Although these two mechanisms should limit the degree to which swelling is triggered, changes in stress around the excavation perimeter are unavoidable and the pressure state in the excavation chamber can become more difficult to control in mixed face conditions. Even the use of quick hardening two-component grouts cannot fully confine the ground after excavation. In addition, hyperbaric interventions, issues with the backfill grouting injections or defects in the grouted annulus cannot be ignored and would all have a detrimental effect on swelling.

In the reference case discussed herein, the high weathering potential of the swelling prone rocks suggests a high potential of developing new cracks or modification of the existing joints/discontinuities allowing water ingress. These considerations led the design team to conclude that swelling remains one of the critical load cases despite the use of a pressurized TBM for excavation.

For the design of the reference Ø12.0m ID segmental lining, the selection of the swelling parameters was critical. Not only was there no other recorded experience of swelling in the region, but the laboratory data suggest highly varying results depending on the type of test performed as previously discussed. Thus, the design process began with a sensitivity analysis where the impact on the tunnel lining of different scenarios consisting of maximum swelling strain and null pressure were evaluated. The upper and lower limits of the analysis were defined by both the lab testing results and characteristic values seen in the literature. All calculations were carried out using the finite element software PLAXIS where the swelling mechanism was modelled using the purpose designed “Swelling Rock Model” constitutive model. This approach avoided complex coupled constitutive models with large number of input parameters difficult to obtain in such heterogenous geological conditions. Ultimately, it was determined that the swelling law be defined by a maximum swelling strain ($\epsilon_1^{q(t=\infty)}$) of 5% and a maximum swelling pressure of 1 MPa, placing this project on the upper end of swelling loads. Figure 3 shows the proposed swelling law as envelope of the existing laboratory data.

These limits were selected in order to envelope all of the ASTM swell test results and provide a sufficient buffer to account for the risk of higher swelling see in the literature. Further, the swell strain and null pressure selected was not too penalizing since the finite element calculation was based on a “coupled” analysis where the volumetric strain is only based on the change of stress rather than the total value of stress (in other words, volumetric strain is only impacted by the slope of the blue line in Figure 3.

Figure 3. Swelling Law proposed after lab testing analysis and risk analysis.

Once the constitutive model was defined, a total of 14 sections were analyzed considering a range of geometrical, phreatic and geological conditions. The 4 most critical sections were selected for additional 2D dynamic models to ensure that lining was capable of handling the combined effect of swelling and earthquake. These dynamic calculations were run for 3 different time histories equivalent to imposing ground motions with a PGA of 1.06-g.

Despite the combined effect of high swelling loads and significant earthquake, the lining was able to be optimized to a 500mm thickness.

Figure 4. Example of numerical model simulating mixed face conditions in swelling ground.

Figure 5. Verification of M-N loads at the analysed swelling-prone sections.

4.4 Impact of swelling during operation

The internal structures of the example project were very sensitive to differential settlements. Thus, it was critical to understand how swelling deformations imposed on the lining would dissipate along the length of the tunnel. Since the swelling mechanism in pressurized TBM tunnels is not well understood, the design of the lining had to account for localized swelling impacting the internal structures in the longitudinal direction in addition to the full swell condition discussed in the previous section.

The total and differential swelling deformations imposed on the lining is a direct function of the length of tunnel over which the swelling occurs, and since it is impossible to know the length of the swelling zone, another sensitivity analysis had to be carried out.

Based on the numerous 2D models carried out for the lining, the design understood well what the potential magnitude of displacement the invert of the tunnel would experience under different swelling scenarios. However, these models fail to capture the tridimensional behaviour of the lining.

Subsequently, these 2D plane strain models were used to calibrate equivalent loads to be used to model swelling in a 3D finite difference model using the software FLAC 3D 7.00.

The 3D model was iterated such that swelling load was applied at progressively longer lengths of the tunnel. The results of each model were combined to investigate the changes in total and differential displacements of the tunnel invert as a function of the number of segmental rings carrying a swelling load. This exercise was carried twice. The first analysis covered the 'green field' condition, aimed at analysis how the tunnel behaves midway between stations. The second sensitivity analysis, addressed the issue of swelling activated close to a fixed point; equivalent to a 'station boundary condition'.

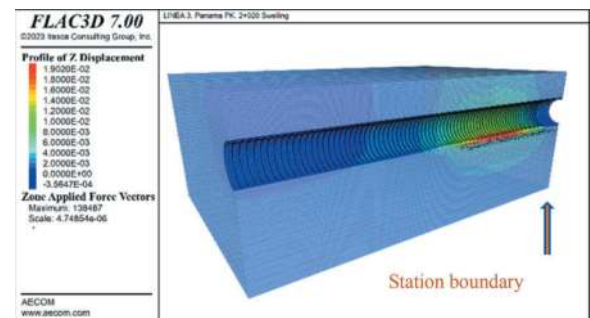

Figure 6. 3D numerical model for sensitive analysis of swelling triggered close to a station boundary.

The first analysis demonstrated that the highest angular distortions were more or less located at the edges of the applied swelling load. The second analysis (shown in Figure 7), illustrates that the presence of a station or shaft wall produces lower total displacements but higher (more critical) angular displacements.

5 CONCLUSIONS

The mechanisms related to swelling in the context of pressurized slurry TBM tunnelling is not well understood yet.

Although there are extensive records of SEM/NATM tunnels impacted by swelling, limited references exist for pressurized EPB/Slurry TBMs. This paper provides a brief overview of the relevant literature and discusses how the uncertainties regarding swelling can be handled in design. Specifically, an example of lining design for a large diameter tunnel excavated by slurry shield in non sulphated swelling rocks is provided. Specifically, it is argued that the risks and uncertainties around swelling loads can be managed by a detailed program of numerical analyses based on lab testing and industry published experience from other projects.

Figure 7. Analysis in terms of angular distortion of the potential swelling impact close to a station boundary.

For segmental lining design, extensive 2D PLAXIS models were useful to capture the mixed ground conditions of the project. The “Swelling Rock Model” was used to incorporate lab data and evaluate the sensitivity of the lining to different swelling parameters.

Greater accuracy needed to predict potential heave during operation was obtained by using 3D models simulating the rings and their longitudinal behaviour.

ABSTRACT: In order to explore the segment floating mechanism of large-diameter shield tunnel in complex strata with abundant water near the sea and take corresponding control measures, this study, based on the Fuzhou Binhai Express Metro project, established a numerical calculation model considering the multi-factor coupling effect of shield machines, segments, slurry, and strata, and analyzed the interaction mode for slurry and segment, and segment floating mechanism under different slurry pressure distribution forms. The results show that: As the slurry pressure at the lower part of the tunnel segment increases, the floating displacement of each tunnel segment will correspondingly increase. At the same time, the floating displacement of the right and lower sides of each tunnel segment is relatively large, while the floating displacement of the upper and left sides is relatively small. The overall structure presents a torsional elliptical state of compression from the diagonal to the center of the segment. The change in the distribution form of slurry pressure has the greatest impact on the floating displacement of the first tunnel segment behind the shield tail, and the change in the distribution form of slurry pressure has a significant impact on the floating displacement difference between the upper and lower positions of the tunnel segment, while the impact on both sides is relatively small. The misalignment between adjacent segments gradually increases with the increase of slurry pressure at the bottom of the segment. The closer it is to the shield tail, the greater the misalignment between adjacent segments. Moreover, the change in slurry pressure distribution at the bottom of the segment has the greatest impact on the misalignment between adjacent segments near the shield tail. As the slurry pressure at the lower part of the segment increases, the growth rates of upper and lower misalignment are 200% and 142.8%, respectively. When the slurry pressure on the upper part of the segment is high, the overall axial force and bending moment at various parts of the tunnel segment are small, and the distribution range of negative bending moments on the upper part of the segment and the value of negative axial force on the lower part are small.

Keywords: Shield tunnel, Segment Floating, Numerical model, Slurry pressure, Segment misalignment

1 INTRODUCTION

During the construction of large-diameter shield tunneling in the soft and water rich strata near the sea, due to the influence of seawater environment, the groundwater head is high and the formation buoyancy is large, which makes it difficult for conventional synchronous grouting mortar to solidify quickly in humid environments. In addition, the bearing capacity of the weak strata is small, so it is unable to effectively constrain the deformation and displacement of the lining segments that detach from the shield tail. Moreover, due to the prolonged flow of the slurry behind the wall, the slurry often accumulates and fills at the

bottom of the lining segment due to uneven diffusion under gravity and construction disturbances^[1,2]. Under the action of formation buoyancy and uneven distribution of slurry pressure, the lining segment often experiences significant floating and misalignment, resulting in a significant deviation between the shape of the tunnel section and the design axis, which exceeds the specification requirements^[3,4].

During shield tunnel construction, the engineering problem of uneven distribution of slurry pressure on the lining segment causing the segment floating has attracted widespread attention from scholars. Some progress has been made in field and indoor experiments, theory, and model calculations. However,

comprehensive analysis shows that during shield tunnel construction, the shield machine, lining segments, slurry, and strata are in a complex interaction state, which causes the segment floating to be influenced by multiple coupling factors [5,6]. In previous studies on slurry and tube theory and numerical calculation models, most of researchers simplified the effects of other factors while analyzing the interaction between the structures. In engineering practice, the deflection and compression effect of the shield machine on the segment and the uneven pressure of the support shoes in each zone of the jack can have an impact on the interaction state of the slurry segment. The overly simplified numerical model and theoretical assumptions in previous studies have caused significant differences between the analysis results and engineering practice [7,8]. Therefore, when constructing the numerical model, the complex coupling effect of the shield machine-lining segment-slurry-strata should be fully considered, to comprehensively evaluate the mutual influence between various components in the model.

Based on the Fuzhou Binhai Express Metro project, this study analyzes the interaction between the slurry and the lining segments during large-diameter shield tunneling construction in the water rich areas near the sea by numerical calculation. Based on the specific construction mode in engineering practice, establish a numerical calculation model for the multi factor coupling effect of shield machine-lining segment-slurry-strata. Through calculation and analysis, the interaction mode between slurry and lining segments under different forms of slurry pressure distribution and the segment floating law are explored, in order to reveal the segment floating mechanism of lining segments in the complex strata environment of rich water near the sea and propose reasonable engineering disposal measures.

2 NUMERICAL CALCULATION AND ANALYSIS OF SEGMENTS FLOATING

2.1 Overview of engineering geology

The outer diameter and inner diameter of a shield tunnel segment on the Fuzhou Binhai Expressway are 8.3m and 7.5m respectively. The starting and ending mileage of the left line is ZDK54+354.106~ZDK58+622.528, with a length of 4246.399 meters. The left line has a total of 2360 linings. The shield tunnel section line is mainly laid along (near) the coastline and is mainly located in alluvial plains, coastal plains, and sea land interaction plains. The strata traversed by shield tunneling are complex and variable, involving (including mud) fine sand, (including mud) silty clay, silt, and muddy soil. The soft soil and water rich conditions make the assembled lining segments bear a significant water buoyancy effect. Under complex geological conditions, the deviation of shield

machine posture results in the lining segments being in a biased state during the assembly process. At the same time, complex geological conditions lead to uneven diffusion of slurry and mud backflow, which causes obvious floating after the lining segments are assembled and detached from the shield tail. The horizontal and vertical posture of the lining segments is poor, as shown in Figure 1.

Figure 1. Horizontal and vertical attitude deviation of segments.

From Figure 1, it can be observed that during the excavation of the shield tunneling in the rich water layer near the sea, the assembled segments have significant deviations in both the horizontal and vertical directions compared to the design axis. Compared to the horizontal difference, the vertical difference value of the segments is larger and the fluctuation is more obvious. According to the statistical results of the first 1280 rings of lining segments, the overall vertical displacement of the lining segment ranges from -75mm to 100mm, with approximately 77% of the lining segments experiencing positive floating displacement. In the range of 900 to 1280 rings, the floating displacement of the lining segment shows a corresponding increasing trend with the ring number, and the correlation coefficient between the two reaches 0.72.

2.2 Numerical model and boundary condition

Based on the actual interaction mode between the shield machine and the lining segment during field engineering practice, this study established a numerical calculation model for the interaction between the shield machine, the lining segment, the slurry, and the strata, as shown in Figure 2.

2.2.1 Components contact mode settings

The adjacent lining segments at the joint are connected by bolts in blocks. After the lining segments are assembled, the pre tightening force quickly applied firmly connects the bolts and the lining segments. The bolts and the lining segments deform

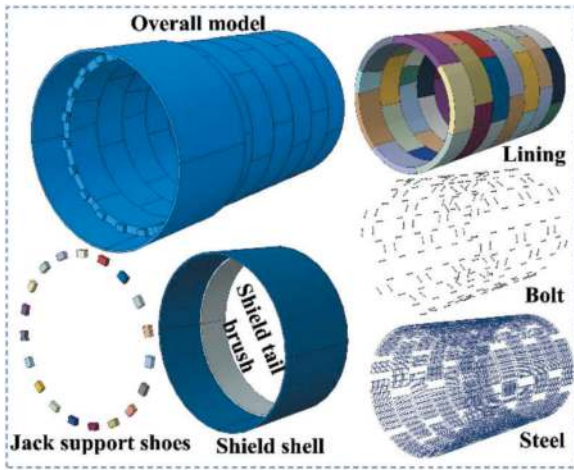

Figure 2. Numerical model of interaction for shield machine-segment-slurry-soil.

harmoniously and bear the force together. At the same time, the steel bars in the lining segments are poured together with the concrete structure, firmly connected to each other and cannot slide. Therefore, in this numerical model, the bolts and steel bars are combined with the lining segments in an embedded interaction form to meet the coordination and unity of the interaction modes between each other. The continuous transmission of mechanics and deformation modes between adjacent segments is achieved through the interaction between interfaces. Not only normal stress is transmitted between adjacent interfaces, but there is also a significant tangential force. The frictional interaction between segments and waterproof rubber pads is simulated using the Coulomb friction model.

2.2.2 Thrust setting of shield machine jack

The geological conditions in the rich water area near the sea are complex, and there is often the posture deviation and forward tilting of the shield during the tunnel construction. The deviation in posture between the shield machine and the lining segment causes each group of jack support shoes to not be in the same plane, and there is a significant difference in the thrust and cylinder stroke of each group of jack. In this numerical model, the non-uniformity of the thrust of each group of jack should be considered, and 19 sets of support shoes should be simulated using solid units. The normal interaction between the support shoe and the lining segment is simulated through hard contact, and the tangential interaction is achieved through Coulomb friction model.

2.2.3 Shield machine and shield tail brush

In this numerical model, a shield shell and shield tail brush model were established. The deviation of the rear cylinder of the shield machine was simulated by the up and down rotation of the shield shell model, and the deflection effect of the shield machine was

simulated by the circumferential rotation of the shield shell, in order to objectively and truly characterize the interaction between the shield machine and the lining segment. According to the field monitoring results of segment floating, the impact range of shield machine construction is revealed. In this numerical analysis model, the segment is set as 7 rings, with the segment that is about to detach from the shield tail being defined as the second ring, and the segment in the first ring behind the shield tail being defined as the third ring. In the model in this study, a whole structure was used to simulate the shield tail brush. The thickness of the shield tail brush model is the width of the pores between the shield shell and the lining segment. The model length is based on the actual length of the tail brush, and the structural properties are set based on the relevant parameters of the steel wire.

2.2.4 Slurry pressure and load distribution form

Engineering practice has shown that the floating of the lining segment mainly occurs during a period of time after detachment from the shield tail. At this time, the slurry on the outer wall of the lining segment is still in a flowing state, and the lining segment floating in the slurry is mainly affected by the static buoyancy and dynamic slurry pressure of the surrounding liquid slurry. The displacement of the lining segment is not limited and is in an floating state. Therefore, the main reasons for the floating of the lining segment in the complex environment of rich water near the sea are the dynamic slurry pressure and the aforementioned shield tail compression effect. The grouting system behind the shield tunneling machine wall is composed of 6 grouting holes, with 2 grouting holes arranged at equal intervals in the upper, middle, and lower parts. During the grouting process behind the wall, the slurry gushes out from the grouting holes. Correspondingly, different mechanical interaction modes can be divided into the following five types as a whole, as shown in Figure 3.

Figure 3. Relative positions of slurry and segments under different working conditions.

During the slurry solidification, the slurry will gradually penetrate into the soil, and the slurry pressure will dissipate accordingly. At the same time, the groundwater content in the water rich strata near the sea is rich, and the slurry is further diluted. Therefore, the slurry pressure will continue to decrease. When the slurry solidifies, the slurry pressure will dissipate to 0, which acts as the contact medium between the soil layer and the lining segment and transfers the soil pressure to the lining segment. The slurry pressure on the outer wall of the segment that has just emerged from the shield tail is the highest, and gradually decreases to 0 along the longitudinal direction of the tunnel. At the position where the slurry pressure is 0, the external load on the segment structure is equal to the soil pressure. The shield machine is subjected to external earth pressure, and the first lining segment located in the shield tail only bears the thrust of the jack, while the second lining segment bears the compression of the tail. The segments of the 3rd and 6th rings not only bear external soil pressure, but also linearly reduced slurry pressure. The segments of the 7th ring bear external normal soil pressure, and the longitudinal distribution of engineering loads in the numerical model is shown in Figure 4.

Figure 4. Engineering load distribution and action mode.

Based on the relative position relationship between the slurry and the lining segment in Figure 4 above, combined with field engineering practice and real-time slurry pressure data of shield machines, and referring to the dynamic slurry pressure calculation method applied to the lining segment in most unfavorable distribution state of slurry (i.e. when the strata water content is relatively high, the permeability of the slurry in the formation is low, and the slurry diffusion method is compaction grouting, with most of the slurry mainly accumulating in the lower part of the lining segment) in reference

[7]. This study set up a total of five calculation conditions, and the load magnitude and parameter distribution of each component of the model under different calculation conditions are shown in Table 1.

2.3 Analysis of calculation results

2.3.1 Floating displacement of lining segment

The working condition 1 in this numerical calculation is based on the field engineering practice. After the segment is assembled, the floating displacement of the third lining segment is obtained through field measurement. After the numerical calculation, the floating displacement of the segment in the numerical model is compared with the field measurement results, as shown in Figure 5.

From Figure 5, it can be seen that under different working conditions, the second and third lining segments both have larger floating displacement on the right and lower sides of the segment, while the floating displacement on the upper and left sides is smaller, which is mainly because in the field engineering practice, when the shield shell produces a rear cylinder pitch angle, the entire shield shell also undergoes circumferential deflection along the design axis. In this study, the shield shell is circumferential counterclockwise deflection. Driven by frictional contact between the shield shell and the second lining segment, the assembled and connected lining segments will also experience

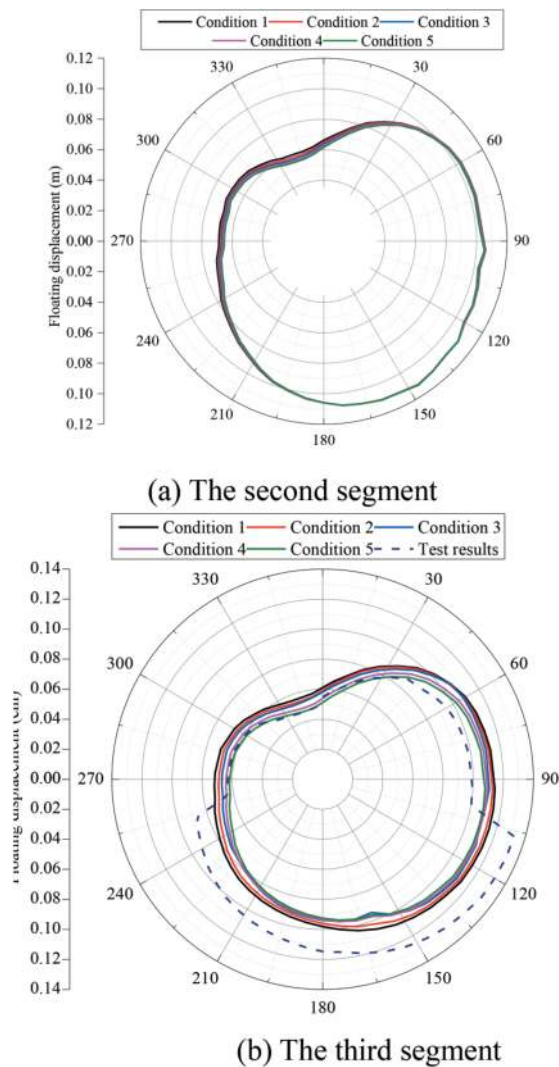

Figure 5. Distribution of numerical calculation results for floating displacement at various positions of segments.

corresponding deflection, and the external slurry of the second and third lining segments has not reached a solidification state at this time, which cannot limit the deflection of the segments. Therefore, the right side of these two lining segments will also deflect upward, resulting in significant vertical floating displacement. The vertical floating displacement of the left and upper parts of the lining segment will be limited by the circumferential deflection of the shield shell. At the same time, it can be observed that the vertical floating displacement of the second lining segment is greater than that of the third lining segment under different working conditions. As the slurry pressure at the lower part of the segment increases, the vertical floating displacement of the second and third lining segments will correspondingly increase. The overall structure of the segment shows a deformation state of squeezing from the center of the segment in the lower right and upper left directions. The

overall pattern of the field segment floating test results and numerical calculation analysis results is in good agreement, with an average error of 17.3%. Therefore, it can be concluded that the numerical calculation model and related boundary condition settings in this study have good engineering applicability.

2.3.2 Comparative analysis of lining segment floating and misalignment results

Engineering practice has shown that after the completion of segment assembly and detachment of the shield tail, complex floating and staggered structures occurred within the longitudinal and transverse ranges. In order to verify the engineering applicability of the numerical model in this study, the distribution of floating and staggered structures in the numerical model was compared and analyzed with the statistical results of the sensitive parts of the segments in engineering practice, as shown in Figure 6.

Figure 6. Comparison of numerical calculation and engineering practice for segments floating.

From Figure 6, it can be seen that after the field lining segments were assembled and detached from the shield tail, the apparent floating displacement occurs in every lining segments, and the difference in floating displacement between each lining segment led to the occurrence of a stepped staggered platform between the adjacent segments. That is, along the longitudinal direction of the tunnel, the N+1 lining segment floated relative to the N ring lining segment, which is more evident in the upper and lower parts of the lining segment. At the same time, under the coupling effect of factors such as the longitudinal and circumferential deflection of the shield machine compared to the design axis, uneven distribution of slurry pressure, and bolt dragging between the adjacent lining segments, the forces acting on each lining segment are extremely uneven within the spatial range, resulting in elliptical

deformation of the segment structure with different shapes, leading to significant segments misalignment and joint opening. The complex external load action modes and distribution states within the spatial range have led to varying degrees of compression and stretching between the various blocks within the segment structure. As the smallest and most irregularly shaped block in the entire lining segment, K block bears complex loads from other blocks during the assembly process, and is often difficult to be in the standard design position during the final installation process. The uneven distribution of external forces can easily cause K blocks to undergo extrusion deformation towards the interior of the tunnel after assembly. The numerical simulation calculation results indicate that under external loads and boundary conditions that are consistent with actual engineering, the proposed numerical calculation model with multi coupling factor in this study can effectively present typical floating displacement and dislocation phenomena such as stepped misalignment at the top and bottom of lining segments, lateral wall ring misalignment, and K-block extrusion in field engineering. From this, it can be concluded that the numerical calculation model in this study has good engineering applicability.

2.3.3 Misalignment and internal force distribution

The above calculation results of the vertical floating displacement of the segments indicate that during the construction of a large diameter shield tunnel, due to the complexity of construction factors and slurry distribution, there are significant differences in the vertical floating displacement between different segments along tunnel. The spatial variation of the floating displacement between adjacent segments can lead to the occurrence of adjacent misalignment. Field engineering practice and numerical calculation results indicate that the values of adjacent misalignment between the upper and lower parts of adjacent segments are often larger compared to other parts, and they are most susceptible to changes in the distribution form of slurry pressure. This study obtained four adjacent misalignment between the 2nd and 6th rings from numerical calculation results, as shown in Figure 7.

From Figure 7, it can be seen that along the tunnel, the adjacent misalignment at the upper position and the adjacent misalignment at the lower position gradually increase with the increase of the slurry pressure at the bottom of the segment. The closer to the shield tail, the greater the adjacent misalignment between adjacent segments, and the misalignment between rings 2 and 3 is the largest. From the comparative analysis of adjacent misalignment under different slurry pressures, it can be concluded that the different distribution forms of slurry pressure in the lower part of the lining segment have the greatest impact on the adjacent misalignment near the shield tail between segments 2 and 3. As the lower slurry pressure increases, the upper adjacent misalignment of segments 2 and 3 increases from 5mm to 15mm, and the lower adjacent misalignment

(a) Lower adjacent misalignment

(b) Upper adjacent misalignment

Figure 7. Analysis of misalignment between adjacent segment under different working conditions.

increases from 7mm to 17mm, with growth rates of 200% and 142.8%, respectively. Among them, in condition 5, the upper and lower adjacent misalignment of the lining segment are relatively small. In comparison, the difference in the distribution of slurry pressure at the lower part of the segment has the smallest impact on the adjacent misalignment between rings 5 and 6. As the lower slurry pressure increases, the adjacent misalignment at the lower and upper parts of rings 5 and 6 increases by 3mm and 1mm, respectively.

The above calculation results indicate that the change in the distribution form of external slurry pressure has the greatest impact on the spatial distribution characteristics of the floating displacement and longitudinal misalignment of the third lining segment. The overall asymmetric deformation of the segment structure can cause extremely uneven internal force distribution. Therefore, this study obtained the bending moment and axial force of the third lining segment along the circumferential direction of various parts under different working conditions, as shown in Figure 8.

(a) Bending moment (N·m)

(b) Axis force (N)

Figure 8. Bending moment and axial force distribution of the third segment under different working conditions.

As shown in Figure 8, the change in the distribution of external slurry pressure on the segment will have a significant impact on the axial force and bending moment distribution of the third lining segment structure. For Condition 1 and Condition 2, when the slurry pressure at the bottom of the lining segment is high, there is a significant bending deformation at the bottom of the lining segment structure, resulting in a larger bending moment at the lower part of the structure. At the same time, in Condition 2, there is a negative bending moment at the local position of the upper part of the lining segment,

which shows a deformation trend of opening outward, which can easily cause tensile cracks on the outer wall of the lining segment, and the outward opening of the joint, further leads to the pouring of groundwater from the outer wall into the lining segments and tunnels, resulting in overall structural leakage. At the same time, from the distribution of axial force, it can be found that compared to other working conditions, there is a significant negative axial force in the lower structure of the lining segments in working conditions 1 and 2, that is, there is a significant tensile stress distributed in the lining segments, and the lower part of the structure is prone to tensile failure. When the external slurry pressure distribution of the lining segment is relatively uniform in Condition 3, the bending moment and axial force values of each part of the lining segment structure are generally small. In this case, when the lining segment floats upward as a whole, the distribution range of negative bending moment and negative axial force values on the upper part of the lining segment is large, that is, there are many parts of the structure that open outward and produce tensile deformation. These parts are sensitive areas for tensile cracks to occur outside the structure, and groundwater outside the lining segment is prone to seeping into the concrete inside the segment. For conditions 4 and 5, compared to conditions 1 and 2, the axial force and bending moment at various locations of the segment structure are generally smaller, and the distribution range of negative bending moment at the upper part and the value of negative axial force at the lower part of the segment are smaller. Therefore, the possibility of structural joint opening and tensile cracks occurring on the outer wall of the segment is higher. It can be concluded that the larger slurry pressure at the upper part of the segment structure can significantly reduce the floating displacement of the segment structure while also improving the structural stress, reducing tunnel leakage disasters caused by the outward opening of segment joints and the development of tensile cracks on the outer wall. At the same time, it can be observed that there is not a significant difference in axial force between the various parts of the segment structure in Condition 4 and Condition 5, but the bending moment values in each part of the segment structure in Condition 5 are smaller and the overall distribution is more uniform. From the distribution of adjacent misalignment under different working conditions mentioned above, it can be observed that compared with Condition 4, the adjacent misalignment at the upper and lower parts of the 2nd and 3rd lining segments in Condition 5 is smaller, and the pulling effect between the bolts and segments between the 2nd lining segments is weakened. Therefore, the bending deformation of the lining segment is small, and the overall bending moment of the lining segment structure is relatively small.

Based on the above analysis, it can be found that changes in the distribution form of slurry pressure

can lead to significant changes in the magnitude and distribution form of the floating displacement of the shield tail and the adjacent misalignment. During the synchronous grouting process of the shield tunnel, the slurry with lower consistency has greater fluidity. Under the influence of factors such as gravity and construction disturbance, the slurry on the upper part of the segment will slide and accumulate along the outer side of the segment to the bottom of the segment, and the slow initial setting speed of the slurry causes the slurry to be in a liquid flow state for a long time. As the upper slurry gradually slides down, a large amount of liquid mortar in a flowing state accumulates in the lower part of the lining segment, resulting in a significant floating force on the lining segment. At this time, the amount of slurry in the upper part of the lining segment decreases, causing a sharp decrease in the downward slurry force. The floating displacement occurs in the lining segment structure in liquid slurry due to the large difference in slurry pressure between the lower and upper parts of the segment, resulting in adjacent misalignment due to the difference in slurry pressure. The segments closest to the shield shell (the 2nd and 3rd rings in this calculation model) are surrounded by the newly injected and most flowable slurry. Therefore, the slurry at the bottom of the segment has the highest buoyancy force. The above calculation results indicate that the larger slurry pressure at the bottom of the segment can cause significant adjacent misalignment between the 2nd and 3rd lining segments. At the same time, it is also easy to cause tension cracks on the outer wall of the lining segment and the outward opening of the joints, thereby increasing the risk of groundwater pouring into the lining segment to corrode steel bars and leak diseases. When the slurry pressure on the upper part of the lining segment is greater than that on the lower part of the lining segment, the control effect of lining segment misalignment is the best. Therefore, during the shield tunneling process, the slurry on the outer wall of the lining segment located at the shield tail and just detached from the shield tail should be quickly condensed, to prevent the upper part of the lining segment from sliding and accumulating slurry at the bottom of the tunnel, and during the synchronous grouting process behind the wall, the amount of grouting at the upper part of the lining segment should be appropriately increased to generate greater slurry pressure, effectively preventing the occurrence of floating of the lining segment structure.

3 CONCLUSIONS

This study established a numerical calculation model for the multi factor coupling effect of shield machine-lining segment-slurry-stratum, and analyzed and explored the interaction mode of slurry-lining segment and the floating law of lining segments under different slurry pressure distribution

forms. The main research conclusions are as follows:

- (1) As the slurry pressure at the lower part of the segment increases, the vertical floating displacement of each lining segment will correspondingly increase. At the same time, the counterclockwise circumferential deflection effect of the shield machine will cause larger floating displacement on the right and lower sides of each lining segment, while smaller floating displacement on the upper and left sides. The overall structure of the segment presents a torsional elliptical state of compression from the diagonal to the center of the segment. Compared with the lining segment in the shield tail, the change in the distribution form of slurry pressure has the greatest impact on the floating displacement of the first lining segment behind the shield tail. The change in the distribution form of external slurry pressure has a greater impact on the floating displacement difference between the upper and lower positions of the segment, while the impact on both sides is relatively small.
- (2) The misalignment between adjacent segments along tunnel gradually increases with the increase of slurry pressure at the bottom of the segment. The closer the segment is to the shield tail, the greater the misalignment between adjacent segments. The change in the distribution of slurry pressure at the bottom of the segment has the greatest impact on the misalignment between adjacent two segments near the shield tail. As the lower slurry pressure increases, the increase in misalignment between the upper and lower segments is 200% and 142.8%, respectively. When the slurry pressure on the upper part of the segment is high, the overall axial force and bending moment at various parts of the segment structure are small, and the distribution range of negative bending moments on the upper part of the segment and the value of negative axial force on the lower part are small.

Analysis of composite shell lining based on laminated theory

Wen Shuyi*

China Railway Academy Co., Ltd

ABSTRACT: Spraying waterproof membrane can make the shotcrete and membrane have a composite effect. However, at present, there is no design guidance and reference literature on the structure analysis of composite shell lining. Using laboratory testing methods, a comparative test was conducted on four point beams bending toughness and energy absorption for structures with and without waterproof membrane. The equivalent thickness of the sandwich structure was calculated based on the flexural strength or deflection reduction ratio. And based on the laminated theory, the equivalent thickness theory was derived, and the rationality of the experimental results was verified through examples; At the same time, it was found that the key factors affecting the equivalent thickness of the laminated are the shear strength of the sprayed waterproofing, the thickness of the sprayed waterproofing, and the equivalent diameter of the tunnel etc through the laminated theoretical formula. The greater the shear stiffness of the sprayed membrane, the thinner the thickness of the sprayed membrane, the thinner the equivalent thickness. It was found that the method used in this article can determine the equivalent thickness, with small dispersion and high degree of fit, and can provide guidance for design company.

Keywords: composite shell lining, laminated theory, sprayed membrane

1 INTRODUCTION

The waterproofing of double shell lining tunnels is achieved by installing prefabricated sheet membrane, which are installed between the primary lining (outer) and the secondary lining (inner). The sheet membrane serves as a separation layer or sliding layer between the lining. However, in tunnels with complex geometric shapes, it is difficult for sheet membrane to closely adhere to the excavation contour, and due to damage or excessive stretching caused by a large number of welds, steel reinforcement installation, and poor installation of secondary concrete lining, the waterproof board often leaks.

When using spray waterproofing with high double-sided bonding strength combined with permanent sprayed concrete as the first and second layers of sprayed concrete, due to the composite behavior between the two layers, the first and second layers of sprayed concrete can be considered as a single composite structure, i.e. composite shell lining^[1].

As a relatively new lining structure, composite shell lining tunnels are less commonly used domestically and internationally, such as the Crossrail and London Underground Bank Station renovation and upgrading projects. Although the International

Tunneling Association released the “ITAtch Design Guidance For Spray Applied Waterproofing Membranes” in 2013 to guide and standardize the application of this technology, it did not provide a clear calculation method for the stress on the lining structure^[2], and there is a lack of measured parameter data. In order to solve this problem, the theory of laminated glass in other industries was mainly used in the early stage. Reference^[3] is a specification for laminated glass, which provides an algorithm for calculating the equivalent thickness of laminated glass. However, compared to concrete, the material properties are different, and no theoretical derivation or analysis is provided. Bennison^[4] studied the mechanical properties of laminated glass and indicated that performance can be improved by combining rigid, structural, non PVB interlayers with modern glass processing methods; However, there has been no research on concrete structures and laminated structures with sprayed membrane. Liu Runquan^[5] conducted in-depth research on the bending theory of composite sandwich beams and calculated the bending stress and deflection of sandwich beams using analytical methods, but did not obtain the equivalent thickness and bending moment distribution. Reference^[6] studies the stress state and potential failure mechanisms of spray membrane

*Corresponding author: 359418435@qq.com

interfaces, as well as membrane testing methods. Some scholars also explore through numerical simulation methods. Reference^[7] used contact surface elements and other forms to simulate the spray membrane, but the setting parameters of the contact surface were mainly based on some assumptions, and the calculation results of different engineering examples varied greatly. Reference^[8] combines drained and undrained conditions to numerical analyze axial force, bending moment, and stress of each layer sprayed concrete under six different second layer thickness conditions of 50mm~300mm. In recent years, some research work has tested simulated components of tunnel lining structures containing spray membrane from an experimental perspective. References^[9-10]: Aecom Corporation in the UK, in collaboration with Warwick University, conducted spray panel tests on composite shell lining under soft soil conditions, and conducted cyclic tensile and shear tests on the core for analysis. Reference^[11,12] conducted laboratory tests on sandwich beams and obtained load-deflection curves, which also proved that there is a high degree of composite effect at spray membrane interface. The University of Cambridge has produced a compression bending test beam containing a spray membrane layer, and tested the stress and strain changes of each section of the specimens during the loading process. A preliminary study was conducted on the mechanical properties of the specimens^[13]. Chinese scholars have also conducted research on its load-bearing mechanism, material characteristics, and structural design. Zhou Ping^[14] used experimental methods to analyze the stress characteristics of multi-layer lining structures under interlayer action. Previous studies have found that each layer of multi-layer sprayed concrete has a radial anti slip effect. When they form a composite lining, they can form an overall load-bearing structure. Jiang Yajun et al. ^[15] established numerical calculation models for double shell lining, composite shell lining, and single shell lining based on the mechanical and interface parameters of the sprayed membrane measured through experiments, and conducted internal force analysis of the composite lining. Jiang Yajun et al. ^[16] investigated the shear failure mechanism and mechanical properties of the interlayer interface of the double-sided bonded tunnel lining structure, and obtained relevant parameters based on the Mohr Coulomb constitutive model, which can serve as a basis for judging the failure of the contact surface of the double-sided bonded tunnel spray membrane lining. Deng Yisan ^[17] quantitatively measured the integrity of structures with strong interlayer bonding, but did not establish a mechanical relationship between the external load and the various composite layers.

This article obtains the equivalent thickness of the sandwich spraying membrane structure through laboratory experiments, and proposes a composite shell lining analysis method based on the Laminated theory for verification.

2 RESIDUAL STRENGTH TEST

2.1 Test purpose

In order to obtain the equivalent thickness of the composite shell lining, the bending toughness is tested using the four point bending method in accordance with the “Technical Specification for Application of Sprayed Concrete”. By comparing the bending strength and residual bending strength of the small beam with and without sprayed membrane, the equivalent thickness of the interlayer structure is obtained. It is determined that the equivalent thickness can be calculated in the analysis to comprehensively consider the influence of sprayed membrane interlayer shear.

2.2 Test method

The cross-section of the small beam is $150 \times 150 \times 550\text{mm}$, the bending toughness is tested using the “SANS” mechanical universal testing machine produced by Meters Industrial Equipment Company, with a loading rate of 0.15mm/min. The deflection change at the center of the beam is tested using a specially designed fixture to fix the sensor. During the testing process, a pair of telescopic displacement sensors and a combination of telescopic and clamp displacement sensors are used on both sides of the beam sample (mutual verification of accuracy), Used to test the deflection of the beam under compression, the installation form of the test is shown in Figure 1.

Figure 1. Beam specimen and deflection test sensors.

2.3 Result analysis

Conduct bending toughness testing on the beam specimen, with BASF Master345 sprayed membrane in the middle, both layers are synthetic fiber concrete. The stress-strain curves is shown in Figure 2. The bending strength and residual bending strength under various working conditions are shown in Table 1.

For synthetic fiber concrete, the proportion of flexural strength incorporating BASF sprayed membrane to the flexural strength without sprayed membrane is 62%, and the proportion of residual flexural strength incorporating BASF sprayed membrane to the residual flexural strength without sprayed membrane is 72%, 55%, 64%, and 87%, respectively. The

Figure 2. Load-deflection curve of concrete beam.

Table 1. Shotcrete (residual) bending moment in each layer.

Item	BASF-PF	BASF-SF	PF	SF
Bending strength	2.98 (62%)	3.26 (56%)	4.82	5.86
Residual strength (deflection 0.5mm)	2.12 (72%)	2.5 (62%)	2.94	4.02
Residual strength (deflection 1mm)	2.03 (55%)	2.7 (74%)	3.68	3.65
Residual strength (deflection 2mm)	2.59 (64%)	3.04 (84%)	4.07	3.60
Residual strength (deflection 4mm)	3.15 (87%)	3.26 (96%)	3.64	3.41

comprehensive judgment ratio is 68%. For steel fiber reinforced concrete, the proportion of flexural strength incorporating BASF sprayed membrane to the flexural strength without sprayed membrane is 56%, and the proportion of residual flexural strength incorporating BASF sprayed membrane to the residual flexural strength without sprayed membrane is 62%, 74%, 84%, and 96%, respectively. Based on comprehensive judgment, the proportion is 74%. Due to the formula for flexural strength being $f_c = \frac{PL}{bd^2}$, the deflection at the midpoint of the span is $y(\frac{l}{2}) = \frac{46PL^2}{108bd^3}$. Therefore, in the case where the deflection of sandwich beams is equivalent to that of homogeneous beams, if the load or flexural strength accounts for 68%, the section height is determined $\sqrt[3]{0.68} \times 150mm = 0.88 \times 150mm = 132mm$. Similarly, the equivalent thickness of steel fiber reinforced concrete sandwich beams is determined by the section height $\sqrt[3]{0.74} \times 150mm = 0.90 \times 150mm = 136mm$.

3 ENERGY ABSORPTION TEST

3.1 Test purpose

The energy absorption of circular plates refers to the “Standard for Testing Methods of Fiber Reinforced

Concrete” (CECS13-2009). By comparing the energy absorption values without and with sprayed membrane, the equivalent thickness of the sandwich structure is obtained. It is determined that the equivalent thickness can be calculated in the analysis to comprehensively consider the influence of interlayer shear.

3.2 Test method

The stress-strain curve of a circular plate under central compression is tested through three point support and central point loading. The deflection value is the displacement of the central compression point of the circular plate, and the loading rate is controlled to 4.0 mm/min according to the regulations. Based on the stress-strain curve of each specimen, the energy absorption values of the specimen under compression to the following characteristic deflection points of 5mm, 10mm, 20mm, and 40mm are calculated through integration.

In the experiment, both steel fiber reinforced concrete and plain concrete follow the normal testing method, where the bottom and top surfaces of the sample during molding serve as the lower support and upper compression surfaces, to ensure uniform stress on the sample. The installation form of the experiment is shown in Figure 3.

Figure 3. Energy absorption specimen.

3.3 Result analysis

Perform energy absorption testing on the plate specimen, with BASF sprayed membrane in the middle of steel fiber reinforced concrete in both layers. The load/energy absorption value deflection curve is shown in Figure 4, and the energy absorption values for various working conditions are shown in Table 2.

For steel fiber reinforced concrete, the proportion of energy absorption value incorporating BASF sprayed membrane at 5mm, 10mm, 20mm, and 40mm to the energy absorption value without sprayed membrane is 100%, 90%, 84%, and 84%,

Figure 4. Load-deflection curve of concrete beam.

Table 2. Shotcrete energy absorption values.

Item	Peak load/ KN	Energy absorption/J			
		5mm	10mm	20mm	40mm
Steel fiber shotcrete	39	104	221	374	509
Steel fiber shotcrete+Master345 +Steel fiber shotcrete	35 (90%)	105 (100%)	198 (90%)	316 (84%)	427 (84%)

respectively, and the comprehensive judgment proportion is 90%; The peak load also accounts for 90%. Due to the deflection of the midpoint of the plate $\delta = \frac{q \times l^4}{64E \times h}$, with a peak load ratio of 90% for 40mm deflection, the equivalent thickness of the sandwich plate also accounts for 90%, which means that if the equivalent thickness of the cross-sectional is $90\% \times 75\text{mm} = 67.5\text{mm}$.

4 LAMINATED THEORY

4.1 Laminated theory analysis

Composite shell lining uses the same material (i.e. concrete) for two layers, and uses bonding material (i.e. spray membrane) between the concrete layers to make sandwich beams. Using the deflection (δ_{eq}) of the composite shell lining to be equal to that (δ_{mean}) of the homogeneous lining, based on the principle of equivalent deflection of a simply supported beam, the overall equivalent thickness of the composite shell lining is estimated. The sandwich simply supported beam is shown in Figure 5.

Figure 5. Laminated simply supported beam.

The key parameters considered in the solution are the thickness and elastic modulus of the main material layer, as well as the shear stiffness of the sprayed membrane. The specific formula is as follows :

$$\delta_{eq} = \frac{Pl^3}{48(EI)_{eq}} + \frac{Pl}{4(AQ)_{eq}} \quad (1)$$

$$\delta_{mean} = \frac{Pl^3}{48E_1I_{eq}} \quad (2)$$

Based on the principle of deflection equivalence, it is inferred that :

$$I_{eq} = \frac{1}{E_1 \left[\frac{12}{(AQ)_{eq}^2} + \frac{1}{(EI)_{eq}} \right]} \quad (3)$$

$$h_{eq} = \sqrt[3]{\frac{12}{E_1 \left[\frac{12}{(AQ)_{eq}^2} + \frac{1}{(EI)_{eq}} \right]}} \quad (4)$$

$$(EI)_{eq} = \frac{E_1 h_1^3}{12} + E_1 h_1 \left(\frac{h_1}{2} - a \right)^2 + \frac{E_2 t^3}{12} + E_2 t \left(\frac{t}{2} + a \right)^2 + \frac{E_1 h_2^3}{12} + E_1 h_2 \left(\frac{h_2}{2} + t + a \right)^2 \quad (5)$$

Considering the thickness of sprayed membrane is thinner, after simplification and organization

$$(EI)_{eq} = E_1 \left[\frac{h_1^3}{12} + \frac{h_1^3}{12} + (h_2^2 - h_1^2 + 2th_2)a + (h_1 + h_2)a^2 + t^2 h_2 + th_2^2 \right] \quad (6)$$

$$(AQ)_{eq} = \frac{G \left(t + \frac{h_1}{2} + \frac{h_2}{2} \right)^2}{t} \quad (7)$$

Substitute formulas (4) and (5) into formula (3) and simplify them to obtain the overall equivalent thickness of composite shell lining:

$$h_{eq} = \sqrt[3]{\frac{12}{E_1 \left[\frac{12t}{G \times B \times l^2} + \frac{1}{E_1 [C \times a \times D \times a^2 + F]} \right]}} \quad (8)$$

Wherein,

$$a = \frac{\frac{h_2^2}{2} + t \left(\frac{t}{2} + h_2 \right)^2 + h_1 \left(\frac{h_1}{2} + t + h_2 \right)}{h_1 + t + h_2} - t - h_2 \quad (9)$$

$$B = \left(t + \frac{h_1}{2} + \frac{h_2}{2} \right)^2 \quad (10)$$

$$C = h_2^2 - h_1^2 + 2th_2 \quad (11)$$

$$D = h_1 + h_2 \quad (12)$$

$$F = \frac{h_1^3}{12} + \frac{h_1^3}{12} + t^2 h_2 + th_2^2 \quad (13)$$

In the formula, δ_{eq} is the deflection of composite shell lining, δ_{mean} is the deflection of the homogeneous lining, P is the concentrated load, a represents the distance from the upper edge of the sprayed membrane layer to the centroid of the composite shell lining, ℓ is the span of the beam (ℓ is approximately equal to the arc length between the plastic points of the tunnel), h_1 is the thickness of the first sprayed concrete, h_2 is the thickness of the second sprayed concrete, t is the thickness of the sprayed membrane layer, and E_1 is the elastic modulus of the sprayed concrete, E_2 is the elastic modulus of sprayed membrane, G is the shear modulus of sprayed membrane, $(EI)_{eq}$ represents the overall stiffness of composite shell lining, and $(AQ)_{eq}$ represents the shear stiffness of composite shell lining. Based on the principle of equal disturbance mentioned above, an equivalent thickness is easy to calculate (considering the influence of sprayed membrane shear in the equivalent thickness).

4.2 Key influencing factors of equivalent thickness

According to section 4.1, the curve shown in Figure 6 can be generated, and the relative relationship between the equivalent thickness and the shear modulus of sprayed membrane, the thickness of sprayed membrane can be obtained.

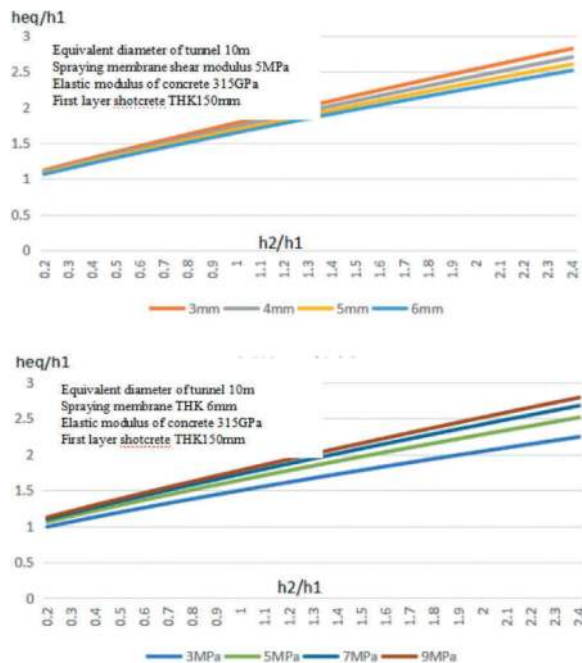

Figure 6. Laminated theory design chart.

From the above figure, it can be seen that when the shear modulus of sprayed membrane remains unchanged, the thicker the sprayed membrane thickness, the smaller the corresponding equivalent thickness; Under the condition that the thickness of sprayed membrane remains unchanged, the greater the shear stiffness and shear resistance of sprayed

membrane, the stronger the corresponding equivalent thickness.

4.3 Example research

Taking a composite shell lining project as an example, when the thickness of the first layer of sprayed concrete is 150mm, corresponding to the thickness of the second layer of 150mm, 100mm, and 50mm, the equivalent thickness h_{eq} of the homogeneous body is calculated. The theoretical analysis and calculation results are detailed in Table 3. For example, when the first layer thickness of sprayed concrete is 150mm, the second layer thickness of sprayed concrete is 100mm, and the spraying membrane layer with a thickness of 6mm jointly form a composite shell lining, the composite shell lining provides the same stiffness as the 233mm homogeneous lining.

The bending toughness test was only conducted on the first layer of concrete and the second layer of concrete with a thickness of 75mm. In this case, the equivalent thickness of the composite shell lining structure accounts for 88% to 90% of the homogeneous structure, approximately 89%; For the cases where the thickness of the second layer is 100mm and 50mm respectively, an approximate value of 89% will be taken, and further experimental research will be conducted in the next stage. According to the deflection formula in the energy absorption test, it can be inferred that the equivalent thickness of sandwich structures accounts for 90% of homogeneous structures. The equivalent thickness obtained from the experiment is shown in Table 3.

Table 3. Equivalent thickness of CSL.

Item	h1=150mm h2=150mm	h1=150mm h2=100mm	h1=150mm h2=50mm
Equivalent thickness of Residual strength test h_{eq}	267mm (89%)	223mm (89%)	178mm (89%)
Equivalent thickness of energy absorption test h_{eq}	270mm (90%)	225mm (90%)	180mm (90%)
Equivalent thickness of Laminated Theory h_{eq}	274mm (91%)	233mm (93%)	190mm (95%)

From the analysis in the above table, considering the influence of interlayer shear, the difference between the equivalent thickness obtained by the on-site test method and the equivalent thickness obtained by theoretical method is small, and the consistency is high, which proves the correctness of the theoretical calculation of the equivalent thickness of the interlayer. However, due to the lack of strain gauges attached to the first and second layers of concrete in laboratory tests,

it is not possible to determine the bending moment distribution of the two layers of concrete. Further research on bending moment distribution will be conducted in conjunction with other inter-layer energy absorption tests.

5 CONCLUSIONS

There is currently no detailed design guidance for the efficient design of composite shell lining tunnels. Sprayed membrane has good bonding strength and shear strength. The equivalent thickness of the sandwich structure was obtained through laboratory experiments, and its rationality was verified through laminated theory, which can provide theoretical guidance for design. The conclusion is as follows:

- (1) The equivalent thickness of the sandwich structure with spray membrane was calculated using the bending toughness of the small beam and the energy absorption test of the disk, and verified using the laminated theory analysis method. The obtained equivalent thickness has a good discrete type and a high degree of fit, indicating that the method of using the deflection equivalent laminated theory is feasible.
- (2) The proportion of equivalent thickness obtained through bending toughness test is 88%~90%, and the proportion obtained through energy absorption test is 90%. Both tests produce load-deflection curves, indicating that the two methods are essentially the same. Similar projects can choose either method for testing in the future.
- (3) Obtain the relative relationship between the equivalent thickness of the interlayer and the shear modulus of spray membrane, as well as the thickness of spray membrane. The larger the shear modulus, the smaller the spray membrane thickness, resulting in a larger equivalent thickness.

Singapore's land transport authority: 25 years of sprayed concrete lining tunnelling

Alvin Sim, Kin Boon Chang, Massimo Marotta*, Chee Keong Poh & Mohd Mohiadeen
Land Transport Authority, Singapore

ABSTRACT: Since 1995, Singapore's Land Transport Authority (LTA) has been developing the expansion of the underground rail and road transport systems within the Island City. The development of the Singapore MRT network system has relied predominantly on the use of Tunnel Boring Machines to ensure rapid and safe construction of the running tunnels. Other than for the construction of Cross Passages connecting the twin bored tunnels, Sprayed Concrete Lining have been extensively used during the construction the MRT network to solve technical challenges as to facilitate underpinning or removal of obstruction prior to bored tunnelling. SCL has also been used for critical undercrossing as the preferred trenchless method as well for the construction of TBM launching chambers, linkways, and more. The paper describes several case studies starting from 1999 till recent.

Keywords: Tunnelling, Sprayed Concrete Lining, SCL

1 INTRODUCTION

The MRT Corporation, now Land Transport Authority, was established on 14th October 1983. The construction of the first line (North South Line) of the Singapore Mass Rap-id Transport system started in October 1993. By January 1988, the construction was completed for Phase I and Phase II. The initial opening of the first 6 km of the North South Line from Yio Chu Kang to Toa Payoh happened on the 7th of November 1987 and by 12 December 1987 the section between Novena to Outram Park was also opened to public.

The rest of the line opened in staged until completion in July 1990. Among the various tunnelling methods, mined tunnels using Sprayed Concrete Lining (SCL) was used in some of the contracts.

The photo in Figure 1 shows one of the first SCL tunnelling in Singapore, excavated through the Fort Canning boulders bed. The soldier piles and lagging temporary support for Raffles Place Station can be seen at the end of the tunnel.

Generally, the use of SCL for MRT tunnelling has been for the construction of the numerous cross passages connecting at regular intervals the twin MRT running tunnels, in compliance with the Fire Safety in Rapid Transit System.

The cross passages have a typical excavation section of around 16-18 m². Over 100 cross passages have been constructed to date.

Figure 1. One of the first SCL tunnels for the North-East Line.

SCL has also been used for the construction of TBM launching chambers, where the TBM shield is assembled within the chamber thus reducing the size required for the launching shaft.

In addition, SCL has also been used as a trenchless solution for the construction of short section of running tunnels, or to solve construction challenges such as underpinning, advance tunnels for removal of obstructions prior to TBM drive, pedestrian underpasses, etc.

*Corresponding author: marotta_massimo@lta.gov.sg

Figure 2. TBM Launching Chamber by SCL.

Most of the SCL tunnelling in Singapore has been challenging in relation to varying and complex geological conditions, the urban context, the necessity of maintaining limited induced deformation and a challenging construction environment.

The next paragraphs will include several case studies of SCL application in the past 25 years.

2 DTSS ADVANCE TUNNEL (1999)

Singapore implemented a Deep Tunnel Sewerage System (DTSS) project as the long-term solution to meet future needs in wastewater collection, treatment and disposal through the 21st century. Under the first phase of this project, 70km of tunnels of diameters varying from 3.3m to 7.2m were constructed between 2001 and 2005 using Earth Pressure Balance (EPB) boring machines. During the early planning stage (1997) the Ministry of Environment (NEA) analysed the possible interference and impact of tunnelling underneath the future operational North-East Line MRT.

Anticipating the additional constraints that could be imposed under the rail protection Act, NEA and the LTA jointly developed plans which included the construction of an advance tunnel using SCL through which the future DTSS TBM could safely undercross the NEL MRT tunnels. The construction of the SCL advance tunnel was then included as part of the Land Transport Authority NEL Contract 705, which also included the construction of two stations and twin bored tunnels 1.7 km in length.

As described in Barraclough et al. (2004) the work commenced with the construction of an access shaft, 31.5 in depth with an internal diameter of 4.8m, followed by the excavation of a 20m long Adit with cross section of 13 m². The 40 m length main tunnel, with a cross section of 56 to 59 m², was constructed using heading/bench & invert with a round length from 0.8 to 1 meter for the heading, and 1.6 to 2.4 meters for bench/invert. The tunnel is located

within cemented Old Alluvium (OA), The SCL design considered the additional stresses during NEL tunnelling.

Figure 3. Advance tunnel for DTSS tunnel to bore trough.

To avoid the need of a steel cradle and launch frame within the advance tunnel, the contractor proposed to backfill the advance tunnel with foamed grout. In April 2002, the EPB TBM passed through the backfilled advance tunnel at a rate of approximately 15 m per 24 hours. The TBM stopped in the inspection chamber for nine days to allow remedial work to be carried out on the cutterhead. The total operation, breaking into the advance tunnel end wall, moving through, stopping for the remedial work, and then breaking out of the opposite less than originally programmed.

3 OVERRUN TUNNELS UNDER ORCHARD ROAD (2005)

The construction of Contract 825, the first phase of the Circle Line (CCL1), required 110m long twin overrun tunnels to be constructed to the west of Dhoby Ghaut station directly under Orchard Road, (Singapore's main shopping road), near to The Istana; the President's residence.

The only available access to construct the tunnels was through the partially complete Dhoby Ghaut interchange station, which was being further developed to add a third line to an already busy interchange station. Consequently, all access was through the shell of a structurally complete station, awaiting electrical and mechanical fit out, and was therefore limited to a small opening in the roof slab. This spatially limited access placed severe constraints on the construction approach that could be used, leaving SCL as the only

viable option. The drive commenced in completely-to-highly weathered mudstone and siltstone, known locally as S4 Jurong and proceeds into the S2 Jurong, with a moderately to slightly weathered grade.

Due to variability of the ground and the proximity of settlement sensitive structures, the initial scheme consisted of an advance pilot tunnel followed by enlargement to the final heading section.

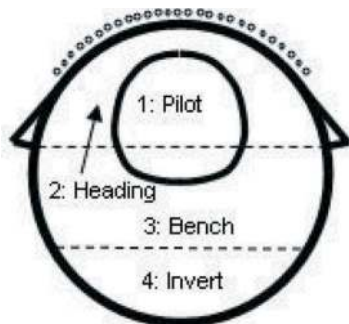

Figure 4. Excavation scheme with Pilot Tunnel.

This scheme was used for around half of the drive then changed to heading/bench/invert once the geological conditions were confirmed satisfactory.

The support design, for the 39 m² cross section tunnel, included a 250 to 350 mm shotcrete with 2 layers of wire mesh and lattice girders. Forepoling were used every second advance as additional heading support measure.

To minimise settlements, a total number of 14 recharge wells were installed along the tunnel alignment. Despite this effort, localized higher settlements (up to a max of 80-100mm) have been recorded on surface. The settlement of the existing MRT station was however within the acceptable level with a maximum-recorded settlement of 7mm.

4 ADVANCE TUNNELS UNDER SERANGOON STN (2006)

Circle Line 3 Contract 852 included a twin tunnel from Serangoon to Bartley station, undercrossing the operational North-East Line (NEL) Serangoon station with low cover ranging from 0.6m to 1.5m in soft ground conditions. Two temporary SCL advance tunnels were built to clear a total number of 42 temporary steel piles (21 for each bound), left in place during the construction of Serangoon station which would obstruct the Tunnel Boring Machine (TBM) drives. The SCL tunnel were backfilled before TBM boring through.

As described in Pearce et al (2006), during the construction of the outer tunnel considerable water inflow of about 500L/min was encountered about 8m away from the existing station during the drilling

Figure 5. Longitudinal profile of advance tunnel.

operation for the installation of forepoles. Instrumentation recorded an immediate drawdown in groundwater table and a corresponding immediate settlement of 8mm in the NEL structures and the elevated expressway located directly above the station.

Figure 6. High water ingress during excavation.

The settlement and the risk for further settlements, caused concerns. Consequently, all works were temporarily stopped to allow for a careful review of the original design and construction methodology. Due to the presence of the backfill shallow cover to the tunnel crown and the a water head of over 20m, the work resumed with the following measures:

- Vertical jet grouting of the first backfill band from road surface as pre-treatment to eliminate crown failure and water ingress into the excavation below.
- Horizontal grouting, with 10 numbers of horizontal pipes drilled from within each tunnel beneath the station base slab. Grout was injected in stages of 600mm through the non-return valves fitted along the pipe sleeve using expandable packers.
- Systematic use of block grouting beyond the tunnel face.
- Systematic installation of pipe roof canopy.

Figure 7. Pipe roof canopy installation.

The settlements of the station after restarting the excavation using the described method have been kept to a further 6mm only. The advance tunnels construction, pile removal & backfilling were completed in April 2006 without interruption to train service and road traffic. The two TBMs had successfully negotiated past the NEL station in July 2006, maintaining the settlements of the stations within the pre-determined review level.

5 KTM RAILWAY UNDERPINNING (2006)

During construction of the Circle Line 4 Contract 855 underpinning works were required for the piled foundations of an existing retaining wall and bridge abutment in the east side of the intersection between Commonwealth Avenue West and North Buona Vista Road. A total number of 19 H piles would have been within the slurry TBM bored tunnel inner drive. The bridge overpasses the Malaysian state KTM railway, linking Singapore to Malaysia.

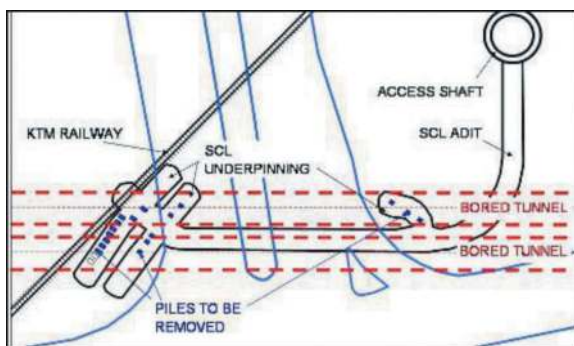

Figure 8. Plan view of the temporary SCL tunnel/shaft.

An 18 m deep access shaft was constructed, followed by a 72 long Adit tunnel, from which the 3 underpinning tunnels were then excavated in Jurong formation. The SCL supports were designed with a shotcrete shell of 200-250mm in thickness, with 2 layers of wire mesh and lattice girders generally spaced at 1m.

Figure 9. Section indicating the piles to be removed.

The removal of sections of H piles was carried out in the following the sequence:

- 1) Mined tunnel excavation, exposing the piles to be removed.
- 2) Casting of the Reinforced Concrete spread footing with a box out around the pile.
- 3) Installation of 2 hydraulic jacks at the sides of the piles to be extracted.
- 4) Cut the portion of H piles within the SCL tunnel
- 5) Extract the H piles in section of 1.5m long.
- 6) Reconnect H piles and repeat steps 2 to 5 for each pile.
- 7) Complete casting the transfer beam
- 8) Backfill of upper half of the SCL tunnel with foamed concrete.

Figure 10. Sequence of piles removal.

The KTM underpinning and piles removal was successfully completed in September 2006 and the TBM tunnels successfully undercrossed the KTM railway in April 2007 with no deformation/impacts on the structure affected by the underpinning.

6 CIRCLE LINE 4 - AYA MINED TUNNELS (2007)

During the construction of the Circle Line Stage 4 and 5 Contract 855, mined tunnels were proposed for

a section of about 70m where cut and cover section was not feasible due to the proximity of the critical utilities such as high voltage electrical cables, gas pipes and telecommunication cables. The mined tunnels section consists of two tunnels undercrossing a busy four-lane two-way roadway (the Ayer Rajah Avenue). The twin tunnels, with an average overburden of 10m, pass through challenging residual soil and highly weathered sandstone and siltstone with distinct discontinuities. The design and construction of the mined tunnels been carried out in a manner that will not cause excessive movement to the utilities and the roadway.

The entire 70m of both inner and outer bound tunnels were divided into four modules each. The length of each module varies from 14m to 21m.

Figure 11. AYA Tunnels excavation modules.

To accommodate a branching railway switch track, two of the modules in the inner bound tunnel (Modules 11 and 12) were larger resulting in a max 100 m² cross section. Those modules were constructed adopting side drift methodology and the typical modules adopting conventional top heading, bench and invert construction methodology. The excavation was supported by pipe roof, shotcrete and steel arch girders. The length of pipe roofing ranged from 21 m to a maximum of 27 m in length with a lapping of 6 m.

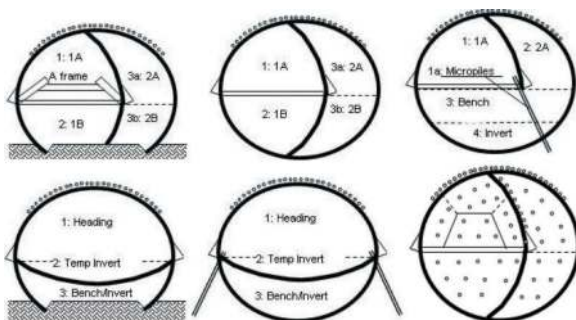

Figure 12. Excavation & Support schemes for different modules.

As the twin tunnels were located very close to each other, the narrowest section resulted in a soil pillar of about 0.5m at the narrowest point. For the execution of the Pipe Roof canopy, pull drilling method has been used, where the pipe roofing steel

pipes are used as casing and progressively installed during the drilling, thus minimizing the risk of settlement due to drilled hole instability. A sacrificial pilot bit allowed retrieval of the drilling string after completion of each pipe.

The improvement the soil in between adjacent pipes was done double packer grouting through non-return valves. Face nailing has been extensively used during all the stages of excavation. The execution of face nailing solved localized instability problems and acted as a confinement at the face to reduce pre-deformations.

Figure 13. Slickensides observed in Jurong Formation rock.

Despite a systematic use of face nailing, some local instability still occurred, mainly due to the narrow spacing of discontinuities and separation planes. This was addressed by increasing the number of face nails installed at the tunnel face (around 1 number/square meter).

7 DTL1 – C905 (2010)

The Downtown Line Stage 1 (DTL1) is a 4.3km underground rail transit system with seven MRT stations. It runs from Chinatown Station, the new downtown Marina Bay Financial Centre, Integrated Resort, Promenade Station and Bugis Station. Contract C905 consists of two stacked TBM tunnels each for the CCL extension line and DTL 1 line. The TBMs were launched from two independent temporary shafts. In addition, there are two twin connection tunnels to the existing Promenade station. Of those, three of the connection tunnels have been excavated using the Sprayed Concrete Lining method (SCL), while the other one using Earth Pressure Tunnel Boring.

7.1 SCL Tunnels under operational MRT

The two Downtown Line connection tunnels are vertically stacked and underpass the existing Circle Line tunnels which became revenue operational on the 17th of April 2010.

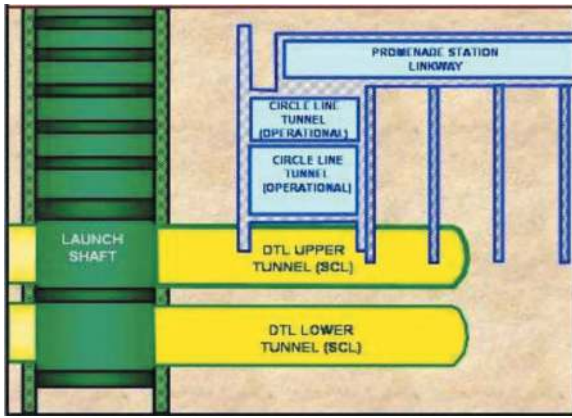

Figure 14. Longitudinal profile of tunnels undercrossing live MRT.

The upper tunnel required localized breaking out of the existing operational tunnel diaphragm wall and linkway piles during the excavation. As a result, a much thicker temporary lining was used for the upper tunnel, comprising of a double layer of shotcrete and 2 lattice arches of a total SCL thickness of 550mm. The geological conditions are of competent Old Alluvium. Nevertheless, tunnelling process was strictly controlled to minimize settlement and vibration to the operational tunnels.

Figure 15. Demolition of CCL tunnel DWall during tunnelling.

While mining undercrossing the CCL tunnels, an extensive monitoring regime of the live tracks was implemented. Monitoring was executed in real time with the use of Automated Total Station. The actual movement to the track due to the excavation of mined tunnel.

7.2 SCL Tunnels under Formula 1 Circuit

The CCL lower tunnel connects the launch shaft to the existing operational Promenade Station wall. The tunnel length is 90 m with an average overburden of 20m. Originally designed at tender as cut & cover tunnel, it was then proposed by the

Figure 16. Extensive monitoring of the live CCL tunnels.

Contractor to adopt a trenchless method following the announcement that public road above the tunnel alignment would become part of the Formula 1 race track. The tunnel excavation diameter is 7.15 m with a support system comprising lattice girders, wire mesh and shotcrete. Forepolings (d.25mm, L = 4m) were used along with length and spacing depending on the geology. Where surface access permitted ground treatment, jet grouting (JGP) was used to stabilise the tunnel heading in poorer ground condition, however this could not be done for the section directly below the F1 track. The excavation commenced on 13 August 2009 and by a month later it was temporarily stopped when the face was at the edge of the F1 track along Raffles Boulevard.

Figure 17. Tunnel excavation on hold prior to F1 race in 2009.

The tunnel face was strengthened with additional shotcrete and monitoring was installed to check any eventual face movement. The F1 criteria for any surface deformation (in term of differential settlements) are in fact quite stringent, with a maximum allowable differential settlement of 3mm over 4 meters. The excavation restarted after the F1 event and was completed in April 2010.

8 DTL 2: SCL UNDER THE NORTH-EAST LINE (2013)

Construction of Downtown Line 2 C921 required two x 60 meters long SCL tunnels constructed just 2 meters below the operational North-East Line tunnels and few meters below an existing underpass. The tunnels pass through the Fort Canning Boulders Bed formation. The construction scheme included the installation of pipe roofing canopy.

Figure 18. Tunnel face in Fort Canning Boulders Bed.

9 CRIPPLE SIDING & VENTILATION PASSAGES (2014)

Construction of Downtown Line 3 C927 required a Cripple Sided tunnel is located in between the two bored tunnels driven from Bedok Town Park Station (BDTP).

The length of the tunnel is about 170m and the tunnel is connected to the Expo drive bored tunnel by 5nos of ventilation passage and the drive 2 by 1no of cross passage.

Figure 19. Plan, Profile and Sections of Cripple siding tunnel.

Geological conditions were predominantly competent Old Alluvium soil with SPT-N value over 100. Overburden ranges from 20.5m to 25.5m in depth. Heading excavation was carried out first, for the entire length of the tunnel 170m maintaining the constant

heading height in all three circular, transition and oval sections. The typical advance length of the heading excavation ranged from 1m to 1.4m. Typical temporary lining design was 300mm thick shotcrete lining of shotcrete grade C30 with two layers of wire mesh and lattice girder. The tunnel geometry consists of a standard section and a higher section or “ventilation section” to facilitate the installation of ventilation equipment.

Figure 20. Variable formwork set up for transition profile.

A special CIFA hydraulic formwork was manufactured with the ability to be adapted, on site, for a total of 10 configurations (8 configurations for the 2 transitions, 1 configuration for the standard section, and 1 configuration for the ventilation section). The 6m formwork was designed for a single stage casting of sidewall and crown, improving productivity, and reducing the number of Construction Joints.

Additionally, 5 contiguous ventilation passage (VP) were constructed between the cripple siding tunnel and the expo bound bored tunnel.

Figure 21. Waterproofing and completed tunnel lining.

10 DOWNTOWN LINE 3 –ENTRANCE LINKWAY (2014)

During the project, the Contractor proposed a change in the construction method of the subway from Bedok Reservoir Station (BDR) to Entrance B.

Figure 22. The five completed ventilation passages.

The original design required a jacking shaft (1), for interlocking pipe-jacking method, which is part of the Entrance B. To mitigate a programme delay, delinking the linkway construction from the Entrance B construction, the Contractor proposed to use SCL tunnel with umbrella pipe-roofing method, carried out from the station side.

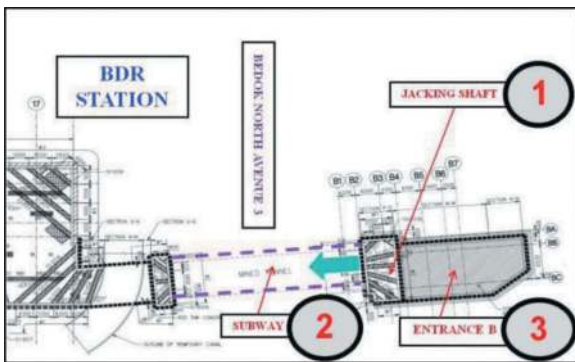

Figure 23. Original sequence using pipe roof by jacking.

Figure 24. SCL double drift maintaining the permanent lining.

The reason for two SCL drifts is due to the shallow tunnel overburden, which would not allow executing with a single circular tunnel around the full permanent lining box.

The excavation is particularly challenging due to the poor geological conditions (OA(C)/OA(D)/OA(E)/Fluvial F1 and F2, and due to the presence of a 1200 mm diameter water pipe (steel pipe) just 1.0 m above the tunnel crown.

Figure 25. Pipe roofing canopy for both drifts.

The excavation was completed on the 24th of October 2014. Nearly 10 months were taken for the completion of drift 1 excavation, with a productivity of 1.2m/week including pipe roofing, while drift 2 took 6.5 months. Permanent lining took 5 months for drift 1 and drift 2.

Figure 26. Pipe roofing by horizontal drilling rig.

Productivity of Drift 1 excavation was 1.2m advance/week.

11 T213 MINED TUNNELS (2017)

11.1 Three arches tunnel in rock

The 3-Arches tunnels were constructed to connect the Station box with the Cut and Cover tunnel, accommodating a cripple siding tunnel in between the two MRT bounds.

Drill & Blast, Drill & Split or Mechanical Excavation were used for the various rock conditions.

Figure 27. The 3-Arches tunnel in rock during permanent lining.

11.2 Two arches tunnel in soil

The 2-Arch tunnels were constructed to connect the Cut and Cover tunnel with the bored tunnel, accommodating the transition to the cripple siding tunnel in between the two MRT bounds. Multi-drift excavation method, with use of pipe roofing and face nailing, was used to excavate the tunnels in weathered rock. Due to mix face conditions, hybrid support system was utilised locally, comprising of soft ground supports and hard rock support such as rock bolts. Drill and split method was used in mix face to break the rock to minimise any disturbance to soil portion.

Figure 28. A partial stage of the 2-Arches tunnel excavation.

12 T226 MINED TUNNELS - GROUND FREEZING (2018)

The Thomson East-Coast line T226 construction required stacked mined tunnels 44 m in length, undercrossing the live MRT. The geology consists of weak ground types of Marine Clay, Estuarine Clay and the weaker layers of Old Alluvium (OA).

Ground freezing was used to prevent the flow of water ingress during SCL tunnel excavation, with the formation of two rows of continuous ice walls (Chua et al, 2018).

With the aid of ground freezing, controlled excavation, and stringent monitoring regime, the SCL tunnel excavation was successfully completed with no impact to the live MRT

Figure 29. SCL tunnels undercrossing live MRT lines.

Figure 30. Model of the live monitoring of Ice Wall.

13 CONCLUSION

From the first applications using traditional techniques and methodology, to the recent complex applications using multi drift method or ground freezing, SCL tunnelling has been a key engineering solution to the many challenges which are typical of tunnelling in an urban environment.

SCL tunnelling has been widely used as trenchless solutions, to facilitate removal of obstruction prior to TBM tunnelling, and it has been widely used for the construction of Cross Passages, TBM Launching Chambers and shafts. Due to the complex and variable geological conditions, various excavation and support methods have been adopted, such as multi drift, side drift, advance pilot tunnel and conventional sequential method, in combination with the use of pre supporting/improvement techniques SCL is a very versatile and adaptable tunnel method, which, if designed and applied correctly, can be utilized to solve a multitude of construction problems in an urbanized environment.

Design of precast bolted universal segmental tunnel lining for the London Power Tunnels phase 2 scheme

Anna Simic*, Oliver Brown & Joseph Ellis
AECOM, Croydon, UK

ABSTRACT: London Power Tunnels (LPT) Phase 2 is a new purpose-built cable tunnel system which will replace the existing buried cable network in the south of London. This £1 billion National Grid scheme comprises 32.5km of 3m internal diameter deep underground tunnels and 8 shafts which will help keep Londoners connected to safe and reliable electricity supplies. The tunnels extend from Wimbledon in the West to Crayford in the East, reaching depths of up to 60m below ground level.

This paper introduces the design of the bolted universal segmental tunnel lining which will house the three new cable circuits. The paper presents the design for four different Tunnel Boring Machine (TBM) tunnel drives by addressing the ground through which the tunnel is built, and the numerical analysis adopted for the lining design. The tunnel route travels through the full stratigraphy of the London Basin, which includes overconsolidated clays, sands and chalk. Extensive parametric studies for different parameters including surface surcharge, groundwater pressures, coefficient of earth pressure at rest (K_0), and degree of stress relaxation have been conducted using PLAXIS 2D to identify the most onerous design scenarios. Loads arising from primary and secondary grouting, gantry wheel loads, the cable installation monorail system and cable brackets were also considered in the analyses. The analyses were supported by closed-form calculations to verify ram forces, bolt capacity, gasket performance and the effects of ring build tolerances. These analyses gave the designer confidence that the tunnel lining will be able to resist the ground, groundwater, construction and long-term loading.

Keywords: Tunnelling, Numerical analysis, Simulation, Tunnel Boring Machine (TBM)

1 INTRODUCTION

London Power Tunnels (LPT) Phase 2 is a new purpose-built cable tunnel system which will replace the existing buried cable network in the south of London. This £1 billion National Grid scheme comprises 32.5km of 3m internal diameter deep underground tunnels and 8 shafts which will help keep Londoners connected to safe and reliable electricity supplies. The project will replace three existing high voltage transmission cable circuits from Wimbledon to New Cross, New Cross to Hurst and Hurst to Crayford. The new tunnels extend from Wimbledon in the West to Crayford in the East, constructed by Tunnel Boring Machines (TBMs) in 5 tunnel drives with a precast concrete segmental lining and reaching depths of up to 60m below ground level. Shaft diameters vary between 9m and 15m and are constructed by a variety of techniques including caisson sinking and underpinning with precast concrete segmental lining, sprayed concrete lining and secant

piling. The shafts will be covered by headhouses to provide access and ventilation for the tunnels. The scheme is currently under construction and due to be completed in 2027. HOCHTIEF-MURPHY Joint Venture are contracted to deliver the Package 2 Tunnels & Shafts and Package 5 Headhouses & M&E contracts on the scheme, and appointed AECOM as permanent works design partner.

This paper presents the design of the bolted universal segmental tunnel lining which is utilised in four of the five tunnel drives and will house two of three new cable circuits.

It will cover the design of four TBM tunnel drives by addressing the ground through which the tunnel is built, and the numerical analysis adopted for the lining design. The four tunnel drives are as follows:

- Drive 2: New Cross to Kings Avenue (via Bengeworth) – 6.3km – TBM Edith
- Drive 3: New Cross to Eltham (via Kidbrooke) – 11.1km – TBM Grace

*Corresponding author: anna.simic@aecom.com

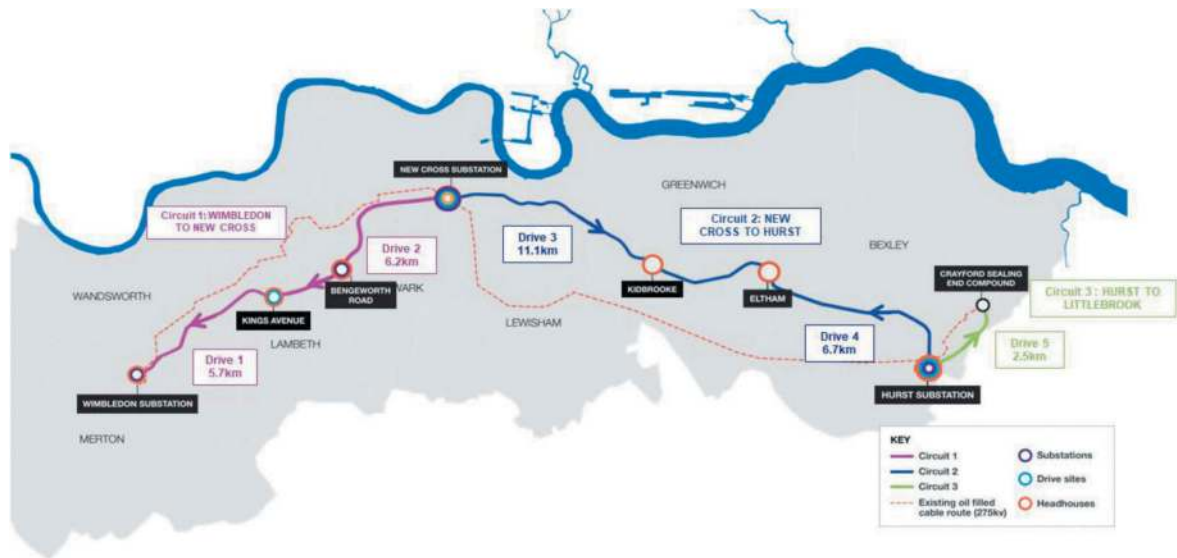

Figure 1. Scheme overview.

- Drive 4: Hurst to Eltham – 6.7km – TBM Christine
- Drive 5: Hurst to Crayford – 2.5km – TBM Christine (relaunched following refurbishment and modifications after the Hurst to Eltham drive)

The tunnel route travels through the full stratigraphy of the London Basin, which includes overconsolidated clays, sands and chalk. Extensive parametric studies for different parameters including surface surcharge, groundwater pressures, coefficient of earth pressure at rest (K_0), and degree of stress relaxation have been conducted using PLAXIS 2D to identify the most onerous design scenarios. Loads arising from primary and secondary grouting, gantry wheel loads, the cable installation monorail system and cable brackets were also considered in the analyses. The analyses were supported by closed-form calculations to verify ram forces, bolt capacity, gasket performance and the effects of ring build tolerances.

2 ELEMENTS OF THE TUNNEL

2.1 Segments

The tunnel lining is formed of steel fibre reinforced precast concrete segmental rings. A universal ring system was adopted where both circumferential faces of the ring are inclined to the tunnel axis. This ring taper is split between the two circumferential faces to enable the tunnel drive to follow the design alignment through rotation of the segmental ring. Each ring has six tapered segments. The geometry of the ring is shown in Figure 2 with a ring length on tunnel centreline of 1.2m. The internal radius is $R_i = 1500\text{mm}$, the thickness of the segment is $T_s = 180\text{mm}$ and the depth of extrados and intrados groove is $d_{ext} = 60\text{mm}$ and $d_{int} = 24\text{mm}$,

respectively. The set of angle for an ordinary segment is $\theta_0 = 60^\circ$, for a top segment is $\theta_t = 69^\circ$ and for the key segment is $\theta_k = 51^\circ$.

2.2 Circumferential joints

High durability plastic dowels were used as the connection device between segments on the circumferential joint. Two dowels per segment was adopted. The use of dowels permits rapid erection of segments and reduced cycle times. The dowels also allow a self-centring function during erection and ensure a close control over stepping between adjacent rings. The dowels were designed so that their design tensile capacity is sufficient to retain the compression in the circumferential joint gaskets when fully compressed on release of the TBM shove rams. The shear capacity of the dowels was also checked to be able to withstand the maximum torque capacity of the TBM.

2.3 Radial joints

Steel bolts were used to secure the radial joints. All bolts and cast-in sockets are a single assembly and of proprietary design. The bolts were designed to have sufficient tensile capacity to retain the compression in the radial joint gaskets when fully compressed on release from the segment erector. Bolting in the radial joints is only required during segment ring assembly and so must be kept in place 100m back from the tunnel excavation face and if adverse local ground conditions are encountered.

2.4 Gaskets

The segmental tunnel lining has to resist external water pressures of up to 6 bar, limiting water ingress/egress to a negligible amount. The seal is

Figure 2. Universal lining segment arrangement.

created by the inclusion of cast-in gaskets in all segments made of ethylene propylene diene monomer (EPDM). The gaskets are supplied as a continuous loop with the joints formed to the correct angles for each type of segment. Further the joint formation has been designed to minimise the additional rubber material forming the joint to avoid hard spots in the gaskets. The gaskets were pressure tested to 10 bar pressure with 10mm offset and a 4mm gap between bearing surfaces in a rig to model a cruciform joint arrangement.

2.5 Reinforcement

All segments contain steel fibre reinforcement, with additional traditional rebar reinforcement cages incorporated in specific locations. The bar reinforced rings are to be used to construct the first 16 rings and the last 16 rings of each drive and where an increased robustness of tunnel lining is required.

3 EXCAVATION AND SUPPORT METHODS

The tunnel will be excavated and constructed using an Earth Pressure Balance (EPB) TBM.

The cutting head diameter is 3636mm, providing a 10.4m² total cutting face area. Behind the cutting head, the shield has a length of 11.6m and a diameter of 3600mm. This difference in radius between the cut radius and the diameter of the tail skin creates an annulus of 18mm allowing ground deformation and settlements to occur. During the excavation, the TBM applies a face pressure to balance the forces within the ground and to control the

Figure 3. TBM edith being lowered into new cross shaft.

ground deformation and settlements. The pressure is applied by regulating the volume of spoil in the plenum and by rams, which allow the TBM to advance. As the TBM advances, after the erection of the ring, the 138mm annulus between the excavation diameter and the external diameter of the lining is grouted through the tail skin.

4 GROUND AND GROUNDWATER CONDITIONS

4.1 Geology

The geology present along the tunnel alignment is presented in Figure 4 and Table 1.

4.2 Groundwater conditions

There are typically two main aquifers in Greater London. Groundwater is present in the surface superficial deposits of Alluvium and the River Terrace Deposits where present, supported by the underlying, low permeability London Clay. This is typically referred to as the 'upper aquifer'. In the vicinity of the River Thames, in the central section of the LPT Phase 2 alignment, the upper aquifer is likely to be tidally influenced by the River Thames.

Groundwater is also present in discrete granular units in the upper section of the Lambeth Group, in particular in the Channel Sands and in permeable layers within the London Clay and the Harwich Formation (the basal layer of the London Clay). The water bearing layers of these strata are referred to as the 'intermediate aquifer'. These water bearing layers within these strata vary significantly in

Figure 4. LPT phase 2 geotechnical overview (national grid/WSP, 2019).

Table 1. Geology along the tunnel alignment.

Era	Period	Epoch	Formation/ Strata	Composition	Depositional Environment	
Cenozoic	Quaternary	Anthropocene	Made Ground	Highly variable. Hard-standing and granular soils of particle sizes varying from clay to cobble and more rarely boulder with fragments of brick and concrete etc. May contain some contaminated or hazardous materials dependent upon former land uses.	Anthropogenic activity.	
		Holocene	Alluvium	Predominantly sand, silt and clay with localised peat and organic matter.	Overbank deposits of flooding fluvial systems.	
		Pleistocene/Holocene	River Terrace Deposits	Predominantly gravel and sand, with localized clay beds and lenses.	Fluvial floodplain.	
	Paleogene	Eocene	Thames Group	London Clay	Brown, and blue grey clay, locally silty and with silt and fine sand layers.	Deepwater marine.
				Harwich	Glauconitic, sandy clay and silt with shells and shell fragments.	Intermediate depth marine.
		Paleogene	Lambeth Group	Woolwich	Clay, locally laminated and locally with abundant shell fragments. Contains sand filled channels.	Marginal marine, estuarine and deltaic.
				Reading	Mottled clay with sand filled channels.	
				Upnor	Calcareous gravely sand.	
Thanet Group	Thanet Sands	Fine sand.	Shallow marine.			
	Bullhead Beds	Locally clayey fine sand with abundant cobbles of rounded flint.				
Mesozoic	Cretaceous		Chalk (Newhaven)	Calcareous white limestone (chalk).	Shallow to intermediate depth warm marine.	

thickness and in their lateral extent across the LPT Phase 2 alignment.

The main water-bearing sequence below the LPT Phase 2 alignment is known as the ‘lower aquifer’ and comprises the Chalk, the overlying Thanet Sand Formation and the granular Upnor Formation, which is the basal unit of the Lambeth Group. Silt and clay bands may be present in the lower part of the Thanet Sand and may reduce the vertical flow, thus impeding hydraulic continuity within the lower aquifer. Groundwater flow in the Chalk is predominantly via fractures which facilitates rapid flow due to the high secondary permeability. The Chalk matrix has a much smaller contribution to groundwater flow due to the lower intergranular permeability.

In the western end of the route, where the London Clay is present at shallow depths with a variable but significant thickness, the groundwater in the lower aquifer below the route alignment in this section is confined under pressure by the overlying low permeability units. In vicinity of the New Cross shaft site and along the majority of the tunnel alignment towards the Hurst shaft site to the east, the overlying Lambeth Group and the London Clay are either absent or present in sections. Where the overlying low permeability units are absent, in these sections, the lower aquifer is unconfined with groundwater potentially present at shallow levels. The eastern end is directly underlain by the unconfined lower aquifer with the Chalk surface present at shallow depths beneath layers of superficial deposits of River Terrace Deposits and Alluvium. The groundwater in the lower aquifer in this area is shallow and is likely to be in hydraulic continuity with the overlying superficial deposits with potential tidal influence where the route alignment is close to the River Thames.

A review of the EA publication for the groundwater levels in the Chalk Aquifer in the London Basin between 2000 and 2018 indicates that the groundwater level in the lower aquifer varies from approximately -2 m OD to -13 m OD in the western end, -8 m OD to -2 m OD in the central area and +15 m AOD to +10 m AOD in the eastern end of the alignment. The groundwater regime in the western and central areas of the LPT Phase 2 alignment are likely to be affected by the geological faults present in this area where up to four faults have been mapped. The faults include the Rotherhithe Fault, the Streatham fault, the Greenwich fault. Several solution features and deneholes have also been identified in the vicinity of the Hurst shaft site. These features have the potential to modify groundwater flows locally, particularly if they extend below the groundwater level.

5 LOAD COMBINATIONS

The design of the segmental tunnel primary lining was based on combinations of the following load cases:

Table 2. Load cases.

Primary grouting pressure	The greater of: Total stress + 50kPa or Groundwater pressure +50kPa,
Secondary grouting pressure	Applied as a localised triangular load equal to the groundwater pressure + 50kPa at crown, shoulder or axis.
Monorail load	Loading applied at the tunnel crown from cable installation using the monorail system: <ol style="list-style-type: none"> i) Cable pulling SW=25kN $F_y=7\text{kN}$ $F_z=4\text{kN}$, $F_x=20$ ii) Laying off cable SW=25kN $F_y=4\text{kN}$ $F_z=1\text{kN}$ iii) Cable sagging SW=25kN $F_y=4\text{kN}$ $F_z=2\text{kN}$
Cable bracket loading	Pull-out force acting on the lining: <ol style="list-style-type: none"> i) Permanent load (22kN) ii) Accidental short-circuit load (40kN)
Allowance for future development or construction surcharge	75kPa surcharge applied at the ground surface covering either: <ol style="list-style-type: none"> i) The full model width ii) Half the model width

SW = self-weight, F_y = vertical, F_z = horizontal, F_x = longitudinal

All load combinations were simulated for upper and lower bound geotechnical parameters (c , c_u , ϕ , E), minimum and maximum earth pressure coefficient ($K_{0\text{min}}$, $K_{0\text{max}}$), and minimum and maximum groundwater level (WL_{min} and WL_{max}).

Temporary handling and stacking loads, TBM ram forces and the effects of steps, lips and ring build tolerances were considered using separate empirical and closed-form calculations not covered in this paper.

Figure 5. Example of completed tunnel lining with cable brackets installed.

6 NUMERICAL ANALYSIS

6.1 PLAXIS analysis

Structural forces and displacements in the precast segmental tunnel lining for each combination of

ground conditions were evaluated using PLAXIS 2D plane strain numerical modelling. The Finite Element Method allows a comprehensive analysis of soil-structure interaction to be carried out which considers the tunnel construction sequence and loads applied to the lining in both the short and long-term.

Loading applied to the tunnel lining in the PLAXIS model includes the primary and secondary grouting pressures, ground surface surcharges, cable bracket loading (including loads imposed by a short-circuit event), as well as the load from the monorail.

6.1.1 Constitutive soil models

Due to the limited ground investigation and laboratory testing data available, the Mohr-Coulomb constitutive model has been adopted, which assumes the stress-strain relationship to be linear elastic-perfectly plastic. Prior to yielding, the gradient of the stress-strain curve is defined as the Young's modulus of the soil (E'). When the stress state reaches exceeds the failure criterion, the ground exhibits a perfectly-plastic behaviour. An increase in soil stiffness with depth has been modelled. However, the model does not account for stress dependency or stress-path dependency of the stiffness. Nor does it distinguish between large stiffness at small strains and reduced stiffness at engineering strain levels. Therefore, the stiffness parameters were specified in accordance with the dominant strain levels associated with TBM tunnel construction, considered to be 0.1 – 1%.

Strata were assigned a drainage type of drained or undrained, depending on the material type (granular or cohesive) and whether short or long-term conditions apply. Where a material is considered to behave in an undrained manner, it was modelled with the undrained (A) drainage type, which enables undrained behaviour to be modelled using an effective stress analysis with effective stiffness and effective strength parameters (c' , ϕ'). With this drainage type, PLAXIS automatically adds the stiffness of the water to the stiffness matrix to distinguish between effective stresses and (excess) pore pressures. Steady state pore pressures were generated based on the phreatic levels specified for each stratum.

6.1.2 Ground model and ground relaxation

The stress relief or relaxation of the ground and three-dimensional arching effect due to shaft or tunnel advancement can be simulated in two-dimensional models using the stress reduction method, often referred to as the β - or λ -method. Initial stresses P_0 acting around the location where the tunnel is to be constructed are divided into a part λP_0 that is applied to the unsupported tunnel opening and a part $(1-\lambda)P_0$ that is applied to the supported tunnel, where P_0 is the in situ stress. To apply this in a PLAXIS two-dimensional analysis, one can use the staged construction option with a reduced ultimate level of ΣM_{Stage} . The ΣM_{Stage} parameter defines the degree of equilibrium achieved in a construction phase, which progresses from zero at

the start of the construction phase (forces out of equilibrium) to unity at the end (full equilibrium reached).

Stress relaxation, λ , was first calculated for each geological stratum using the expression for an isotropic elastic medium after Panet (1979) and for an isotropic elastic-plastic medium after Panet (1995). The PLAXIS 2D plane strain analysis was then calibrated to match the predicted radial displacement and volume loss from these closed form solutions. This is performed in the model by de-activating the soil elements within the tunnel and running the analysis to the required value of ΣM_{Stage} to reach the target displacement.

Table 3 summarises the minimum and maximum values of stress relaxation for each soil type. Due to the similar ranges of values for each soil type, an overall minimum and maximum value of 30% and 62% will be adopted for all materials in the 2D finite element (FE) analysis, respectively.

Table 3. Values of PLAXIS ΣM_{Stage} parameter corresponding to the elastic (Panet, 1979) and elastic-plastic (Panet, 1995) solutions for ground relaxation for each soil type.

Material	ΣM_{Stage} Parameter	
	Elastic	Elastic-Plastic
London Clay Formation	0.30	0.59
Harwich Formation (Cohesive)	0.31	0.62
Harwich Formation (Granular)	0.34	0.62
Lambeth Group (Granular)	0.35	0.59
Lambeth Group (Cohesive)	0.31	0.54
Thanet Formation	0.35	0.59
Chalk	0.34	0.50
Adopted value for design (upper and lower bound for all materials)	0.30	0.62

6.1.3 Modelling of the tunnel lining

The precast segmental tunnel lining was modelled in PLAXIS 2D using two-dimensional plate elements with isotropic stiffness properties equivalent to concrete grade C50/60. Radial joints were not modelled explicitly, but instead represented by reducing the flexural stiffness of the lining according to the approach proposed by Muir Wood (1975). This approach considers a reduced second moment of area based on the number of joints, as given by Equation 1.

$$I_e = I_j + I_s \left(\frac{4}{n_s} \right)^2 \quad (1)$$

Where, I_e is equivalent second moment of area; I_j is second moment area of the joint (m^4); I_s is second moment area of the segment (m^4); n_s is number of segments in a ring (including key).

Interface elements were applied to the extrados of the tunnel lining to simulate soil-structure interaction by limiting the degree of shear force transferred.

6.2 LUSAS analysis

A separate LUSAS analysis was also prepared to assess the structural behaviour of the tunnel lining due to either eccentric loads or concentrated loads such as gantry wheel loading. This model includes a more detailed simulation of the radial joints in the tunnel lining and therefore is able to more accurately assess the localised effects of large, concentrated loads on these joints.

6.2.1 Modelling of the tunnel lining

The tunnel lining was modelled using a two-dimensional bedded beam analysis. The bedded-beam spring model describes the tunnel lining as a series of beams of rectangular cross-section connected to a series of radial and tangential springs, representing the interaction between the lining and the ground. The springs are allocated with a stiffness, which is dependent on the Young's modulus and the Poisson's ratio of the ground and the radius of the tunnel. The stiffness of the support springs will be based on Duddeck & Erdmann (1985).

$$k = \frac{E_c (1 - \nu)}{R(1 - 2\nu)(1 + \nu)} \quad (2)$$

Where, k is radial spring stiffness (kN/m^3), E_c is Young's Modulus of the continuum (kN/m^2); ν is poisson's ratio; R is tunnel radius (m).

The radial spring stiffness is modelled in LUSAS as a lift-off spring to ensure that they only work in compression.

In the longitudinal direction, the trailing edge of each ring is connected to the previous rings and therefore the nodes are fixed in the longitudinal direction.

Hinges (pinned end connections) between beam elements were used to represent the bolted connection between the segments in each ring. As the location of the segmental joints will rotate as the tunnel lining is constructed, the gantry wheel loadings could be positioned in numerous configurations in relation to the joints. In order to ensure the most onerous loading scenario is considered, the tunnel lining was checked for each wheel loading type positioned close to a segmental joint, as well as in the centre of the segment.

7 RESULTS OF NUMERICAL ANALYSIS

The results of the PLAXIS 2D analysis for each tunnel section, for upper and lower bound soil parameters, is presented in Figure 6 and Figure 7.

Figure 6. Lining forces extracted from PLAXIS 2D model (lower bound geotechnical parameters).

Figure 7. Lining forces extracted from PLAXIS 2D model (upper bound geotechnical parameters).

8 CONCLUSIONS

The purpose of the analyses described in this paper was to assess the behaviour of the precast segmental lining under all loading conditions.

The results of the FE models were corroborated by additional empirical and closed form calculations.

These analyses gave the designer confidence that the tunnel lining will be able to resist the ground, groundwater, construction and long-term loading.

ACKNOWLEDGMENTS

The authors would like to thank the contractor HOCHTIEF-MURPHY Joint Venture, National Grid and their engineering partners for their collaboration during the design and construction process and for their support with this paper.

Annie Ellison & Chris Barret

BMB, London, UK

ABSTRACT: The Thames Tideway Tunnel is the biggest infrastructure project the UK water industry has undertaken since its privatisation in 1989. The 25km-long tunnel is split into the West, Central and East contracts. The West contract is approximately 7km long from Acton to Carnwath Road in West London. The 7 km-long, 7.2m internal diameter main sewer tunnel was originally designed as a precast segmental lining tunnel with cast in-situ concrete secondary lining using 40kg/m³ steel fibre to achieve both mechanical performance and durability in 120 years of design life. BAM Nuttall, Morgan Sindall, Balfour Beatty Joint Venture (BMB) is the contractor on the Tideway West section. Before starting the main tunnel secondary lining construction, BMB initiated an exercise to value engineer the original secondary lining concrete mix. As the Category 3 checker for the main sewer tunnel, Ramboll has supported client BMB in its pursuit. Working in collaboration with the main tunnel designer, Ramboll helped develop a testing regime for a new mix which reduces the quantity of steel fibre from 40kg/m³ down to 35kg/m³. This has involved undertaking a large-scale beam testing programme to verify the new mix to understand its pre-crack and post-crack behaviour based on the monitoring results from traditional strain gauges and leading-edge digital imaging correlation techniques. With close collaboration with the contractor and the main tunnel designer, Ramboll guided the back-analysis of the beam test results and concluded that the new concrete mix performed as well as the previous one. The works have been carried out in conjunction with Tideway, which has subsequently approved using the new mix with the lower fibre content. The new concrete mix has saved up to 230 tonnes of steel fibres for the 7 km-long west section of the main tunnel, bringing significant environmental and financial benefits.

1 INTRODUCTION

London, a major global city, is still relying on a combined sewerage system, which was designed by Sir Joseph Bazalgette and constructed in the 1860s. This system that captures both rainwater runoff and sewage has a design capacity of four million people. As London's population grew to eight million by 2012, the sewerage system could not cope with the volume of the combined sewage overflows (CSOs), leading to increasingly frequent overflows to the river Thames. These discharges have to be reduced to improve the ecology of the

river Thames and comply with the EU's Wastewater Treatment Directive (EU, 1991).

The overall Tideway scheme is a significant new combined sewage storage and transfer system that will help protect the river Thames by tackling the problem of overflows from the capital's ageing sewers. The Main Tunnel, a major component of the system, will run from Acton in West London to Abbey Mills Pumping Station in East London. It will intercept, store, and convey the flows from the most polluting CSOs, which currently discharge directly into the river. The flow will then run to the Beckton Sewage Treatment Works via the Lee Tunnel (Jewell

*Corresponding author: Jiang.su@atkinsrealis.com

& O'Connor, 2012), the construction of which was already completed in January 2016 (Ashenden & Garrett, 2016).

There are three Main Works contracts for the scheme: West, Central and East. BAM Nuttall, Morgan Sindall, Balfour Beatty Joint Venture (BMB) Joint Venture is responsible for the delivery of the West Main Works contract. This contract covers all works between Acton in West London and Carnwath Road in the east, approximately 7km in length (Figure 1). The tunnel designer is Morgan Sindall Engineering Solutions (MSES), and the Category III check is performed by Ramboll UK.

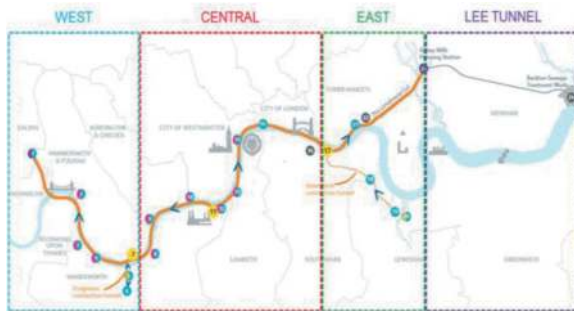

Figure 1. Thames Tideway and Lee Tunnel Route and Sites (Courtesy of Tideway).

As the west section main tunnel is constructed exclusively in London Clay, an earth pressure balanced (EPB) tunnel boring machine was used. The external and internal diameter of the main tunnel primary lining is 7.8m and 7.1m, respectively. The main tunnel primary lining is formed from steel fibre-reinforced precast concrete segmental rings. The external and internal diameter of the main tunnel secondary lining is 7.1m and 6.5m, respectively. The main tunnel secondary lining is formed from steel fibre-reinforced cast in-situ concrete.

The primary lining has been designed to be able to resist all the long-term external ground and groundwater pressure, plus any future surcharge loads as specified in the project design requirements. The secondary lining is designed to resist the internal water pressure with the confinement from the primary lining and surrounding ground. The secondary lining is also designed for long-term durability purposes as the sewage water is corrosive in nature.

2 LINING DESIGN AND VALUE ENGINEERING

2.1 Secondary lining critical load case

The main tunnel secondary lining design was considered very challenging. The reasons are explained in detail below. When the main tunnel primary

lining is constructed, all the short-term external ground load and groundwater pressure will be applied to the primary lining. With the perfect circular shape of the main tunnel, little bending moment will be generated in the primary lining. Hence, the whole primary lining cross-section will be in compression. When the secondary lining is installed, it will not take any short-term external ground load or groundwater pressure. The early-age thermal and shrinkage effect of the secondary lining will lead to the secondary lining contracting in volume slightly, potentially leaving a gap between the primary lining intrados and the secondary lining extrados. This gap will then be filled back with no-shrink grout to ensure good contact between the two layers of lining and form a composite lining with full composite action, which will provide a greater overall capacity to any external or internal loads. It should be noted that the secondary lining, despite being incorporated into the composite lining system, is at a stress-free status. As the tunnel is constructed in London Clay, long-term consolidation ground and long-term water pressure will be applied to the extrados of the primary lining at a later stage. These additional external loads will be shared between the primary and the secondary linings according to the relative axial stiffness ratio between the two linings. Therefore, a small magnitude of axial compression and bending will be generated in the secondary lining to resist the external load, as shown in Figure 2 (a). The darker and lighter blue colour in the primary and secondary linings represents greater and less axial compression, respectively.

The most challenging load case for the secondary lining is when the internal surcharge pressure is applied to the intrados of the secondary lining. This simulates an extreme rainfall or flooding scenario in which the whole Thames Tideway tunnels are fully stored with stormwater with a water head from the tunnel level up to the ground level. Under this load case, the composite lining will resist the internal water pressure, which results in axial tension being generated in the tunnel linings. This axial tension is not a design challenge for the primary lining because its magnitude, which was determined by the maximum water head, is less than the axial compression induced by the external ground load and groundwater pressure. In comparison, this axial tension is a significant design challenge for the secondary lining because the magnitude of the axial tension is usually greater than the axial compression generated under the effect of long-term consolidation loads. Hence, the secondary lining needs to be designed under a full tension stress status while still satisfying the stringent maximum crack width requirements to ensure its long-term durability. The lining stress status of this stage is shown in Figure 2 (b), with the light blue and red colours representing reduced axial compression and tension in the primary and secondary linings, respectively.

Figure 2. Lining stress status under external load only (a) and under both internal and external loads (b).

2.2 Strain-hardening behaviour of concrete lining

With the understanding of the critical load case for the secondary lining, the next step was to decide what types of reinforcement should be used in the secondary lining to resist the axial tension in the lining in the most efficient way. Steel fibres were selected as the main reinforcement in the concrete secondary lining as they could provide sufficient post-crack ductility, crack width control and reduced concerns about the impact of sewage water-induced corrosion on the reinforcement.

Bekaert's Dramix steel fibres are the most widely used ones in the UK tunnelling market. It has three main types of steel fibres, each with different tensile strength, number of hooks, length and aspect ratios, suiting different types of applications. While Dramix 3D has mostly been used for the sprayed concrete lining application, the Dramix 4D and 5D have been used more in the precast and cast in-situ concrete lining (De Rivas, 2020). From a structural performance perspective, the concrete reinforced by the Dramix 3D steel fibres usually demonstrates a strain-softening behaviour, whilst those reinforced by the Dramix 5D steel fibres usually demonstrate a strain-hardening behaviour, as shown in Figure 3 below. The visual difference between the two types of behaviour is that a single crack is usually formed under a typical 3-point or 4-point bending test for the former, whilst multiple cracks are usually formed for the latter, which could result in reduced crack width when compared with the scenario when a single crack is developed. Typical sprayed concrete lining using Dramix 3D steel fibres under a 4-point

Figure 3. Performance of steel fibre reinforced concrete (SFRC) using Dramix 5D steel fibre (Bekaert, 2018).

bending test showing a single crack with increased crack width under increasing external loading can be found in Su and Bloodworth (2018).

2.3 Value engineering of the secondary lining

The main tunnel designer, MSES, was also the tunnel designer for the Lee Tunnel project, which adopted the same lining configuration as the Tideway West Contract but was constructed at a much deeper level (Psomas et al., 2014). The designer was trying to replicate the successful design and construction experience from the Lee Tunnel to the Tideway West Contract by utilising the beneficial effects of multiple cracking modes by using high-performance steel fibre-reinforced concrete to satisfy the project's stringent crack width limit for the tunnel secondary lining when under internal surge pressure. For the Lee Tunnel project, a 40kg/m^3 dosage of Bekaert Dramix 5D 6560BG was used for the main tunnel secondary lining. The adoption of this concrete mix was verified through large four-point beam laboratory tests undertaken at the Building Research Establishment (BRE). The test results were rigorously reviewed and verified prior to the construction (Psomas, 2020). With past successful experience, the same dosage of steel fibre was proposed for the Thames Tideway West main tunnel secondary lining.

Prior to the construction of the tunnel's secondary lining, BMB undertook a comprehensive value engineering exercise with the objectives of reducing the construction cost, programme, and embodied carbon. One of the potential value engineering options is to reduce the steel fibre dosage from 40kg/m^3 to 35kg/m^3 in the secondary lining without compromising its performance under the critical internal surge pressure loading condition. Hence, a value engineering investigation of this potential option was proposed and carried out in the following stages.

This value engineering comprises testing of five large 35kg/m^3 dosages of SFRC beams under a 4-point bending test configuration. The performance of the beams was monitored using strain gauges, potentiometers, and digital image correlation (DIC). These results were compared with the test results from the Lee Tunnel project large beams, which used 40kg/m^3 steel fibres in the same concrete mix and under the same 4-point bending test configuration. The objective of this test is to prove that this new Tideway West Contract proposed 35kg/m^3 concrete mix will perform at an equivalent or better than the previous 40kg/m^3 concrete mix adopted in the Lee Tunnel project.

The first author of this paper previously worked as the technical director of the Category III checker. He was commissioned by the Contractor BMB as a special adviser to witness the large beam tests, analyse the beam test results against the previous Lee Tunnel beam results, and produce evidence documents to convince senior technical leads from both

the Contractor BMB and the Thames Tideway to adopt this new concrete mix with reduced quantity of steel fibres. This paper describes this process.

This paper will first describe the large BRE beam tests, followed by a qualitative and quantitative comparison between the new and previous concrete mix in the aspects of (1) load-deflection, (2) load-strain, and (3) crack spacing and crack width. A conclusion is drawn in the end.

3 BRE BEAM TESTS

3.1 Beams production, transportation and storage

A laboratory testing program was devised to validate the performance characteristics of a 35 kg/m³ SFRC beam. Five large-scale beams, each weighing approximately 4 tonnes, were cast by Tideway West, and subsequently transported to the Structural Test Laboratory at BRE (Building Research Establishment) for testing.

The five specimens consisted of three SFRC beams, one hybrid composition integrating both steel fibres and steel bars reinforcement, and one entirely unreinforced beam. All specimens shared common dimensions, measuring 5400 mm in length, 1000 mm in width, and 300 mm in depth. The samples were cast as slabs on a release membrane to ensure a smooth bottom surface. The sides of the beams had a matt texture consistent in appearance with the use of a conventional steel or timber shutter and release agent. Furthermore, to mitigate the risk of damage during transportation, the beams were positioned on one of their long edges, resembling deep beams.

On arrival at BRE's Structural Test Laboratory, the samples were unloaded carefully and placed in a temporary storage position still oriented as deep beams, as shown in Figure 4. Lifting points were cast into each side of the samples, and suitable lifting links were supplied for use during the delivery and testing by Tideway West. After completion of the delivery, the three fibre-reinforced samples and the single conventionally reinforced sample were carefully rolled over such that the bottom surface at the time of casting was now the upper surface of each of the samples. The fifth unreinforced sample was not rotated until

Figure 4. Beam samples unloaded and stored on edge.

some space had been created by the testing of the earlier samples. All these efforts were made to avoid any potential damage to the beams, which in turn would affect the performance of the beams in the tests.

3.2 Beams test configurations

Inverted four-point flexural tests were conducted on all five beam samples. Each sample was securely restrained at both ends, and loads were incrementally applied at the third span positions until structural failure was observed. To provide context, it is worth noting that the most closely related small-scale laboratory test, BS EN 14488-3, is typically performed on sprayed concrete beams with dimensions approximately one-tenth the size of the tests detailed in this study.

Figure 5 illustrates the specific dimensions and support configurations employed in the beam tests. Load application was facilitated through pairs of hydraulic cylinders with a capacity of 250 kN at each third-span position. These cylinders had a maximum potential displacement of 200 mm. At each loading point, the two cylinders were coordinated via a common loading bar measuring 1200 mm in length, featuring a curved contact surface with a nominal radius of 50 mm. Similar curved contact surfaces were utilized at the locations of end restraints. All four cylinders were interconnected through a manifold and length-matched pipework. The force exerted by each hydraulic jack was quantified using a 100 kN load cell. Three of these load cells were integrated into the data logging system, while the remaining one was connected to a digital readout unit, offering real-time monitoring of applied forces.

To assess vertical movement during testing, linear variable differential transformers (LVDTs) were strategically positioned at the loading points, at the centre span, and at the supports. Figure 6 schematically represents the arrangement of hydraulic rams and potentiometers. Additionally, Figure 7 provides a photographic depiction of the beam test setup.

Figure 5. Dimension of loading and supports for beam tests.

3.3 Strain monitoring

Direct contact strain measurements were conducted employing demountable transport research laboratory pattern vibrating wire strain gauges. These strain gauges featured a nominal gauge length of 140 mm. A total of 14 pairs of gauge

Figure 6. Positions of hydraulic rams and potentiometers.

Figure 7. Laboratory beam test set-up.

targets were arranged along the centreline of the specimen, establishing a measurement zone spanning from the mid-span section of the tension face of the beam to a point extending beyond the loading positions at the third-span locations, as depicted in Figure 5. The cumulative length encompassed by the strain gauges equated to 1950 mm. Additionally, a single pair of gauge targets was affixed to the compression surface of the beam at its mid-span position. The secure attachment of all gauge mounting targets was ensured through the use of a polyester resin-based filler applied to a clean and dust-free surface of the samples. The strain gauges were interconnected with a DataTaker 615 logger. The resulting data were stored within the logger for subsequent download and in-depth analysis following the conclusion of the test.

3.4 Digital image correlation

The Digital Image Correlation (DIC) monitoring of the test beams was conducted by the National Physical Laboratory (NPL). To capture high-resolution images, three cameras were strategically positioned at the front, back, top and perpendicular to the specimen face under investigation. Lighting conditions were carefully managed, utilizing a combination of work lights provided by BRE and laboratory lighting to ensure optimal image quality.

The camera solution utilised a resolution of 8256x5504 pixels, recorded in the NEF format, and compressed to 12-bit depth to accommodate the acquisition of a sufficient number of images. Image

acquisition occurred at intervals of 0.5 seconds, utilizing three synchronized cameras, each with internal clocks set to less than 0.3 seconds for precise coordination. An intervalometer setting was utilized to guarantee synchronization across all images. Furthermore, the front camera also captured a load indicator, providing a load timestamp for the datasets. The configuration of the DIC system is illustrated in Figure 8.

Figure 8. DIC arrangement for beam tests.

4 VALIDATION OF THE TEST RESULTS

This section compares the test results between the new concrete mix with 35kg/m³ steel fibres and the previous one with 40kg/m³ steel fibres. To ease the comparison, the SFRC beams using 35kg/m³ concrete mix will be referred to as the new beams, whilst those using 40kg/m³ concrete mix will be referred to as the previous beams. All other constituent materials are the same. Selected test results are presented and compared in the following aspects:

1. Load-displacement results
2. Load-strain results
3. Crack spacing results
4. Crack width results

4.1 Load-displacement results

As the load-displacement curves for the three new SFRC beams (beams no.1-3) are very similar, only the beam no.2 curve is presented here in Figure 9. Certain strain-hardening behaviour was observed, from the first crack load (approx. 100kN) to the peak load (approx. 135kN), followed by a strain-softening behaviour. The post-peak stress displacement was developed asymmetrically. This depends on which side of the beam will first develop a big crack.

Figure 10 shows the load-displacement curve for the hybrid beam (no.4). For the hybrid beam, a similar level of first cracking load around 100kN was observed. A much greater level of strain-hardening behaviour was observed, which led to a peak load of up to 400kN. This is much greater than the SFRC

Figure 9. Load-displacement curve for new beam no.2.

Figure 11. Load-displacement curve for plain concrete beam no.5.

Figure 10. Load-displacement curve for hybrid beam no.4.

Figure 12. Load-displacement curve for a previous beams.

beam, which only has a peak stress of around 135kN. Figure 11 shows the load-displacement curve for the plain concrete beam (no.5). As expected, a brittle behaviour was observed with a slightly lower pre-crack peak load around 95kN. No ductility was observed.

A typical load-displacement curve for the previous SFRC beam is shown in Figure 12. When comparing to the new beam no.2 curve in Figure 7, the following interim conclusions can be drawn: (1) For the first crack loading, the previous beam is 20% higher than the new concrete mix (120kN vs 100kN). (2) For the peak loadings, the previous and new beams are similar, around 135kN. (3) Both previous and new beams have demonstrated similar and sufficient ductility at a moderate displacement range (i.e., up to 15-20mm displacement). It should be noted that the critical load case for the Tideway West main tunnel secondary lining is the serviceability limit state (SLS) lining crack width check under a full internal surge water loading scenario. Hence, the main focus on the load-displacement curve is on the small and moderate displacement range.

4.2 Load-strain results

This section presents the strain-displacement results for the selected new beam No.2 and compares them with the results from the selected old beams.

Figure 13 shows the strain-time curve in a longer cycle (i.e., time) sequence for strain gauges at the non-crack positions. It can be observed that the strain develops linearly up to the peak strain and then retains a slightly reduced level of strain for a certain period while the beam displacement is still developing. This is a clear demonstration of the ductility of the concrete beam, with steel fibres at the cracking position still providing residual tensile strength.

Figure 14 shows detailed load-strain displacement curves. It can be seen that the peak load occurs between 120-140kN with a corresponding strain between 100-110 $\mu\epsilon$. After peak load, load suddenly drops with slightly increased strain between 110-120 $\mu\epsilon$. Maximum strain up to the end of the loading testing stage is around 135 $\mu\epsilon$. Strain-hardening behaviour is observed at the residual strain stage.

Figures 15 and 16 show the strain-time curve for previous beams. It can be seen that the first crack occurs when strain reaches between 150-190 $\mu\epsilon$. Residual strain ranges from 120 to 180 $\mu\epsilon$.

Figure 13. Strain-time curve for new beam no.2.

Figure 14. Strain-displacement curve for new beam no.2.

Figure 17 shows the strain-time curve for strains at cracking positions for the new mix beam no.2. Much greater strain levels, between 2000–4500 $\mu\epsilon$, were observed. This is similar to that observed for previous beams, the results of which are not presented here due to space limit.

Figure 15. Strain-displacement curve for previous beams.

Figure 16. Strain-displacement curve for previous beams.

Figure 17. Strain-displacement curve for new beam no. 2 at cracks.

4.3 Crack spacing results

This section presents the crack spacing results from both manual observation and digital imaging correlation (DIC).

Figure 18 shows manual crack spacing measurement in the laboratory right after the completion of the test for new beam no.2. Crack depth was also marked in red. It was concluded that visible crack spacing is between 250-400mm. Figure 19 shows crack spacing for one previous beam, which ranges between 170mm and 530mm, indicating a higher variation.

Figure 20 shows the DIC crack spacing results, ranging from 80mm to 370mm. Based on Figure 9, the right-hand side beam first developed a bigger crack. Hence, the crack spacing on the right-hand side of the beam is more representative. It can be found all crack spacing on the right-hand side of the centreline of the beam is less than 300mm.

4.4 Crack width results

This section presents the crack width results from both the new SFRC beam no.2 and the selected beam results with the previous concrete mix.

Figure 18. Manual crack spacing measurement on new beam no.2.

Figure 19. Manual crack spacing measurement on previous beam.

Figure 20. DIC crack spacing measurement on new beam no.2.

Figure 21 shows that the maximum crack width at the level of 15mm below the beam top surface was around 0.3mm when the beam was under a peak load of 134.4kN. The blue line and the green lines at the level 50mm below the top beam surface, both show a value around 0.5mm, are treated as outliers because these values don't follow the crack development pattern, which should have a bigger crack width closer to the tension surface (i.e., top beam surface) and gradually reduces with the increasing depth.

Figure 22 shows typical crack width results for a beam using the previous concrete mix. A red line was drawn to identify the maximum crack under the same loading of 134.5kN. It shows the maximum crack width for this beam is around 0.35mm and

between 0.3-0.6mm for other beams using the previous concrete mix. In comparison, the maximum crack width for the beams using the new concrete mix shows higher consistency, all ranging around 0.3mm.

Figure 21. Crack width for new SFRC beam no.2.

Figure 22. Crack width for selected beams using the previous concrete mix.

5 CONCLUSIONS

This large BRE beam test results have significant implications on the understanding of the performance of the SFRC lining, in both mechanical behaviour and the design approach.

Traditionally, 40kg/m³ steel fibres have been used as a default dosage for SFRC mix. This BRE beams test used the same concrete mix with a slightly reduced 35kg/m³ steel fibre dosage. Their performance under the same testing regime was compared like for like. The comparison shows that the new 35kg/m³ steel fibre concrete mix performs at least at the equivalent level as the 40kg/m³ steel fibre concrete mix under the applicable small displacement range.

From a designer's perspective, it is evident from the load-displacement and load-strain curves, that

a strain-hardening post-cracking behaviour was observed in all SFRC beam test results. This provides confidence in the adoption of the multiple cracking modes for the tunnel lining design.

These test results also inform the industry of a key design assumption for calculating the maximum design crack width, which is that the crack spacing is equivalent to the lining thickness. With the use of DIC technology, this design assumption has been verified and can be used in predicting the maximum crack width when the tunnel's secondary lining is under internal surge pressure.

In addition to that, the DIC crack depth results also show that the crack is developing in a linear pattern and propagating from the lining surface into the concrete lining. Hence, a linear relationship in terms of the crack width at different depths is also a valid assumption.

With the combined effects of the above factors as well as the close collaboration between the contractor, designer and the Category III checker, this new concrete mix with 35kg/m³ steel fibre dosage has been used, and the tunnel secondary lining design based on this concrete mix has also passed the rigorous Category III checking process. This has led to a saving of 230 tonnes of steel fibres for a 7km long Thames Tideway West main tunnel, achieving significant savings on construction cost and embodied carbon without compromising the tunnel lining's structural and durability performance. In addition, the case study presented in this paper can be used as a reference for future similar value engineering exercises on the use of SRFC tunnel linings.

ACKNOWLEDGEMENTS

The authors would like to take this opportunity to thank the contribution made by BRE and NPL, as well as the people involved in this study from the BMB and MSES. The authors would also like to thank the approval from Tideway for the publication of this paper.

ABSTRACT: With the rapid development of urban transportation construction, numerous engineering projects involving the construction of new roads crossing established underground railway lines have emerged. The vibratory compaction of road surfaces has a significant impact on the structural integrity of subway stations to some extent. In the context of the crossing of Road 5 with the established shallow-buried subway station, numerical simulation methods were employed to study the dynamic response characteristics of the shallow-buried subway station under the action of surface vibration loads. Furthermore, sensitivity analysis was conducted on factors such as vibration frequency and excitation force. The research results indicate that under the influence of surface vibration loads, the acceleration response of the station's structure exhibits a trend of attenuation from top to bottom and from the center towards both sides, specifically: top plate > middle plate > side walls > bottom plate. As the vibration frequency increases, the acceleration response of the station's structure gradually intensifies. Based on the aforementioned research findings, it is recommended that the optimal construction parameters for vibratory compaction of the roadbed above this shallow-buried subway entail a vibration frequency of 28-33Hz and an excitation force ranging from 150-300kN.

Keywords: ultra-shallow buried metro station, adjacent construction, surface vibration load, structural dynamic response

1 INTRODUCTION

With the rapid advancement of urban transportation infrastructure, a plethora of engineering instances has emerged where new road construction intersects established underground railway tunnels. In the construction of such contemporary urban roads, there is a preference for the application of asphalt mixtures as protective layers. This is done to mitigate the direct abrasion of the roadbed caused by vehicular wheels, while simultaneously distributing the vehicular loads, thus providing a smooth and slip-resistant road surface for vehicular travel. In our nation, it is generally to utilize vibratory compactors for the dynamic compaction

of roadbeds. The compaction of road surfaces by vibrating road rollers constitutes a dynamic process. When a vibratory roller is acted on the road surface, it can be considered as a surface vibration load (Peng A. P et al., 2019). The construction of new roads crossing established underground stations, in our country, presents significant technical challenges and a multitude of uncertainties. Inadequate control measures during the construction process not only jeopardize the smooth operation of subway vehicles but also pose a substantial risk to the safety of traffic. Hence, the impact of vibrating road rollers during construction above established underground railway tunnels warrants particular attention concerning subway structural

*Corresponding author: dlj2540306792@outlook.com

integrity. Precisely elucidating the dynamic response characteristics of super-shallow buried subway station structures under the influence of surface vibration loads holds practical significance.

Many scholars employ various methodologies, including field research, theoretical analysis, numerical simulations, and model experiments, to research the characteristics of structural dynamic response under surface vibration loads. Lai, J et al. (2016) showed that surface vibration loads can affect subway tunnels in the range of approximately 14 m depth of burial. The genesis of surface vibration loads primarily stems from vehicular-induced vibrations, explosive detonations, and vibrations generated during road construction; Yi, H et al.(2019) conducted an analysis using numerical simulations and model experiments to explore the enduring impact of surface vibration loads on the cumulative deformation and dynamic response characteristics of subway tunnel linings. Their research demonstrates that tunnels situated beneath high-speed rail lines exhibit the phenomenon of cumulative deformation under the prolonged influence of vibration loads. This underscores the imperative need to account for the effects of vibration loads in engineering design (Zhang, X et al., 2021); CAO Z.G et al. (2018) have pioneered the provision of analytical solutions for the dynamic response of tunnels under the influence of surface moving loads. They have undertaken a comprehensive examination of the underground tunnel vibration issue induced by surface traffic loads, considering varying load speeds, positions, lining structures, and tunnel depths; Jin, ZY et al. (2021) have conducted an analysis of the long-term vehicular-induced vibrations on the mechanical behavior and waterproofing performance of prefabricated underground passages; Xu, Ret al. (2023) employing on-site explosive vibration monitoring, has researched surface vibration velocities and instantaneous energy obtained from various blasting schemes. This study highlights the significant impact of tunnel depth on surface vibrations; Peng, A.P et al. (2019) through a combination of field experiments and numerical simulations, have undertaken an analysis of the dynamic response of concrete beam bridges with varying cross-sectional designs under the vibratory compaction of asphalt road surfaces on the bridge decks. Currently, there is a limited body of research regarding the dynamic interaction between roller-induced vibrational loads and subterranean structures. Hence, there is a compelling need to embark on a mechanistic exploration of the effects of surface vibration loads generated by roller operations on the dynamic interaction with the foundation and underground structures. This entails considering factors such as ground load frequency and excitation force to more accurately assess the vibrational response of subterranean structures induced by surface vibration loads.

Therefore, in the context of the Road 5's close proximity crossing with the Beijing Daxing

International Airport line, this paper undertakes an analysis of the impact of various roller models on structural safety and examines the influence of surface vibration loads generated at different frequencies on the vibrational response of subway station main structures.

2 THEORETICAL ANALYSIS OF VIBRATORY COMPACTION

2.1 *Dynamics model of the vibration system of roller*

When a vibratory road roller compacts the roadbed, the compacted layer experiences a dynamic force, the magnitude of which is contingent upon mechanical parameters such as the vibration wheel's frequency, amplitude, static weight, and excitation force. Due to the inherently complex and stochastic nature of vibratory road roller compaction, the vibrational forces exerted by the vibration wheel on the compacted layer are simplified for analysis purposes. The operational mechanism of the vibratory road roller involves the rolling wheel utilizing its own gravity to press down, while the rear wheel (the vibration wheel) carries out the compaction operation. The force exerted by the rolling wheel on the construction material can be regarded as a constant force in motion:

$$P_1 = G_1 \quad (1)$$

G_1 is the gravitational force of the rolling wheel in kilonewtons (kN).

During the operation of a vibratory road roller, the centrifugal force generated by the rotation of the eccentric block within the vibration wheel results in highly efficient and continuous vibrational impacts on the compacted layer. The force exerted by the vibration wheel on the roadbed is approximately equal to the sum of the vibration wheel's weight and the excitation force:

$$P_2 = G_2 + F \quad (2)$$

G_2 is the gravitational force of the vibration wheel (kN)

F is the force exerted by the circular vibrational motion of the vibration wheel on the ground (kN)

The centrifugal force is generated by the rotation of the eccentric block

$$F_0 = M_e \omega^2$$

M_e represents the eccentric distance of the eccentric block (kN·m); ω is the vibration frequency (rad/s)

The force exerted by the circular vibrational motion of the vibration wheel on the ground is the

vertical component of the centrifugal force produced by the rotating eccentric block, denoted as F_0 ;

$$F = F_0 \sin \omega t \quad (3)$$

Typically, the excitation force F_0 of the vibration wheel is about 2-3 times greater than the weight of the vibration wheel itself. When a road roller is laying pavement, the vibrational force of the vibration wheel on the road surface can be expressed as follows:

$$P_2 = \begin{cases} G + F_0 \sin \omega t & P_2 > 0 \\ 0 & P_2 \leq 0 \end{cases} \quad (4)$$

During the compaction process with the vibrating steel wheel, assuming the contact surface of the compacted material is rectangular, measuring $0.2 \times 1.8\text{m}$ (as shown in Figure 2); Analyze the dynamic response of the station structure under the vibrational load of the road roller, assuming a uniform distribution of contact stress. Substituting the formulas for Zhi et al. (2003) into equations (1) and (4) yields:

$$p_1 = \frac{13G_1}{WL} \quad (5)$$

$$P_2 = \begin{cases} \frac{13(G+F_0 \sin \omega t)}{WL} & F > 0 \\ 0 & F \leq 0 \end{cases} \quad (6)$$

W is the diameter of the vibration wheel (mm)
 L is the width of the vibration wheel (mm)

Utilize the ABAQUS DLOAD subroutine to compute the load applied to the compacted road surface by the vibratory road roller, as described by formula (6).

Figure 1. Vibratory roller vibration load time history curve.

Figure 2. The pavement is subjected to uniform vibration loads diagram.

3 NUMERICAL MODELLING

3.1 Relative position of structures

According to the planning needs of urban development, the construction of the soil roadbed of planning Road 5 above the established Daxing International Airport Line is carried out using vibratory roller compacting to improve operational efficiency. The construction section of which the interval is K35+475.232-K35+495.232 is in parallel with the main structure of the metro station, as shown in Figure 3; the vibratory roller compacts the first layer of soil 2m away from the station top plate, and the width of the main structure of the station is 30m, and the height is 16m.

Figure 3. Longitudinal section of the station along the established Daxing International Airport line.

3.2 Calculation parameters

The center columns of the established Daxing International Airport Line are C50 reinforced concrete; the

wall, slab, and beam structures are C40 reinforced concrete. The stratum distribution in the calculation model is from top to bottom: miscellaneous fill, powdery clay, silt, fine sand, and pebbles. The parameters of the physical and mechanical properties of each soil layer and structure are shown in Table 1. The modulus of elasticity and Poisson's ratio of the soil layer are taken as kinetic parameters according to the wave velocity test of the ground investigation data.

3.3 Calculation model

In this paper, ABAQUS finite element analysis software is used to carry out numerical simulation research on the influence of the vibration load of the roller on the overburdened soil of an ultra-shallow buried underground station. According to the above relative position relationship between the new construction and the established construction, the numerical calculation model is established as shown in Figure 4. When the ratio of the dimension of the foundation plane to the dimension of the structure plane is greater than 5, the results of the dynamic calculation tend to be stable, and the influence of the lateral boundaries can be ignored (Huai-feng et al., 2016). Considering the calculation time and the storage capacity of the computer, the Z-axis length of the calculation model in this paper is 20m for the 3-span structure, and the width of the X-axis is taken as 4 times the length of the station, which is 120m; the vertical direction (Y-axis) is taken as 50m up to the pebble layer, and the embedment at the top plate of the station is 2 m. To satisfy the requirements of the accuracy of power calculations, it is desirable to take the mesh size within 1/8~1/10 of the wavelength of the highest frequency; the enclosing rock and the reinforced concrete structure solid cell simulation is adopted, and Mohr-Coulomb criterion and plastic damage model are used respectively.

Figure 4. Finite element calculation model.

4 VIBRATION RESPONSE ANALYSIS

4.1 Description of the calculation

To ensure the continuous deformation resistance and load-bearing capacity of the station's main structure during the construction of the road surface with a vibratory road roller, an analysis was conducted under the vibrational effects of three different models of road rollers at a vibration frequency of 33Hz and a speed of 10km/h. The analysis focused on the vibrational velocity and vertical deformation of the station's main structure. Table 2 presents the operational parameters of various models of vibratory road rollers. Figure 5 and Table 3 depict the maximum deformations and maximum vibrational velocities of the station's main structure under the influence of different models of road rollers. The XS202 road roller model exhibits a maximum vertical deformation of -3.521mm, while the YZ18 road roller model displays a maximum vertical deformation of -3.168mm, both of which do not meet the safety control values for rail transit structures.

Table 1. Physico-mechanical parameters of surrounding rock and structures.

Objects	Name	Thickness/m	Density/ ($\text{kg}\cdot\text{m}^{-3}$)	Elastic modulus/ MPa	Poisson's Ratio	Cohesion/ kPa	Friction angle/($^{\circ}$)
Soil Layer	Miscellaneous fill	2.0	2090	47	0.40	17.0	17.0
	Powdery clay	16.0	1980	125	0.38	23.0	12.0
	Silt	8.0	1960	223	0.36	20.7	27.6
	Fine sand	12.0	1900	346	0.35	0.0	28.0
	Pebble	12.0	2000	568	0.33	0.0	35.0
The Main Structure of the Subway Station	Sidewall	0.9	2500	32500	0.20	-	-
	Top plate	0.9	2500	32500	0.20	-	-
	Floor	0.4	2500	32500	0.20	-	-
	Bottom floor	1.0	2500	32500	0.20	-	-
	Roof beam	1.8	2500	32500	0.20	-	-
	Floor beam	0.9	2500	32500	0.20	-	-
	Bottom beam	2.0	2500	32500	0.20	-	-
Pillar	0.8 \times 1.0	2500	34500	0.20	-	-	

Conversely, the YZ16JC road roller model records a maximum vertical deformation of -1.578mm, with a main structure vibrational velocity of 2.26 cm/s. The main structure of the station did not show any deformation that threatened structural safety and thus complies with regulatory requirements.

Table 2. Working parameters of the vibratory roller.

Number	Vibrating Wheel Weight (kg)	Roller Weight (kg)	Vibration Frequency (Hz)	Excitation Force (kN)
XS202	13500	6500	28/33	370/255
YZ18	12000	6000	33/38	328/220
YZ16JC	7700	8300	28/33/38	300/150

In light of the calculations and the project context mentioned above, the choice has been made to employ the YZ16JC road roller for the road surface construction above the station's main structure.

4.2 Effect of vibration frequency on the station structure

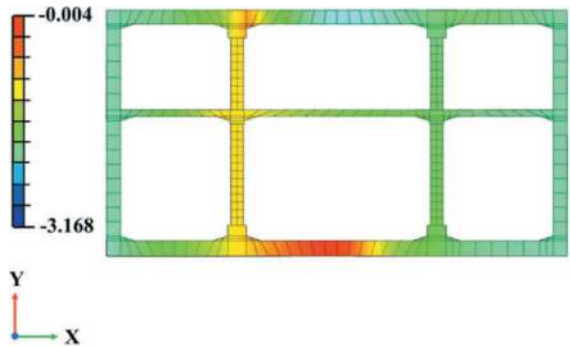

The compaction efficiency of a vibratory roller depends mainly on the operating frequency of its vibrating wheel. Consequently, the operational frequency of the roller significantly impacts the reliability of the station's main structure and the compaction quality of the asphalt pavement. Furthermore, the dynamic response of various underground structural components and the attenuation characteristics of different vibrational frequencies have consistently remained focal points and challenges in research. Therefore, this study, in conjunction with the YZ16JC roller, which features three distinct operational frequencies: 28Hz, 33Hz, and 38Hz, analyzes the influence patterns of different frequencies on the vibration characteristics of the station's main structure. The sensor placement across various sections of the station's main structure is illustrated in Figure 6. The top, middle, and bottom plates monitor vertical responses, while Sidewalls monitor lateral structural response.

Under the influence of surface vibration loads, the distribution of peak accelerations at various measurement points on the station's main structure at different frequencies is shown in Figure 7. Simultaneously, the classification of measurement points is done based on different sections, and the peak accelerations for each section are summarized, as presented in Table 4.

From Figure 7, it is discernible that the acceleration response of the station's main structure exhibits a fundamentally symmetrical distribution, with

(a) Vertical deformation corresponding to YZ16JC

(b) Vertical deformation corresponding to YZ18

(c) Vertical deformation corresponding to XS202

Figure 5. Deformation of the main structure of the station according to different rollers.

Table 3. Deformation and vibration speed of our main structure when getting off different rollers.

Number	Vertical Displacement (mm)	Vertical Speed (cm/s)	Position
XS202	-3.521	3.098	Roof Span Center
YZ18	-3.168	2.781	Roof Span Center
YZ16JC	-1.578	2.262	Roof Span Center

Figure 6. Diagram of measurement point layout.

a decreasing trend in the vertical direction from top to bottom and in the lateral direction from inner to outer. Specifically, the order of magnitude is as follows: top plate > middle plate > side walls > bottom plate. In other words, the closer the measurement point is to the vibration source, the greater the dynamic response, with a maximum peak acceleration of 1.239 m/s^2 (at $f=38\text{Hz}$). At the same frequency, there is a substantial difference of approximately 0.652 m/s^2 between the maximum peak accelerations observed at the top plate and the bottom plate measurement points. As the frequency increases, the peak accelerations at all measurement points gradually increase from 0.533 m/s^2 to 1.239 m/s^2 . Furthermore, under the vibration frequencies of 33Hz and 38Hz , the peak accelerations at each measurement point are respectively 35% and 126% higher than those observed at 28Hz . Notably, the maximum peak accelerations for both the top plate and the bottom plate occur at the mid-span.

As depicted in Figure 8, with the increase in frequency, the peak accelerations at various sections of the station's main structure witness a rise. The most significant increase in peak acceleration occurs when transitioning from 33Hz to 38Hz . Specifically, as the frequency shifts from 28Hz to 33Hz , there is an average increase of 24.75% in peak acceleration across all sections. When moving from 33Hz to 38Hz , this average increase in peak acceleration rises to 43.86% . Overall, it is evident that the vibrational response of the top plate is more significantly influenced by frequency, exhibiting a greater attenuation magnitude compared to other sections. The attenuation amount for peak acceleration on the top plate is 0.706 m/s^2 , with an attenuation rate of 56.9% .

To elucidate the temporal variations in acceleration responses of the subway station's main structure during the operation of the upward vibratory roller, the peak acceleration measurement points for frequencies of 33Hz and 38Hz . The resulting acceleration time history curves for these points are presented in Figure 9.

From Figure 9, it is evident that the acceleration responses at various measurement points on the station's main structure exhibit pronounced periodic

(a) $f=28\text{Hz}$

(b) $f=33\text{Hz}$

(c) $f=38\text{Hz}$

Figure 7. Peak acceleration distribution of station main structure measurement points according to different frequencies (m/s^2).

Figure 8. Change pattern of peak acceleration with frequency for each part of the station's main structure.

Table 4. Peak acceleration of each part of the main structure of the station at different frequencies.

Frequency	Peak Acceleration/(m·s ⁻²)			
	Top Plate	Middle Plate	Bottom Plate	SideWalls
28	0.533	0.210	0.258	0.123
33	0.744	0.337	0.337	0.162
38	1.239	0.587	0.587	0.312

variations at different frequencies, with the amplitude of each cycle not remaining constant. Furthermore, Figure 9 also illustrates that changes in frequency scarcely affect the temporal patterns of structural vibration responses, and only influence the magnitude of the response intensity.

5 CONCLUSIONS

This study employs numerical simulation techniques within the context of the crossing of Road 5 with the established Daxing International Airport Line. It investigates and analyzes the dynamic responses of road surface structures during construction by different vibratory rollers with varying excitation forces, and frequencies. The primary conclusions are as follows:

- (1) In the case of the engineering project involving the crossing of Road 5 with the existing shallow-buried subway station, to ensure the continuous deformability and load-bearing capacity of the station's main structure, it is advisable to employ the YZ16JC vibratory roller for construction. With an increase in the frequency of the station's main structure, the peak acceleration at each measurement point increases by 24.75%. Although the deformation of the

(a) Vertical acceleration according to $f = 33$ Hz

(b) Lateral acceleration according to $f=33$ Hz

(c) Vertical acceleration according to $f=38$ Hz

(d) Lateral acceleration according to $f=38$ Hz

Figure 9. Time history curves of measurement points recording peak acceleration in each part of the main structure of the station.

station's main structure does not exceed the allowable limit, it exceeds the safety warning value for rail transit. Therefore, it is not recommended to use high-frequency rollers (even though high frequencies can enhance the compaction height of asphalt pavement). Additionally, monitoring of the Daxing International Airport Line section and track structure is warranted.

- (2) The amplitude response of acceleration in the station's main structure is as follows: top plate > middle plate > side walls > bottom plate. This indicates a vertical attenuation from top to bottom and a lateral attenuation from the center towards both sides, with a maximum difference in peak values of approximately 111.073%.
- (3) Frequency variations have almost no impact on the peak distribution in the time domain and the temporal patterns of the structure. At different frequencies, the measurement points for recording peak accelerations on the station's main structure's top plate are consistently located at the mid-span of the top plate, and each measurement point exhibits consistent periodic variations in the time history curve.

Jiangong Liu*, Zhigang Wang & Ming Shi

Beijing University of Technology, Beijing, China

ABSTRACT: Based on the Taiyuan subway tunnel project crossing through an active fault zone, this paper utilizes ABAQUS software to construct a three-dimensional refined model. The model aims to investigate the mechanical behaviour and fault-resistant design methods of urban shallow subway tunnels that cross normal faults. Using numerical simulation and mathematical induction, the study explores the impact of two primary factors, namely fault dip angle and fault displacement, on the mechanical response and damage degree of the subway tunnel structure. In addition, ellipticity is employed to unveil the spatial deformation characteristics of the tunnel cross-section. The findings indicate that due to normal fault dislocation, the lining structure deflects at a specific angle to adjust to the fault's forced displacement. This results in local segments of the structure becoming de-hollowed and out of sync with the soil layer's movement. Secondly, the hanging wall's damage area and stress-strain exceed that of the footwall by several times. Thirdly, the tunnel deformation's maximum position depends on the fault dislocation's location. The implementation of segmental lining mitigation measures notably diminishes the detrimental impact of fault displacement, ultimately leading to a reduction in both the magnitude of destruction and the affected area of the tunnel structure.

1 INTRODUCTION

Many urban areas in China are situated in seismic zones with high intensities and a widespread distribution of rupture zones. Examples of such cities include Beijing, Urumqi, Taiyuan, and others. In response to the demands of economic and social objectives, the route design of tunnel structures with linear characteristics will inevitably traverse the active fault zones. Given the significance of active fracture damage severity and the necessity for tunnel structure construction, acquiring a profound comprehension of fracture zone damage mechanisms and design methods in urban shallow underground tunnel structures is crucial for maintaining tunnel infrastructure and ensuring public safety.

Extensive research has been conducted by scholars worldwide on the harm process of the soil layer above, the mechanics and harm process of the tunnel construction, and the development of fault resistance for fault displacement. With regard to the

damage of the overlying soil body, Cole and Lade (1984) found, through experiments on sandy soil, that the shape and location of the damage surface of the surface fault are determined by the depth of the soil body, expansion angle, and the fault dip angle. Liu (2004) concluded, through model experiments, that when the damage surface propagates to the surface, the ratio of the vertical displacement to the thickness of the soil body ranges from 4% to 8%, which is independent of the fault dip angle. Liu et al. (2005) investigated the horizontal and vertical displacement of bedrock through centrifuge experiments and found that the impact of vertical displacement of bedrock on the overlying sediment is greater than that of horizontal displacement. Guo et al. (2002) employed finite element calculations to demonstrate that, under equal fault dislocation, reversed faults have the greatest destructive effect on the overlying sediment layer, followed by normal faults, and strike-slip faults have the least destructive

*Corresponding author: 1492319496@qq.com

effect. Regarding the damage mechanisms of tunnel structures crossing active faults, Liu et al. (2013, 2014a, b) undertook an analysis of the stresses and distribution of damage in tunnel structures, considering different fault displacements. Additionally, they carried out extensive investigations into circumferential and longitudinal strains, in addition to the pressures from surrounding rock. Zhong et al. (2020) also explored this subject in their research, where numerical simulations were carried out to examine fault movement, tunnel-fault intersection angles, and the mechanical characteristics of the rock surrounding the tunnel through numerical parameter analyses. Following the strike-slip fault's action, damage indicators were used to evaluate the extent of the tunnel's damage. Regarding the fracture-resistant design of cross-fault tunnel structures, Jiang et al. (2011) examined the articulated design and overcuts design, and proposed techniques for computing section length and stiffness at the section. Moreover, Tao et al. (2022) utilized numerical analysis and model tests to derive the analytical solution for the longitudinal direction of the tunnel structure when under the action of the fault. Lastly, An et al. (2021) contributed to this research topic. and Wang et al. (2023) discovered varying mitigation effects of flexible joints at different locations, identifying fault displacement surface position as the optimal location for achieving maximum mitigation of tunnel damage.

In summary, there are still deficiencies in the mechanical response of city shallow subway tunnels that cross active fault zones. Based on the Taiyuan Subway Line 1 project, this paper examines an interval tunnel that crosses the active fault zone in Jiaocheng. A three-dimensional refinement model of the tunnel-fault is established using ABAQUS to investigate the mechanical response of the tunnel lining and the disaster mechanism of the change of inclination and displacement when the normal fault is in action. At the same time, it has been confirmed that the segmental lining has a mitigating effect, which provides valuable reference points for the relevant engineering design.

2 PROJECT OVERVIEW

The dissertation centres on the initial phase of Taiyuan City's Urban Rail Transit Line 1 scheme, a subterranean transport network spanning 28.737 km, encompassing 24 subways all arranged in an "L" configuration. The F_{1-1} and F_{1-2} Jiaocheng fault zones are traversed by the Line 1 Phase I plan as determined through ground investigative data, superficial seismic interpretation findings, and joint profile analysis between Jinyang Road station and Xiaojingyu station illustrated in Figure 1. The tunnel covering is 9 m thick and cuts orthogonally across the Jiaocheng fault. In urban metro tunnels, the overburden ratio H/D falls between 0.6 and 1.5 for shallow tunnels (Wang, 2006).

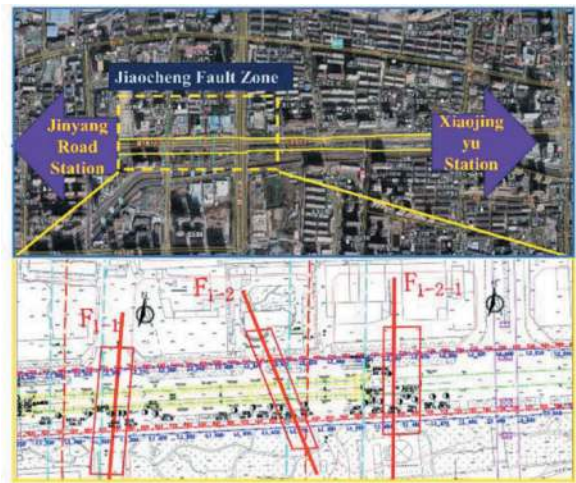

Figure 1. Layout of station interval and distribution of active fault zones in Jiaocheng.

3 MODELLING AND PARAMETER SELECTION

3.1 Numerical model establishment

Based on the engineering data, we constructed a refined three-dimensional fault tunnel model which can be seen in Figure 2. To enhance the accuracy of our calculations, we ensured that the model's length is 120m, width is 30m, height is 35m and the overburden thickness is 9m, while also eliminating any influence from boundary effects. The soil layer along the z-axis is gridded at intervals of 2m while the tunnel structure is gridded at intervals of 1m. The circular tunnel is divided into 48 grids around its perimeter. The tunnel lining measures 6m in outer diameter, 5.2m in inner diameter, and 0.4m in thickness. To consider the apparent mechanical response of the structure during the fault displacement process, a finer grid is used in the 15m vicinity surrounding the tunnel. The model's side and bottom surfaces are normally restrained surfaces, while the

Figure 2. Three-dimensional nonlinear numerical model.

Figure 3. Three-dimensional numerical model section.

top surface is free, as illustrated in Figure 3. The normal contact surface between the fault and the tunnel employs hard contact, while the tangential contact surface employs coulomb friction with a friction coefficient of 0.3.

3.2 Model material parameters

C3D8R elements were implemented in ABAQUS software to replicate the fault and tunnel geometry. The soil material is presumed to be elastic-plastic in adherence to the Mohr-Coulomb criterion. The soil and lining structure parameters are displayed in Table 1. The C40 tunnel lining was employed, while the Concrete Plastic Damage Model (CDP) was applied to investigate the concrete's damage characteristics such as compression cracking and tension under the effect of displacement. Table 2 provides some damage parameters of the concrete.

Table 1. Soil and lining parameters.

Type of material	Density (kg·m ⁻³)	Modulus of Elasticity/MPa	Poisson's Ratio	Internal friction angle(°)
Lining parameters	2400	24150	0.2	22
Soil	2010	13.6	0.33	18

6.1	0.00742	0.8448	0.26	0.00081	0.9002

3.3 Calculation analysis

Due to the complexity of the lining-soil contact relationship in the actual project, we simplify the model as follows: (1) The tunnel structure in the model is horizontal. (2) The tunnel structure assumes a circular cross-section. (3) Each unit in the model is assumed to be isotropic.

Numerical simulation procedure: (1) Calculate initial soil stress equilibrium by applying normal constraints to the bottom and sides of the 3D model and gravity loads, as illustrated in Figure 4(a). (2) Apply fault displacement. Release the lower and lateral boundary constraints of the hanging wall, and implement a uniform and consistent displacement load in the direction of the fault displacement. The boundary constraints of the footwall should remain unchanged to imitate the downward movement of the hanging wall, illustrated in Figure 4(b). Taking into account only the impact of fault displacement, it has been determined that the influence of speed on the outcomes can be disregarded as long as the displacement is limited to 0.02mm during the simulation.

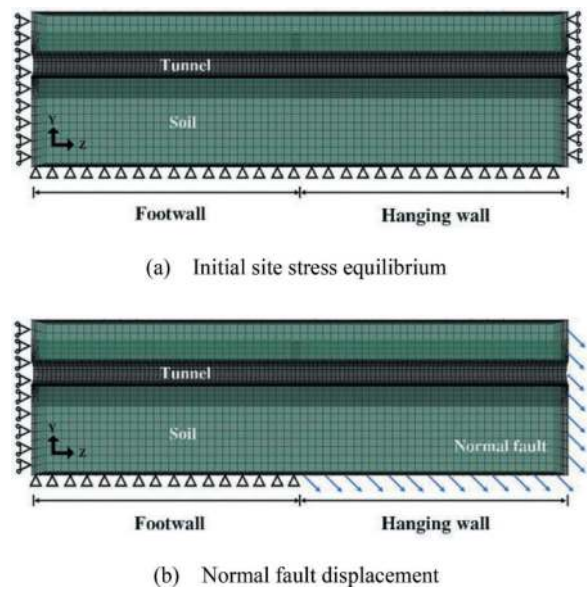

Figure 4. Procedures of numerical simulation.

The study employs the control variable method to investigate the influence of fault dip angle and fault displacement on the tunnel structure. Table 3 illustrates the varying working conditions.

4 RESULTS

4.1 Analysis of fault dip angles

The tunnel ellipticity expresses the cross-sectional deformation of the tunnel, and it can be calculated as follows (GB 50446-2017):

$$T = 2^*(a - b) \div D \quad (1)$$

Table 3. The calculation conditions of the numerical models.

Fault dip (°)	Vertical dislocation volume/m	Horizontal dislocation volume/m	Fault dip (°)	Vertical dislocation volume/m	Horizontal dislocation volume/m
30	0.225	0.13	45	0.13	0.13
45	0.13	0.13	45	0.33	0.33
60	0.075	0.13	45	0.56	0.56
75	0.035	0.13	45	0.75	0.75

Where, T is the ellipticity; a is the long half-axis of the tunnel(m); b is the short half-axis of the tunnel(m); D is the radius of the tunnel(m). In order to calculate the ellipticity of the tunnel under the effect of the normal fault, the vertical displacement difference c at the bottom of the tunnel vault and the horizontal displacement difference d at the left and right supply waists of the tunnel are extracted, and then the ellipticity of the tunnel can be obtained from Equation (1):

$$T=(c + d) \div D \quad (2)$$

Figure 5 shows the ellipticity distribution curves of the tunnel structure in the axial direction for various fault dip angles. It can be observed that maximum values of ellipticity for fault dip angles of $\alpha=30^\circ$, $\alpha=45^\circ$, $\alpha=60^\circ$ and $\alpha=75^\circ$ are 7.72‰, 4.69‰, 3.72‰, and 1.69‰ respectively. It is worth noting that for a dip angle of 30° , the maximum ellipticity exceeds 55.4% of the required limit of 5‰ set by the acceptance specification for shield tunnels. The ellipticity gradually reduces with increasing fault dip angle, while the location of maximum deformation in the tunnel section remains unaffected by fault dip angle.

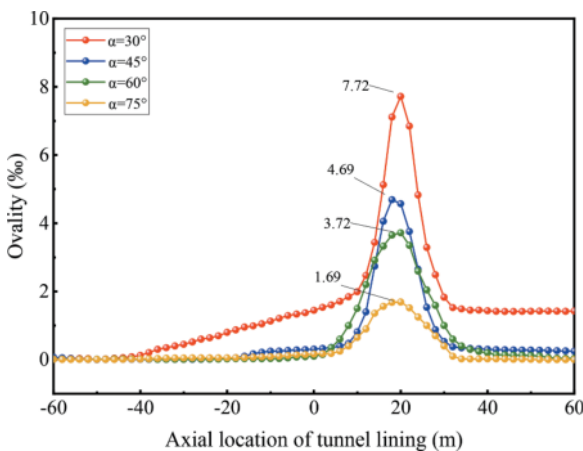

Figure 5. Ellipticity distribution of lining at different fault dip angles.

The plastic and shear strain cloud diagrams of the tunnel under various fault dip angles are illustrated

in Figure 6. Additionally, Figure 7 displays the plastic damage factor cloud diagrams. From Figure 8, it can be observed that the largest values of plastic strain under the four operating conditions of $\alpha=30^\circ$, $\alpha=45^\circ$, $\alpha=60^\circ$, $\alpha=75^\circ$ are $6080\mu\epsilon$, $3931\mu\epsilon$, $4378\mu\epsilon$ and $2291\mu\epsilon$ respectively. Additionally, the largest values of intra-annular shear strain under the four conditions are $6893\mu\epsilon$, $3126\mu\epsilon$, $2285\mu\epsilon$ and $2264\mu\epsilon$. It is evident that the values of plastic damage and annular shear strain decrease significantly with an increase in fault dip angle.

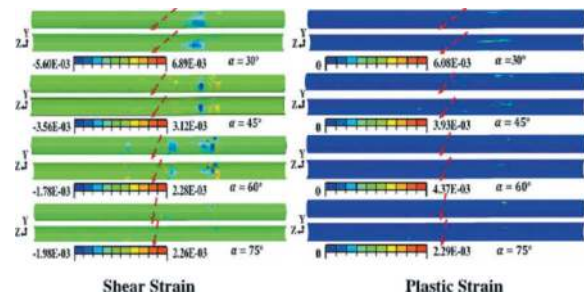

Figure 6. Cloud of shear strain and plastic strain indicators for tunnels with different fault dip angles.

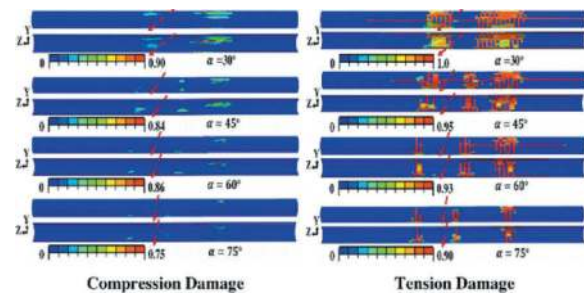

Figure 7. Cloud of compression damage and tension damage indicators for tunnels with different fault dip angles.

Figure 9 displays the tension damage factors that were calculated for different working conditions. The maximum tension damage factor is 1.0, reached when $\alpha=30^\circ$, whereas the other tension damage factors are 0.95, 0.93 and 0.9 respectively. Additionally, the tunnel structure contributes maximum compressive

Figure 8. Comparison of damage indicators of lining structures for different fault dip angles.

Figure 9. Comparison of volume indicators of lining structures for different fault dip angles.

damage factors of 0.9, 0.84, 0.86, and 0.75 respectively. The extent of the maximum tension damage experienced by the tunnel structure decreases as the fault dip angle increases and the area of damage reduces significantly (Figure 7).

Based on the above analysis, it is evident that the lining structure sustains varying degrees of damage at different fault dip angles. The degree of damage to the structure was assessed using four qualitative indicators, namely plastic strain, shear strain, section ellipticity, and tunnel damage factor. The degree of damage to the tunnel is highest at the dip angle of $\alpha=30^\circ$ when there is a fixed amount of vertical displacement. As the dip angle increases, the damage to the tunnel decreases gradually.

4.2 Analysis of fault displacements

The axial distribution curves of ellipticity for the tunnel structure, under different fault displacements, are depicted in Figure 10. It is observed that the values of maximum ellipticity for four different

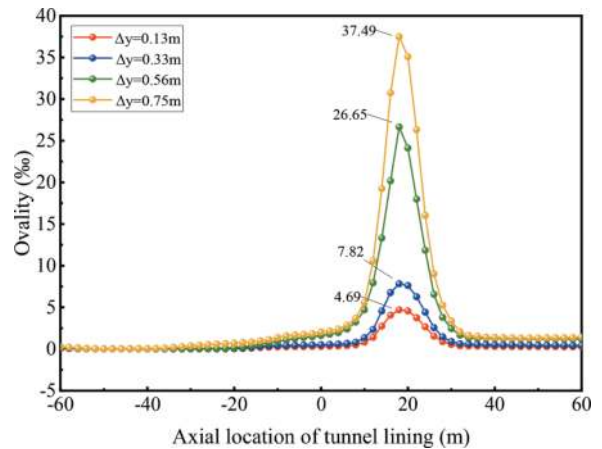

Figure 10. Ellipticity distribution of the lining at different fault displacements.

conditions of vertical displacements $\Delta y=0.13\text{m}$, $\Delta y=0.33\text{m}$, $\Delta y=0.56$ and $\Delta y=0.75\text{m}$, are 37.49%, 26.65%, 7.82%, and 4.68%, respectively. The first three conditions surpassed the maximum ellipticity limit of 5‰ mandated by the shield tunnel acceptance specification by 6.5-fold, 4.3-fold, and 0.6-fold, correspondingly. Consequently, the tunnel went beyond the permitted value of cross-sectional deformation during fault displacement, leading to damage. Additionally, the tunnel section's ellipticity amplifies with a higher degree of vertical displacement and is far greater than the variation ascribed to the fault dip angle. The level of fault dislocation remains unaffected by the location of maximum deformation within the tunnel section.

The plastic and shear strain of the tunnel caused by different fault displacements are displayed in Figure 11, along with the plastic damage factor presented in Figure 12. Based on the findings presented in Figure 13, the maximum values of plastic strain were 1545μ ϵ , 4066μ ϵ , 4935μ ϵ , and 6078μ ϵ for the four working conditions of $\Delta y=0.13\text{m}$, $\Delta y=0.33\text{m}$, $\Delta y=0.56\text{m}$, and $\Delta y=0.75\text{m}$. The maximum values of shear strain were 3934μ ϵ , 11600μ ϵ , 23870μ ϵ , and 28160μ ϵ respectively under four conditions. It is evident that as the displacement increases, the plastic damage and annular shear strain of the tunnel also increase significantly.

Figure 11. Cloud of shear strain and plastic strain indicators for tunnels with different fault displacements.

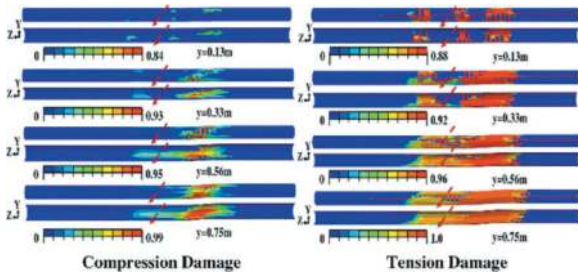

Figure 12. Cloud of compression damage and tension damage indicators for tunnels with different fault displacements.

Figure 13. Comparison of damage indicators of lining structures for different fault displacements.

Figure 14 displays the computed tension and compression damage factors for various working conditions. The maximum value of the compression damage factor is 0.99 at $\Delta y=0.75$ m, while the remaining tensile damage factors are 0.95, 0.93, and 0.84. Meanwhile, the tunnel structure exhibits maximum tension damage factors of 0.88, 0.92, 0.96, and 1.0, respectively. As the level of displacement becomes greater, there is a corresponding increase in the maximum level of tension damage experienced by the tunnel structure, and the resulting damage spreads across a broad range (Figure 12).

The above analyses indicate varying levels of damage to the lining structure caused by different amounts of displacement. The degree of damage was evaluated using four factors-plastic strain, shear strain, section ellipticity, and tunnel damage factor. Displacement is a crucial factor in tunnel lining damage as it directly impacts the circumferential shear strain of the tunnel structure and the deformation of the tunnel interface. The extent of displacement is a determining factor in the resulting damage.

4.3 Mitigation effects of segmental lining

After installing flexible joints, the normal fault caused a 0.2m vertical displacement and 0.035m horizontal displacement. Figure 15 illustrates the damage indices

Figure 14. Comparison of volume indicators of lining structures for different fault displacements.

of the lining structure. A comparative analysis was conducted on the structural damage of the lining structure with and without flexible joints, specifically in terms of the maximum damage index value and range. In comparison to Figure 16, the lining structure's maximum plastic strain value is 2.05×10^{-3} , which is 50.96% lower after the installation of flexible joints. Consequently, the plastic strain damage area is significantly reduced and concentrated mainly in the vicinity of the flexible joint. Compared to the readings presented in Figure 16, the maximum damage factor for tensile stress incurred by the concrete structures with flexible joints was 0.88, whilst the corresponding figure for structures without flexible joints was significantly higher at 0.94. Furthermore, the damage area resulting from such stress was significantly more contained in the former. Meanwhile, the maximum level of shear stress experienced by the rings was 1.18×10^{-3} , indicating a reduction of 47.79% when compared to the other measurements. The greatest instances of tension damage, compression damage, and intra-ring shear strain in the lining structure happen near the flexible joints and fault displacement within the section lining. The scrutiny indicates that the installation of flexible joints contributes to a better adaptation of the

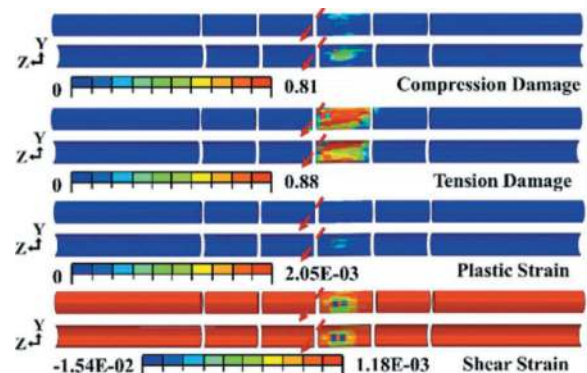

Figure 15. Cloud of strain and volume indicators for segmental lined tunnels.

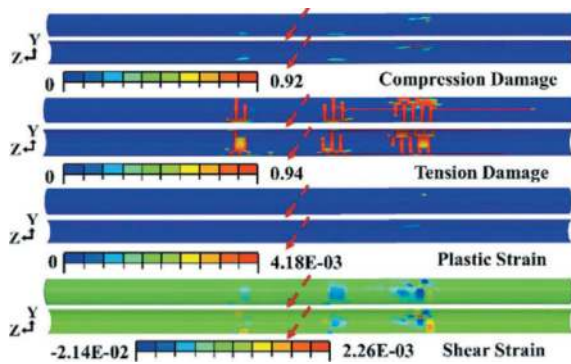

Figure 16. Cloud of strain and volume indicators for tunnels without segmental lining.

lining structure towards the fault-induced deformation and a more effective reduction of structural damage caused by fault displacement.

5 CONCLUSIONS

The paper utilizes the Taiyuan Subway Line 1 Project's interval tunnel, which crosses the Jiaocheng fault zone, to create a refined 3D model that simulates the normal fault dislocation. Through the analysis of two critical variables, fault dip angle and fault displacement, the study extracts the mechanical response and catastrophic mechanism of the tunnel construction under various influencing factors. Structural damage degree is evaluated using three aspects: tunnel cross-section ellipticity, tunnel maximum tension and compression damage factor, and tunnel structure strain. Furthermore, the mitigation effect of segmental lining is investigated based on the maximum tension and compression damage factor, and structure strain. The primary conclusions are as follows:

- (1) The deformation of the cross-section of the tunnel decreases as the fault dip angle increases. However, when the fault dip angle is 30° , the largest deformation generated by the tunnel cross-section occurs and the deformation decreases from the dislocation position towards both ends. The vertical fault displacement is a key influence on the tunnel section deformation. The position of maximum tunnel cross-section deformation is not influenced by fault dip angle or displacement, but is instead determined by the fault misalignment position.
- (2) Normal fault results in an evident upper disk effect. The emergence of a local dehiscence section between the lining structure and soil layer causes slight strain in the lower disk. The upper disk displays maximum values of circumferential shear strain and plastic strain, as depicted in the cloud diagram. Furthermore, the damage volume of the upper disk exceeds that of the lower disk.
- (3) Implementing measures to mitigate segmental lining, such as reducing the plastic strain and

shear strain of the tunnel structure under normal fault, leads to a decrease in the degree and scope of tension and compression damage. This leads to an improvement of the tunnel structure's damage from large-area to localized lining section, visibly enhancing fault-resistant performance in subway tunnels through faults.

Analytical solution for longitudinal response of cross-fault mountain tunnels based on foundation beam model

Lianjin Tao, Mingyang Qiu*, Haixiang Zhang, Zhibo Jia & Cheng Shi

The Key Laboratory of Urban Security and Disaster Engineering, Ministry of Education, Beijing University of Technology, Beijing, China

Beijing Key Laboratory of Earthquake Engineering and Structural Retrofit, Beijing University of Technology, Beijing, China

ABSTRACT: Tunnel crossing active fault is a common issue in mountain tunnels. Researching the analytical solutions for the longitudinal response of tunnels under fault dislocation is of great importance for disaster prevention in mountain tunnels. This paper summarizes the mechanical models for analytical solutions of longitudinal responses in tunnels crossing faults, compares the characteristics and applicable conditions of various foundation beam models, analyzes the key factors affecting the accuracy of the analytical solutions of foundation beam models, and finally proposes a general model for calculating longitudinal deformation in foundation beams. The results show that the current analytical solution models for foundation beams crossing faults seldom consider factors such as the form of fault sliding, tunnel joint methods, and external forces on tunnels. The general foundation beam model can introduce new parameters without changing the algorithm and enhance the efficiency of displacement analysis. This study provides guidance for subsequent displacement prediction and disaster prevention in mountain tunnels crossing active faults.

1 INTRODUCTION

With the implementation of ‘the Belt and Road’, the construction of tunnel projects in the high-intensity areas of Southwest China is increasing. These projects inevitably cross active fault zones. Consequently, numerous scholars have conducted extensive research on the longitudinal dynamic response of tunnels under fault displacement. These researches include theoretical analysis, numerical methods, and model experiment simulations. Most of them analyse the shear dislocation effects caused by fault displacement on tunnels, specifically the longitudinal deformations and internal forces. This is crucial to prevent excessive deformation of tunnels, which can lead to leakage or longitudinal tensile damage, ensuring the safe operation of tunnels. As a verification and supplement to numerical methods, analytical solutions directly reflect the mechanisms of core parameters in function form and calculate the equivalent models quickly in the preliminary design of tunnels.

The analysis of underground pipelines crossing active faults has developed into a complete system. In

1975, Newmark et al (Newmark et al., 1975) first proposed the small deformation analysis method of shallowly buried pipelines under fault displacement, considering that fault displacement only causes axial deformation of the pipeline, but did not take into account the bending deformation of the pipeline. Kennedy (Kennedy., 1977) expanded the research of Newmark, treating the pipeline as a cable with only tensile stiffness but no bending stiffness under bending deformation, and then he studied the impact of single curvature large deformation bending beams on pipelines under fault displacement. This simplified method of longitudinal structure was widely used in strike-slip and normal faults for many years. Based on Kennedy’s work, Wang et al (Wang et al., 1985) considered the bending stiffness of pipelines. Both Kennedy and Wang used a single curvature model to study the mechanical response of buried pipelines to strike-slip fault displacement, but they overestimated the effect of soil resistance on bending strain. Based on the simplified methods of pipelines, many scholars began to use the foundation beam model to study the analytical solution for tunnels crossing faults.

*Corresponding author: qiumy0417@163.com

Considering the fault zone width had an impact on tunnel structural internal forces and deformations, some scholars (Liu et al., 2020; Yu et al., 2023; Tao et al., 2022) proposed an analytical solution for the longitudinal response of tunnels under active fault displacement based on the Pasternak two-parameter foundation beam model. Li et al (Li et al., 2023) considered the influence of horizontal friction, simplifying shield tunnels as Timoshenko beams in Vlasov two-parameter foundation. Integrating this model into the analytical framework, he examined the response patterns of existing shield tunnels to fault displacement, highlighting the significant influence of factors such as the vertical distance between tunnel and fault, fault fracture zone width, and structural longitudinal bending stiffness on the tunnel's maximum longitudinal internal force. Zhao (Zhao., 2019) simplified the tunnel as a shear beam on homogeneous elastic surrounding rock, deriving the tunnel's longitudinal response analytically through Green's function method. His research particularly focuses on comparing the effects of fault fracture zone length and surrounding rock's elastic resistance coefficient on the dynamic response of tunnel lining structures. Luo (Luo., 2023) simplified the tunnel as an Euler-Bernoulli beam, assessing the impact of fault dip angle and tunnel-fault intersection angle on the tunnel's mechanical response. Adaptations and additions to the foundation beam model parameters for varying geological conditions have been made to more accurately describe the tunnel's longitudinal mechanical response. However, many studies had idealized assumptions about the geological and dynamic characteristics of faults, along with fault sliding forms, tunnel joint methods, and external forces on tunnels, leading to less precise and efficient calculations and analyses of tunnel internal forces and deformations. As research progresses, more parameters will be incorporated into the foundation beam model. Therefore, establishing a universal model calculation approach and adjusting the influencing parameters based on this model to rapidly and accurately obtain the foundation beam's dynamic response is an imperative issue to be addressed.

This paper will first conclude and analyse the research progress of theoretical analytical solutions for longitudinal responses in tunnels crossing faults. Subsequently, it will comprehensively analyse factors affecting the accuracy of analytical solutions and propose a universal approach for calculating these solutions. Finally, the paper will summarize the characteristics and future development directions of research on longitudinal analytical solutions for tunnels crossing faults.

2 THE ANALYTICAL MODEL FOR LONGITUDINAL DEFORMATION OF TUNNEL

Current research on analytical models for the mechanical response of pipelines crossing faults is extensive

(Wang et al., 2011), with the elastic foundation beam model being a commonly used mechanical model. Wang et al. (Wang et al., 1985) first divided the pipeline into four segments, as shown in Figure 1. The AC segment, a high-curvature area, was bisected by the fault trace at point B into AB and BC sections. Within this area, the pipeline was considered as a beam undergoing large single-curvature deformation, while the pipeline outside this high-curvature area (A'A, CC') were treated as elastic foundation beams. Based on the continuity requirements between adjacent sections, it was able to calculate the bending moment at the junctions of the large deformation beam and its adjacent elastic beams. Karamitros et al. (Karamitros et al., 2006) referred to the elastic plate theory and Wang's segmentation of pipelines and treated pipelines as elastic beams in the fault zone. The remaining areas were considered as semi-infinite elastic foundation beams. Their calculations took into account the bending stiffness of the pipeline cross-section, as well as the axial and lateral interactions between soil and pipeline. This approach was used to study the influence of curvature on axial strain, enabling a more precise determination of maximum strain.

The segmentation approach for pipelines initially assumes a high-curvature area. The shear force, bending moment, and rotation outside this high-curvature area are calculated using the foundation beam theory. Subsequently, iterative solutions within the high-curvature zone are conducted using boundary continuity conditions, aiming to identify the most adverse combination of axial and bending strains. Finally, based on the balance between externally applied axial forces and the internal stresses developed on the pipeline's cross-section, the maximum strain of the pipeline is calculated. This method significantly improves the precision of analytical predictions for pipelines crossing faults and provides convenience for researchers to consider the interaction between the surrounding rock and tunnel.

Figure 1. Pipeline analysis model proposed by Wang and Yeh.

Based on existing underground pipeline mechanical models, scholars had gradually applied the foundation beam model to the longitudinal stress analysis of tunnels crossing faults. The segmentation approach for cross-fault pipelines and tunnels differs as follows: (1) Cross-fault tunnels take into account

the width of the fault fracture zone, using this as a boundary condition to differentiate between fault and non-fault areas; (2) Compared to pipelines, tunnels have greater stiffness, and their deformations under fault displacement can be considered small, suitable for calculation using the elastic foundation beam model; (3) The joint forms in tunnels are more complex. Liu et al. (Liu et al., 2020), based on the Karamitros et al. model, factored in the thickness of the fault fracture zone, dividing the tunnel under fault displacement into three regions as shown in Figure 2. They were the displacement affected zone, the transitional influence zone, and the non-influenced zone, the tunnel in each zone as an elastic foundation beam. Many studies of the seismic response analytical solutions for tunnels crossing faults, had generally simplified the cross-fault tunnel model into three areas: the hanging wall, the fault zone, and the footwall. This segmentation approach no longer considers the intermediate fault zone as a single elastic beam, but rather takes into account the interaction between the tunnel and surrounding rock. Using foundation beam theory for all areas, it enables a more straightforward and rapid calculation of the impact of fault displacement on the tunnel's longitudinal mechanical response.

Figure 2. Tunnel analysis model proposed by Liu.

3 THE KEY FACTORS IN ANALYTICAL SOLUTION

Currently, analytical solutions mainly develop around the elastic foundation beam model. In this model, the tunnel structure is treated as a simplified beam, and the surrounding rock is regarded as a simplified foundation. The fault displacement is imposed on the soil or rock layer in forms such as concentrated, distributed, or harmonic vibration, and introduced into the analytical solution as an external load. Factors like the shear effects of the beam, the choice of foundation model, and the ground reaction coefficient are crucial in influencing the accuracy of the analytical solution.

3.1 The type of beam

The concept of longitudinal analytical solutions for tunnels posits that shield tunnels can be longitudinally equated to a beam. This idea was first proposed and extensively researched by Shiba Y et al. (Shiba Y et al., 1988). Based on the theory of longitudinal structure-

soil interaction in tunnels, shield tunnels are typically simplified as Euler-Bernoulli beams and Timoshenko beams. These two types of beams are commonly used to describe the deformations of tunnels caused by fault displacements. The Euler-Bernoulli beam considers only bending deformations and does not account for shear effects. In its force analysis, line segments perpendicular to the beam's axis before deformation remain perpendicular and unchanged in length after deformation. Timoshenko et al. (Timoshenko et al., 1921) expanded on the Euler-Bernoulli beam by incorporating shear deformations, proposing that after deformation, the sections are no longer perpendicular to the neutral axis. The action of shear forces creates a shear angle in the beam, as shown in Table 1.

Some scholars considered the real stress-strain state during tunnel fault displacement, had incorporated the effects of tunnel segmentation and joints in their theoretical analyses. Yu et al based on the Pasternak two-parameter foundation beam theory, derived an analytical solution for the longitudinal seismic response of tunnels with segmented flexible joints crossing faults. Li et al considered the impact of plastic deformation of annular joint connections on the longitudinal mechanical response of tunnels, simplifying the tunnel as a Timoshenko beam on Vlasov two-parameter foundation. He found that the mechanical response characteristics calculated by the analytical model were consistent with those obtained from model experiments and numerical calculations. Yan et al. (Yan et al., 2022) proposed elastic and viscoelastic foundation beam models to analyze the seismic response of cross-fault tunnels with flexible joints. Geng et al. (Geng et al., 2021) established a longitudinal calculation model for cross-fault shield tunnels considering the nonlinear contact effects of annular joints. For tunnels crossing faults, incorporating joints as a flexible adaptation to surrounding rock deformations is an effective seismic mitigation measure. Thus, introducing joint design into the foundation beam model, simplifying the tunnel as short beams of finite length suitable for the shear deformation of Timoshenko beams, can better simulate the actual conditions of tunnel displacement damage.

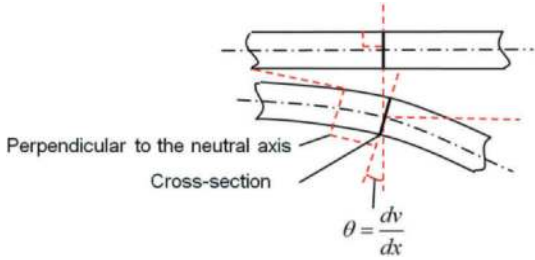

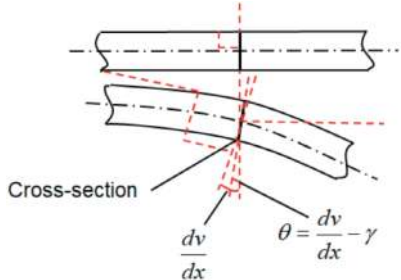

3.2 The type of foundation beam

The foundation beam model takes into account the interaction between the tunnel and the surrounding rock. The commonly used foundation beam models in cross-fault tunnels can be broadly categorized into two types based on whether they consider damping effects: elastic and viscoelastic. The elastic foundation beam includes the Winkler model, the two-parameter model, and the three-parameter model; the viscoelastic foundation models include the Maxwell model, Kelvin model, etc.

3.2.1 Elastic foundation beam

In 1867, Winkler proposed an idealized soil parameter model, the Winkler model, which assumes that the stress at any point on the foundation is directly

Table 1. The difference between Euler-Bemoulli beam and Timoshenko beam.

Type	Euler-Bemoulli beam	Timoshenko beam
Deformation characteristics	1. No shear strain; 2. The cross-section remains perpendicular to the neutral axis after deformation	1. Shear strain; 2. The cross-section does not remains perpendicular to the neutral axis after deformation
Force Analysis	Only one variable v : Vertical displacement γ : Rotation angle caused by shear deformation	Two variables v, γ
scope of application	Very long beams and thin plates.	Short beams and thick plates.
basic formula	$\theta = \frac{dv}{dx}$	$\theta = \frac{dv}{dx} - \gamma$
Sketch Map	Euler-Bemoulli beam: 	Timoshenko beam: 

proportional to the settlement of the foundation at that point. In 1954, Pasternak et al. (Pasternak et al., 1954) further expanded on the Winkler foundation model, incorporating shear effects and proposing the two-parameter Pasternak foundation beam model. In the same year, Kenney et al. (Kenney et al., 1954) showed a critical load velocity that significantly alters the response of the beam. In 1965, Kerr et al. (Kerr et al., 1965) introduced a new three-parameter foundation beam model. In 1966, Vlasov et al. (Vlasov et al., 1966) introduced a stochastic parameter γ to describe the vertical displacement distribution of an elastic foundation, proposing a modified Vlasov two-parameter foundation beam model.

Although the Winkler elastic foundation beam model involves fewer parameters, it is widely applied in industrial, agricultural, and civil building foundations, including the simulation of underground pipelines and surrounding rocks, making it the most extensively used and easily understood pipeline analytical solution model. Li et al. (Li et al., 2023) used the Winkler elastic foundation beam model to construct elastic foundation beam elements based on analytical functions. In studies of the mechanical response of cross-fault tunnels, the two-parameter foundation beam model is more common. Compared to the Winkler

elastic foundation beam, it also considers the effect of shear. Luo et al. (Lou et al., 2016) used the two-parameter elastic foundation beam model and the Timoshenko beam model to construct finite elements, suggesting that the beam base model elements are not suitable for calculations of the Pasternak elastic foundation Timoshenko beam under non-uniform load. The three-parameter foundation beam model no longer views the foundation as a single-property soil but considers the impact of different soil layers on the analytical solution, which is widely applied in the study of the impact of nearby construction on tunnels (Han et al., 2023; Feng et al., 2022). The more parameters a foundation beam model has, the more complex the calculations, but the more precise the results. Therefore, when calculating the longitudinal mechanical response of tunnels, the foundation beam model should be selected flexibly according to different external environmental conditions.

3.2.2 Viscoelastic foundation beam model

Elastic foundation beams do not account for damping factors present in practical engineering. Many scholars have gradually recognized the impact of foundation viscosity on the vibrational characteristics of foundation beams, leading to the development of

research on viscoelastic foundation beams. In 1994, Huang et al. (Huang et al., 1994) studied the dynamic response of viscoelastic Winkler foundation beams. Calim et al. (Calim et al., 2009) investigated the dynamic response of viscoelastic Pasternak foundation beams under pulse excitation using integral transforms. Fu et al. (Fu et al., 2020) considered a Timoshenko beam on a viscoelastic Pasternak foundation and studied the beam's transverse free vibration characteristics. The mechanical behavior of real foundations strongly depends on the properties of the soil, often exhibiting creep phenomena and demonstrating rheological behavior that is time- and frequency-dependent. Therefore, considering the viscoelasticity of the foundation can better reflect the coupling between the foundation and the beam.

In research on tunnels crossing faults, Yan et al. considered the impact of shear deformations and used a Kelvin viscoelastic foundation to simulate the interaction between surrounding rock and tunnel. He derived an analytical expression for the longitudinal seismic steady-state response of tunnels crossing faults. Compared to the Kelvin model, the standard solid model or the Zener model has a stronger ability to describe creep and relaxation behavior, better reflecting the mechanical behavior of viscoelastic solids. Moreover, natural faults typically exhibit segmentation in their average displacement rates and sliding modes (referred to as creep slip and viscous slip), with few cases of uniform overall sliding. However, whether it is creep slip or viscous slip displacement, the displacement caused by such scenarios in tunnels crossing faults is considered as a known condition. There is still room for improvement in process simulation.

4 THE APPROACH OF GENERAL MODEL CALCULATION

When calculating the longitudinal mechanical response of tunnels crossing faults, different foundation beam models are selected based on varying condition parameters and the desired level of detail, with more parameters making the solution process more complex. To facilitate easier computation and parameter introduction, this paper summarizes the deflection control equations of various models and provides a general calculation approach for quickly and conveniently obtaining the dynamic response analysis of foundation beams.

Based on the fundamental principles of elasticity and starting from the analysis of infinitesimal beam segments, the deflection control differential equation for the beam on the foundation is derived by introducing parameters considered during force analysis. This facilitates the analysis of the internal forces of foundation beams in different fault zones. Referring to the cross-fault diagram mentioned earlier, and taking the Pasternak foundation beam as an example, the internal forces of the beam are analyzed in segments. Parameters are introduced in 4.1 and 4.2, as detailed below:

4.1 The balance equation of tunnel

$$EI \frac{d^4 \omega}{dx^4} + p(x)b = q(x) \quad (1)$$

Where, $p(x)$ is the reaction force generated beneath the tunnel; $q(x)$ is the external load applied to the tunnel; ω is represents deflection; b is the tunnel width.

When using the Winkler foundation beam, $p(x) = k\omega$

When using the Pasternak two-parameter foundation beam:

$$p(x) = k\omega - G_p b \frac{d^2 \omega}{dx^2}$$

4.2 The control equation of beam's deflection

For an Euler-Bernoulli beam:

$$EI \frac{d^4 \omega}{dx^4} + kb\omega - G_p b \frac{d^2 \omega}{dx^2} = q(x) \quad (2)$$

For a Timoshenko beam:

$$\left(1 + \frac{bG_p \mu}{GA}\right) EI \frac{d^4 \omega}{dx^4} + kb\omega - \left(\frac{bk\mu}{GA} + \frac{bG_p}{EI}\right) EI \frac{d^2 \omega}{dx^2} = q(x) \quad (3)$$

Where, $\frac{bG_p \mu}{GA}$ is represents the beam's shear stiffness; G_p is the foundation's shear stiffness; k is foundation reaction.

4.3 Simplification of the differential equation

$$\omega^{(4)} - 4\lambda^2 \rho \omega'' + 4\lambda^4 \omega = \frac{q(x)}{EI} \quad (4)$$

Where, $\lambda = \sqrt[4]{\frac{kb}{4EI}}$, $\rho = \frac{G\lambda^2}{k}$

4.4 General solution for the deflection equation

$$\omega = e^{\alpha x} (c_1 \cos \beta x + c_2 \sin \beta x) + e^{-\alpha x} (c_3 \cos \beta x + c_4 \sin \beta x) \quad (5)$$

Where $\alpha = \lambda \sqrt{1 + \rho}$, $\beta = \lambda \sqrt{1 - \rho}$

4.5 Depending on zone to establish general solution

Assuming the fault displacement amount is y , and based on the segmentation diagram in Figure 2.

when the active fault boundary $x \rightarrow -\infty$, $\omega \rightarrow 0$;

when the active fault boundary $x \rightarrow +\infty$, $\omega \rightarrow 0$,

Therefore, the simplified formula for each zone as follows:

$$\begin{cases} \omega_1 = e^{\alpha_1 x} (A_1 \cos \beta_1 x + A_2 \sin \beta_1 x) & x < 0 \\ \omega_2 = e^{\alpha_2 x} (A_5 \cos \beta_2 x + A_6 \sin \beta_2 x) + e^{-\alpha_2 x} (A_7 \cos \beta_2 x + A_8 \sin \beta_2 x) - y & 0 \leq x \leq d \\ \omega_3 = e^{-\alpha_3 x} (A_{11} \cos \beta_3 x + A_{12} \sin \beta_3 x) & x \geq d \end{cases} \quad (6)$$

Where, A_1 、 A_2 、 A_5 、 A_6 、 A_7 、 A_8 、 A_{11} 、 A_{12} are undetermined coefficients.

4.6 Establishing boundary constraint equations

The deflection, angle of rotation, bending moment, and shear force of the tunnel structure at points A and B must satisfy continuity requirements, resulting in 8 boundary constraint equations:

$$\begin{cases} \omega_1|x=0 = \omega_2|x=0 \\ \omega'_1|x=0 = \omega'_2|x=0 \\ -EI\omega''_1|x=0 = -EI\omega''_2|x=0 \\ -EI\omega'''_1|x=0 = -EI\omega'''_2|x=0 \end{cases} \quad (7)$$

$$\begin{cases} \omega_2|x=d = \omega_3|x=d \\ \omega'_2|x=d = \omega'_3|x=d \\ -EI\omega''_2|x=d = -EI\omega''_3|x=d \\ -EI\omega'''_2|x=d = -EI\omega'''_3|x=d \end{cases} \quad (8)$$

Establishing Boundary Constraint Equations to Solve for Undetermined Coefficients.

4.7 Differentiation of the deflection curves

Further differentiation of the deflection curves yields the angle of rotation θ , bending moment M , and shear force Q in different affected zones of the tunnel:

$$\theta = \begin{cases} \omega'_1, x < 0 \\ \omega'_2, 0 \leq x \leq d \\ \omega'_3, x \geq d \end{cases} \quad (9)$$

$$M = \begin{cases} -EI\omega''_1, x < 0 \\ -EI\omega''_2, 0 \leq x \leq d \\ -EI\omega''_3, x \geq d \end{cases} \quad (10)$$

$$Q = \begin{cases} -EI\omega'''_1, x < 0 \\ -EI\omega'''_2, 0 \leq x \leq d \\ -EI\omega'''_3, x \geq d \end{cases} \quad (11)$$

5 CONCLUSIONS

This paper discusses the research progress of analytical solutions for the longitudinal response of tunnels crossing active faults, analysing factors that affect the accuracy of the analytical solution models and providing a general calculation approach for analytical solutions. The following conclusions can be drawn:

- (1) According to analyse the development of mechanical response models for tunnels crossing faults, it is observed that the foundation beam model for cross-fault tunnels adequately considers the impact of the fault fracture zone. The segmentation of tunnels with the width of the fracture zone as a boundary condition for establishing constraint equations further enhances the precision of the analytical solution. Compared to the stiffness of pipelines, the stiffness of tunnels

is greater, allowing tunnel deformations to be considered as minor under fault displacement, and the use of elastic foundation beams enables rapid calculation of tunnel deformation.

- (2) Most theoretical solutions for tunnels crossing faults use the elastic foundation beam model. Existing models have shortcomings in reflecting the geological characteristics of active faults and the dynamic properties of viscous sliding. Factors such as fault displacement rate, horizontal friction resistance, and segment joint forms are seldom involved in overall analytical solutions. The researches should fully consider the impact of these factors on the analytical solution for tunnels crossing faults to improve the accuracy of fault displacement calculations.
- (3) A general elastic foundation beam model for solving the longitudinal response of tunnels crossing active faults is proposed. The general model can modify parameters according to external conditions, addressing the issue of excessive parameters and complex solving processes in cross-fault foundation beam models. The model lays the foundation for constructing analytical elements, ultimately enhancing the efficiency and accuracy of deformation calculations.

ABSTRACT: The excavation process of large cross-section highway traffic tunnels causes significant disturbance, making it difficult to control the deformation of the surroundings. After the application of traditional support, there are often insufficient strength, buckling instability of the support structure arch, and engineering diseases such as primary support falling and intrusion. Steel-concrete composite support (SCCS) is a promoting type of support with high strength and good stability, which can provide a viable solution for the support problem in loess tunnels, however, the research on the bearing capacity of grouted π -type SCCS arch in loess highway tunnels is not sufficient. This paper conducted a large-scale ring model test to investigate the mechanical behaviour of the grouted π -type SCCS arch under typical surrounding loess pressure. The failure pattern, ultimate bearing capacity, the progressive deformation and strain development were presented via the model test. It is concluded that the ultimate bearing capacity of grouted π -type SCCS arch was 195.44 kN, and its failure presented a symmetrical deformation pattern, shaping with arch crown and arch shoulder converging inward and arch foot expanding outward, and it underwent coordinated radial deformation which was resulting that the deformation at the shoulder and foot was the most pronounced. The result is providing reliable theoretical guidance for further on-site applications.

1 INTRODUCTION

The steel-concrete composite structure fully utilizes the characteristics and performance of steel and concrete through the interaction between materials, which has advantages such as high load-bearing capacity and high stiffness. It is gradually promoted and applied as the support form in tunnel engineering (Wang et al., 2018; Wang et al., 2020; Li et al., 2015). When the tunnel is constructed in weak and fractured strata, loose soil strata and high stress strata, the case including the excessive deformation of surroundings and failure of support structures will be encountered frequently, the steel-concrete composite structure can be fully reflected the principle of strong support in the construction, which play a good supporting effect. It has good practical application significance and research value. (Wang et al. 2017; Jiang, 2016; Wang et al. 2021).

The essence of the tunnel support structure lies in protecting the bearing capacity of the surroundings and maintaining its three-dimensional stress state before being disturbed (Zhu et al. 2022; Gong et al,

2023; Gu et al, 2022). The support function of steel-concrete composite structure in tunnel construction stage is often reflected in two aspects: (1) The installation stage of the steel frame, a reasonable cross-section of the steel frame should be constructed as soon as possible to play a bearing role, achieving convenient construction and simplifying the construction process, reducing the generation of loose loads by the surroundings. (2) The pouring stage of the core concrete, the advantages of the materials are fully utilized through combined action to achieve collaborative work effects. Numerous scholars have developed different composite structures as skeleton arch structures for tunnel support based on different tunnel conditions, and have conducted in-depth research on its combined effect of bearing performance via theoretical derivation, experimental research, and on-site application. Li et al. (2016) proposed a three-dimensional constrained concrete support system for the deformation of surrounding rock in deep underground engineering, studied the mechanical performance and failure mechanism of the support system, and verified the rationality of the

*Corresponding author: wangzc@chd.edu.cn

support system through theoretical calculations and loading tests. Wang et al. (2021) used a large-scale mechanical testing system for traffic tunnel support structures to conduct large-scale mechanical performance comparison tests on composite I-steel arches, composite confined concrete arches, and single confined concrete arches, and proposed engineering suggestions for the application of confined concrete support systems in traffic tunnels. Sun et al. (2023) conducted pure bending indoor tests on steel tube concrete support structures considering the bond slip characteristics of arch concrete, and conducted in-depth analysis of the mechanical response of the components under bending moments. Wang et al. (2019) studied the failure mechanism and mechanical properties of confined concrete arches through a full-scale mechanical testing system, and obtained a formula for calculating the bearing capacity of confined concrete arches. Jiang et al. (2023) studied the mechanical properties of constrained concrete arches with different cross-sectional shapes under different load modes and cross-sectional parameters using a large-scale support structure loading system. Wang et al. (2020) used a large cross-section tunnel constrained concrete composite arch mechanical test system to study the overall bearing capacity and deformation mechanism of the composite arch, and conducted on-site applications based on the research results. Huang et al. (2018) applied the steel tube concrete support system in deep tunnels, fully demonstrating the obvious advantages of high bearing capacity and good stability of steel concrete composite support.

The above research has achieved many important results, but there are few reports on the bearing capacity of steel-concrete composite arch frame under the pressure from loess tunnel. Although Wang et al. (2021) developed π -type SCCS support system suitable for loess tunnel construction, and investigated the bearing capacity of the π -type SCCS arch without grouted via experiment. However, the failure characteristic and the bearing capacity of grouted π -type SCCS arch remains necessary to explore, where it is acting the load from surrounding loess.

This paper designed the large-scale ring model test for a grouted π -type SCCS arch based on the principle of similarity. Firstly, the grouting performance parameters were determined by conducting concrete ratio tests and compressive strength

tests, and model specimens were made subsequently. Then, it is gradually loading until the specimen failed, the deformation, strain development patterns, and failure characteristic modes of the support structure were obtained by simulating the pressure of the surrounding of loess. The result is providing reliable theoretical guidance for further on-site applications.

2 TEST MATERIAL AND SPECIMEN PROCESSING

2.1 Law of similarity

Based on the general law of similarity, the similarity of model test can be deduced by the following equation.

$$\frac{\sigma}{E} = f\left(\frac{P}{E l^2}, \frac{\gamma l}{E}, \mu\right) \quad (1)$$

Where, stress σ is correlated with the elastic modulus E , buck density γ , Poisson's ratio μ , load P , and geometric dimension l . Depending on the dimension of the model, the reduced scale is defined to $C = 10$, Prototypes and models use the same materials and the gravity is ignored. The similar relationship between prototype and model experiments is shown in Table 1. Herein, "m" represents model and "p" represents prototype.

2.2 Material used for modeling

For satisfying the requirements of the scale experiment, the grouted concrete for model test should keep flow ability and compressive strength during being packed into the hollow π type SCCS arch. The experimental material was a mixture of cement, fly ash, sand, stone ($d < 5$ mm), water, expander, and water reducer (rate of 25%) in a weight ratio of 310:80:770:1108:162:31.2:3.9 (kg/m^3), and with an age of 28 days. The properties of trial concrete are described in Table 2.

2.3 Specimen processing

1	48.4
2	46.9
3	44.5
Average value	46.6

- (2) Welded line Sealing. Before grouting the core concrete, the welded line needed to be polished and then coated with transparent glass adhesive to seal the welds to prevent slurry loss during the grouting process.
- (3) Cut the grouting hole. The grouting hole should be cut in the top of the complete specimen and it was also should be polished the opening to prevent cutting of workers.
- (4) Grouting preparation. The specimen was fixed the on the concrete vibration table and adjusted its position to keep horizontal, which is to prevent the slurry from not flowing and not being dense.
- (5) Grouting core concrete. Poured the prepared concrete into the hollow arch frame, and used steel rods for vibration to fully flow the slurry
- (6) Concrete maintenance. Sealed the injection port with plastic film to prevent water loss. Sprayed water mist on the grouting port every 3 hours to ensure the humidity and curing conditions of the concrete.

3 EXPERIMENT METHOD

3.1 Test apparatus

The laboratory test apparatus is shown in Figure 1. which has such characters: (1) the control system manages fifteen loading cylinders to accurately achieve the expected load, and each loading cylinder worked independently with a loading stroke of 230 mm, rated pressure of 10 MPa, loading accuracy of 0.175 kPa, and a minimum loading speed of 90 s/mm. (2) The pressure sensor measures the pressure in real-time and transmitted the data to the control system.

3.2 Loading pattern and observation design

One loading pattern of symmetrical loads in the spandrel was applied for reproducing the tunnels that undergo the typical surrounding loess pressure, which is summarized by the literature (Wang et al., 2023). The specific monitoring instrument layout plan is shown in Figure 2.

3.3 Test method

The flowchart of the scale experiment is described in Figure 3. The experiment adopted graded level for

Figure 1. Test loading system.

Figure 2. Monitoring instrument layout plan.

loading, the preload setting should not exceed 2% of the ultimate load, and the formal loading should begin after 5 minutes of holding pressure. The formal loading was set as one level every 0.5 kN, the loading rate was set to 0.05 mm/s, and the holding time was set to 5 minutes. Except the oil cylinders of F7-F10 as the passive carrying cylinders, which provided the reaction, each loading level ensured synchronous for each oil cylinder, maintaining a 2:1 loading ratio between F3, F4, F13, and F14 oil cylinders and other loading cylinders. The test was stopped until the specimen was loaded to the point of destruction.

4 TEST RESULTS

(1) Overall failure mode

The deformation of the specimen continued to increase with increasing load. When the load of the single oil cylinder continued to increase to 16 kN, the internal weld nodes of the arch foot collapsed, causing local wrinkles and bulges. At the same time, the arch bottom gradually converged inward and undergoes bending deformation. However, the overall integrity of the arch frame was good and can continue to bear the load. When the load increased to 22 kN, there was a large area of paint peeling and wrinkling damage at the arch foot. Through out the cracks, it

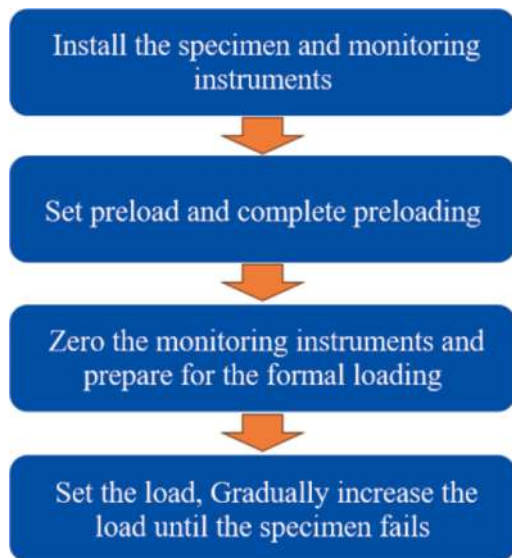

Figure 3. Loading test process.

can be clearly seen that the core concrete was broken, and the arch frame was unstable and damaged. The damage basically follows a symmetrical distribution, as shown in Figure 4.

(2) Displacement variation characteristics

Figure 5 shows the load displacement relationship curve of the single oil cylinder in the key parts of the arch frame. It can be found that the load of F3-4 and F13-14 was twice that of other active loading cylinders, and the loading synchronization of each cylinder was good, meeting the preset load conditions of the test. Until the time was reaching 4813s, the load displacement curve of each oil cylinder (as shown in Figure 6) showed a turning point, and the total load borne by the arch began to decrease. At this point, the ultimate bearing capacity was 195.44 kN. It is worth noting that as a key part of transmitting the upper load, the arch foot generated local stress concentration, which resulted in the load of F6 and F11 cylinders being much greater than that of other cylinders.

Figure 4. Overall failure of arch frame.

At the end of the loading test, the maximum positive displacement of the arch was at the arch shoulder (31.87 mm), and the maximum negative displacement occurred at the left arch foot (-15.23 mm). This is because after applying double the load on the symmetrical arch shoulder, resulting in coordinated radial deformation and transmitting the force to the lower part. The arch foot was located in the stress concentration area, with the maximum force, resulting in outward extrusion deformation, negative displacement, and accompanied by local wrinkles and buckling.

Figure 5. Load displacement curve.

(3) Strain variation characteristics

According to Figure 7, the strain distribution at the same position of the arch showed a symmetrical development trend. The average strain of Y1 measuring point was $2065 \mu\epsilon$, the strain of Y1 was 1.809 times greater than the elastic-plastic threshold strain. The maximum strain was the circumferential strain of the lower flange, which was $-5776 \mu\epsilon$.

Figure 6. Total load time curve.

Figure 7. Strain of steel arch frame at Y1 measurement point.

5 CONCLUSION

This paper was based on the principle of similarity to create a 1:10 large scale model test for investigated the mechanical property of the grouted π -type SCCS arch, and conducted failure tests using a large underground engineering loading platform. The test was under the pressure of loess surroundings simulated by applied the symmetrical biased loads. It was focus on the tunnel support with its failure form, strain and displacement development law, and bearing capacity. The following conclusions are drawn in this article:

- (1) The grouted π -type SCCS arch exhibited a symmetrical deformation pattern with the shape of “the crown and shoulder converging inward, and arch foot expanding outward”.
- (2) The ultimate bearing capacity of the grouted π -type SCCS arch was 195.44 kN, and the steel section showed the highest stress on the lower flange.
- (3) The grouted π -type SCCS arch underwent coordinated radial deformation and it is resulting that the deformation at the shoulder and foot was

most pronounced, the stress concentration and buckling of the foot were damage-prone areas which should strengthen the bearing design.

ABSTRACT: Tunnel is frequently necessary to cross the active fault zone due to the constraints of geological conditions and route design. In this study, a three-dimensional finite element model of large-scale tunnel crossing normal fault is created based on the second underwater tunnel project in Jiaozhou Bay, Qingdao. The width of the deformation joint is the primary element that influence the deformation and stress of the tunnel. The findings indicate that when the width of the deformation joint is between 0.1 m and 0.2 m, it may effectively reduce the abrupt change of the staggered platform at the intersection of the tunnel and the fault zone, and there are no overt benefits or drawbacks. The first principal stress distribution pattern in the cross-section of a tunnel follows the sequence of Hance < Invert < Arch foot < Spandrel < Crown.

Keywords: Mining tunnel, Normal fault, Fault dislocation, Anti-fault measures, Joint width

1 INTRODUCTION

The vast territory of China has a complex and diverse geography. Localized tectonic plates are shifting, and numerous active faults may be seen everywhere. China is presently constructing its transportation infrastructure quickly thanks to the traffic power plan idea, and the advancement of line traffic engineering will usher in a new peak hour. The active fault zone will have to be crossed by several mining tunnels^[1-2].

A type of geological risk with fault structural features is active fault dislocation. The upper and lower plates move in relation to one another as a result of the fault dislocation, which creates complicated spatial three-dimensional deformation and stress characteristics. The tunnel will encroach on the limit, fracture, experience severe deformation, and potentially collapse as a result of the fault's displacement. Numerous instances have demonstrated that the cross-fault tunnel has resulted in significant damage as a result of fault dislocation^[3]. For instance, the Longdongzi tunnel^[4, 5] in the Longmenshan fault zone was severely damaged in the 2008 Wenchuan earthquake, with damage including the slope collapse at the right line's exit,

rockfall at the left line's entrance section, cracking at the left line portal's end wall, circumferential staggered platform damage, secondary lining collapse at the upper side wall, top arch, and more. As an example, the Shigangba diversion tunnel in the active Chelongpu fault region had a shearing slip in the 1999 ChiChi earthquake with a numerical dislocation of 4 m and a horizontal dislocation of 3 m^[6].

The mechanical reaction of cross-fault tunnels to fault dislocation is now being researched both domestically and internationally. Through the use of model tests, Liu et al.^[7, 8] investigated the mechanical reaction of the tunnel under various dip angle reverse fault conditions. Through the use of a numerical model using the finite difference technique, Zhao^[9] investigated the stress and deformation law of tunnel lining under the influence of reverse fault dislocation and described the failure form of tunnel lining. By developing a comprehensive mechanical model of the buried pipeline-soil, Jin & Li^[10] examined the pipeline's buckling stability under the influence of a thrust fault. Karamitros^[11] estimates the stress distribution properties of subterranean pipelines

*Corresponding author: qiwang@swjtu.edu.cn

under the influence of fault dislocation through theoretical analysis. When it comes to fortification techniques for navigating an active fault tunnel, it is common practice to increase the lining section, shorten segment length, install shear joints, and other strategies^[12]. For the Wushaoling Tunnel spanning the F7 active fault, Liang et al.^[13] conducted the extended section design with a reserved displacement of 100 years. In order to strengthen the structural toughness of the tunnel and pass through active faults, Yang^[14] suggests applying high toughness cement-based composite (ECC) to the weak spot of the tunnel lining and to a mountain tunnel. Russo^[15] uses the Bolu tunnel in Turkey as an example and discusses geometric deformation and load distribution.

As can be observed, the research mentioned above findings provide a valuable point of reference for investigating the mechanical response and failure mechanism of cross-fault tunnels under the influence of fault dislocation. They also establish a framework for the investigation of cross-fault tunnel fortification techniques. However, various areas, different structures, and different types of active faults have extremely diverse impacts on tunnels because of the periodic dislocation of these faults. Thus, the second underwater tunnel in Jiaozhou Bay, Qingdao, is used as an engineering example in this work. The tunnel that crosses the active fault using the mining approach is simulated using the finite element method. A comparison is made between the sensitivity of the tunnel construction to deformation joint width. Technical reserves for engineering construction are provided by studying the tunnel's deformation and stress characteristics.

2 NUMERICAL MODELS AND ASSUMPTIONS

2.1 Project overview

Shibei District of Qingdao City and Huangdao District are connected by the second underwater tunnel over Jiaozhou Bay in Qingdao. The entire tunnel is 17.48 km long, of which 14.36 km is the main line tunnel. Drilling and blasting and the shield method

are the combined construction schemes used in this tunnel (Figure 1). The entire tunnel is situated in the North China fault block area, where the fault structure is developed, according to the geological survey report of the engineering site and the seismic safety evaluation report of the site. The tunnel in the drilling and blasting section in the sea area primarily passes through the Cangkou fault.

The Cangkou Fault is located on the eastern margin of the Jiaoliao-Taihang Uplift in the North China Craton. The Muping-Jimo Fault Zone's southern region has a significant Late Pleistocene active fault that is distinguished by its normal fault characteristics. The fault dips to the northwest (NW), trends northeast (NE), and generally has a rather straight track. The severe dip angle of the fault is typically between 70° and 88°, with occasional local variations between 60° and 80°. The abrupt displacement in a century is predicted to be 0.49 m, and the typical fault fracture zone width is 50 m. The second underwater tunnel's mining portion will cross the southern part of the Cangkou fault in Jiaozhou Bay in Qingdao at an angle of roughly 80 degrees, which will have a significant impact on the project.

In order to examine the impact of width of deformation joints on the anti-dislocation performance of the tunnel, this research investigates the dynamic response of a mining tunnel with different width of deformation joints under the action of a normal fault dislocation.

Tunnel	Concrete grade	Elastic modulus	Density	Poisson's ratio
	C40	32.5 GPa	2500 kg/m ³	0.2

2.2 Model parameters and boundary conditions

A three-dimensional finite element calculation model is created in the finite element program ABAQUS^[16] in accordance with the particular engineering geology and mining technique tunnel section, as illustrated in Figure 2. The model's overall dimensions are length×width×height=360 m×105 m×130 m, with a tunnel depth of 80 m. The Cangkou fault zone has a width of 50 m, a dip angle of 75 degrees, and a tunnel construction that traverses an active fault. The tunnel and soil layer are in a coulomb friction contact, the normal direction is in a hard contact, and the tangential friction coefficient is 0.8^[17-18]. The model's upper surface is considered to be a free surface, the remaining lower portion is subject to normal fixed restrictions, and the lower surface of the upper plate of the model is subject to a vertical displacement of 49 cm in order to replicate the normal fault dislocation. The Mohr-Coulomb constitutive is adopted by the surrounding rock, whereas the isotropic elastic constitutive is adopted by the deformation joints and the tunnel. Table 1 displays the physical and mechanical properties of the formation as per the engineering geological survey report. The main structure of the tunnel is made of C40 concrete, and the tunnel deformation joints are considered to be flexible materials. The elastic modulus is 325 MPa (0.01×E_{C40}), and the density is 1.12×10³ kg/m³. Model parameters are listed in Table 2.

2.3 Calculated cases

Two different joint width are merged, as shown in Figure 3. With 0.1 and 0.2 m of width for vertical joint. Of these, the vertical deformation joint is perpendicular to the tunnel axis. The specific cases are shown in Table 3.

3 RESULTS

3.1 Effect of deformation joint width

It is discovered that the fault table amount of each section is essentially the same, which is restricted to the space, after the fault table amount of the cross section with the deformation joint width of

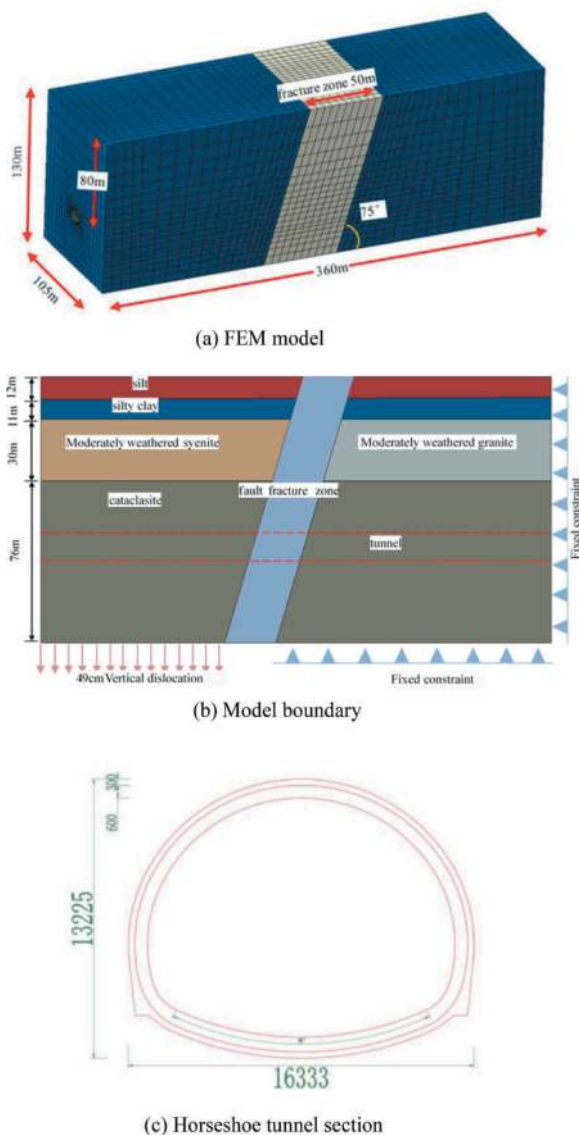

Figure 2. Schematic diagram of calculation model.

0.1 m and 0.2 m is extracted, respectively. As seen in Figure 4, it only provides the incorrect table quantity for the vertical joint. The distribution law is comparable, the peak value of the incorrect tables under the width of the two types of deformation joints is not significantly different, and the rapid

Table 3. Design cases of deformation joint.

Case	Burial depth (m)	Modulation length (m)	Expansion joint form	Joint width (m)
1	80	12	Vertical tunnel axis	0.1
2	80	12	Vertical tunnel axis	0.2

change of the incorrect platform happens at the deformation joint's location. It is important to note that for vertical seams, the amount of fault of two deformed joints surpasses 2 cm when the width of deformable joint is 0.1 m. However, only one deformation joint has more incorrect platforms at the arch waist than 2 cm when the deformation joint's width is 0.2 m. It demonstrates that a wider deformation joint within a suitable range helps to enhance the deformation performance of the tunnel that through the fault.

Figure 3. Schematic diagram of calculation cases.

3.2 Deformation distribution

The maximum amount of incorrect platform among the five tunnel monitoring locations is determined by comparing the deformation and the amount of incorrect platform for each type

of deformation joint, as indicated in Table 4. The extreme value of the incorrect platform at the tunnel's arch waist is often much greater than its values at the other four measuring places, suggesting that the shear failure there is the strongest. Additionally, the quantity of staggered abutment in the tunnel is decreasing from the arch waist to the arch crown and inverted arch, suggesting that the deformation of the staggered abutment is centered at the arch waist and progressively extends to the higher and lower sides.

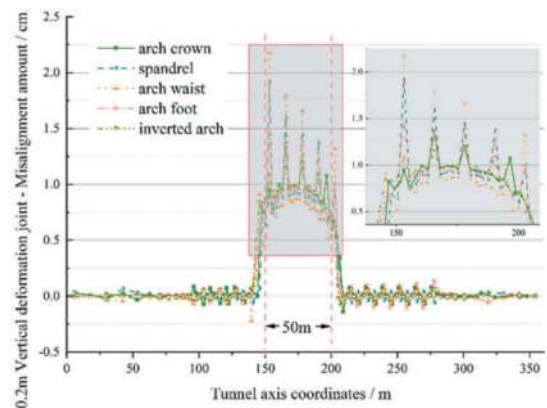

When comparing the breadth of deformation joints, there is no discernible difference between 0.1 m and 0.2 m, although there are fewer deformation joints under 0.2 m that have displacement of more than 3 cm at the arch waist. It is evident that when it comes to enhancing the deformation performance of the tunnel that crosses the active fault zone, the case of 0.2 m performs better than the case of 0.1 m. Under cases of 0.1 m and 0.2 m, the width of the deformation joint has no discernible influence, and it is not seen that the deformation of the tunnel grows considerably as the width of the deformation joint increases. The displacement of the tunnel abutment at the junction and fault zone is very minor. The dislocation deformation will be somewhat lessened when the deformation joint width is 0.2 m.

Table 4. Extreme value of dislocation of tunnel structure under different joint width (cm).

Location	Case 1	Case 2
Crown	2.085	1.357
Spandrel	2.237	1.918
Wist	2.253	2.178
Arch foot	2.106	1.473
Invert	2.140	1.189

(a) Joint width 0.1m

(b) Joint width 0.2m

Figure 4. The amount of vertical deformation joints of tunnel with different width of deformation joints.

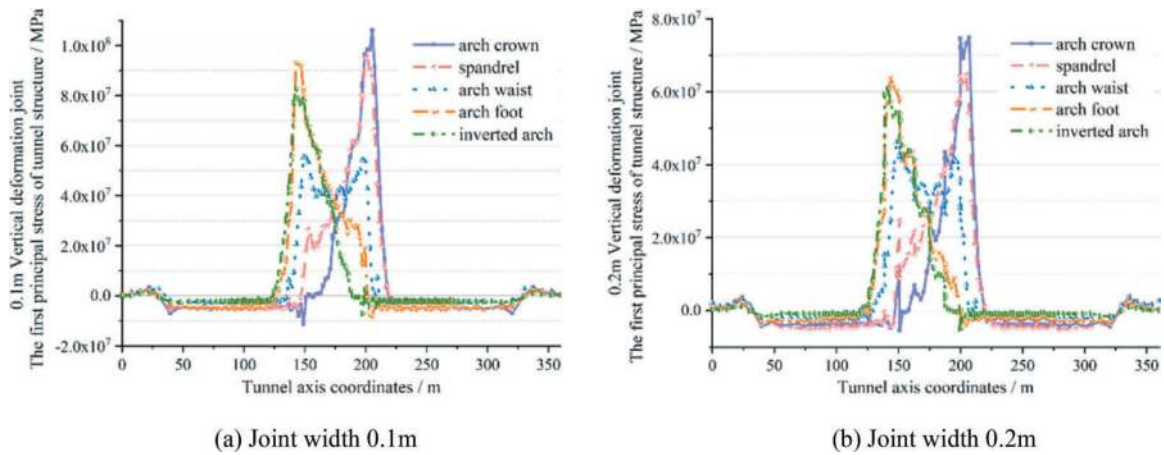

Figure 5. Stress distribution of tunnels with different deformation joint widths.

3.3 Stress distribution

The first principal stress of the cross section of the tunnel structure is extracted as shown in Figure 5. From a numerical perspective, the highest main stress of the tunnel with a 0.1 m deformation joint is 107.0 MPa, whereas the maximum principal stress with a 0.2 m deformation joint is 75.69 MPa, representing a drop of 29.26%. This is due to the breadth of the deformation joint. Tunnel stress dramatically reduces with increasing deformation joint width, and the broader deformation joint may effectively mitigate the effects of active faults on the tunnel.

Regarding the two cases, the law of arch waist < inverted arch < arch foot < arch shoulder < vault applies to the initial primary stress of each segment of the tunnel cross section. The first primary stress at the inverted arch, arch foot, arch shoulder, and vault is shown by the longitudinal distribution as a single peak, whereas the arch waist displays a double peak. The peaks are all situated near the fault plane, suggesting that the fault displacement causes visible stress at the lower wall tunnel's vault and shoulder as well as the upper wall tunnel's inverted arch and arch foot. There is clear stretching of the lining on the upper and lower fault planes at the arch waist.

4 CONCLUSIONS

The following conclusions are made for the peculiar normal fault dislocation form of the Jiaozhou Bay Second Submarine Tunnel Project in this research based on the finite element analysis of the anti-normal fault dislocation and taking into account the impact of width of deformation joints:

- (1) The 49-cm displacement of the normal fault clearly caused deformation in the tunnel. Furthermore, the locations of the deformation joints in the fault zone and the intersection of the fault plane with the upper and lower walls are where

the majority of the fault platforms are found. As one moves away from the fault line, the misalignment rapidly diminishes and the deformation fluctuation is contained to a radius of about 10 m beyond the fault plane. The vertical seam may deform by approximately 1 cm.

- (2) The law of arch waist<inverted arch<arch foot<arch shoulder<vault is the first principal stress distribution of the tunnel cross section, according to research and analysis of the stress characteristics of the tunnel lining. This is because fault dislocation-induced earth pressure acts on various areas of the tunnel.

Analysis of issues in the theory and calculation methods of composite lining for hard rock tunnels

Ning Wang & Xiangjun Yang

China Railway Academy Co., Ltd., Chengdu

ABSTRACT: Currently, in the design of tunnels for highways and railways in China, the use of composite lining or segmental lining for support is more prevalent, with very few instances of employing single-layer lining as a support method. For hard rock tunnels, the surrounding rock itself possesses inherent stability. However, adhering to conventional Chinese design methods necessitates the use of composite lining, leading to significant material waste, low construction efficiency, and slow project progress. Through literature review and theoretical analysis, this paper addresses the current design situation and existing regulations. It provides insights into the methods and analyses employed in the current theoretical framework for composite lining in China, focusing on rock classification methods, surrounding rock pressure, and lining structure calculations. The paper identifies the irrationalities in the existing theory and design methods for hard rock composite lining in China and offers recommendations for improving the design of lining structures in hard rock tunnels in China.

Keywords: Hard Rock, Surrounding Rock Analysis, Lining Design, Problem Analysis

1 INTRODUCTION

Since the establishment of the People's Republic of China in 1949, the country's infrastructure was in dire need of development. The nation embarked on railway construction projects, with railways such as Chengdu-Chongqing, Tianjin-Lanzhou, and Baoji-Chengdu successively commencing construction. With the introduction of advanced foreign concepts, the construction of the 14.295-km Dayaoshan Extra-Long Tunnel, designed and constructed using the New Austrian Tunneling Method (NATM), began smoothly, marking a rapid development in China's railway tunnel construction technology^[1]. Through continuous research exploration and the summarization of design and construction experiences, several tunnels such as Nanling Tunnel, Liupanshan Tunnel, and Yuntai Mountain Tunnel were successively completed^[2]. In 1988, the former Ministry of Railways compiled the Guidelines for the New Austrian Tunneling Method in Railway Tunnels^[3], signaling the transition of China's railway tunnel construction from traditional mining methods to the "New Austrian Tunneling Method." Since the beginning of the 21st century, data indicates that by the end of 2021, the total number of operational railway tunnels reached 17,532, with a total length of 21,055 kilometers. Among them, 734 new operational railway tunnels were added, contributing 1,425 kilometers to the total length. Additionally, there are 23,268 road tunnels with a cumulative length of

24,698.9 kilometers, including 1,952 new operational road tunnels spanning 2,699.6 kilometers^[4]. China has truly become a tunneling powerhouse. After more than 40 years of rapid development, China's tunnel construction technology has achieved significant technological innovations in theoretical research, special soils, shield tunneling, and other aspects^[5].

In the process of rapid development, some issues arise. Through researching the construction of hard rock tunnels both domestically and internationally, it is observed that in China, the use of single-layer lining as a permanent support method is relatively rare, and its widespread application is far less than in foreign countries^[6]. Compared to composite lining, single-layer lining has various advantages such as simplified procedures, rapid construction, and economic feasibility. Foreign practices have also demonstrated that single-layer lining can meet durability requirements. However, in the field of hard rock, its extensive use has not been widely explored in China^[7]. To investigate this issue, we start by examining the current status of tunnel design in Chinese railways and highways, contrasting it with the design concepts and methods used in hydraulic tunnels. We analyze the shortcomings in the existing analysis and design of hard rock tunnel surrounding rock from the perspective of commonly used standards and methods in engineering design.

Hard rock primarily refers to grade I to III surrounding rocks with uniaxial compressive strength greater than 30 MPa.

2 DEFINITION AND CHARACTERISTICS OF HARD ROCK

The tunnel structure is located within the surrounding rock, and its structural integrity, stability, and the surrounding rock are closely interrelated. Different types of surrounding rock correspond to different forms of damage^[8]. Wang Tao^[9] believes that accurately assessing the quality of tunnel surrounding rock and providing a rational tunnel design scheme are the foundation for ensuring construction safety. Designers need to conduct in-depth analyses of the deformation and failure patterns of surrounding rock during tunnel construction, and provide timely and accurate scientific evaluations of the stability of tunnel surrounding rock to ensure construction safety and personnel safety^[10]. Therefore, when investigating the surrounding rock and design issues of hard rock tunnels, it is necessary to first summarize and analyze the relevant conditions based on domestic rock analysis.

The determination of the hardness of rocks can be done through various methods, including uniaxial saturated compressive strength determination, Young's modulus determination, and point load testing. Different standards have subtle differences in the definition of hard rock, but mainly rely on qualitative and quantitative criteria. Standard for Engineering Classification of Rock Mass (GBT50218-2014)^[11], Code for Design of Railway Tunnel (TB 10003-2016)^[12], Specifications for Design of Highway Tunnels (JTG 3370.1-2018)^[13], Code for Geotechnical Investigations of Urban Rail Transit (GB 50307-2012)^[14], and Code for Hydro-power Engineering Geological Investigation (GB 50287-2016)^[15], each standard classifies hard rock as follows:

For quantitative classification of hard rock, domestic standards universally use saturated uniaxial compressive strength (f_r) for determination. The standards generally consider $f_r > 30\text{MPa}$ as hard rock, and $f_r \leq 30\text{MPa}$ as soft rock. Therefore, when conducting the analysis, this criterion serves as the basis for the assessment.

3 ROCK MASS CLASSIFICATION

The foundation of tunnel design in China relies on rock mass classification, where different rock mass grades have a decisive impact on the choice of tunnel support methods and support parameters.

Therefore, it is essential to conduct a research analysis of the relevant regulations on rock mass classification in various domestic industry standards.

3.1 Relevant regulations in standards

(1) Relevant provisions of the Standard for Engineering Classification of Rock Mass (GBT50218-2014) and Highway Tunnel Design Code (JTG 3370.1-2018) are as follows:

Both standards have similar requirements for rock mass classification, employing both qualitative and quantitative methods. During engineering classification, it is necessary to consider both qualitative and quantitative classifications, mutually validating each other to obtain a more accurate rock mass classification.

The qualitative characteristics of the rock mass's basic quality are determined by two factors: rock hardness and rock integrity. The combination of these factors allows for a qualitative classification of the rock mass's basic quality, as detailed in Table 1.

The quantitative division of rock mass basic quality adopts a comprehensive index method composed of multiple parameters. Two quantitative indicators, the rock saturated uniaxial compressive strength (R_c) and the rock mass integrity index (K_v), are used as parameters to calculate the rock mass basic quality index (BQ). This index serves as the quantitative basis for classification. The basic quality index, formed by and, can be expressed in various mathematical forms, with popular methods including the product-quotient method and the sum-difference method.

The standard employs stepwise regression, stepwise discrimination, and other methods to establish and validate the calculation formula for the basic quality index (BQ), which belongs to the sum-difference model. The calculation model considers and as factors, with BQ as the dependent variable. Through regression comparison, a binary linear regression formula with two specified conditions is selected. During application, coefficients are adjusted based on engineering practicalities. The final result is an existing formula with good rationality, as shown in Equation 1.

$$BQ = 100 + 3R_c + 250K_v \quad (1)$$

When conducting detailed classification of rock mass quality, if there is the presence of groundwater,

Table 1. Rock basic quality qualitative classification.

	Intact	Slightly Intact	Moderately Fractured	Fractured	Extremely Fractured
Hard Rock	I	II	III	IV	V
Moderately Hard Rock	II	III	IV	IV	V
Moderately Soft Rock	III	IV	IV	V	V
Soft Rock	IV	IV	V	V	V
Extremely Soft Rock	V	V	V	V	V

the stability of the rock mass is influenced by structural planes, and there exists a set of controlling factors, and the engineering rock mass exhibits three initial stress states characterized by the strength-to-stress ratio, it is necessary to adjust the rock mass basic quality index (BQ) accordingly, as detailed in Equation 2. The rock mass classification is then determined based on the modified engineering rock mass quality index obtained.

$$[BQ] = BQ - 100(K_1 + K_2 + K_3) \quad (2)$$

In the equation:

[BQ]-the underground engineering rock mass quality index.

K_1 -the correction coefficient for the influence of groundwater in underground engineering.

K_2 -the correction coefficient for the influence of the main structural orientation in underground engineering.

K_3 -the correction coefficient for the influence of the initial stress state.

(2) Relevant provisions of the Code for Design of Railway Tunnel (TB 10003-2016) are as follows:

The Railway Design Code align with Table 1 in the classification of rock mass quality. However, their classification is more detailed, not only categorizing based on the hardness and integrity of the surrounding rock but also relying on qualitative assistance from engineering geological features, structural characteristics, and the intact state after surrounding rock excavation. Additionally, quantitative rock mass classification is performed using the elastic longitudinal wave velocity of the surrounding rock.

(3) Relevant provisions of the Code for Hydropower Engineering Geological Investigation (GB 50287-2016) are as follows:

Three indicators, namely rock strength, rock integrity, and rock structure type, serve as the basis for preliminary classification. The quantitative rock mass classification primarily adopts the Hydropower Classification (HC) method^[16]. This method uses the total score of five factors – rock strength (A), rock integrity (B), structural plane condition (C), groundwater (D), and main structural orientation (E) – to control the stability of the surrounding rock, as indicated in Equation 3. The rock mass strength-to-stress ratio (S) is used as the limiting criterion, and the determination table is provided in Table 2.

$$T = A + B + C + D + E \quad (3)$$

In addition to the classification specified in this code, the Geological Investigation Code for Hydropower Engineering stipulates that the classification of rock mass in large-span underground chambers should also undergo comprehensive evaluation based on other relevant national standards. Furthermore, international commonly used rock mass classifications, such as the Q system classification, can be used for comparison.

Table 2. Basic quality classification table for rock mass in hydraulic engineering.

Rock Mass Category	Total Evaluation Score (T)	Rock Mass Strength-to-Stress Ratio (S)
I	$T > 85$	> 4
II	$85 \geq T > 65$	> 4
III	$65 \geq T > 45$	> 2
IV	$45 \geq T > 25$	> 2
V	$T \leq 25$	-

3.2 Summary and problem analysis

(1) The engineering rock mass classification standard belongs to the second-level general standard of national standards^[11]. It is applicable to rock engineering in various departments and industries, covering different types of rock engineering such as mines, tunnels, waterworks, railways, and highway tunnels, as well as various underground chamber projects like underground factories, mining areas, and underground warehouses. Code for Design of Railway Tunnel, Specifications for Design of Highway Tunnels, Code for Geotechnical Investigations of Urban Rail Transit, and Code for Hydropower Engineering Geological Investigation serve as technical standards for their respective industries.

The engineering rock mass classification standard and the rock mass classification provisions for hard rock in railway tunnels and highway tunnels are essentially consistent. They mainly use the BQ method for rock mass classification, supplemented by qualitative judgments for final determination.

In contrast, the hydropower industry, as outlined in the mentioned code, uses the HC method for classification, with additional correction based on the rock mass strength-to-stress ratio. It is noteworthy that, for the first time, the code suggests that the rock mass in large-span underground chambers in hydropower engineering can be compared using internationally recognized rock mass classifications such as the Q system classification.

(2) The BQ method, HC method, and Q system method have classification indicators as shown in Table 3. All three rock mass classification methods incorporate rock strength, rock integrity, groundwater, and initial stress state indicators into the classification factors. Among them, the Q system method and HC method consider structural plane condition indicators, while the BQ method considers the relationship between structural planes and the tunnel axis.

The BQ method for rock mass classification employs two main indicators as control factors, supplemented by other factors for result correction. Similar to the Q-system, the BQ method relies on the sum and difference method for calculation. The main indicators in the BQ method

Table 3. Classification parameter indicators for rock mass classification methods.

Classification Parameter Indicators		Q System Method	HC Method	BQ Method
The primary indicators	Rock Strength	SRF	A, Rb	Rc
	Rock Integrity	RQD, Jn	B, Kv	Kv, Jv
	Groundwater	Jw	D	K ₁
	Initial Stress State	SRF	S	K ₃
	Structural Plane Condition	Jr, Ja	C/E	-
	Relationship Between Structural Plane and Tunnel Axis	-	-	K ₂

are chosen for their convenience and efficiency, but the wide range of values for various correction parameters places a high demand on the experiential knowledge of geological and design personnel^[17].

In the BQ method, the compressive strength of the rock mass (R_c) holds a disproportionately significant weight in the BQ value. This overemphasis on compressive strength limits the application of the BQ method in hard rock tunnels under high stress conditions. According to Wang Guangde's research^[16], the BQ method demonstrates the lowest correlation with actual rock mass categories in hard rock tunnels compared to the RMR, Q-system, and the hydropower sector's HC classification method. Chen Lixiang^[18] conducted regression analysis on the correlation between BQ method rock mass classification and Q-system rock mass classification based on actual engineering geological conditions. The obtained relationship curve has a correlation coefficient of 0.788, indicating a relatively weak correlation between BQ values and Q values.

The HC method for rock mass classification determines classifications based on five main factors. Among these factors, rock strength, rock mass integrity, and structural plane conditions have a significant impact on the results, while the influence of groundwater and structural plane orientation is relatively minor^[19]. Wang Tao et al.^[20], through literature research, found a high degree of consistency between the HC method and the Q system in assessing rock mass quality. They conducted regression analysis on a large amount of data from the literature, establishing a relationship equation between HC values and Q values with a correlation coefficient of 0.866. This indicates a significant correlation between the HC method and the Q system in evaluating rock mass quality.

The Q-system rock mass classification employs six basic parameters for classification determination. It comprehensively considers geological factors, and

its calculation formula is clear. It utilizes a product calculation method and is applicable under various stress conditions. It is mostly suitable for formations of medium to hard rock and is less suitable for soft or weak formations.

- (3) Based on the above, the BQ classification method widely used in most domestic industries demonstrates better applicability in the field of soft rock, while its application in the field of hard rock is less satisfactory. It is recommended that, in the future, for the surrounding rock analysis of hard rock caverns, the HC method used in hydraulic tunnels or the adoption of the Q classification method from foreign sources be considered for rock mass classification.

4 SURROUNDING ROCK PRESSURE

The determination of surrounding rock pressure is a prerequisite for tunnel design and a fundamental research topic in the field of tunnel engineering^[21]. The rational determination of tunnel surrounding rock pressure not only ensures the safety of the design but also influences its economic feasibility. In the design specifications for railway and highway tunnels in China, provisions are made for surrounding rock pressure. The specifications for the surrounding rock pressure of rock caverns in urban rail projects are implemented according to the standards of railway tunnel design specifications. This article only presents normative clauses related to the surrounding rock pressure of hard rock caverns, limited by space constraints, and does not list all related regulations.

4.1 Relevant specification provisions

- (1) The Code for Design of Railway Tunnel (TB10003-2016) adopts the calculation formula for the surrounding rock pressure of deep-buried tunnels as shown in Equation 4:

$$q = 0.45 \times 2^{S-1} \times \gamma w \quad (4)$$

In the equation:

- q-the vertically distributed pressure;
- S-the rock mass classification;
- R-the rock mass density;
- W-the width influence coefficient, $w = 1 + i(B - 5)$;
- B-the tunnel width;
- i-The rate of change of surrounding rock pressure for each additional 1 meter:when $B < 5\text{m}$, i is set to 0.2; when $B > 5\text{m}$, i is set to 0.1.

- (2) In the Specifications for Design of Highway Tunnels (JTG3370.1-2018), the formula for calculating surrounding rock pressure is stipulated to be the same as Equation 4, but with slight adjustments to the width correction coefficient i .

- (3) In the Guidelines for Design of Highway Tunnel (JTGT D70-2010), the calculation of surrounding rock pressure is specified as follows:
- The loose rock pressure is the sum of the pressure acting on all tunnel support structures. When calculating internal forces for initial support or secondary lining, an appropriate method should be employed for load distribution to determine the corresponding calculated load for the support layer.
 - For shallow-buried tunnels, only the loose rock pressure should be considered. For deep-buried tunnels, not only should the loose rock pressure be taken into account, but also the deformation pressure of the surrounding rock. For continuous arch tunnels and tunnels with small clearances, the deformation pressure may be omitted.
 - The vertical surrounding rock pressure in deep-buried tunnels can be calculated using the Prandtl formula or a method similar to Equation 4. The horizontal surrounding rock pressure aligns with the specifications in both railway tunnel design codes and highway tunnel design codes.
- (4) In the Code for Hydropower Engineering Geological Investigation (NB_T 10391-2020), the calculation of surrounding rock pressure and in-situ stress should comply with the relevant provisions of the current industry standard Load Standards for Hydraulic Structures (GB/T 51394-2020). The relevant provisions of Load Standards for Hydraulic Structures are as follows:
- For surrounding rock with good self-stabilizing conditions and stable deformations after excavation, the surrounding rock pressure may be omitted in the design of permanent support structures.
 - When measures such as anchor spraying support or steel frame support are taken during the excavation process, resulting in the basic stability of the surrounding rock, the design should consider minimal or no impact of surrounding rock pressure on permanent support structures.
 - For blocky, medium-thick to thick-layered structures of surrounding rock, the standard value of surrounding rock pressure can be determined based on the gravitational effects of unstable rock blocks within the surrounding rock.
 - For thin-layered and fragmented, loose structures of surrounding rock, the loosened portion of uniformly distributed surrounding rock pressure is recognized as 0.2 to 0.3 times the excavation width of the tunnel.
 - For shallow-buried tunnels where a stable arch cannot be formed, the standard value of surrounding rock pressure should be calculated based on the gravitational effects of the overlying rock mass on the tunnel arch, with adjustments made according to the construction measures adopted.

4.2 Summary and problem analysis

Comparing the various specifications regarding the regulations on surrounding rock pressure leads to the following conclusions:

- (1) The methods used for calculating surrounding rock pressure differ among the specifications. The methods for calculating surrounding rock pressure in highway and railway tunnel design specifications are generally consistent. However, the highway tunnel design guidelines sometimes apply the Prandtl theory to calculate surrounding rock pressure. This can result in significant differences in the calculated surrounding rock pressure compared to that obtained from highway tunnel design specifications, significantly impacting structural design.
- (2) The existing formulas for calculating surrounding rock pressure in railway and highway tunnel design specifications are based on statistical data from 127 single-track tunnels with 417 construction collapse data, including the Chengkun and Guikun railways. These formulas assume that the self-weight of the collapsed rock mass acts entirely on the lining structure, using the self-weight of the collapsed rock and soil as the basis for surrounding rock pressure^[22]. For rock tunnels, there is a critical block effect, and the instability of a critical block can trigger a chain reaction, leading to collapse. However, if the critical block is stabilized through methods such as shotcrete or anchor reinforcement, the surrounding rock pressure on the lining structure is much less than the self-weight of the collapsed rock mass statistically obtained. This results in calculated surrounding rock pressure values for hard rock tunnels being much higher than the actual values, affecting the economic feasibility of lining structure design.
- (3) The design specifications for hydraulic tunnels differ significantly from those for railway, highway, and subway tunnels. Hydraulic tunnels do not use collapse statistical formulas for calculating surrounding rock pressure in hard rock caverns. Instead, they employ different methods based on the specific nature of the surrounding rock. In completely stable caverns, surrounding rock pressure may be disregarded. For locally unstable caverns, only the pressure from locally unstable blocks is considered. For thin-layered and fragmented, loose structures of surrounding rock, the surrounding rock pressure is approximately 0.2 to 0.3 times the width of the tunnel excavation. Under conventional spans, the calculated surrounding rock pressure is less than that specified in railway, highway, and urban rail regulations.
- (4) Zhu Hehua^[23] simulated the damage to surrounding rock at different depths and found that with increasing depth, the damaged area of the surrounding rock gradually expanded, leading to an increase in collapse load. The statistical

formulas for deep-buried rock pressure in railway and highway tunnels ignore the influence of depth, significantly impacting the calculated results of surrounding rock pressure.

5 LINING STRUCTURE DESIGN

5.1 *Relevant regulations of specifications*

(1) The relevant provisions of the Code for Design of Railway Tunnel (TB10003-2016) are as follows:

- For the initial support of shotcrete lining and composite lining, design parameters can be determined by the engineering analogy method. During construction, corrections should be made through monitoring and measurement. For tunnels with complex geology, large spans, multiple lines, and special requirements, in addition to using the engineering analogy method, numerical methods or approximate methods should be combined for analysis and determination.
 - When calculating composite lining, the initial support should be calculated based on the main load-bearing structure. The secondary lining in Class I to III surrounding rock can be considered as a safety reserve, while in Class IV to VI surrounding rock and specific conditions, it is advisable to design according to the load-bearing structure.
 - Composite lining is recommended for tunnels, and load-structure models should be used for lining calculations. When using the load-structure method to calculate the internal forces and deformations of tunnel lining, the constraining effect of surrounding rock on lining deformation, such as elastic reaction force, should be considered. The magnitude and distribution of elastic reaction force can be determined by using local deformation theory based on factors such as lining structure type, backfill condition, and the deformation characteristics of surrounding rock.
 - The design parameters for initial support and secondary lining should be determined by engineering analogy and theoretical analysis based on tunnel rock classification, rock structure characteristics, and ground stress conditions.
 - The lining of tunnel sections in dark tunnels and open-cut sections should be checked for section strength at the damage stage. Different safety factors should be used in the calculations for different load combinations that the structure is subjected to.
- (2) The relevant provisions of the Specifications for Design of Highway Tunnels (JTG 3370.1-2018) are as follows:
- Highway tunnels should be equipped with lining, and the selection of shotcrete lining, integral lining, or composite lining should be based on tunnel rock grade, construction conditions, and usage requirements. Composite lining is

recommended for expressways, first-level highways, and second-level highways.

- The type of lining structure and support parameters should be determined through comprehensive analysis using engineering analogy and structural calculations based on usage requirements, rock grade, engineering geology and hydrogeological conditions, tunnel burial depth, structural load characteristics, and in consideration of surrounding engineering environment, support methods, and construction methods.
 - For the design of composite lining, engineering analogy can be used, and theoretical analysis may be applied if necessary.
 - The initial support of composite lining should primarily be designed using the engineering analogy method. When necessary, support parameters can be determined by the stratum-structure method, and separate verifications should be conducted for usage and construction stages.
 - The secondary lining of composite lining should be primarily calculated using the load-structure method, taking into account the influence of factors such as elastic resistance.
 - When both the secondary lining and initial support of composite lining jointly bear the surrounding rock pressure and other external loads, the stratum-structure method can be used to calculate internal forces and deformations. Verification can also be carried out using the load-structure method.
- (3) The relevant provisions of the Code for Hydraulic Tunnel Design (NB_T 10391-2020) are as follows:
- For Class I and Class II surrounding rock, tunnels with excavation diameters (tunnel width) less than 5 m may not require support. For diameters between 5 m and 10 m, it is advisable to use shotcrete support, and for tunnels larger than 10 m, anchor spraying support is recommended. In the presence of locally unstable blocks, random anchor rods or bundled anchor rods should be used for reinforcement.
 - Class III surrounding rock is suitable for mesh anchor spraying support; Class IV surrounding rock is suitable for reinforced concrete lining. Depending on the tunnel scale and geological conditions, combined support methods such as anchor spraying, mesh support, or steel support can also be used after analysis. Class V surrounding rock should undergo reinforced concrete or other permanent lining.
 - The design of unsupported and anchor spraying support should be determined using the engineering analogy method. For high-pressure or important projects with concrete-lined tunnels, finite element analysis of seepage and load-carrying structures is recommended. The thickness and reinforcement of the lining can be comprehensively determined based on calculation results, engineering analogy, and structural requirements.

- The structure of hydraulic tunnels should be designed based on persistent conditions, transient conditions, and accidental conditions.

5.2 Summary and problem analysis

Comparing the relevant provisions of different specifications regarding lining structure design, the following conclusions can be drawn:

- (1) Railway, highway tunnel design codes, and hydraulic tunnel design codes generally use the engineering analogy method for initial support design, placing a significant emphasis on the experience of the design personnel.
- (2) Both railway and highway tunnel design codes propose that the secondary lining can be calculated using the load-structure method for internal forces and deformations. However, they do not explicitly specify the proportion of surrounding rock pressure shared by the secondary lining. Additionally, the codes do not clearly define the proportion of reserves when the secondary lining serves as a safety reserve. In practical design, due to the challenging assurance of the construction quality of initial support, often the entire surrounding rock load is considered as a safety reserve.
- (3) The construction quality and durability of shotcrete are challenging to ensure. In the selection of lining structure forms, both railway and highway tunnel design codes generally recommend using composite lining. The railway tunnel code specifies that mining method tunnels should adopt composite lining support structures, and the highway tunnel design code clearly recommends composite lining for specific grades of highways.
- (4) The hydraulic tunnel code explicitly specifies the support forms for different rock classes. For Class I and II rock, anchor spraying support is recommended; Class III rock is suitable for mesh anchor spraying support, and Class IV and V rock are suggested for reinforced concrete lining.
- (5) In railway and highway tunnel codes, the commonly used load-structure method tends to separate the analysis of initial support and secondary lining, deviating from the actual situation.
- (6) The hydraulic tunnel design code recommends using finite element analysis (stratum-structure method) for lining structure analysis, which better considers the overall coordination among surrounding rock, initial support, and secondary lining.

6 CONCLUSION

This paper, starting from the current state of railway and highway tunnel design in China, compares the design concepts and methods of hydraulic tunnels. It analyzes the shortcomings in the classification of

hard rock tunnel surrounding rock, surrounding rock pressure, and lining design from the perspective of commonly used standards and methods in engineering design. The following conclusions are drawn:

- (1) Surrounding Rock Classification: Railway and highway tunnels mainly use a combination of qualitative and quantitative methods for surrounding rock classification. The BQ method is employed for quantitative analysis, relying on two main indicators as control factors and supplemented by other factors for result correction. The BQ method is convenient and fast, but its application in hard rock tunnels with high ground stress is greatly restricted due to the excessive weight given to rock compressive strength (σ) in the BQ values. The BQ method shows the lowest agreement rate with actual surrounding rock categories in hard rock tunnels. It is recommended to make relevant corrections to the BQ method in the analysis of hard rock tunnels, improving its applicability to hard rock caverns.
- (2) Surrounding Rock Pressure: Different specifications use varying methods for calculating surrounding rock pressure, leading to significant differences in the results. For hard rock tunnels, their self-supporting capability is strong, and according to related studies, surrounding rock pressure is related to tunnel depth. The empirical formulas for surrounding rock pressure used in railway and highway tunnel construction statistics do not consider depth factors and are overly conservative compared to actual situations. It is suggested to abandon existing empirical formulas for hard rock tunnels, analyze surrounding rock pressure based on rock grade and self-supporting capability, and pay attention to the treatment of locally unstable blocks.
- (3) Lining Structure Design: The railway and highway tunnel design codes do not prescribe suitable lining support forms based on rock type, often recommending composite lining. In structural calculations, the load-structure model is employed without considering the coordination of surrounding rock, initial support, and secondary lining as a whole, leading to differences from actual conditions. During load distribution, the specifications do not explicitly specify the magnitude of loads, resulting in designs often considering the entire surrounding rock pressure. It is suggested that for hard rock tunnels, appropriate support forms should be adopted, and structural calculations should consider the coordinated forces of surrounding rock and lining structures, emphasizing the stabilizing effect of initial support on surrounding rock.
- (4) Hydraulic tunnels have large tunnel dimensions and significant variations, often located in well-rocked chambers with strict water treatment requirements. Their design concepts

and methods differ significantly from railway and highway tunnel design specifications. However, hydraulic tunnels have a deep understanding of hard rock properties, and in the classification of surrounding rock, surrounding rock pressure, and lining structure design, they handle hard rock economically and ensure safety through industry validation. It is recommended that in the railway and highway tunnel design process, relevant design concepts and methods from hydraulic tunnels can be selectively absorbed and borrowed, balancing safety and economy in hard rock tunnel design.

The use of shotcrete as a permanent structure in the European region has a long history. Currently, many engineering cases in China also use shotcrete as a permanent lining structure for hard rock tunnels. With the development of shotcrete technology, factors such as shotcrete quality and durability that impact the development of single-layer lining structures will be overcome. Hard rock tunnels are expected to experience comprehensive development in theory, design, construction, materials, etc., ushering in the flourishing development of single-layer lining structures for hard rock tunnels.

ABSTRACT: The construction method of double-arch tunnel without middle drift has complex interaction between surrounding rock and supporting lining, which needs to be explored. Based on the engineering background of the Xisujiao No.2 Tunnel of the Yijin Expressway, a three-dimensional numerical simulation method was used to establish a finite element model of the unexcavated middle tunnel connected arch tunnel. The excavation and support processes of the tunnel were simulated, and the mechanical responses and displacement change laws of the surrounding rock, support structures, etc. were obtained at various construction stages. Optimization analysis was also conducted. The results show that the excavation and support of the later tunnel will increase the deformation and stress of the earlier tunnel. As the excavation progresses, there is a significant stress concentration phenomenon in the supporting structure, and tunnel partition wall is the part that bears the largest force. The stress on the tunnel secondary lining structure in the first tunnel is significantly uneven. In order to address these issues, appropriate measures need to be taken.

Keywords: Arch tunnel, Numerical simulation, displacement, stress

1 INTRODUCTION

Traditional methods such as central pilot tunneling or three-guide tunneling in the construction process of continuous arch tunnels present issues such as complex construction procedures, long construction period, and high costs. Moreover, they can lead to significant disturbance to surrounding rocks and poor waterproofing effect, severely impacting the construction efficiency and quality of continuous arch tunnels. Therefore, the search for an efficient, fast, and cost-effective construction method has become an important research direction in the field of tunnel construction. In this regard, the construction of continuous arch tunnels without a central pilot tunnel has been studied by scholars. It utilizes a structural system composed of continuous arch frames and prefabricated segments, enabling simultaneous excavation and lining of the tunnel, which saves the excavation and support of the central pilot tunnel, thereby reducing construction costs and time.

Existing studies on double-arch tunnels have mainly focused on the mechanical behavior analysis of central pilot tunnel excavation. Wang (2020)

developed a mechanical testing system for large-section combined arches in continuous arch tunnels and conducted comparative experiments on restrained concrete arches and traditional I-shaped steel arches. They proposed a novel technique for restrained concrete arch support that effectively controls the deformation of large-section tunnel surrounding rock. Bo Min (2020) employed a combined approach of numerical simulation and model testing to analyze the influence of different cavity sizes on the crack characteristics, deformation response, and stress state of tunnel linings, revealing the mechanism of lining cracking caused by cavities. Cheng et al. (2023) combined distributed fiber optic monitoring, inversion analysis methods, and finite element simulation capable of reflecting concrete cracking behavior to obtain and analyze various information on deformation, internal forces, and cracking of linings during the construction process of continuous arch tunnels.

As a result, double-arch tunnel without middle drift has fundamentally different force forms and construction procedures compared to the middle drift tunnel construction method. Therefore, it is not

appropriate to simply apply the experience from middle drift construction to the construction of double-arch tunnels without it. In terms of on-site monitoring, Zeng et al. (2019) examined the example of the Bailongpo Tunnel on the Wuyi Expressway in Yunnan Province and analyzed the technical difficulties encountered in the construction process of continuous arch tunnels without a central pilot tunnel, such as ensuring the stability of the middle partition wall and protecting the preceding tunnel structure. Li et al. (2022) analyzed the mechanical behavior of tunnels under different excavation methods using finite element numerical simulation and found that the method of continuous arch tunnel construction without a central pilot tunnel has strong feasibility and applicability in shallow and weak strata. Regarding theoretical calculations, Jiang et al. (2023) investigated the impact of existing support structures in the preceding tunnel and the construction of the subsequent tunnel on loosened loads, proposed a calculation formula based on the Pusch theory, and conducted comparative analysis in conjunction with on-site monitoring data from the Manla Tunnel. Although these studies provide some guidance for engineering practices of continuous arch tunnels without a central pilot tunnel, further research is still required on the mechanical behavior analysis and construction process improvement of such tunnels.

In the construction method of continuous arch tunnels without a central pilot tunnel, the excavation of the intervening rock pillar will inevitably affect the distribution of secondary stress. The unexcavated subsequent tunnel plays a crucial supportive role for the adjacent side and surrounding rock around the preceding tunnel. Compared to segmented tunnels, tunnels with smaller clearances, or central pilot tunnel advanced construction, the distribution area, spatial pattern, and variation characteristics of the loose ground pressure zone in continuous arch tunnels without a central pilot tunnel are significantly different. Hence, it is necessary to conduct numerical simulations to determine the deformation of surrounding rocks and the force parameters of the support system. By thoroughly exploring the characteristics and mechanical behavior of continuous arch tunnels without a central pilot tunnel, a better understanding of their engineering performance can be achieved, enabling the optimization of construction plans and ensuring the safety and reliability of tunnel engineering. This study aims to provide technical support and reference for tunnel engineering construction and holds significant engineering application value.

2 ENGINEERING GEOLOGICAL CONDITIONS

The West Su Jiao No. 2 Tunnel is generally oriented in a north-south direction. The designed entrance and exit mileposts for the left lane are ZK80+488 to ZK82+311.5, with a tunnel length of approximately 1823.5m and a maximum depth of 300m. For the

Figure 1. Tunnel geological conditions.

right lane, the designed entrance and exit mileposts are K80+500 to K82+322, with a tunnel length of approximately 1822m and a maximum depth of 320m. As shown in Figure 1, it mainly traverses the Lower Cambrian strata such as the Canglangpu Formation and the Longwang Temple Formation. The lithology of the tunnel surrounding rocks mainly includes dolomitic limestone, fine sandstone, siltstone, and argillaceous siltstone. The rock types are complex, with significant variations in hardness, uneven layer thickness, and poor interlayer bonding. The integrity of the rock mass is fragmented, and local intense joint zones are developed due to significant structural influences. The eastern side of the tunnel exit is adjacent to the Yewladda River. The shallow surface of the slope is mainly covered with boulders and gravel, with a few steep cliffs and rock exposures at steep slopes. The surface vegetation mostly consists of weeds and low shrubs.

The main tunnel body falls within Grade IV, with well-developed joint structures in the fragmented rock mass, including thick-layered structures and intercalated fractured structures. The stability of the surrounding rocks is poor, and phenomena such as collapse and falling blocks are prone to occur in the crown of the tunnel. The stability of the sidewall rock mass is also poor, with a potential for collapse. Grade V surrounding rocks are relatively low in proportion and are mainly present at the tunnel entrance and exit sections, as well as in the Lower Cambrian Longwang Temple Formation, where gypsum layers exist. The integrity of the rock mass is fragmented to fractured, and the stability of the surrounding rocks is poor. Significant deformation occurs in localized soft rock and fractured zones after excavation and requires enhanced support. The crown is susceptible to collapse and falling blocks, and the stability of the sidewall rock mass is poor.

3 NUMERICAL SIMULATION

3.1 Assumption conditions

The traditional method of constructing middle drift tunnel has achieved good practical results, with

certain economic benefits. It has advantages such as strong adaptability and mature technology. However, it also has prominent issues such as complex procedures, large temporary support requirements, excessive material waste, and significant disturbance to the surrounding rock.

The method of double-arch tunnel without middle drift has advantages over the traditional method in terms of simpler procedures, shorter construction period, lower cost, and less disturbance to the surrounding rock. It is suitable for the construction of large-span continuous arch tunnels and has been increasingly favored by scholars and companies in recent years. Specifically, this method eliminates the excavation of a central pilot tunnel and adopts controlled excavation of the leading tunnel together with the downward stepping of the intermediate partition wall. Advanced support and systematic anchoring are used in the deformed pressure zone and loosened pressure zone above the intermediate partition wall. Then, a prefabricated steel arch or lattice arch is placed in the empty position of the intermediate partition wall to form a closed loop. After completing the secondary lining support of the leading tunnel, the excavation of the trailing tunnel is carried out.

Figure 2. Construction sequence diagram.

The simulated continuous arch tunnel in this study adopts the construction method without a central pilot tunnel. The right-side tunnel (leading tunnel) is excavated using a benching method. After completing the upper bench excavation, the lower bench is excavated in two stages, with the part near the central partition wall excavated first, and the remaining part excavated last. While the left tunnel (trailing tunnel) is excavated in multiple controlled blasts. In this simulation, the thickness of the partition wall is 600mm. The construction sequence is illustrated in Figure 2, where the numbers in the figure correspond to the construction steps described in Table 1.

3.2 Computation model

The simulation of working conditions should be kept as consistent as possible with the actual situation. However, due to the complexity of the actual construction process, it is susceptible to various influencing factors. Therefore, appropriate simplifications

Table 1. Construction sequence.

Right line		Left line	
number	process	number	process

can be made during the simulation process to reduce computational complexity while emphasizing key aspects of the research problem. The model's upper surface is a free boundary, and normal velocity constraints are applied to all other surfaces except the upper one. The tunnel surrounding rock employs a Mohr-Coulomb constitutive model, while initial support, intermediate partition walls, and secondary lining all utilize elastic constitutive models. Solid elements are used to simulate the rock, initial shotcrete, secondary lining, and intermediate partition walls. Cable elements are employed for anchor rods, and shell elements with equivalent stiffness transformation are used to simulate steel frames and longitudinal connecting reinforcement. The physical parameters of relevant materials are listed in Table 2.

Table 2. Material parameters.

Rock	2.64	0.40	1.2	0.15	25
Primary support	25	0.25	20		
Secondary lining	25	0.2	30		

4 ANALYSIS OF CALCULATION RESULTS

4.1 Displacement analysis

The deformation pattern of the surrounding rock during tunnel excavation is shown in Figure 3. The displacement of the monitoring point is shown in Figure 4. After the excavation of the upper step in the right line, the displacement of the right line's crown and invert rapidly increases, and within a certain range, it tends to stabilize. The maximum

displacement of the crown is 6.32mm, and the maximum displacement of the invert is 9.32mm. The crown and invert of the left line exhibit a slight downward trend and gradually reach an equilibrium state. This indicates that during the upper step excavation, the right line experienced significant disturbance, while the deformation of the surrounding rock in the left line was minor. During the excavation of the lower step in the right line, the displacement of the crown and invert in the left line remains relatively unchanged, indicating that the left line remains stable. The displacement of the crown in the right line also remains constant, indicating effective support during the upper step excavation. However, the displacement of the invert in the right line continues to increase, reaching 10.15mm, suggesting a significant impact from the lower step excavation on the invert of the right line.

During the upper step excavation in the left line, significant subsidence occurred in both the crown and invert of the right line. The crown subsided by 3.6mm, and the invert subsided by

0.7mm, indicating that the upper step excavation in the left line caused certain interference to the right line. The invert of the left line rose by 11mm, while the crown subsided by 6.3mm, and these changes occurred rapidly. This suggests that the upper step excavation in the left line caused significant disturbance to the left line itself. When excavating the lower step in the left line, apart from slight uplift observed in the invert of the left line, the displacement of other monitoring points remained relatively unchanged, indicating that the surrounding rock had reached a relatively stable state at this point.

According to the figure, it can be observed that the displacement of the surrounding rock at the arch crown and arch bottom is most significant during the section formation stage (i.e., the stage of upper bench excavation), with the highest rate of change. The influence of lower bench excavation stage on the displacement of the surrounding rock is relatively small. Therefore, it is crucial to select a reasonable initial support method and carry out timely construction of

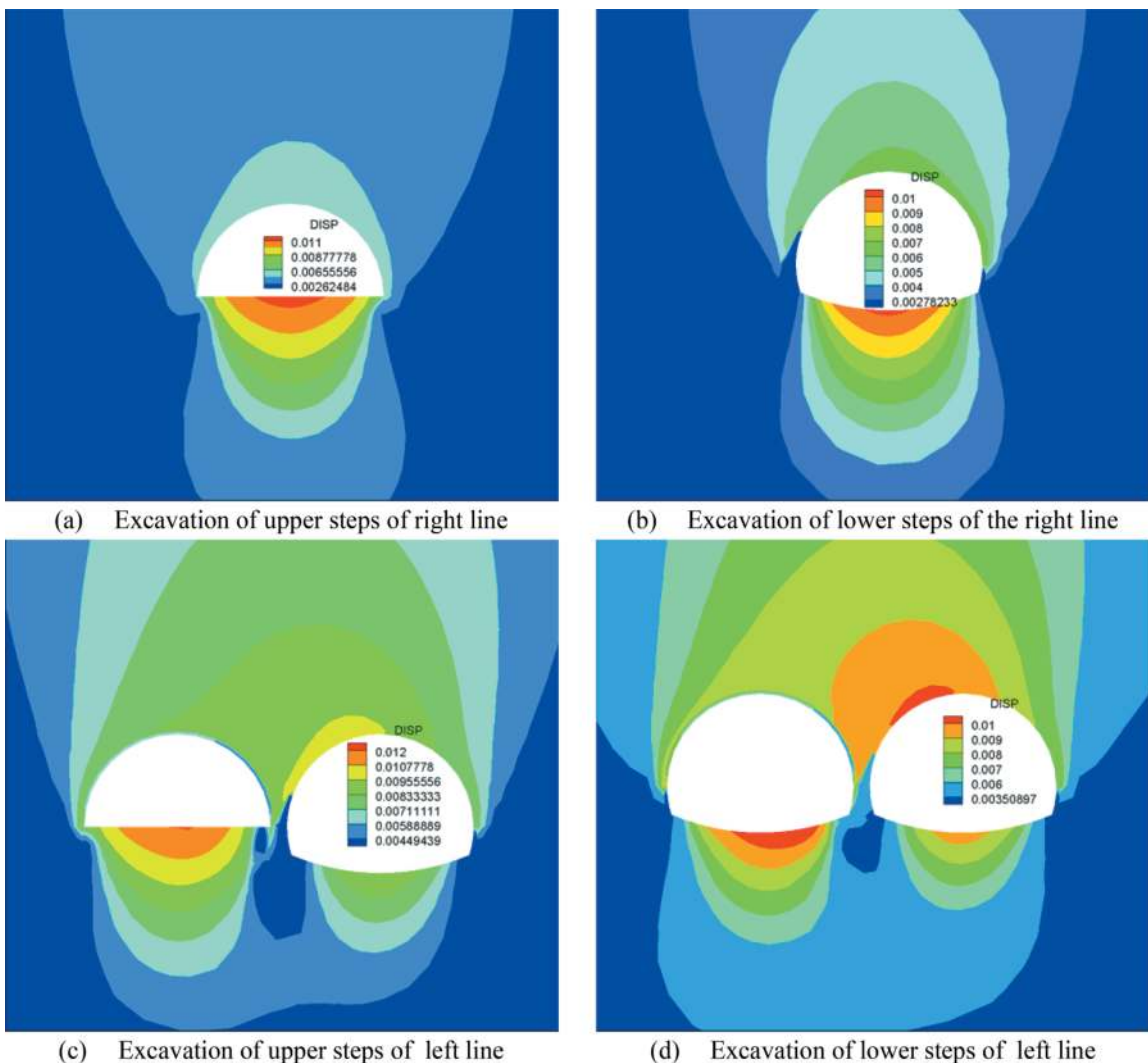

Figure 3. Cloud diagram of rock displacement.

Figure 4. Displacement of tunnel surrounding rock.

the initial support to ensure the safety and stability of the tunnel. When the surrounding rock reaches a stable equilibrium state, the maximum settlement at the arch crown of the right tunnel is 9.8 mm, and the maximum uplift at the arch bottom is 9.4 mm. The maximum settlement at the arch crown of the left tunnel is 8.8 mm, and the maximum uplift at the arch bottom is 10.5 mm. After the construction of the double-arch tunnel without middle drift, the vertical displacement magnitudes of the arch crowns and arch bottoms in the left and right tunnels are basically consistent. However, it should be noted that during the excavation of the left tunnel, the right tunnel has already completed the secondary lining construction, and a significant settlement phenomenon occurred at the arch crown of the right tunnel when the left tunnel was excavated in the upper bench stage. This may lead to cracking or damage in the secondary lining of the right tunnel's arch crown. Therefore, during the excavation of the left tunnel, it is necessary to strengthen monitoring and inspection of the arch crown of the right tunnel, and promptly identify and address any potential issues.

With the excavation of the tunnel, the monitoring points at the arch crowns of both the left and right tunnels move towards the excavation face, causing loosening and deformation of the surrounding rock. During the excavation of the lower bench in the right tunnel, significant movement of the surrounding rock is observed at the location of the partition wall, which is mainly caused by the displacement resulting from the re-construction of the partition wall. Since the partition wall is constructed only during the excavation of the lower bench in the right tunnel, it experiences uneven pressure from the surrounding rock on both sides during the construction process, resulting in deformation and displacement of the partition wall. To reduce the displacement of the partition wall, it is necessary to minimize the construction time of the partition wall and adopt a rational primary support method.

During the excavation of the left tunnel, significant displacement is often observed at the arch crown monitoring points in the right tunnel, indicating that the excavation of the left tunnel has an impact on the surrounding rock of the right tunnel. Due to the distance between the left and right tunnels, the excavation of the left tunnel exerts lateral pressure on the surrounding rock of the right tunnel, resulting in displacement at the arch crown of the right tunnel. To control the displacement of the arch crown in the right tunnel, it is necessary to strengthen the monitoring of the right tunnel's arch crown during actual construction and promptly implement reinforcement measures.

It is worth noting that after the excavation of the left tunnel, the rate of displacement change at the monitoring points is significantly higher than during the excavation of the right tunnel. This indicates that the left tunnel is more significantly affected, and there may be more complex deformation and damage to the surrounding rock. Therefore, in actual tunnel engineering, special attention should be given to the deformation and damage conditions at different parts of the tunnel in order to implement corresponding support and reinforcement measures, ensuring the safe and stable operation of the tunnel.

4.2 Stress analysis

4.2.1 Analysis of surrounding rock stress

As shown in Figure 5, with the excavation of the tunnel, the originally stable surrounding rock is disrupted, and the rock undergoes deformation to reach a new stable state. However, the support system hinders this deformation process, resulting in stress concentration. After the completion of the excavation of the right tunnel, the stress distribution in the surrounding rock gradually stabilizes. At this point, the stress in the surrounding rock is mainly concentrated at the

tunnel's arch position, while the stress distribution in the top surrounding rock of the tunnel is relatively small and uniform. The stress in the middle of the surrounding rock is lower, but stress concentration phenomena also occur.

With the completion of the left line excavation, the stress in the surrounding rock redistributes. Stress mainly concentrates at the positions of the arch feet of both tunnels and the position of the middle partition wall. This phenomenon occurs because the excavation of the left line disrupts the originally concentrated stress in the rock mass, and the surrounding rock undergoes stress readjustment to achieve a new stable state. At this point, the stress distribution on the top surrounding rock of the tunnel becomes relatively uniform and lower, indicating that during excavation, the stress on the tunnel's top is relatively low, and the

rock deformation is more influenced by gravity. The horizontal stress during excavation is mainly transmitted through the tunnel's sidewalls rather than its top. The stress contour maps showing the change in rock stress after excavation also reveal that the impact of tunnel excavation on the surrounding rock decreases with increasing distance from the tunnel.

4.2.2 Analysis of secondary lining stress

According to the analysis results from Figure 6, the stress distribution of the secondary lining structure in the right tunnel exhibits notable non-uniformity. This is particularly evident in areas such as the arch bottom, arch top, and corners of the tunnel walls, where stresses are relatively high and both tensile and compressive stresses are present. Notably, there is a pronounced tensile stress at the left side of the arch

(a) Cloud diagram of maximum principal stress after excavation of the right line

(b) Cloud diagram of maximum principal stress after excavation of the left line

(c) Cloud diagram of minimum principal stress after excavation of the right line

(d) Cloud diagram of minimum principal stress after excavation of the left line

Figure 5. Cloud diagram of rock stress.

bottom, reaching up to 1.27 MPa, which might lead to cracking. Additionally, a significant tensile stress of 1.1 MPa is observed at the left side of the arch top, warranting enhanced monitoring and maintenance. While there is some localized accumulation of compressive stress at the corners of the right tunnel's walls, it is relatively minor and not sufficient to cause damage.

In contrast, the stress distribution of the secondary lining structure in the left tunnel is more uniform, with stress values at various locations falling within reasonable ranges. Only a slight stress concentration is present at the right corner of the tunnel's wall, which does not affect the structural safety.

Comparatively, the analysis reveals that the secondary lining structure in the right tunnel experiences pronounced stress concentration, which could potentially lead to structural damage or instability. Therefore, in practical construction, appropriate support

measures, such as reinforcement or additional structural elements, are necessary to ensure the stability and safety of the secondary lining structure. Simultaneously, further research and analysis on the stress distribution patterns of the secondary lining structure are needed to provide more scientifically and rationally designed solutions for actual construction.

4.2.3 Analysis of in the partition wall stress.

Analyzing the stress variation pattern of the central partition wall. According to Figure 7, it can be observed that the stress distribution on the central partition wall is relatively concentrated, and the stress values fluctuate within a certain range. This indicates that the central partition wall undergoes relatively small stress variations during the construction process, exhibiting good stability.

In the figures, the maximum tensile stress on the central partition wall is 2.6 MPa, and the maximum

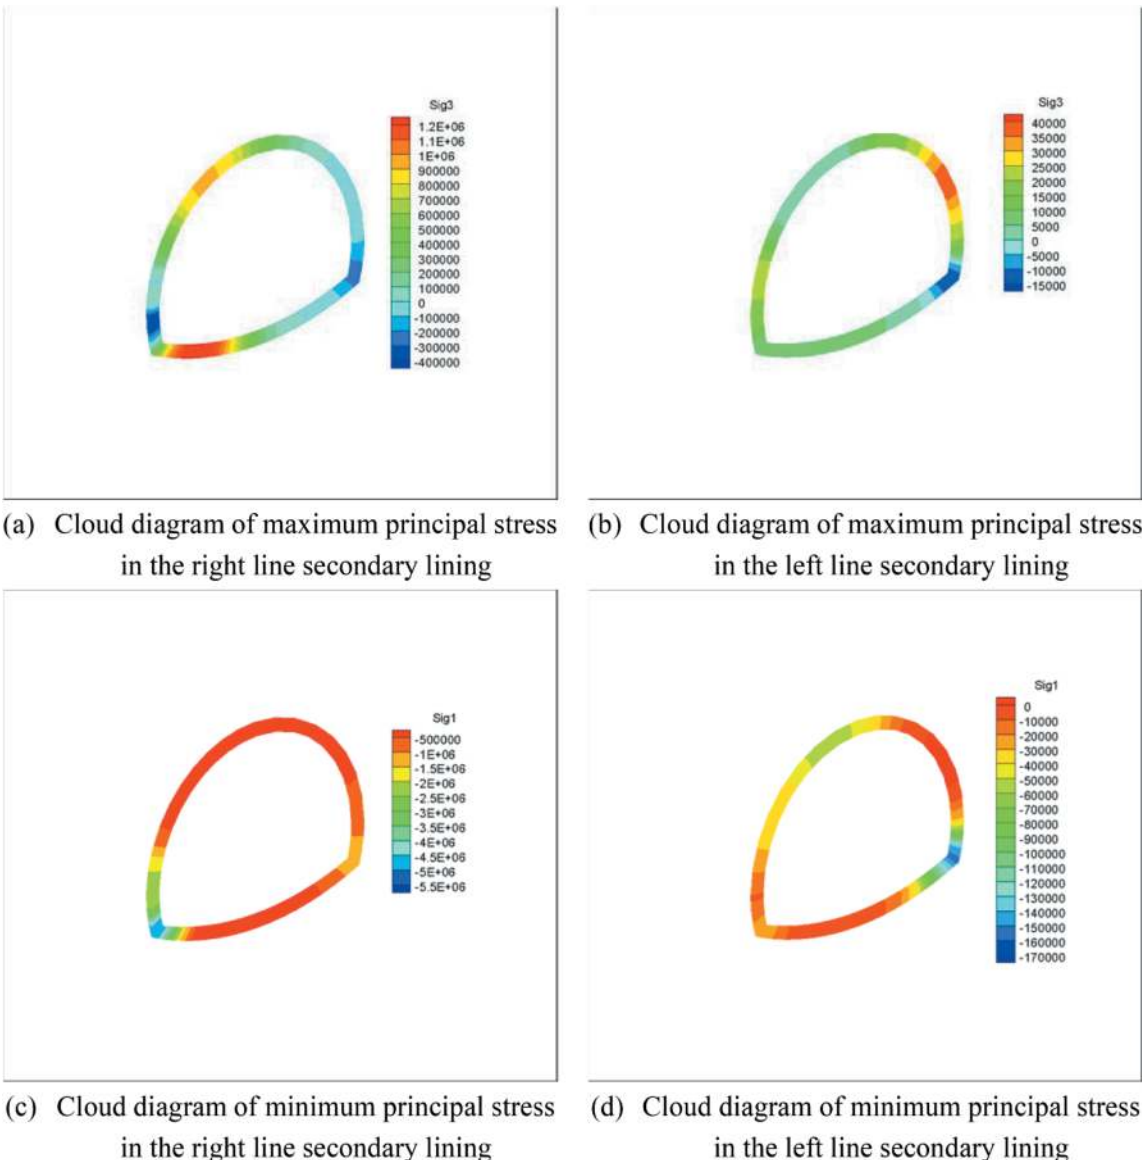

Figure 6. Cloud diagram of secondary lining stress.

(a) Cloud diagram of minimum principal stress in the partition wall

(b) Cloud diagram of minimum principal stress in the partition wall

Figure 7. Cloud diagram of partition wall stress.

compressive stress is 10 MPa, with the maximum tensile stress located at the lower right end of the wall and the maximum compressive stress on the left side. This may imply that, due to high tensile stress, the lower part of the wall is more prone to cracking or deformation. Moreover, during usage, the stress on the central partition wall may change due to variations in tunnel environment and geological conditions. To enhance the safety and stability of the wall during usage, appropriate measures can be taken to reinforce the central partition wall, reducing stress concentration at the lower part of the wall, such as increasing wall thickness, using high-strength materials, or installing additional reinforcement structures.

4.3 Conclusion

1. The stress distribution in the surrounding rock is dynamic and changes as the excavation process progresses. Stress concentration mainly occurs at the crown, intermediate wall, and corners of the tunnel. The intermediate wall experiences the highest stress and requires reinforcement with steel mesh and improved foundation. The construction of secondary lining and the excavation of adjacent tunnels also affect the stress distribution in the surrounding rock.
2. The secondary lining structure exhibits significant stress concentration in certain areas, especially in advance tunnels, which can lead to cracking or damage. Therefore, it is necessary to implement appropriate support measures, such as strengthening support or installing reinforcement structures, to ensure the stability and safety of the secondary lining structure.
3. When the left and right tunnels overlap, it is important to pay attention to protecting the structure of the leading tunnel and timely pour the

secondary lining for the arch and walls. This helps to improve the overall stiffness and load-bearing capacity of the continuous arch tunnel.

4. The displacement and stress of the surrounding rock and support structures are primarily influenced by the excavation of the upper bench, while the impact of excavation of the lower bench is relatively smaller on them.

5 OPTIMIZED CONSTRUCTION PROCESS

In the construction of consecutive tunnels, the secondary lining of the leading tunnel lags behind the tunnel excavation, and when constructing the following tunnel, the fact that the secondary lining of the leading tunnel has not reached the specified age must be taken into account. In this situation, the excavation of the following tunnel will exert significant vibration effects on the secondary lining of the leading tunnel, leading to disturbance and deformation of the surrounding rock, and resulting in stress concentration in the already poured secondary lining of the leading tunnel, which can even lead to cracking. In the construction of double-arch tunnels under this circumstance, it is necessary to develop a reasonable construction plan to ensure that the secondary lining of the leading tunnel reaches the specified age as soon as possible, and to take effective measures to minimize the impact of the excavation of the following tunnel on the secondary lining of the leading tunnel. For instance, controlling the excavation progress and the amount of explosives used in blasting can be implemented during the construction of the following tunnel to avoid excessive vibration effects. Furthermore, it is essential to precisely control the construction sequence and timing during the process of bench installation and inverted

arch construction, ensuring a uniform stress distribution during the construction process and avoiding stress concentration phenomena. Therefore, the pouring of the secondary lining in the leading tunnel and the excavation of the following tunnel must be carefully coordinated.

The construction environment of double-arch tunnels is typically challenging, and the complexity and variability of geological conditions are significant difficulties in construction. Especially when adopting the method of double-arch tunnel without middle drift, risks such as ground stress release, rock burst, and roof collapse caused by rock excavation need to be addressed. Therefore, before construction, it is necessary to conduct thorough investigation and analysis of the geological conditions in order to develop a reasonable construction plan and appropriate measures to address the challenges.

The method of double-arch tunnel without middle drift in continuous arch tunnels has significant advantages compared to traditional construction methods. However, this method requires the use of advanced construction techniques, and it is necessary to ensure the smooth progress of the construction face during the construction process while maintaining the overall stability of the tunnel structure. Therefore, before construction, it is necessary to thoroughly debug and inspect the equipment, as well as develop detailed construction plans and implement safety management.

During the construction process, it is necessary to tightly control the tunnel excavation, support, drainage, and other aspects. Real-time monitoring and control of parameters such as tunnel displacement and stress are also required to ensure the overall stability and safety of the tunnel. Additionally, the management and maintenance of the construction site are essential aspects of construction process control.

Finally, in the construction of double-arch tunnel without middle drift, it is required to immediately carry out support work after excavation, and the pouring of the intermediate partition wall should closely follow the excavation face. This places high demands on construction organization and coordination abilities. This method has a certain range of

adaptability to surrounding rock conditions but is not suitable for special geological conditions, such as large cross-sections, great depths, significant lateral pressures, or abundant joint and crack formations. Additionally, this method lacks sufficient construction experience and data support, and it carries certain risks and uncertainties. It requires continuous summarization and improvement through practical engineering projects.

A mechanical analysis model for tunnels crossing active fault zones

Mingnian Wang, Xiao Zhang* & Li Yu

School of Civil Engineering, Southwest Jiaotong University, Chengdu, China

Key Laboratory of Traffic Tunnel Engineering Ministry of Education, Southwest Jiaotong University, Chengdu, China

ABSTRACT: Tunnels that cross active fault zones will inevitably be damaged, and a proper mechanical analysis model is an effective tool for tunnel design. Generally, there are three types of active faults, i.e., strike-slip, dip-slip (normal and reverse) and oblique-slip (normal and reverse strike-slip) faults. However, there is no mechanical analysis model that suitable for all types of active faults. In this work, a mechanical analysis model for tunnels crossing active fault zones is proposed, which is applicable to different kinds of active faults. To be specific, a prediction method of stratum displacement under different types of faults is proposed by using a mathematical statistical analysis of field measured data; then, the calculation method of longitudinal tunnel displacements and forces is established based on the beam-spring model; finally, the analysis model of tunnel cross-section displacement and forces is presented based on the deformation-structure method. Additionally, the calculation results obtained from the proposed model agree well with those from model tests and numerical simulations under the action of strike-slip, dip-slip and oblique-slip faults. The proposed model improves the existing analytical models in terms of accuracy and applicability, and it is valuable for fast, economic, and reliable analysis and design of tunnels crossing active faults.

Keywords: Active faults, Tunnel engineering, Coseismic-slip, Mechanical analysis

1 INTRODUCTION

Affected by intense tectonic activity, numerous faults are distributed worldwide due to the interaction between different tectonic plates, such as the East African Great Rift Valley, San Andreas Fault, and Hayward Fault. Consequently, many tunnels must cross these active faults to meet route planning requirements. However, the dislocation resulting from earthquakes when a tunnel crosses an active fault can cause irreversible damage, including cracking, substantial deformation, and even structural collapse. Consequently, the seismic impact of active faults on tunnels has garnered significant attention among researchers and practitioners alike.

A series of model tests (Baziar et al., 2014; Burridge et al., 1989; Cai et al., 2019) and numerical simulations (Ranjbarnia et al., 2020; Sabagh and Ghalandarzadeh, 2020; Zhao et al., 2019) have been conducted to investigate the tunnel response under faulting. The results show that the tunnel is subjected to a combination of tensile (compressive), bending and shearing, and experiences an elongated ‘S’-shaped

deformation along the tunnel axial; the tunnel internal forces increase with the increase of fault displacement, stratum stiffness and tunnel stiffness; under the action of fault zone displacement, the tunnel will be severely damaged, especially near the fault zone, where tunnel collapse and cracking may occur.

However, the numerical simulation of a tunnel crossing an active fault zone takes several hours even in a high-performance computer, which is not applicable to engineering design. Therefore, a series of analytical models have been proposed for the mechanical response analysis of a tunnel or pipeline under the action of faulting. Newmark and Hall (Newmark and Hall, 1975) firstly proposed a cable-like model for a pipeline under a strike-slip fault without considering the contribution of lateral stratum resistance. Kennedy (Kennedy et al., 1977) extended this model by considering stratum resistance, but the pipeline’s flexural stiffness is still not considered. Later, Wang and Yeh (Wang and Yeh, 1985) partitioned the pipeline into four segments to compensate the limitation of the cable-like models in neglecting the contribution of pipeline’s flexural stiffness. After that, this model is

*Corresponding author: xiao.zhang@swjtu.edu.cn

improved and developed by many authors (Hu et al., 2022; Karamitros et al., 2007; Karamitros et al., 2011; Talebi and Kiyono, 2021; Trifonov and Cherniy, 2010; Wang and Wang, 1995) and some shortcomings have been overcome. Despite the ongoing improvements and development of analytical models, they are not without shortcomings. These include:

- (1) The existing models for analyzing faulting in tunnels tend to oversimplify the permanent fault displacement by treating it as a constant value, which avoids the need for solving complex equations. However, the permanent fault displacement resulting from faulting is actually nonlinear, and this simplification does not reflect the true nature of the phenomenon.
- (2) Different fault types show different mechanical characteristics, in which the normal fault is in tension, the reverse fault is in compression, the strike-slip fault is in shear, and the oblique-slip fault is in combined state. However, the current analytical models for assessing the interaction between tunnels and faults do not fully take into account these distinct mechanical characteristics. As a result, there is a need for a comprehensive analytical model that can be applied to all types of active faults.

To this end, this paper presents a novel approach for predicting the stratum coseismic-slip and tunnel response under fault dislocation. The proposed method is highly accurate, and is applicable to all types of active faults.

2 PREDICTION METHOD OF STRATUM COSEISMIC-SLIP

2.1 Statistical analysis of stratum coseismic-slip characteristics

For the sake of enabling further analysis, the coordinate system Oxyz is established to lie along the fault plane. Specifically, the horizontal (x-axis) aligns parallel to the fault plane, the longitudinal (y-axis) aligns perpendicular to the fault plane, and the vertical (z-axis) aligns perpendicular to the horizontal plane, as illustrated in Figure 2.

Figure 1. 3D coordinate system.

2.1.1 Statistics of stratum coseismic-slip curve

A total of 45 stratum coseismic-slip curves were measured, primarily originating from the Taxkorgan,

Yutian, Wenchuan, and West Kunlun Mountain earthquakes (Chenxia et al., 2011; Guihua et al., 2008; Guihua et al., 2009a; Guihua et al., 2022; Guihua et al., 2009b; Wen-qiao et al., 2011; Xiwei et al., 2010; Xiwei et al., 2002; Xiwei et al., 2008; Yong et al., 2008; Z et al., 2021), encompassing normal fault, reverse fault, and right-lateral strike-slip fault, as presented in Figure 3. These curves exhibit an “S” type configuration, with a prevalent trend of larger coseismic-slip near the fault plane. Moreover, the dislocation decreases gradually to convergence as the distance from the fault increases. The curve’s shape is predominantly determined by the two parameters of the coseismic-slip’s maximum value and range.

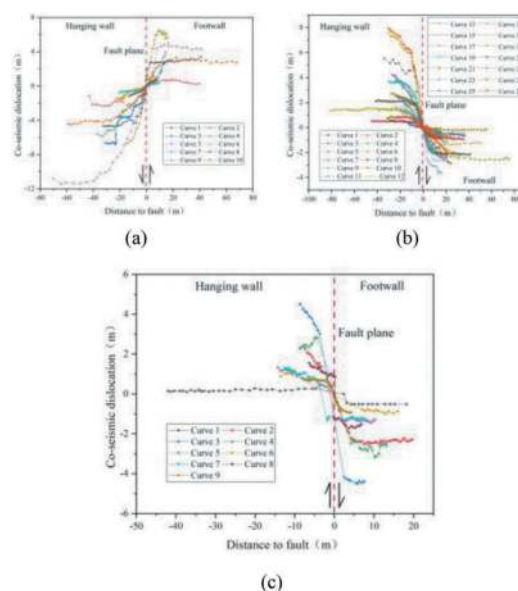

Figure 2. Measured stratum coseismic-slip curves: (a) normal fault, (b) reverse right-lateral strike-slip fault (vertical direction), (c) reverse right-lateral strike-slip fault (horizontal direction).

2.1.2 Normalization of stratum coseismic-slip curve

Based on the observation that coseismic-slip is maximal at the fault plane and gradually declines on either side, the measured stratum coseismic-slip curve is shifted accordingly. Additionally, due to the distinct geographical locations and topography of each curve, the data is discrete, and normalization is carried out using the influencing factors of curve shape. For design convenience, coseismic-slip curves of the hanging wall and footwall are normalized separately, while the coseismic-slip’s range and maximum value i and u_{max} are defined as depicted in Figure 4. Furthermore, to validate the precision of the proposed method for predicting coseismic-slip, a randomly selected curve for each fault type is excluded from normalization processing and fitting analysis, and solely employed for verification purposes.

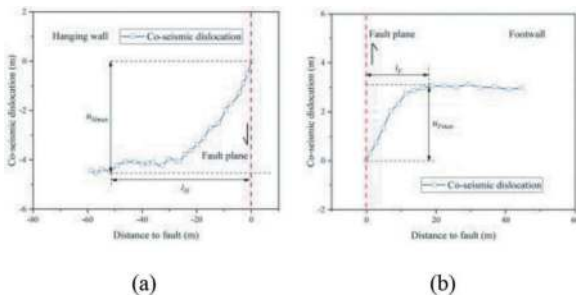

Figure 3. Schematic diagram of normalization index: (a) hanging wall, (b) footwall.

The normalization index is employed to normalize both the co-seismic stratum dislocation u and fault distance y :

$$\bar{u}_H = \frac{u_H}{u_{H\max}} \quad (1)$$

$$\bar{u}_F = \frac{u_F}{u_{F\max}} \quad (2)$$

$$\bar{y}_H = \frac{y}{i_H} \quad (3)$$

$$\bar{y}_F = \frac{y}{i_F} \quad (4)$$

where \bar{u}_H and \bar{u}_F are the normalized stratum coseismic-slip of the hanging wall and footwall respectively; u_H and u_F are the original stratum coseismic-slip of the hanging wall and footwall respectively; \bar{y}_H and \bar{y}_F are the normalized fault distance of the hanging wall and footwall respectively; y is the original fault distance.

Upon normalization of the stratum coseismic-slip curve, the largest coseismic-slip is observed at the fault plane. As fault distance increases, coseismic-slip

Figure 4. Normalized stratum coseismic-slip data: (a) vertical direction (hanging wall), (b) vertical direction (footwall), (c) horizontal direction (hanging wall), (d) horizontal direction (footwall).

gradually reduces, eventually reaching a minimum value beyond the deformation range, and then remaining relatively constant. This is demonstrated in Figure 5.

2.2 Fitting analysis of stratum coseismic-slip range

To develop a comprehensive method for predicting the stratum coseismic-slip applicable to various fault types, it is necessary to account for the direction of the coseismic-slip based on the nature of the fault. For establishing a consistent approach for data analysis, positive values of the coseismic-slip data for normal and reverse faults are unified as the vertical direction data, whereas positive values of the coseismic-slip data for left-lateral and right-lateral strike-slip faults are unified as the horizontal direction data. The subsequent analysis is based on the established three-dimensional coordinate system.

2.2.1 Fitting analysis of vertical coseismic-slip range

The fitting analysis is conducted based on the positive values of the vertical coseismic-slip range of both the hanging wall and the footwall, as presented in Figure 6. The goodness of fit is 0.82, and the calculation formulas are established as follows:

$$i_{Hz} = 11.09u_{Hz\max}^{0.44} \quad (5)$$

$$i_{Fz} = 11.09u_{Fz\max}^{0.44} \quad (6)$$

where i_{Hz} and i_{Fz} are the coseismic-slip range of the hanging wall and the footwall in the vertical direction respectively; $u_{Hz\max}$ and $u_{Fz\max}$ are the maximum coseismic-slip of the hanging wall and the footwall in the vertical direction respectively, which can be obtained according to the earthquake safety evaluation.

Figure 5. Vertical coseismic-slip range fitting diagram.

2.2.2 Fitting analysis of horizontal coseismic-slip range

Analogously, a fitting analysis is performed based on the range data of horizontal coseismic-slip, as presented in Figure 7. The goodness of fit is 0.85, and the resulting calculation formulas are as follows:

$$i_{Hx} = 5.04u_{Hx\max}^{0.24} \quad (7)$$

$$i_{Fx} = 5.04u_{Fx\max}^{0.24} \quad (8)$$

where i_{Hx} and i_{Fx} are the coseismic-slip range of the hanging wall and the footwall in the horizontal direction respectively; $u_{Hx\max}$ and $u_{Fx\max}$ are the maximum coseismic-slip of the hanging wall and the footwall in the horizontal direction respectively, which can be obtained according to the earthquake safety evaluation.

Figure 6. Horizontal coseismic-slip range fitting diagram.

2.3 Fitting analysis of stratum coseismic-slip

Based on the influence factors and deformation characteristics of the stratum coseismic-slip curve, the fitting principles are guided by several criteria. Firstly, the fitting curve should attain the maximum coseismic-slip. Secondly, the fitting curve should accurately represent the deformation range. Thirdly, the fitting curve must exhibit the maximum coseismic-slip on the fault plane and decrease gradually towards both sides. Finally, the goodness of fit of the fitting curve should be maximized.

2.3.1 Fitting analysis of vertical coseismic-slip

(1) Hanging wall.

Using the normalized coseismic-slip data of the hanging wall in the vertical direction as a basis, this study selected four functional forms, including linear, exponential, peck, and power function, for fitting analysis. The results of the fitting analysis are presented in Table 1 and Figure 8.

Figure 7. Normalized data fitting of hanging wall in vertical direction.

The fitting curve of the linear and exponential functions fails to attain the maximum coseismic-slip,

Table 1. Comparison of fitting functions.

Serial number	Functional form	Fitting formula	Goodness of fitting
1	Linear function	$\bar{u}_{Hz} = 0.49 + 0.19\bar{y}_H$	0.36
2	Exponential function	$\bar{u}_{Hz} = e^{\bar{y}_H - 0.28}$	0.70
3	Peck function	$\bar{u}_{Hz} = e^{\frac{-\bar{y}_H^2}{0.19}}$	0.78
4	Power function	$\bar{u}_{Hz} = 0.99 * 9.28^{\bar{y}_H}$	0.87

displays low goodness of fitting, and fails to converge. In contrast, the fitting curve of the peck function and power function successfully reaches the maximum coseismic-slip, conforms to the deformation characteristics of the measured curve, and shows high goodness of fitting. Consequently, the subsequent fitting analysis focuses on the peck and power functions. The power function exhibits a goodness of fit of 0.87, while the peck function displays a goodness of fit of 0.78. Therefore, the calculation formula of the normalized coseismic-slip of the hanging wall in the vertical direction selects the power function fitting formula.

$$\bar{u}_{Hz} = 0.99 * 9.28^{\bar{y}_H} \quad (9)$$

A conversion process is carried out to obtain the actual calculation formula of coseismic-slip for the hanging wall in the vertical direction:

$$u_{Hz} = \varphi_1 u_{Hz\max} (0.99 * 9.28^{\frac{y}{i_{Hz}}}) \quad (10)$$

where φ_1 is the fault type judgment coefficient, 1 for normal fault and -1 for reverse fault.

(2) Footwall

The normalized coseismic-slip data of the footwall in the vertical direction was subjected to fitting analysis, as shown in Figure 9. Among the different function forms, the power function exhibited the highest goodness of fit at 0.85. Hence, the power function was selected to determine the calculation formula of the footwall coseismic-slip in the vertical direction:

$$\bar{u}_{Fz} = -0.99 * 0.16^{\bar{y}_F} \quad (11)$$

$$u_{Fz} = \varphi_1 u_{Fz\max} (-0.99 * 0.16^{\frac{y}{i_{Fz}}}) \quad (12)$$

2.3.2 Fitting analysis of horizontal coseismic-slip

The normalized coseismic-slip data of both the hanging wall and footwall in the horizontal direction underwent fitting analysis, as depicted in Figure 10. The power function fitting curve yielded a high goodness of fit of 0.97 and 0.95 for the hanging wall and footwall, respectively. Thus, it was selected as the calculation formula for the horizontal coseismic-slip:

Figure 8. Normalized data fitting of footwall in vertical direction.

$$\bar{u}_{Hx} = -0.99 * 10.49 \bar{v}_H^H \quad (13)$$

$$u_{Hx} = \varphi_2 u_{Hx \max} (-0.99 * 10.49 \frac{v}{v_{Hx}}) \quad (14)$$

$$\bar{u}_{Fx} = 0.99 * 0.03 \bar{v}_F^F \quad (15)$$

$$u_{Fx} = \varphi_2 u_{Fx \max} (0.99 * 0.03 \frac{v}{v_{Fx}}) \quad (16)$$

where φ_2 is the fault type judgment coefficient, 1 for right-lateral strike-slip fault and -1 for left-lateral strike-slip fault.

Figure 9. Normalized data fitting in horizontal direction: (a) hanging wall; (b) footwall.

2.3.3 Fitting analysis of longitudinal coseismic-slip

After the dislocation of the active fault, the coseismic-slip data measured in the vertical and horizontal directions are typically more detailed than that of the longitudinal coseismic-slip data. The latter is challenging to measure and as such, the available longitudinal data is often limited. However, the longitudinal data can be inferred based on parameters such as the fault type and fault dip angle, as shown in Table 2.

It can be seen that the relationship between the longitudinal coseismic-slip and the vertical coseismic-slip of an active fault can be expressed as the tangent value of the fault dip angle:

$$u_y = \frac{u_z}{\tan \alpha} \quad (17)$$

Hence, considering that normal faults are mainly subjected to tension in the longitudinal direction while reverse faults are mainly subjected to compression, the formula for predicting the longitudinal coseismic-slip is derived as:

$$u_{Hy} = \frac{u_{Hz}}{\tan \alpha} = \varphi_1 \frac{-u_{Hz \max} (0.99 * 9.28 \frac{v}{v_{Hz}})}{\tan \alpha} \quad (18)$$

$$u_{Fy} = \frac{u_{Fz}}{\tan \alpha} = \varphi_1 \frac{u_{Fz \max} (-0.99 * 0.16 \frac{v}{v_{Fz}})}{\tan \alpha} \quad (19)$$

where α is the fault dip angle.

3 ANALYSIS OF TUNNEL RESPONSES UNDER FAULT DISLOCATION

3.1 Analysis of the longitudinal tunnel coseismic-slip

The coseismic-slip data of tunnels crossing active faults are often scarce due to various factors, such as topographic conditions, survey difficulties, and safety concerns. A commonly accepted assumption is that the resistance of the tunnel, being a long and linear structure, can be neglected in the face of stratum deformation, which is in turn assumed to be equivalent to the deformation of the tunnel structure (Kawashima, Kazuhiko, 1994). In the scenario where a tunnel intersects an active fault, the coseismic-slip of the tunnel is equal to that of the stratum when the tunnel is perpendicular to the fault. However, in actual engineering, it is common for the tunnel to intersect the fault at an intersection angle, as illustrated in Figure 14 (a). In such a case, the coseismic-slip of the tunnel can be obtained by considering the geometric relationship between the tunnel and the stratum, as depicted in Figure 14 (b):

Table 2. Coseismic-slip parameters of wenchuan earthquake (Xibin et al., 2013).

Observation point	Horizontal coseismic-slip (m)	Vertical coseismic-slip (m)	Fault dip angle (°)	Longitudinal coseismic-slip (m)
Xiaoyudong West	2.15	1.36	37	1.84
Xiaoyudong East	2.71	1.51	32	2.44
Qingping	2.58	3.70	61	2.01
Bailu middle school	1.63	2.00	51	1.63

$$u_{T-z} = u_z \quad (20)$$

$$u_{T-x} = u_y \cos \beta + u_x \sin \beta \quad (21)$$

$$u_{T-y} = u_y \sin \beta - u_x \cos \beta \quad (22)$$

Namely:

$$u_{T-Hz} = \varphi_1 u_{Hz \max} (0.99 * 9.28^{\frac{y_T}{i_{T-Hz}}}) \quad (23)$$

$$u_{T-Fz} = \varphi_1 u_{Fz \max} (-0.99 * 0.16^{\frac{y_T}{i_{T-Fz}}}) \quad (24)$$

$$u_{T-Hx} = \varphi_1 \frac{-u_{Hz \max} \cos \beta (0.99 * 9.28^{\frac{y_T}{i_{T-Hz}}})}{\tan \alpha} + \varphi_2 u_{Hx \max} \sin \beta (-0.99 * 10.49^{\frac{y_T}{i_{T-Hx}}}) \quad (25)$$

$$u_{T-Fx} = \varphi_1 \frac{u_{Fz \max} \cos \beta (-0.99 * 0.16^{\frac{y_T}{i_{T-Fz}}})}{\tan \alpha} + \varphi_2 u_{Fx \max} \sin \beta (0.99 * 0.03^{\frac{y_T}{i_{T-Fx}}}) \quad (26)$$

$$u_{T-Hy} = \varphi_1 \frac{-u_{Hz \max} \sin \beta (0.99 * 9.28^{\frac{y_T}{i_{T-Hz}}})}{\tan \alpha} - \varphi_2 u_{Hx \max} \cos \beta (-0.99 * 10.49^{\frac{y_T}{i_{T-Hx}}}) \quad (27)$$

$$u_{T-Fy} = \varphi_1 \frac{u_{Fz \max} \sin \beta (-0.99 * 0.16^{\frac{y_T}{i_{T-Fz}}})}{\tan \alpha} - \varphi_2 u_{Fx \max} \cos \beta (0.99 * 0.03^{\frac{y_T}{i_{T-Fx}}}) \quad (28)$$

where u_{T-Hz} , u_{T-Fz} , u_{T-Hx} , u_{T-Fx} , u_{T-Hy} , and u_{T-Fy} are the tunnel coseismic-slip; β is the intersection angle; y_T is the distance from a point on the tunnel to the fault plane, $y_T = \frac{y}{\sin \beta}$; i_{T-Hz} , i_{T-Fz} , i_{T-Hx} , and i_{T-Fx} are the coseismic-slip range of tunnels crossing active faults, $i_T = \frac{i}{\sin \beta}$.

3.2 Analysis of the tunnel cross-section coseismic-slip

In any cross section of the tunnel (the fault distance at the center of the tunnel is y_0), n feature points are taken along the perimeter of the tunnel, i.e., $N_1(x_1, y_1, z_1) \dots N_i(x_i, y_i, z_i) \dots N_n(x_n, y_n, z_n)$, as shown in Figure 11.

According to the geometric relationship in Figure 10, the calculation formula of fault distance y_i of point $N_i(x_i, y_i, z_i)$ is obtained as follows:

$$y_i = y_0 - z_i \cot \alpha + x_i \cos \beta_i \quad (29)$$

Figure 10. (a) intersection angle; (b) geometric relationship.

Figure 11. Schematic diagram of tunnel cross section feature points.

The deformation u'_i ($u'_{x,i}$, $u'_{z,i}$) of point N_i can be obtained by substituting fault distance y_i into the tunnel deformation calculation formula in Section 3.1.

3.3 Calculation method of the longitudinal tunnel response

Once the vertical, horizontal, and longitudinal coseismic-slip u_{T-z} , u_{T-x} , and u_{T-y} of the tunnel are acquired (see Section 3.1), the Euler-Bernoulli beam theory can be utilized to determine the longitudinal axial force N , bending moment M , and shear force V :

$$N = EA \frac{du_{T-y}(y_T)}{d(y_T)} \quad (30)$$

$$M_x = -EI \frac{d^2 u_{T-x}(y_T)}{d(y_T)^2} \quad (31)$$

$$V_x = -EI \frac{d^3 u_{T-x}(y_T)}{d(y_T)^3} \quad (32)$$

$$M_z = -EI \frac{d^2 u_{T-z}(y_T)}{d(y_T)^2} \quad (33)$$

$$V_z = -EI \frac{d^3 u_{T-z}(y_T)}{d(y_T)^3} \quad (34)$$

Namely:

$$N = EA \left[\varphi_1 \frac{B_1 \sin \beta \ln(C_1)}{D_1 \tan \alpha} F_1 * C_1^{\frac{y_T}{D_1}} - \varphi_2 \frac{B_2 \cos \beta \ln(C_2)}{D_2} F_2 * C_2^{\frac{y_T}{D_2}} \right] \quad (35)$$

$$M_x = -EI \left[\varphi_1 \frac{B_1 \cos \beta \ln^2(C_1)}{D_1^2 \tan \alpha} F_1 * C_1^{\frac{y_T}{D_1}} + \varphi_2 \frac{B_2 \sin \beta \ln^2(C_2)}{D_2^2} F_2 * C_2^{\frac{y_T}{D_2}} \right] \quad (36)$$

$$V_x = -EI \left[\varphi_1 \frac{B_1 \cos \beta \ln^3(C_1)}{D_1^3 \tan \alpha} F_1 * C_1^{\frac{y_T}{D_1}} + \varphi_2 \frac{B_2 \sin \beta \ln^3(C_2)}{D_2^3} F_2 * C_2^{\frac{y_T}{D_2}} \right] \quad (37)$$

$$M_z = -EI \varphi_1 \frac{B_3 \ln^2(C_3)}{D_3^2} F_3 * C_3^{\frac{y_T}{D_3}} \quad (38)$$

$$V_z = -EI \varphi_1 \frac{B_3 \ln^3(C_3)}{D_3^3} F_3 * C_3^{\frac{y_T}{D_3}} \quad (39)$$

$$M = \sqrt{M_z^2 + M_x^2} \quad (40)$$

$$V = \sqrt{V_z^2 + V_x^2} \quad (41)$$

where B_n , C_n , D_n , and F_n are the calculation parameter s, $n=1, 2, 3$, specific values are shown as Table 3; E is the equivalent elastic modulus of the tunnel; A is the tunnel section area; I is the tunnel moment of inertia.

Table 3. Calculation parameters value.

Value of n		Calculation parameters			
		B_n	C_n	D_n	F_n
$n=1$ (N)	Hanging wall	$-u_{Hz \max}$	9.28	i_{T-Hz}	0.99
	Footwall	$u_{Fz \max}$	0.16	i_{T-Fz}	-0.99
$n=2$ (M_x, V_x)	Hanging wall	$u_{Hx \max}$	10.49	i_{T-Hx}	-0.99
	Footwall	$u_{Fx \max}$	0.03	i_{T-Fx}	0.99
$n=3$ (M_z, V_z)	Hanging wall	$u_{Hz \max}$	9.28	i_{T-Hz}	0.99
	Footwall	$u_{Fz \max}$	0.16	i_{T-Fz}	-0.99

3.4 Calculation method of the tunnel cross-section response

The deformation of n nodes of support structure is calculated by the method of cross section deformation of tunnel through active fault zone, see Section 3.2. Then, after loading the deformation into the model shown in Figure, the internal force of the tunnel cross-section can be obtained.

Figure 12. Internal force calculation model of tunnel cross section.

4 VERIFICATION

To verify the internal force calculation method of tunnels crossing active faults, a finite element model is established using the Midas GTS NX 2022 software. In the model, the tunnel is simulated using beam elements with an element length of 0.5 m to ensure precise calculations. A tunnel with a total length of 100 m, an external diameter D of 15 m, and a thickness t of 0.7 m is modeled for the analysis. The material used for the tunnel is C35 reinforced concrete with an elastic Young's modulus of 32.5 GPa and Poisson's ratio of 0.2.

Due to its prevalence and complexity in practical engineering, the oblique-slip fault is often the focus of seismic hazard analyses. In this study, the analysis model utilizes a normal left-lateral strike-slip fault with a dip angle α of 76° and an intersection angle β of 80° . The coseismic-slip is 1m in both the vertical and horizontal directions, with 0.5m occurring in the hanging wall and 0.5m occurring in the footwall. To ensure appropriate boundary conditions, the coseismic-slip of the analysis case is specified to the boundary nodes. Figure 15 displays the relevant details of the boundary conditions.

Figure 16 to Figure 18 depict the axial force, bending moments, and shear forces of the tunnel. The analytical results are represented by solid lines while the finite element method (FEM) results are represented by symbols. The theoretical model displays remarkable agreement with the FEM-based analysis.

5 CONCLUSIONS

This study presents a novel approach for predicting the stratum coseismic-slip and tunnel response under fault dislocation. The main findings of this research can be summarized as follows:

- (1) The coseismic-slip of active faults exhibits an “S” shape, with the maximum coseismic-slip occurring at the fault plane and decreasing gradually as the fault distance increases. The form of the coseismic-slip curve is primarily affected by the range and maximum value of the coseismic-slip.
- (2) By conducting mathematical statistical analysis, the prediction method of the vertical and horizontal coseismic-slip range of active faults is fitted. The theoretical calculation values exhibit excellent agreement with the measured values, which can serve as a useful reference for determining the engineering fortification range crossing or near the active fault.
- (3) In view of the crucial parameters such as the coseismic-slip range and maximum, a prediction method for the stratum coseismic-slip is formulated. The derived theoretical values exhibit excellent agreement with the empirical measurements. The proposed approach is universally applicable for all types of faults and offers high computational accuracy and efficiency.
- (4) Based on the prediction method for stratum coseismic-slip, the calculation method is developed to determine the coseismic-slip and response of tunnels. The results obtained from the proposed method demonstrate excellent quantitative agreement with the corresponding finite element analysis results.

ABSTRACT: In order to solve the large deformation problem of Haitai Yangtze River tunnel and improve the stiffness of longitudinal joint, a DDCI connection structure for longitudinal joint is proposed in this paper. By using the numerical software ABAQUS, the DDCI connection structure model was established, and the tensile and shear characteristics of the structure were studied. According to the numerical results, the influence of the form, size and material of the component on the mechanical characteristics of DDCI connection structure was analysed, and the optimization scheme of DDCI connection structure is proposed, which provides a reference for related engineering applications.

Keywords: DDCI connection structure, Longitudinal joints, Mechanical characteristics Tunnelling

1 INTRODUCTION

The Haitai Yangtze River tunnel is a cross-river tunnel connecting Haimen and Taicang with a total length of 11.2km, which is an important infrastructure construction project. Due to the fact that the tunnel is located under water, the tunnel confronts the challenge of large structural deformation, which means higher requirements to the joints. It is well known that the joint structure type is greatly significant in the design of shield tunnel structure, which should not only consider the surrounding geological conditions, load and waterproof requirements, but also the construction convenience, economic rationality, construction period pressure, maintenance difficulty and other factors.

Currently, most of the longitudinal joints of the existing shield tunnel segments are bolted, which can be caught in a dilemma when it comes to the tunnel with large diameter. If single-row bolts are used, the corresponding longitudinal joint stiffness is small and the structural deformation is large, which is not conducive to the structural safety. Otherwise, if double-row bolts are used, the large hand holes will greatly

weaken the force section of segment structure, thus reducing the bearing capacity of the structure and affecting the structural safety. Moreover, the hand holes can reduce the suction force of the vacuum sucker used in the assembly of lining segments, which pose threat to construction safety. In order to avoid the adverse influence of hand holes and achieve rapid assembly, the present scheme adopts the quick connection method with embedded parts, mostly relating to CT-type connection. However, the female joints of CT-type connection method are generally hollow embedded components, which causes great reduction on the thickness of the segments and also requires extremely high fabrication accuracy and construction accuracy. In addition, the existing quick connection method can potentially affect the waterproof safety for changing the conventional segment assembly method.

In view of the technical problems such as that the existing conventional inclined bolts cannot meet the deformation requirements of the shield tunnel, the construction difficulty and poor waterproof safety of CT-type connection, as is shown in Figure 1, this paper proposes a new longitudinal segment joint,

Figure 1. Section view of DDCI connection.

DDCI connection, which can realize multi-point connection without hand holes. By combining this connection and the traditional inclined bolts in the longitudinal joints of lining segments, the relative sliding of the joint surface can be reduced during assembly and meanwhile the impairment of concrete section can be avoided. Also, the waterproof safety can be ensured with DDCI connection. The following sections will analyse the mechanical response of the new DDCI connection structure by numerical simulation method, and propose the optimized structure design.

2 MODEL EXPERIMENT

This study intends to carry out systematic scientific research on the mechanical behaviour of DDCI longitudinal joints connection through numerical calculation by ABAQUS, including the optimization of the form, material and geometric size of the DDCI connection.

2.1 Numerical model

The numerical model of DDCI connection is composed of concrete blocks, major-D part, minor-D part, C part, I part and anchor bar, as shown in the Figure 2. The major-D part and the minor-D part which are embedded in two adjacent concrete blocks respectively are connected to the concrete by anchor steel bars. The length of the concrete block is 800mm, the thickness is 400mm, and the width is 2000mm. The diameter of the anchor steel bar is 25mm, and the spacing is 155mm. Other values of form and size vary in the DDCI studies. For materials, the segments are made of concrete of C60 and the anchor bar is designed as HRB500. The model is calculated using an eight-node linear hexahedron element.

In order to investigate the influence of different forms, sizes and materials on the mechanical properties of DDCI connections, a number of working conditions were designed by numerical experiments. To fasten DDCI connection and provide preload, two types of I parts are studied, which can be named as form A and form B. As is shown in Figure 3, form A consists of a steel rod and a sleeve, of which the

Figure 2. DDCI connection of longitudinal segments.

outer side is designed with evenly distributed barbs, and the angle between the barbs and the sleeve is 45 degrees. When the A-form I part is inserted into the gap between the major-D part and the C part, the presence of barbs render the I part an expansion force, thus fixing the DDCI connection. Form B includes two wedge members of different lengths. The longer wedge member is firstly inserted into the gap between the major-D part and the C part during assembly, and then the shorter wedge member is inserted. The deeper the wedge inserted, the greater the preload provided.

Figure 3. I parts of DDCI: form A (left); form B (right).

In terms of size, in order to acquire better mechanical properties of DDCI connection, the study changes the size of C part and D part. The thickness of the C part is set as 8mm and 10mm, the thickness of the D part is set as 8mm, 10mm and 12mm, and the length of the cantilever end of minor-D part is set as 14mm and 42mm respectively. In summary, considering the influence of size, four groups of working conditions are designed as is shown in Figure 4.

Obviously, the materials of the structure have a significant influence on its mechanical response, so the effects of different materials are also taken into consideration in the study. For D part and C part, the test uses a variety of steel types, including Q690, Q550 and Q345, and the size scheme of C10-D12-14 is adopted in the experiment. For I part, the materials of the sleeve in form A and wedge members in form B are designed experimentally using polyamide and polytetrafluoroethylene. To sum up all above, the working conditions are listed in Table 1.

Figure 4. Four working conditions of different sizes.

Table 1. Working conditions of DDCI model.

I part	C part and D part
1 Form A - polyamide	C10-D10-42-Q550
2 Form A - polytetrafluoroethylene	C10-D10-42-Q550
3 Form B - polyamide	C10-D10-42-Q550
4 Form B - polytetrafluoroethylene	C10-D10-42-Q550
5 Form A - polytetrafluoroethylene	C8-D8-42-Q550
6 Form A - polytetrafluoroethylene	C10-D10-14-Q550
7 Form A - polytetrafluoroethylene	C10-D12-14-Q550
8 Form B - polyamide	C10-D12-14-Q690
9 Form B - polyamide	C10-D12-14-Q550
10 Form B - polyamide	C10-D12-14-Q345

In the study of all working conditions, the tensile behaviour of concrete segment joints is used as evaluation criteria. In the model shown in Figure 5, the vertical and horizontal displacement of the left concrete block is limited, and the vertical displacement of the right concrete block is limited. Meanwhile, the tensile forces are applied at two ends of the concrete blocks equally. In order to study the stiffness of DDCI connection, the opening of concrete segments during the increase of the tensile force is an important observation value.

Figure 5. Tensile experiment on DDCI numerical model.

2.2 Physical model

To verify the results of the numerical simulation, the study also supplemented some physical experiments on DDCI connection. In the experiment shown in Figure 6, two T-shape rectangular concrete blocks were poured with fiber concrete labeled C60, of which the optimized DDCI connection obtained by numerical simulation was installed in the middle. Besides, the anchor bars

of D parts and the reinforcement cage in the concrete are designed according to the actual scheme of the Haitai Yangtze River Tunnel. In physical experiments, hydraulic jacks are used to exert tension on concrete blocks and pull rod displacement gauges are used to measure the opening of concrete segments under different tensile forces, so as to evaluate the stiffness of DDCI connection.

Figure 6. Tensile experiment on DDCI physical model.

3 DISCUSSION

Through numerical simulation and validation of physical experiments, a deep understanding of DDCI connection is acquired. In this section, the influence of form, size and material on the DDCI connection will be discussed in order to obtain the optimal structural solutions.

3.1 Influence of form

In terms of form, the influence of form A and form B on DDCI connection stiffness was both analysed by numerical simulation. For form A, the length of the barbs was changed to 18mm and 45mm respectively. As is shown in Figure 7, the results show that when the segment opening is 4mm, the tensile force borne by DDCI connection with 18mm barb is about 0.5MN, while the tensile force borne by DDCI connection with 45mm barb is about 0.7MN. However, the stiffness of form A is significantly lower than that of the inclined bolt connection.

For form B, the study modified the jacking force of the wedge member to 0 and 100kN. As is shown in Figure 8, the results show that when the segment opening reaches 4mm, the tensile force borne by DDCI connection is about 2.7MN and the stiffness of the connection with jacking force of 100kN is slightly higher than that without jacking force. On the whole, DDCI connection of form B has a better effect, of which the stiffness is greatly improved compared with the inclined bolt connection.

3.2 Influence of size

In order to test the influence of size, four working conditions were studied, where the dimensions of D part and C part were designed differently, including the thickness and the length of the cantilever

Figure 7. Tension-opening curve of DDCI of form A.

Figure 8. Tension-opening curve of DDCI of form B.

end. According to the size of the DDCI connection, the four working conditions are named as C8-D8-42, C10-D10-42, C10-D10-14 and C10-D12-14, which is shown in Figure 4. To clarify that the thickness of C part is 10mm, the thickness of C part is 12mm and the cantilever end length of minor-D part is 14mm.

Figure 9. Tension-opening curve of DDCI of different sizes.

The experimental results are shown in the Figure 9, from which it can be found that the overall stiffness of DDCI connection with minor-D part of short cantilever end is obviously larger than that of DDCI connection with minor-D part of long cantilever end. The stiffness of DDCI connection of C10-D12-14 is the highest, of which the tensile force is over 1.4MN when the joint opening is 4mm. Also, the raise in the thickness of DDCI may lead to the increase in the stiffness of connection. As a consequence, the connection of C8-D8-42 has the lowest stiffness because of its long cantilever end and small thickness. Moreover, with the gradual increase of the joint opening, the stiffness differences in different working conditions will become more obvious. Confronted with large structural deformation, the stiffness of DDCI connections of C10-D10-14 and C10-D12-14 is even larger than that of the connection with inclined bolts.

3.3 Influence of material

Numerical simulation experiment shows that different materials can lead to different mechanical behaviours of DDCI connection. The I part is designed with polyamide and polytetrafluoroethylene. However, considering the effect of practical engineering and material property, it is well believed that the use of polytetrafluoroethylene for sleeve of form A and polyamide for wedge members of form B is the most appropriate scheme.

For the materials of D part and C part, the numerical simulation experiment is carried out for an insightful analysis, where steel of Q690, Q550 and Q345 are involved. The results are shown in Figure 10, from which it can be concluded that when the joint opening is less than 3mm, the different types of steel have little influence on the stiffness. Nevertheless, when the joint opening reaches 4mm, the stiffness of the working conditions with Q690 and Q550 is slightly higher than that of the working condition with Q345. With the gradual change of the joint opening, the stiffness of the condition with Q345

Figure 10. Tension-opening curve of DDCI of different materials.

is obviously the worst, but the stiffness of working conditions with Q550 and Q690 are just similar. Taking the construction economy into consideration, Q550 is the best choice for D part and C part due to its comparably better effect and low price.

3.4 Validation of physical experiment

The optimum DDCI connection scheme was obtained by the numerical experiments, including wedge members made of polyamide material as I part. The dimensions of D part and C part are determined according to the working condition C10-D12-14, which are made of Q550 steel. Following the design above, test blocks were poured and DDCI connection was installed to perform physical experiments in order to verify the results of the numerical simulation. The T-shaped concrete blocks were placed vertically and the hydraulic jacks were fixed to the concrete with the steel frame, which is shown in Figure 11.

Figure 11. Physical experiment of DDCI connection.

The displacement meters are arranged on the two surfaces of the segment joint to measure the value of opening at both ends and the middle of the surfaces. Several strain gages are installed inside the concrete to measure the mechanical behaviour of the anchor bars of major-D part and minor-D part. In the physical experiment, in order to test the tensile properties of DDCI connection, the computer-controlled hydraulic jacks applied load to the structure step by step according to the loading scheme shown in Table 2.

The outer surface of the concrete segment is denoted as plane A and the inner surface is denoted as plane B. The measuring points of the joint opening from one end to the other end are denoted as 1, 2 and 3 respectively. Therefore, the six displacement meters can be named as A1, A2, A3 and B1, B2, B3. Similar to the numerical simulation, the change in the opening of the segment joint as the tensile force increased was recorded, of which the results are shown in the Figure 12.

Table 2. Loading scheme.

Step	Load/kN	Time/min
1	120	preload
2	240	5
3	360	5
4	480	5
5	600	5
6	720	5
7	840	5
8	960	5
9	1080	5
10	1200	5
11	-	10

Figure 12. Tension-opening curve of DDCI in physical experiment.

The results show that when the average joint opening is 4mm, the tensile force that the concrete segments can withstand is about 1MN, which is slightly smaller than the numerical simulation results. However, considering the influence of test site factors, the reduction of stiffness is permissible. In terms of mechanical behaviour, the results of numerical simulation are basically verified by the physical experiments.

4 CONCLUSIONS

In order to investigate the mechanical properties of DDCI connection, a great number of numerical simulation and physical experiments have been carried out so far. Based on the analysis results, some important conclusions concerning DDCI connection can be drawn as follows:

- (1) The feasibility of DDCI connection is verified by the experiments. Through a special mold and pouring method, major-D part and minor-D part can be fixed in the concrete segments with anchor bars, which make them work together. With the jacking device, C part and I part can be

- smoothly installed into the gap of D parts, through which a certain preload will be provided.
- (2) The optimum design of DDCI connection is given by the discussions above. The form of I part is determined as form B, which includes two wedge members of different length. The dimension plan of C part and D parts is determined according to the working condition of C10-D12-14, which means the thickness of C part is 10mm, the thickness of D part is 12mm and the length of the cantilever end of minor-D part is 14mm. Considering the requirements of construction economy and structural mechanics, the material of I part is designed as polyamide and the material of C part and D parts is designed as steel of Q550.
 - (3) The strength and stiffness of the DDCI connection is proved by the experiments. Although the results of physical experiments are not as good as that of numerical simulation, the strength and stiffness of DDCI connection can meet the structural requirements of Haitai Yangtze River Tunnel. Combined with inclined bolts, DDCI connection can effectively reduce the large deformation of tunnel structure.

ACKNOWLEDGMENTS

The great support for this work of ‘Study on structural mechanical behaviour test and numerical

simulation of DDCI new connection for longitudinal joints of lining segments in Haitai Yangtze River Tunnel project’ is appreciated.

Research on support parameters of the second Jiaozhou Bay Subsea tunnel based on the total safety factor method

Mingqing Xiao, Wenhao Sun, Libao Chen & Linsen Jin
China Railway Siyuan Survey and Design Group CO., LTD, Wuhan, China

ABSTRACT: Although China has gained some experience in submarine tunnel construction, there are still some theoretical unclear areas in the design of support structures for drilling and blasting method tunnels, such as the exact role and load-bearing capacity of primary support during construction and operation. Therefore, the design of primary support is generally based on empirical analogy method. This research article proposed support parameters for the Second Jiaozhou Bay subsea tunnel based on empirical analogy, then conducted quantitative analysis of support parameters such as anchor rod length, anchor rod spacing, and shotcrete thickness by total safety factor method. The results indicate that the support structure design parameters based on empirical analogy have a larger overall safety factor and optimization space. The bearing arch effect of the surrounding rock and anchor rock is significant, and the length increase of the anchor rod has a significant effect on the safety factor improvement, especially for the III-level surrounding rock. Under the condition of unchanged or slightly increased safety factor, properly increasing the length and spacing of anchor rods can significantly reduce the anchor rod quantity. Economic and technical comparison analysis results show that the support parameter optimized by the method of total safety factor has significant economical advantages.

1 INTRODUCTION

With the development of the national economy, the demand for cross-sea transportation is increasing. Cross-sea transportation can be achieved through bridges and tunnels. Submarine tunnels are increasingly showing their superiority due to advantages such as being unaffected by typhoons, minimal environmental impact, and no interference with shipping. In recent years, during the selection process of different cross-sea transportation schemes, tunnel schemes often become the preferred choice.

The main factors that influence the selection of tunnel lining structure types and the design of support parameters include the type of tunnel usage, engineering geological and hydrogeological conditions, and construction methods. For deep-buried submarine tunnels, the external water pressure is high, and circular lining structures are suitable for fully sealed tunnels. Tunnel Boring Machines (TBMs) are suitable for circular lining structures, while drilling and blasting methods are suitable for various lining structure types.

Composite lining is commonly used in transportation tunnels. Many scholars at home and abroad have conducted in-depth research on the calculation methods of initial support for composite lining, proposing methods such as engineering analogy, characteristic curve method, formation-structure method, and limit

analysis-based formation-structure method. However, there is a lack of clear load values and safety factor calculations. In the calculation of secondary lining, the load-structure method is generally used. Due to the different calculation methods used for initial support and secondary lining, it is difficult to evaluate the overall safety of the composite lining structure as a whole. To address this issue, Xiao Mingqing et al. established a method for designing the total safety factor of composite lining tunnels and used this method to analyze the safety of railway tunnels. They also conducted research on controversial issues such as the role of anchor rods, tunnel load-bearing structure, and optimization of support parameters.

2 ENGINEERING BACKGROUND

The Jiaozhou Bay Second Subsea Tunnel is located within the city limits of Qingdao on the Shandong Peninsula, between the existing Jiaozhou Bay Tunnel and Jiaozhou Bay Bridge. Once completed, it will serve as an important link between the West Coast New Area and the main urban area of Qingdao on the East Coast.

The Qingdao Jiaozhou Bay Second Subsea Tunnel project is a bi-directional 6-lane urban expressway with a design speed of 80km/h. The total length of the project is approximately 17.5km, with the tunnel section

accounting for 14.37km. The underwater section is approximately 10km long. The tunnel layout consists of two main tunnels and a central service tunnel, making it the largest and longest underwater tunnel in China upon completion. The construction method for this project combines drilling and blasting, shield tunneling, and open-cut methods. The drilling and blasting section of the tunnel is 9,427m long, while the shield tunneling section is 3,253m long.

Figure 1. General plan layout diagram of the tunnel.

Figure 2. Cross-sectional illustration of the tunnel.

3 SUPPORT PARAMETERS BASED ON EMPIRICAL ANALOGY METHOD

Considering that the Jiaozhou Bay Second Subsea Tunnel has a much greater burial depth compared to the Jiaozhou Bay Tunnel, Xiamen Xiang'an Tunnel, and Haicang Tunnel, the support parameters for the Jiaozhou Bay Second Subsea Tunnel were preliminarily determined through the empirical analogy method based on the design and construction experiences of the aforementioned projects. The support parameters for the subsea section are shown in Table 1.

Table 1. Support parameters for the jiaozhou bay second subsea tunnel based on empirical analogy method.

Lining Type		Type III	Type IV	Type V
Rock Grade		III2	IV2	V2
Initial Support	Anchor	φ22 multiple corrosion-resistant anchors for arch, L=3.5m, spacing 1.2×1.2m	φ22 multiple corrosion-resistant anchors for arch wall, L=3.5m, spacing 1.0×1.0m	φ22 multiple corrosion-resistant anchors for arch wall, L=4.0m, spacing 0.75×1.0m
	Steel Mesh	Local, φ8	φ8, 20×20cm	φ8, 15×15cm
	Shotcrete	C35 10cm	C35 28cm	C35 26cm
	Steel Frame	--	φ22H170 grid, spacing 1.0m	φ25H220 grid, spacing 0.5m
Secondary Lining	Arch, Wall	C50, 50cm※	65cm※	70cm※
	Inverted Arch	--	80cm※	90cm※
	Reinforcement	φ22mm @150mm	φ25mm @150mm	φ28mm @150mm

Note: The “※” in the secondary lining thickness represents C50 reinforced concrete lining; without “※” represents C50 plain concrete lining; Shotcrete: plain concrete is CF45 steel fiber reinforced concrete.

4 SUPPORT PARAMETERS BASED ON TOTAL SAFETY FACTOR METHOD

4.1 Total safety factor method

This method focuses on the tunnel approaching or reaching the failure stage and integrates the geological-structural method with the load-structural method. It establishes a unified approach to evaluate and calculate the safety of tunnel support structures by organically integrating the rock mass, loads, and support structures.

The calculation of rock pressure is based on the “design value of rock pressure.” Considering that tunnel rock pressure varies with multiple factors such as support parameters, timing of support installation, and characteristics of support materials, the design of hypothetical support force is obtained to simultaneously meet the safety and economic requirements of tunnel support structures when the tunnel approaches or reaches the failure stage.

In the calculation of support structures, the tunnel support structure is divided into three layers: the rock-bearing arch, the shotcrete layer (including steel frames), and the secondary lining. The safety factors of the rock-bearing arch, shotcrete layer, and secondary lining are calculated separately. The lower limit of the total safety factor of the support structure can be approximately calculated using the following formulas:

Construction phase (without secondary lining):

$$K_c = \eta K_1 + K_2 \quad (1)$$

Operation phase: When using durable anchor rods,

$$K_{op} = \eta K_1 + \xi K_2 + K_3 \quad (2)$$

When using non-durable anchor rods,

$$K_{op} = \xi K_2 + K_3 \quad (3)$$

Where, K_1 , K_2 , and K_3 represent the safety factors of the rock-bearing arch, shotcrete layer, and secondary lining when subjected to the design value of rock pressure. η is the modification coefficient for the safety factor of the rock-bearing arch, and ξ is the adjustment coefficient for the bearing capacity of the shotcrete layer.

4.2 Safety verification of support parameters using empirical analogy method

The rock mass parameters refer to the 《Feasibility Stage Survey Report of the Second Subsea Tunnel in Qingdao》 and the 《Highway Tunnel Design Code》 (JTJ 3370.1-2018). The recommended lower 1/3 quantile values of rock mass level parameters are shown in Table 2.

Based on the selected types of lining (Type III-V) using the empirical analogy method, the results show that the safety factors of initial support and secondary lining of each type of lining can meet the

Table 2. Physical and mechanical parameters of rock mass levels.

Rock Mass Level	III	IV	V
Density (kN/m ³)	25.17	23.17	18.83
Elastic Resistance Coefficient Ke (MPa/m)	733.33	300	133.33
Deformation Modulus E (GPa)	10.67	2.87	1.00
Poisson's Ratio	0.28	0.33	0.43
Internal Friction Angle φ (°)	42.67	31.00	22.33
Cohesion c (MPa)	0.97	0.37	0.10

requirements. The construction phase total safety factor Kc ranges from 3.80 to 8.80, meeting the minimum safety factor requirement of 1.8. The operation phase total safety factor Kop ranges from 9.72 to 28.90, meeting the minimum safety factor requirement of 3.6. Overall, the safety factors of the support parameters are relatively high, indicating significant potential for optimization.

4.3 Research on support parameters using the total safety factor method

4.3.1 Research plan for initial support parameters

In the design of composite lining structures, there are three different design concepts based on the different functions of initial support and secondary lining: the first concept treats the initial support as a temporary structure and the secondary lining as the load-bearing main body; the second concept treats the initial support as the load-bearing main body and the secondary lining as either a safety reserve or for bearing minimal loads; the third concept treats both as load-bearing main bodies. Different design concepts result in different support parameters.

From the perspective of initial support, there are three possible structural schemes for initial support (for ease of explanation, regardless of whether the shotcrete contains steel mesh or steel frame, it is simply referred to as the “shotcrete layer”):

- (1) Structure without systematic anchor support, where the initial support mainly consists of the shotcrete layer, without systematic anchor support, only local anchors are installed to prevent spalling.
- (2) Combined support of shotcrete and anchor, where the initial support consists of both the shotcrete layer and systematic anchors.
- (3) Anchor-dominated support structure, where the rock pressure is entirely borne by systematic anchors, and the local loose load between anchors is borne by the shotcrete layer, with a minimum structural thickness of 8cm.

In summary, this study first divides the initial support schemes into three categories based on their load-bearing roles, and then further divides each category into three research schemes based on different

combinations of anchors and shotcrete. The specific schemes are shown in Table 3.

Table 3. Classification of research schemes for initial support design parameters.

Role of Initial Support	Combination of Anchors and Shotcrete	Remarks
1 Scheme 1: Initial support bears only construction	Subscheme 1-1: Without systematic anchors	Common anchors
2 phase load; secondary lining bears all rock	Subscheme 1-2: Anchor-dominated	
3 pressure and water pressure during operation	Subscheme 1-3: Combined anchor and shotcrete	
4 Scheme 2: Initial support and secondary lining bear the	Subscheme 2-1: Without systematic anchors	Durable anchors
5 load together, with secondary lining bearing	Subscheme 2-2: Anchor-dominated	
6 all water pressure	Subscheme 2-3: Combined anchor and shotcrete	
7 Scheme 3: Initial support serves as the load-bearing main	Subscheme 3-1: Without systematic anchors	Durable anchors
8 body, with secondary lining bearing only	Subscheme 3-2: Anchor-dominated	
9 water pressure	Subscheme 3-3: Combined anchor and shotcrete	

4.3.2 Preliminary determination and optimization principles of initial support parameters

There are many strength grades for shotcrete and secondary lining concrete in initial support. In order to reduce the computational workload, this study adopts a uniform strength grade of C35 for shotcrete based on similar engineering experience and durability design requirements.

The minimum construction requirement for shotcrete thickness is 8cm, and the minimum construction requirement for secondary lining thickness is 35cm (based on the minimum value of secondary lining thickness in the design specifications for three-lane tunnels in highway tunnels).

The anchor rods are all $\Phi 22$ anchor rods, with a minimum length of 2.5m. The length is selected within the range of 2.5m to 5.0m, and for specific conditions, 6.0m and 7.0m long anchor rods are used for calculation. The spacing between anchor rods is not greater than half the length of the anchor rod.

Referring to the research results of “Calculation and Research on Support Parameters of High-Speed Railway Tunnels” (Xiao M. Q., et al), the recommended values for the safety factor of initial support are as follows: for Scheme 1 and Scheme 2, the total safety factor Kc during the construction phase

should be greater than or equal to 2.1, and for Scheme 3, the total safety factor K_c during the construction phase should be greater than or equal to 3.0.

4.3.3 Preliminary support parameter design scheme comparative analysis

4.3.3.1 Scheme 1

(1) Scheme 1-1 (Without Systematic Anchors)

Based on the minimum thickness of the shotcrete layer of 8cm, with a thickness increment of 2cm, multiple schemes were developed for rock grades III-V, and the initial support safety factors for each scheme are shown in the table below.

Table 4. Calculation results for scheme 1-1.

	Rock Grade	Shotcrete Thickness (cm)	Total Safety Factor K_c
1	III	8	1.24
2		10	1.94
3		12	2.32
4		14	2.69
5		16	3.06
6		18	3.42
7	IV	12	1.44
8		14	1.68
9		16	1.91
10		18	2.14
11		20	2.37
12		22	2.59
13	V	20	1.46
14		22	1.60
15		24	1.74
16		28	2.01
17		30	2.15
18		32	2.29
19		8	1.24

From Table 3.3-2, it can be observed that when considering only the load-bearing capacity during the construction phase and without installing anchors, the minimum shotcrete thickness required for rock grades III-V is 12cm, 18cm, and 30cm, respectively, to meet the requirement of the initial support safety factor $K_c \geq 2.1$ during the construction phase. Increasing the thickness of the shotcrete improves the safety factor to some extent, but the effect is not significant. Therefore, for rock grades IV and V, it is not economical to rely solely on shotcrete to increase the safety factor.

(2) Scheme 1-2 (Anchor as Dominant Support)

In the anchor-dominant support scheme, the minimum shotcrete thickness of 8 cm was chosen for rock grades III-V based on construction requirements. Then, various support schemes were proposed based on different anchor rod lengths and spacing.

From Table 5, it can be seen that when considering only the construction phase load in the initial support,

Table 5. Calculation results for scheme 1-2.

	Rock Grade	Shotcrete Thickness (cm)	Anchor Rod Length (m)	Anchor Rod Spacing (m)	Total Safety Factor K_c
1	III	8	2.5	1.0×1.0	7.49
2		8	2.5	1.2×1.2	7.00
3		8	3.0	1.5×1.5	7.61
4		8	4.0	2.0×2.0	8.95
5	IV	8	3.5	1.5×1.5	2.83
6		8	4.0	2.0×2.0	2.92
7		8	4.5	2.0×2.0	3.16
8		8	5.0	2.5×2.5	3.26
9	V	8	4.5	1.0×1.0	1.91
10		8	5.0	1.0×1.0	2.07
11		8	6.0	1.0×1.0	2.37
12		8	7.0	0.8×0.8	2.26

for rock grade III with good rock properties and strong arch bearing capacity of the anchor rock, the overall safety factor is larger. Additionally, increasing the length of the anchor rod significantly improves the safety factor. For rock grade IV, anchor rods with a length of 3.5m and spacing of 1.5m, or a length of 4.0m and spacing of 2.0m, can meet the requirement of the total safety factor $K_c \geq 2.1$ during the construction phase. For rock grade V, when the shotcrete thickness is 8cm and the anchor is the dominant support, anchor rods with a length of 6.0m or above are required to meet the requirement of the total safety factor $K_c \geq 2.1$ during the construction phase. However, the overall safety factor is relatively small, and the short length and spacing of the anchor rods result in a longer construction period and inconvenience in construction.

(3) Scheme 1-3 (Anchor-Spray Combination Support)

In this scheme, the initial support needs to bear the load together with the anchor rock arch and the shotcrete. The overall safety factor of the initial support is obtained by adding the safety factors of the shotcrete and the anchor rod. In the anchor-spray combination support, there are various combinations. Based on the results of Scheme 1-1 and Scheme 1-2, it can be concluded that for rock grades III, IV, and V, when the shotcrete thickness exceeds 12 cm, 18 cm, and 30 cm respectively, the total safety factor during the construction phase can be met. By considering different combinations of shotcrete thickness, anchor rod length, and spacing, the following design schemes are proposed, and the safety factors of the shotcrete, anchor rock arch, and anchor-spray combination are calculated as shown in the table below.

From the table above, it can be seen that rock grade III has a relatively high overall safety factor. For rock grades IV and V, if the shotcrete thickness required for the steel frame is not considered, a shotcrete thickness of 12 cm with anchor rods of

Table 6. Calculation results for scheme 1-3.

	Rock Grade	Shotcrete Thickness (cm)	Anchor Rod Length (m)	Anchor Rod Spacing (m)	Safety Factor		
					Shotcrete	Anchor Rock Arch	Anchor-Spray Combination
1	III	8	3.0	1.5×1.5	1.24	6.37	7.61
2		10	3.5	2.0×2.0	1.94	7.30	8.83
3		10	4.0	2.0×2.0	1.94	8.56	10.5
4	IV	12	4.0	1.5×1.5	1.44	2.43	3.87
5		14	4.0	1.5×1.5	1.68	2.54	4.22
6		16	4.5	2.0×2.0	1.91	2.72	4.63
7	V	20	4.0	1.0×1.0	1.45	1.27	2.72
8		24	4.0	1.0×1.0	1.74	1.36	3.10
9		26	5.0	1.5×1.5	1.88	1.36	3.24
10		28	5.0	2.0×2.0	2.01	1.26	3.27

length 4.0m and spacing 1.5m can meet the safety factor requirement during the construction phase for rock grade IV. Similarly, for rock grade V, a shotcrete thickness of 20 cm with anchor rods of length 4.0m and spacing 1.0m can meet the safety factor requirement during the construction phase. Considering the overall cost, the anchor-spray combination scheme provides a higher safety factor for the initial support compared to the scheme without a systematic anchor rod or the anchor-dominant support scheme.

4.3.3.2 Scheme 2

Schemes 1 and 2 both involve the normal operation of ordinary anchor rods and durable anchor rods during the construction phase, representing the same working conditions. The difference lies in the failure of ordinary anchor rods during the operational phase. Scheme 1 requires a stronger secondary lining to maintain the safety factor during the operational phase compared to Scheme 2. Therefore, the safety factor calculation for the initial support is not listed here. Please refer to Section 3.3.3.1 for details on Scheme 1.

4.3.3.3 Scheme 3

In this scheme, the initial support is considered as the main bearing body. Therefore, in this section, rock grades III-V are calculated with the safety factor based on the initial support bearing 100% of the rock pressure, without considering the contribution of the secondary lining to the bearing. For cases where the shotcrete serves as a permanent support structure, steel fiber reinforced concrete or steel frame reinforcement is used, providing good ductility, and the total safety factor is considered not less than 3.0.

(1) Scheme 3-1 (No Systematic Anchor Rods)

From Table 7, it can be seen that when the initial support is considered as the main bearing body without using anchor rods, the minimum shotcrete thickness required for rock grades III-V to meet the total safety factor $K_c \geq 3.0$ is 16cm, 26cm, and 38cm, respectively.

Table 7. Calculation results for scheme 3-1.

	Rock Grade	Shotcrete Thickness (cm)	Total Safety Factor Kc
1	III	14	2.69
2		16	3.06
3		18	3.42
4	IV	24	2.83
5		26	3.07
6		28	3.31
7	V	36	2.89
8		38	3.01
9		40	3.13

(2) Scheme 3-2 (Anchor-Dominant Support)

For rock grades III-IV, the shotcrete thickness is taken as the minimum construction requirement of 8cm. For rock grade V, based on preliminary calculations, when the shotcrete thickness is between 8cm and 18cm, the required anchor rod length or diameter is too large, exceeding the range of materials commonly used in construction. Therefore, the minimum shotcrete thickness is taken as 20cm. Various support schemes are proposed based on different anchor rod lengths and spacing, and the results of the safety factor calculations for each scheme can be found in Table 8.

From Table 8, it can be seen that when the initial support is considered as the main bearing body, for rock grade III (with an 8cm shotcrete thickness), configuring a shotcrete thickness according to the minimum length of 3.0m for anchor rods and anchor rod spacing less than 1.5m, the total safety factor for the initial support is 7.61, meeting the requirements for the total safety factor. For rock grade IV (with an 8cm shotcrete thickness), selecting anchor rods with a length of 3.5m and spacing of 1.0m can satisfy the requirement of a total safety factor $K_c \geq 3.0$ during the construction phase. For rock grade V (with a 20cm shotcrete thickness), selecting anchor rods

Table 8. Calculation results for scheme 3-2.

	Rock Grade	Shotcrete Thickness (cm)	Anchor Rod Length (m)	Anchor Rod Spacing (m)	Safety Factor		
					Shotcrete	Anchor Rock Arch	Anchor-Spray Combination
1	III	8	3.0	1.5×1.5	1.24	6.37	7.61
2		8	3.5	1.5×1.5	1.24	7.33	8.57
3		8	4.0	2.0×2.0	1.24	7.71	8.95
4	IV	8	3.5	1.0×1.0	0.97	2.21	3.18
5		8	4.0	1.2×1.2	0.97	2.30	3.27
6		8	4.5	1.5×1.5	0.97	2.37	3.34
7		8	5.0	2.0×2.0	0.97	2.41	3.38
8	V	20	4.0	1.0×1.0	1.45	1.27	2.72
9		20	5.0	1.0×1.0	1.45	1.57	3.02
10		20	6.0	1.2×1.2	1.45	1.96	3.06
11		20	7.0	1.5×1.5	1.45	1.62	3.07

with a length of 5m and spacing of 1.0m can meet the requirement of a total safety factor $K_c \geq 3.0$, but the safety factors for rock grades IV and V are relatively low.

(3) Scheme 3-3 (Anchor and Shotcrete Combination Support)

The calculations for Scheme 3-1 indicate that for rock grades III-V, when the shotcrete thickness is greater than 16cm, 26cm, and 38cm respectively, the requirement of a total safety factor greater than 3.0 can be met without setting anchor rods. In the anchor and shotcrete combination scheme, different combinations of shotcrete thickness, anchor rod length, and spacing are proposed (considering the use of steel frames for rock grades IV and V, with minimum shotcrete thicknesses of 20cm and 24cm respectively). The calculated safety factors for shotcrete, anchor-rock arch bearing, and the combination are shown in the following table.

From the table above, it can be seen that rock grade III generally has higher safety factors. For rock grade IV, considering the use of steel frames and a required shotcrete thickness of 20cm, selecting

anchor rods with a length of 4.0m and spacing of 1.5m can meet the safety factor requirements during the construction phase. For rock grade V, with a shotcrete thickness of 24cm, selecting anchor rods with a length of 4.5m and spacing of 1.2m can meet the safety factor requirements during the construction phase. When the initial support is considered as the main bearing body, taking into account the quantity of shotcrete and anchor rod works and assuming comparable overall costs, the anchor and shotcrete combination scheme provides higher safety factors for the initial support compared to the scheme without systematic anchor rods or the anchor-dominant scheme.

4.3.4 Study on secondary lining parameters

The initial support structure of the tunnel needs to bear all the additional loads released during excavation. It is the main body of the support system and integrates with the surrounding rock, essentially assisting in bearing the load of the surrounding rock. The secondary lining structure is usually considered as a safety reserve, but due to its inherent stiffness, it will share part of the load with the initial support after construction.

Table 9. Calculation results for scheme 3-3.

	Rock Grade	Shotcrete Thickness (cm)	Anchor Rod Length (m)	Anchor Rod Spacing (m)	Safety Factor		
					Shotcrete	Anchor Rock Arch	Anchor-Spray Combination
1	III	8	3.5	1.5×1.5	1.24	7.33	8.57
2		10	4.0	2.0×2.0	1.94	8.26	10.20
3		12	4.0	2.5×2.5	2.32	8.20	10.52
4	IV	20	4.0	1.5×1.5	2.37	2.87	5.24
5		22	4.5	1.5×1.5	2.59	3.13	5.72
6		24	4.5	2.0×2.0	2.83	3.04	5.87
7	V	24	4.5	1.2×1.2	1.74	1.34	3.08
8		26	5.0	1.5×1.5	1.88	1.36	3.24
9		28	5.0	2.0×2.0	2.01	1.26	3.27

For the rock section of grade III in this project, the surrounding rock is self-stable, so the load borne by the secondary lining structure is relatively smaller compared to the rock sections of grade IV and V. Based on empirical analogies, reinforcing bars may not be necessary for the secondary lining in the grade III rock section, while for the grade IV and V rock sections, reinforced concrete structures are considered. The strength grade of the secondary lining concrete is selected as C50 for reinforced concrete and C40 for plain concrete or steel fiber reinforced concrete.

4.3.4.1 Grade III Rock

The minimum structural requirement for the secondary lining thickness is 35cm. Based on empirical analogies, the determined thickness for the secondary lining is 50cm. Considering that the secondary lining in this project needs to withstand certain water pressure, a comparative study was conducted for three thicknesses: 40cm, 45cm, and 50cm. The analysis results are as follows:

Table 10. Analysis results of secondary lining for grade III rock section.

	Lining Thickness (cm)	Safety Factor K3	Total Safety Factor Kop
1	40	9.86	27.41
2	45	10.63	28.39
3	50	9.31	29.76

From the table above, it can be seen that the calculated overall safety factors are all greater than 27, meeting the requirement of not less than 3.6. Therefore, the thickness of the secondary lining for the grade III rock section is determined as 40cm.

4.3.4.2 Grade IV Rock

Based on empirical analogies, the determined thickness for the arch wall of the grade IV rock section is 70cm. Since the load on the secondary lining in the grade IV rock section is greater than that in the grade III rock section, the thickness of the secondary lining for the grade IV rock section is compared based on the grade III rock section.

Table 11. Analysis results of secondary lining for grade IV rock section.

	Lining Thickness (cm)	Reinforcement Details	Crack Width (mm)	Safety Factor K3
1	40	∥ 25@100	0.21	7.91
2	50	∥ 25@100	0.16	10.34
3	60	∥ 25@100	0.136	12.74
4	70	∥ 25@100	0.116	15.13

Therefore, the thickness of the arch wall for the grade IV rock section is determined as 50cm.

4.3.4.3 Grade V Rock

Following the same approach as mentioned above, the thickness of the secondary lining for the grade V rock section is considered as 55cm, with reinforcement details of ∥ 28@100.

4.3.5 Calculation of secondary lining under water pressure

For the above-mentioned secondary lining schemes, the safety factors obtained when subjected to a water head pressure of 20m are shown in the table below:

Table 12. Safety factors of secondary lining under water pressure.

Rock Grade	III	IV	V
Safety Factor K3	10.42	6.00	5.22

For the grade III rock section, plain concrete is used, and the calculated safety factor is 10.42, meeting the safety factor requirement of not less than 3.6. For the secondary lining from grade IV to grade III rock section, reinforced concrete structures are used, and the calculated safety factors are 6.00 and 5.22, respectively, both meeting the safety factor requirement of not less than 3.0.

4.3.6 Recommended support parameter scheme

Based on the total safety factor method, the recommended support parameter scheme for the second submarine tunnel is shown in the table below:

4.4 Comparison analysis of design results between empirical analogy method and total safety factor method

4.4.1 Safety factor comparison

The safety factors for the lining types determined by the empirical analogy method and the total safety factor method are shown in the table below:

From the above table, it can be seen that the safety factors of the support parameters determined by both methods meet the requirements. However, the safety factors corresponding to the support parameters determined by the total safety factor method are slightly lower than those determined by the empirical analogy method. This indicates that the total safety factor method provides a more detailed analysis of the components of the support system, and the design results are more economical while meeting the specified safety factor conditions.

Table 13. Support parameter table for the second submarine tunnel based on the total safety factor method.

Lining Type		Type III	Type IV	Type V
Rock Grade		III2	IV2	V2
Initial Support	Anchor	φ22 multiple corrosion-resistant anchors for arch, L=4.0m, spacing 2.0×2.0m	φ22 multiple corrosion-resistant anchors for arch wall, L=4.5m, spacing 2.0×2.0m	φ22 multiple corrosion-resistant anchors for arch wall, L=5.0m, spacing 1.5×1.5m
	Steel Mesh	–	φ8, 20×20cm	φ8, 20×20cm
	Shotcrete	C35 10cm	C35 22cm	C35 26cm
	Steel Frame	–	φ22H160 grid, spacing 1.0m	∟20a Steel frame with spacing of 0.75m
Second-ary Lining	Arch, Wall	CF45, 40cm	50cm×	55cm×
	Inverted Arch	–	60cm×	65cm×
	Reinforcement	–	∥ 25mm @100mm	∥ 28mm @100mm

Table14. Safety factor comparison for each lining type.

Lining Type		Empirical Analogy Method			Total Safety Factor Method		
		Type III	Type IV	Type V	Type III	Type IV	Type V
Rock-Load Arch	Reduction Coefficient η_1	1.00	0.68	0.35	1.00	0.81	0.45
	Construction Phase K_{Ic}	7.64	3.19	1.37	8.27	3.09	1.36
	Reduction Coefficient η_2	1.00	1.00	0.76	1.00	1.00	1.00
	Operation Phase K_{Iop}	16.11	4.23	1.37	16.42	5.03	1.61
Shotcrete	Reduction Coefficient ξ	1.00	1.00	1.00	1.00	1.00	1.00
	Safety Factor K_2	1.16	3.19	2.43	1.94	2.59	1.88

Initial Support (Total)	Construction Phase K_c	8.80	6.38	3.80	10.21	5.68	3.24
Total	Operation Phase K_{op}	28.90	14.37	9.72	28.78	13.62	8.71

Table 15. Comparison of major engineering quantities for each lining type.

Lining Type	Empirical Analogy Method			Total Safety Factor Method			Unit Price Indicators (CNY)
	Type III	Type IV	Type V	Type III	Type IV	Type V	
Excavation (m3)	131.5	171.38	174.70	127.1	161.40	165.58	340.22
Initial Support Shotcrete (m3)	4.25	13.66	14.68	2.86	10.48	12.41	1351.80
Steel Fiber (kg)	–	–	–	128.7	–	–	7.96
Steel Mesh (t)	–	0.123	124.17	–	0.119	120.45	9.06
Anchors (m)	72.92	105	168	29	32.63	68.35	103.76
Secondary Lining Concrete (m3)	14.75	29.91	32.21	11.89	23.1	25.35	1567.91
Longitudinal Reinforcement (t)	1.110	2.243	2.823	–	3.33	4.19	9062.41
Project Cost (10,000 yuan)	9.12	15.60	17.39	6.98	13.99	15.90	/

4.4.2 Comparison of major engineering quantities

The calculated meter quantities of major engineering works for the lining types determined by the empirical analogy method and the total safety factor method were compared, and combined with the unit price indicators of the project budget, the quantity and cost comparison are shown in the table below:

From the above table, it can be seen that compared to the support parameters determined by

the empirical analogy method, the support parameters recommended by the total safety factor method are significantly more cost-effective. For Grade III lining (corresponding to Grade III rock), the project cost is reduced by approximately 23.5%. For Grade IV lining (corresponding to Grade IV rock), the project cost is reduced by approximately 10.32%. For Grade V lining (corresponding to Grade V rock), the project cost is reduced by approximately 8.6%.

5 CONCLUSION

The support structure design parameters determined by the empirical analogy method generally have a large safety factor, indicating room for optimization.

The rock-load arch effect of each rock grade is significant, and increasing the anchor length has a noticeable effect on increasing the safety factor, especially for Grade III rock.

By appropriately increasing the anchor length and spacing while keeping the safety factor unchanged or slightly increased, the number of anchor works can be greatly reduced.

Economic and technical comparative analysis results show that the optimized support parameter design results based on the total safety factor method are significantly more cost-effective.

ABSTRACT: At Present, the research on the joint sealing performance of the shield tunnel segment mainly focuses on joint waterproof performance. However, many shield tunnels pass through methane gas strata. Gases and liquids having different physical properties lead to different leakage characteristics. Therefore, it is necessary to research the joint airproof performance of the shield tunnel segment. In this article, we set up an experimental platform to test the joint airproof performance and use a picosecond laser to construct microstructures on the surface of the EPDM sealing gasket. We observe the microstructures of the gasket surface processed with different laser powers, scanning speeds and scanning spacings by microscope and analyze the relationship between the hydrophilic property and the airproof performance of the gasket. It is found that using lasers to construct microstructures on the gasket surface effectively improves the airproof performance of the gasket.

Keywords: shield tunnel, segment joint, picosecond laser, surface microstructure, gas leakage

1 INTRODUCTION

Many researchers have researched the microstructure and sealing properties, especially the hydrophilic and hydrophobic properties and surface wettability. Sizhu Wu^[1] discussed femtosecond laser processing of various microstructures and summarized the results of femtosecond laser fabrication of infiltrating surfaces. Xiqin HE^[2] researched the laser processing of micropores and microcolumns. Maolin Zhou^[3] researched superwetting surfaces. Guangfei Wang^[4] researched super-hydrophobic fabrication methods of silicone rubber materials and summarized them to provide an overview of the up-to-date research state and progress in detail. Xue Bai^[5] used a femtosecond laser to create a microgroove array structure and obtained an anisotropic and super-hydrophobicity surface. Guoqiang Li^[6] processed metal surfaces to obtain a variety of surface structures by combining the femtosecond laser micro/nano machining technology and the bionic design principles. Mingqing XIAO^[7] proposed that the contact surface of the gasket is uneven

and has tiny leakage holes; its waterproof ability is controlled by the maximum contact stress of the contact surface and the flow resistance of the tiny holes between the contact surface. Improving the evenness of the contact surfaces can reduce the number and size of tiny holes, and it is also a critical factor in strengthening the waterproof ability. Wenqi DING^[8] carried out a series of test sets and evaluated the joint waterproof performance of the shield tunnel in the Nanjing Weisan Rd.

From the above research, it can be seen that many researchers have extensively researched the preparation of sealing gasket surfaces with special wetting properties using different methods and techniques. However, the research on the joint sealing performance of the shield tunnel segment mainly focuses on joint waterproof performance. The research on the airproof performance of the microstructure of the gasket surface is relatively limited. In this article, we use a picosecond laser to construct microstructures on the surface of the EPDM gasket, set up an experimental platform to test its airproof performance, research the

effect of different gasket surface microstructures on airproof performance, verify constructing microstructures on the gasket surface can improve its airproof performance.

2 AIRPROOF PERFORMANCE OF THE GASKET SURFACE MICROSTRUCTURE

2.1 Experimental platform

The experimental uses an ultrashort pulsed laser manufactured by EdgeWave Germany, model PX200-3-GFH, which has a maximum power of 100W, a wavelength of 1064nm and a maximum repetition frequency of 2MHz. Figure 1(a) shows a schematic diagram of the laser system. Figure 1(b) shows the tested EPDM gasket. It has an outer shape of 70mm by 70mm, an inner shape of 46mm by 46mm, a thickness of 8mm and a chamfer radius of 6.5mm. Before using the laser to construct the gasket surface microstructure, the gasket requires to be ultrasonically cleaned for 15 minutes in anhydrous ethanol and deionized water. Afterwards, take it out, air-dried naturally, and place it in sample bags for later use. The experimental platform consists of a 6MPa pressure gauge, a three-way valve, and two flanges to secure the gasket, as shown in Figure 1(c).

When testing the airproof performance of the gasket, place two similarly treated gaskets inside the two flanges and then fix the gasket and the flange with chloroprene rubber adhesive, and wait for 90 minutes. After stood for 90 minutes, assembling and tightening the flanges, maintaining a compression gap of 8mm, inputting air pressure between the two flanges by using an inflation pump and recording the breakdown pressure of the gasket from the pressure gauge.

2.2 Results of airproof performance experimental

While testing the airproof performance of the gasket surface micro-structure, try to exclude interference factors such as environmental temperature, external air pressure, and the dryness of the gasket surface. Each group of parameters conducts three replicate experiments and averages the results. For groups with differing results, additional experiments are needed to ensure the relative accuracy of the experimental results. The results are shown in Table 1.

3 ANALYSIS OF TEST RESULTS

3.1 Analysis of surface microstructure and airproof performance

The surface microstructure of the gasket is photographed using a microscope, and a three-dimensional map and a height distribution map of its surface microstructure are generated using VK analysis software.

Figure 2(a) shows the smooth control group surface with no microgroove array structure. Only some shallow microgroove arrays appear when using 9.85W laser power to process the gasket surface, as shown in Figure 2(b). There is no prominent microstructure. It might be due to the lower laser power, resulting in less energy being delivered to the surface per unit time, causing most of the surface not to be processed or completely processed. When the laser power is increased to 13.25W, as shown in Figure 2(c), the surface receives more energy per unit of time, and as a result, the surface forms a uniform and neat microstructure. Due to the laser scanning spacing of 60 μ m, the observed surface consists of microgroove arrays with a spacing of 60 μ m. When the laser power is further increased to 16.2W, as shown in Figure 2(d),

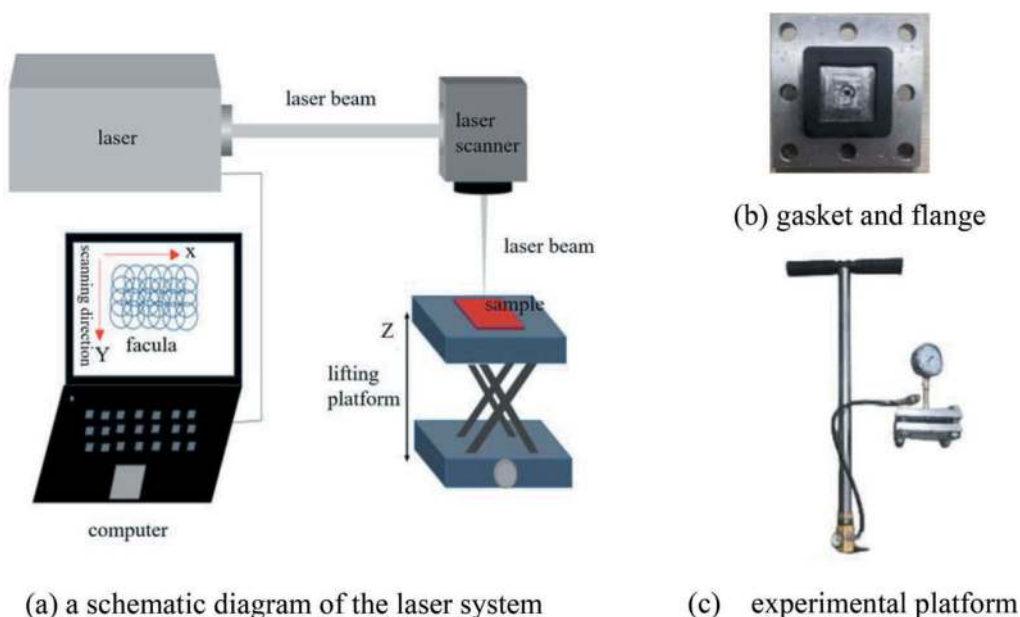

Figure 1. Airproof performance experimental platform.

Figure 2. Three-dimensional micrographs at different powers.

the laser power is relatively high, the surface absorbs the most energy per unit time, and a series of processes such as melting, vaporization, and reformation occur more completely. This results in more pronounced and uniform microstructures. The height of the microgroove arrays increases slightly.

Figure 3 shows that as the scanning speed increases from 0.3m/s to 2m/s, the surface of all samples has linearly arranged microgroove arrays. When scanning at a lower speed of 0.3m/s, the surface absorbs more energy per unit time and more of the base material was removed from the surface. This leads to the maximum height of the microgroove arrays, as shown in Figure 3(a). However, there are some imperfections in the microgroove array, and its height is uneven, which can affect the airproof performance. When the scanning speed is increased to 0.5m/s, the microgroove arrays are neatly arranged at a consistent height, with a high average height, as shown in Figure 3(b), and the airproof performance is improved. When the laser scanning speed is further increased to 1m/s, less energy is applied to the material surface per unit time, resulting in a smaller microgroove array height, as shown in Figure 3(c). When

the scanning speed reaches the maximum of 2m/s, laser processing is faster but less complete, resulting in the least pronounced groove structures with the lowest height, as shown in Figure 3(d).

As can be seen from Figure 4(a), when the scanning spacing is 40 μm , due to the small scanning spacing, the laser repeatedly processes the same position, which will lead to dense groups of microgroove arrays on the surface or even the phenomenon of squeezing each other and the degree of neatness is inferior to that of the surface of the scanning spacing of 60 μm . The airproof performance is relatively poor, which is also confirmed by the experiment results. In addition, the airproof performance of the test experiment with scanning spacing of 80 μm and 100 μm is also good so that the scanning spacing can be appropriately larger.

3.2 Analysis of contact angle and airproof performance

Take the control group and the first to the sixth test group samples, and measure the surface contact angle with a JC2000 instrument. During the test,

Figure 3. Three-dimensional micrographs at different scanning speed.

Figure 4. Three-dimensional micrographs at different scanning spacing.

place the sample, drop the deionized water droplets onto the sample surface, and control the volume of each drop to be at eight μL . Using a camera to capture and shoot the image of the sample surface, analyze its contact angle microscopic image by the software Drop Mete and measure the size of the contact angle by the software ImageJ. The contact angle and airproof performance for each group are shown in Figure 5.

Figure 6 compares the airproof performance and contact angle for each group. It is obvious that the contact angle is the largest in the control group, about 89° , while smaller in the other groups, from 30° to 75° . In addition, all the other groups improved airproof performance compared to the control group. The first, second, fourth, and sixth groups show more remarkable improvement because their contact angles are smaller, and the third and fifth groups show more

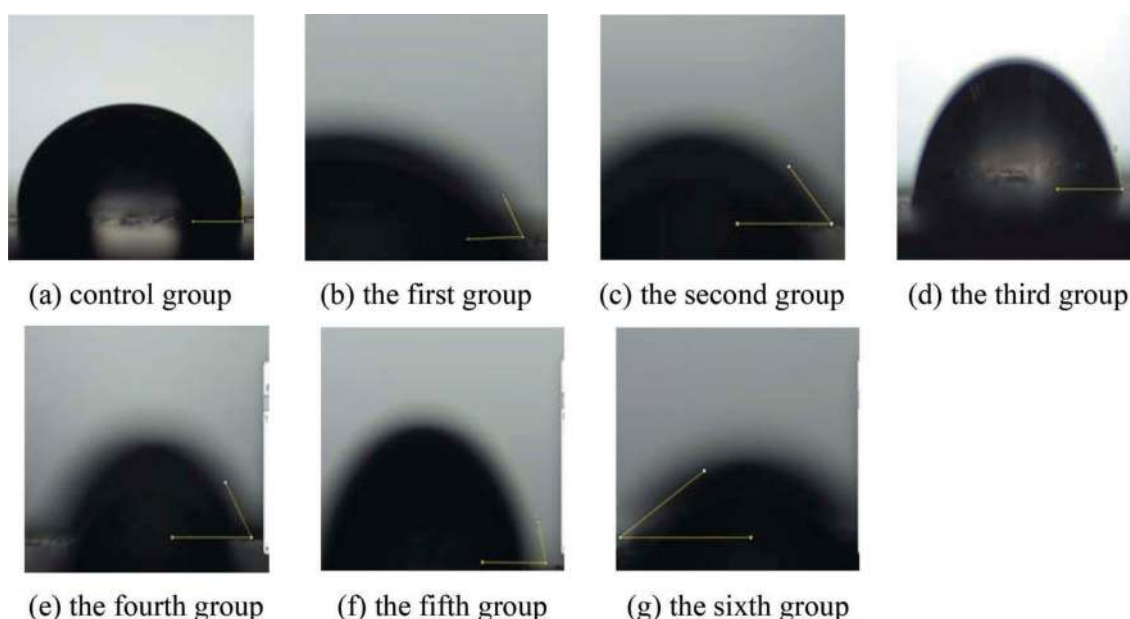

Figure 5. Contact angle comparison diagram.

Figure 6. Comparison of the airproof performance and contact angle for each group.

remarkable improvement because of their larger contact angles. In particular, the sixth group, which has the best airproof performance, use a laser power of 16.2 W, a scanning speed of 0.5 m/s, and a scanning spacing of 60 μm to form a neat and uniform microgroove array structure. Its contact angle reaches a minimum of 30°, and its airproof performance improves by about 30% compared to the control group.

It can be said that the contact angle of the gasket is smaller after laser processing, and with the increase of laser power, the contact angle tends to become smaller. At the same time, the smaller the contact angle is, the better the airproof performance is.

3.3 The experiment of airproof performance of the gasket surface microstructure

The experimental platform consists of three steel templates, two L-shaped and one square-shaped steel template. When assembled, these three steel templates form a T-shaped joint, as shown in Figure 7. The laser parameters for the gasket surface are given in section 3.3.2. The gasket was compressed to an opening of 8 mm, under 15 mm offset, firstly, and connected to an air pressure loading device at one end and to an airproof performance test device, Air pressure it until 2MPa. At this time, the air pressure between the two sealing gaskets should be recorded every day. The

Figure 7. Platform of airproof test.

Table 2. The air pressure results between the two sealing gaskets (MPa).

Gasket Type	Days(day)									
	1	5	10	15	20	25	30	35	40	45
gasket 1 (unprocessed)	2	1.38	0.94	0.73	0.59	0.5	0.43	0.37	0.32	0.29
gasket 2 (processed)	2	1.73	1.53	1.34	1.18	1.05	0.94	0.86	0.82	0.80
gasket 3 (processed)	2	1.74	1.54	1.36	1.19	1.07	0.96	0.87	0.84	0.81

whole experiment was divided into three groups. The first group used an unprocessed sealing gasket, while the gaskets of the second and third groups were processed. Each group of experiments was recorded for 45 days, and Table 2 shows the air pressure results between the two sealing gaskets for each five days. From the table, we can see that the residual air pressure of the laser-processed gasket is 0.80Mpa. It is much larger than the unprocessed gasket, which is 0.29Mpa, verifying the effectiveness of constructing microstructures on the gasket surface in enhancing its airproof performance.

4 CONCLUSIONS

In this article, we use a picosecond laser to construct microstructures on the surface of the sealing gasket and set up an experimental platform to test airproof performance. We analyze the effects of laser power, scanning speed, and scanning spacing on the airproof performance of the gasket as well as the hydrophilic properties of the gasket surface after being processed with a picosecond laser. The gasket surfaces with uniform and appropriately sized microstructures have extraordinary airproof performance. The main conclusions are as follows:(1) When the gasket surface is not processed by laser, its hydrophilic property is poor, and the contact angle between the drop and the surface is almost at right angles. (2) The airproof performance of the gasket is improved after its surface is processed by laser. (3) The better the hydrophilic property of the gasket surface, the better the airproof performance. In the future, we will continue to research the correlation between the laser processing parameters and the hydrophilic properties of the gasket surface in order to obtain a better gasket surface.

ABSTRACT: In order to prevent the cracking of marine engineering mass concrete, and the water seepage deterioration of the structure is caused. The double-control technology (temperature and expansion deformation control of concrete) with anti-cracking agent is used instead of the cooling water pipe to control concrete crack. The mixing ratio is low cement dosage, high content mineral admixture and 8% anti-cracking agent. The anti-crack agent can reduce the heat release rate of early hydration and compensate shrinkage of concrete in the temperature drop stage. At the same time, the work performance, mechanical properties and durability of the concrete are excellent. After the calculation and analysis of cracking risk through finite element simulation, when the length of the anti-cracking concrete is poured within 20m, the cracking risk value is less than 0.7, and the concrete will not crack, meet design and construction requirements.

Keywords: marine, mass marine concrete, anti-cracking agent, crack control

1 PREFACE

Once the problem of cracking occurs in Marine mass concrete, the erosion of seawater will accelerate the deterioration of reinforced concrete. In the world, the crack control of Marine mass concrete is mainly based on temperature control of concrete, which is to restrain the formation of concrete temperature cracks by reducing the concrete entering temperature, the peak temperature of concrete, and the temperature difference of concrete inside and outside. However, a large number of engineering cases show that in some structures with strong constraints and shrinking, even if extremely strict temperature control measures are carried out, concrete cracking still exists, and the existence of cracks will lead to the deterioration of the concrete in Marine engineering, which is unfavorable to the stability of the concrete structure.

Concrete cracking is a complex multi-factor coupling process. In the crack control design of mass

concrete, researchers usually only consider the shrinkage cracking caused by temperature drop, but the actual process is often much more complicated. The cracking of concrete can be summarized as that when the shrinkage of concrete is constrained (both internal and external constraints), the tensile stress generated is greater than the ultimate tensile strength of concrete. The strain deformation of concrete is an important parameter for concrete cracking. Of course, the driving forces causing strain deformation of concrete include temperature stress, dry shrinkage deformation, self-shrinkage, etc. For some parts with large volumes and large constraints, shrinkage deformation is superimposed on each other, and simple temperature control measures are often difficult to achieve the purpose of cracking control of the concrete.

Through the research, the anti-crack agent developed by special technology can effectively delay the hydration heat release and compensate for the concrete shrinkage in the whole process by reducing the

*Corresponding author: 517472351@qq.com

early hydration heat release rate of the cementing material and the dual control technical means of the whole process compensation of concrete shrinkage in stages, to achieve the purpose of concrete crack control. In general, it can simplify the temperature control measures (no cooling water pipe is arranged), speed up the construction progress, and reduce the project cost, which has great significance for the crack control construction of mass concrete.

2 TEST

2.1 Raw materials

The test raw materials are shown in Table 1.

Table 1. Concrete mix ratio (kg/m³).

Raw material	Index
Cement	P·II 42.5 cement
Sand	Medium sand of Ganjiang II area with fineness modulus of 2.6, with mud content less than 2.0%
Gravel	5~25mm continuous gradation, good grain shape, hard texture, the linear expansion coefficient of small clean gravel
Fly ash	Grade I fly ash, in line with the requirements of "fly ash used in cement and concrete" (GB/T1596-2005) Class F I requirements
Mineral powder	Tangshan S95 grade slag powder, the specific surface area is not more than 500 m ² /kg
Water reducing agent	Jiangsu Subote reduced high-performance polycarboxylic acid water reducing agent (water reducing rate of 26.3%, solid content of 20%, the amount of mixing is calculated by solution)
Anti-cracking agent	The anti-cracking agent (HME-V) developed by Jiangsu Subote New Materials Co., Ltd. is composed of calcium oxide, lightly-burned magnesium oxide and hydration heat control material
Mixing water	tap water

2.2 Concrete design

This project is a tunnel side wall structure in the Marine environment, the thickness of the side wall is up to 1.5m, and the length of a single pouring is 20m, which is a typical large-scale concrete for Marine engineering. Because the side wall structure is poured on the bottom plate, the side wall will be constrained by the finished bottom plate during the temperature drop stage, resulting in the stress concentration of the side wall. As a result, concrete is prone to cracking.

In view of the above situation, the design strength of the concrete structure is C_{28d}45, C_{56d}50, the design principle of the concrete mix ratio is low

temperature rise, and has a certain degree of expansion, with shrinkage compensation. by adding anti-cracking agent, on the one hand, the hydration temperature rise inhibitor is used to reduce the heat release rate and temperature rise in the cement hydration acceleration period. On the other hand, based on the characteristics of the deformation process of the solid structure, the expansion components (calcium oxide and magnesium oxide) with different expansion characteristics are used to realize the compensation shrinkage in stages and the whole process.

The actual mix ratio shall be reasonably designed with reference to the design principles of Specification for mix proportion design of ordinary concrete (JGJ 55-2011) and the requirements of Standard for Construction of Mass Concrete (GB 50496-2018) and Specification for Concrete Construction of port and Waterway Engineering (JTS 202-2-2011). After comprehensive consideration, the concrete mix ratio is shown in Table 2.

Table 2. Concrete mix ratio (kg/m³).

number	cement	fly ash	slag	HME-V	sand	gravel	Water	water reducing agent
1#	189	105	126	0	769	1063	143	appropriate amount
2#	189	105	92	34	769	1063	143	appropriate amount

3 TEST RESULTS AND ANALYSIS

3.1 Effect of anti-cracking agent on dosage of water-reducing agent and strength of concrete

The anti-cracking agent of Jiangsu Subody New Materials Co., Ltd. is added to replace 8% of the cementing material (instead of 34kg/m³ mineral powder), the water-binder ratio of concrete is 0.34, and the dosage of the water-reducing agent is calculated as a percentage of the total cementing material. The specific dosage is determined according to the slump of the concrete mix is 200mm, and the dosage of other materials is unchanged. The mixing performance of concrete is shown in Table 3.

Table 3. Concrete performance (kg/m³).

number	HME-V/%	slump/mm	water reducing agent/%	Compressive strength/MPa		
				7d	28d	56d
1#	/	200	1.0	48.7	59.8	63.4
2#	8.0	200	1.15	43.5	57.6	65.1

Comparing the mix ratio of 1# (ordinary concrete) and 2# (crack-resistant concrete), it can be seen that to maintain the same concrete fluidity after the

addition of crack-resistant agent, the amount of water-reducing agent will slightly increase, which may be due to the adsorption effect of crack-resistant agent on water-reducing agent, but this can be adjusted by the amount of water-reducing agent, but the overall effect on the workability of concrete is little. It can be seen from the strength data that the strength of 1# and 2# both meet the strength design requirements. The strength of 7d and 28d of the group with anti-cracking agent 2# is slightly lower than that of the group without anti-cracking agent, but the strength of 56d is higher than that of the comparison group. This is because the anti-cracking agent can delay the hydration heat release rate of cement on the premise of ensuring the total heat release is unchanged, so the early compressive strength of 2# concrete is lower than 1#, but with the increase of age, the compressive strength of 2# group 56d concrete gradually catches up.

3.2 Effect of anti-cracking agent on chloride ion permeability coefficient of concrete

In addition to the cracking damage caused by temperature drop and self-shrinkage of Marine concrete, the deterioration damage caused by chloride ion erosion of concrete reinforcement also needs attention. The chloride ion permeability coefficient is an important parameter that directly reflects the resistance of concrete to chloride ion permeability. The test results of the chloride ion permeability coefficient based on the Standard of Test methods for long-term Performance and Durability of ordinary Concrete(GB/T50082-2009) RCM method are shown in Table 4.

Table 4. Results of the chloride ion permeability coefficient test.

number	HME-V/%	Chlorine permeability/ 10^{-12} cm/s
1#	0	2.9
2#	8%	1.8

As shown in Table 3, the chloride ion permeability coefficient of concrete is reduced after the anti-cracking agent is added, indicating that the anti-cracking agent can improve the chloride ion permeability resistance of concrete. This is mainly due to the expansion of the anti-cracking agent role can influence the structure of the aggregate and cement mortar surface structure, the structure of hardened cement paste pore, improve the concrete slurry aperture distribution, reduce the straight hole, thus reducing the porosity of concrete structure compactness, thus improve the resistance to chloride ion permeability of concrete for Marine (harbor) engineering were, prevent the chloride ion erosion damage of reinforced concrete.

3.3 Regulation of hydration heat of anti-cracking agent

The lower the adiabatic temperature rise of concrete, the smaller the temperature drop range in the temperature drop process, and smaller the temperature stress on the concrete itself, which is beneficial to the improvement of the anti-crack performance of the overall structure. This project delays the hydration rate of cement through the hydration regulation effect of anti-cracking agent, so that the heat release of the cementing material can be released in a longer period. At the same time, the heat dissipation performance of the open surface of the structure can finally reduce the maximum temperature peak value of the solid engineering structure, to reduce the risk of structural cracking.

Figure 1. Results of adiabatic temperature rise test.

In order to compare the control effect of hydration heat of anti-cracking agent, the adiabatic temperature rise test of 1# and 2# concrete was carried out. As can be seen from Figure 1, the adiabatic temperature appreciation of 2# concrete at different stages is significantly lower than that of 1# concrete, and the statistical value of specific characteristic temperature rise is shown in Table 5. Through the data, it is found that the anti-cracking agent has a significant effect on the regulation of cement hydration and heat release. In 3d, the adiabatic temperature rise of 1# concrete is 42.16°C, while the adiabatic temperature rise of 2# concrete is only 28.56°C. The anti-cracking agent greatly delayed the hydration heat release rate of early cement. At 9d, the adiabatic temperature appreciation of 1# concrete was 45.35°C, while the adiabatic temperature appreciation of 2# concrete was 42.24. According to the analysis in Figure 1, the adiabatic temperature appreciation of 1# concrete was flat, while the adiabatic temperature appreciation of 2# concrete still had a certain upward trend. The hydration regulation effect of anti-cracking agent is only to prolong the heat release process but has little effect on the final total heat release, which is also in line with the development law of slightly decreasing strength in the early stage and gradually catching up with strength in the later stage as shown in Table 3.

Table 5. Characteristic adiabatic temperature rise of concrete ($^{\circ}\text{C}$).

number	Characteristic value of temperature $^{\circ}\text{C}$					
	1d	2d	3d	5d	7d	9d
1#	18.76	34.94	42.16	44.87	45.34	45.35
2#	4.22	17.41	28.56	37.48	40.05	42.24

3.4 Effect of anti-cracking agent on the regulation of expansion process of Marine concrete

The actual construction conditions are complex, the temperature field of concrete is changing, and the deformation performance tested under constant temperature laboratory conditions is quite different from that of solid. Therefore, to study the strain deformation law of offshore concrete in solid structures, the temperature variable deformation law of 1# concrete and 2# concrete was tested by simulating the actual temperature field. The anti-cracking agent was mixed with 8% and other materials remained unchanged. The temperature variable deformation results of concrete are shown in Figures 2-4.

Figure 2. Temperature change deformation test results.

As shown in Figure 2, under the condition of temperature change, the concrete strain increases first and then decreases, and the maximum deformation occurs at the temperature peak of 3d, where the maximum strain value of concrete 1# is $262.5\mu\epsilon$, while the maximum strain value of concrete 2# is $600.0\mu\epsilon$, indicating that concrete doped with anti-crack agent expands $337.5\mu\epsilon$ more than ordinary concrete at the temperature rise stage. During the expansion of the early temperature rise stage, the concrete structure will produce pre-compressive stress when constrained, and this part of the compressive stress will be stored in the structure, which is beneficial to resist the shrinkage deformation in the later temperature drop stage. After the temperature peak of concrete, the temperature of concrete began to decrease, and the strain value of concrete also decreased. At 14d, the strain of ordinary concrete was negative $-108.5\mu\epsilon$ and the stress state of concrete was tensile stress, while the strain of crack-resistant concrete was still positive $353.9\mu\epsilon$.

Figure 3. Temperature rise deformation test results.

Figure 4. Temperature drop deformation test results.

In the control of the expansion process, the expansion performance not only plays in the temperature rise stage but also needs to play the ability of continuous expansion in the temperature drop stage to compensate for the shrinkage deformation of concrete in the temperature drop stage. According to Figures 3 and 4, the temperature rise and temperature fall processes were analyzed in stages. We found that the unit temperature deformation values of ordinary concrete and crack-resistant concrete were $7.6\mu\epsilon/^{\circ}\text{C}$ and $21.4\mu\epsilon/^{\circ}\text{C}$ respectively in the temperature rise stage (Figure 3), indicating that the anti-crack agent had begun to play an expansion role in the temperature rise stage. At the same time, in the temperature drop stage, the temperature peak point is zero. Figure 4 shows that the final shrinkage values of ordinary concrete and crack-resistant concrete are $-364.1\mu\epsilon$ and $-246.0\mu\epsilon$, respectively, indicating that the crack-resistant concrete is still undergoing shrinkage compensation in the shrinkage stage, and the compensated shrinkage strain value reaches $118.1\mu\epsilon$, which is in line with the expectation and is beneficial to crack control.

3.5 Finite element software simulation and analysis

Combined with the above concrete mix ratio data and the engineering entity structure, due to the high temperature in summer, the risk of cracking is generally large, so the mix ratio of 1# concrete and 2# concrete are simulated and calculated respectively under the summer construction conditions, the mold temperature is 32°C , and the cracking risk coefficient is calculated respectively according to the section length.

$$\eta = \sigma(t)/f_t(t)$$

Where $\sigma(t)$ is the maximum tensile stress of concrete at time t , and is the tensile strength of concrete at $f_t(t)$ time t . According to the Technical Specification for Thermal Cracking Control of Mass Concrete of Port and Waterway Engineering (JTS 202-1-2010), the evaluation criteria for concrete cracking risk are as follows: It is generally believed that concrete will crack when it is $\eta > 1.0$; Considering the fluctuation of material properties, it is considered that concrete has a greater risk of cracking when $0.7 < \eta < 1.0$; When the value is less than 0.7, the concrete will not crack basically. The finite element calculation model of the risk coefficient of pouring length cracking is shown in Figure 5, and the calculation results are shown in Figure 6.

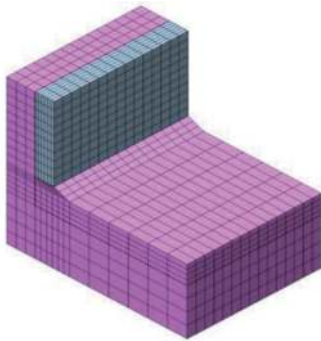

Figure 5. Finite element modeling.

Figure 6. Simulation result.

According to the calculation results in Figure 5, the cracking risk of anti-cracking concrete under the same pouring conditions is lower. According to the calculation, when the length is less than 20m, the cracking risk coefficient is less than 0.7, and the length of one-time pouring is much higher than that of ordinary concrete, which has obvious crack control advantages. As shown in Figure 7, the side wall of the 20cm tunnel was poured at one time, and no cracking was found after observation after mold removal.

Figure 7. Construction diagram of side wall.

4 CONCLUSIONS

The experiment shows that the anti-cracking concrete has excellent performance in terms of working performance, adiabatic temperature rise and deformation, and the analysis and calculation of the side wall structure combined with the simulation calculation method show that the cracking risk coefficient of the concrete with anti-cracking agent can be reduced, and the side wall will not crack basically, which provides valuable experience for crack control of such large-scale concrete in Marine engineering. Summarise as follows:

- (1) The addition of anti-cracking agent will slightly increase the amount of water-reducing agent, which can be solved by increasing the amount of water-reducing agent, which has basically no impact on the working performance of concrete. The anti-cracking agent will slightly reduce the 28d strength, but the 56d strength gradually overtakes the ordinary concrete.
- (2) The anti-crack agent has the dual control function of temperature and expansion field, can reduce the early hydration rate and adiabatic temperature appreciation of concrete, and can compensate the deformation in the temperature drop stage, and the compensation shrinkage value is $118.1\mu\epsilon$, which has a significant effect on inhibiting the later shrinkage cracking of concrete.
- (3) According to the simulation calculation, the cracking risk coefficient of concrete with anti-cracking agent is less than 0.7, and the side wall will not crack basically, and the scheme meets the requirements of construction design when the single pouring length is 20m and the casting mold temperature is 32°C .

Development and application of wall-climbing grinding robot for tunnel lining steel formwork

Ke Yan*

China Railway Construction Heavy Industry Corporation Limited, Changsha, China

ABSTRACT: In order to solve the problems of high safety risk, high labor intensity and low operation efficiency when manually grinding the steel formwork for tunnel lining, an integrated, lightweight and modular design method is adopted to develop a wall-climbing grinding robot with small size, light total weight, convenient disassembly and assembly, which can be suitable for narrow working conditions of tunnel lining. The self-adaptive intelligent operation of the robot in tunnel lining formwork with different curvature radius is realized by flexible grinding mechanism, dual ranging sensor and difference algorithm. A static model is created to analyze the stress of main frame and verify the reliability of robot structure. Finally, the robot has been verified in practical engineering applications. By adjusting the parameters such as grinding speed, working walking speed, wire brush press amount and wire brush diameter, the grinding efficiency is improved to 5–6 times of manual operation efficiency, effectively solving a series of problems existing in manual maintenance of secondary lining trolley.

Keywords: wall-climbing robot, tunnel lining, self-adaptive, industrial verification

1 INTRODUCTION

In the tunnel drilling and blasting construction, the secondary lining trolley is the most core construction equipment to ensure the secondary lining operation. In order to ensure the lining quality of the tunnel surface, it is required that the steel formwork surface shall be polished and oiled once within a limited operation time after each lining by the lining trolley.

The existing operation is mainly completed by manually holding the angle grinder. For the upper end of side formwork and lower end of top formwork of lining trolley, manual direct operation is impossible. It is necessary to set up a temporary walking platform between the outer side of steel formwork surface and the tunnel surface through the lining grouting window to help workers complete the whole formwork grinding operation. When manual grinding is carried out in the tunnel, the working space between the steel formwork and the tunnel lining surface is narrow, with high operation intensity and inconvenient operation. In addition, to control the operation time, multiple workers need to cross-operate on the temporary walking platform synchronously, which has a high safety risk and causes great physical damage to operators when dust is generated during operation. Therefore, there is an urgent need to develop a device to meet the needs of mechanized grinding for secondary lining trolley ^[1, 2, 3].

Figure 1. Manual grinding of secondary lining trolley in tunnel.

At present, a number of wall-climbing robots have been developed at home and abroad, which are mostly used in large-scale wall cleaning, inspection, spraying and other operation scenarios, such as petrochemical storage tank maintenance, ship maintenance, wind power operation and maintenance and building cleaning. In the above application scenarios, the operation space is large and the field of vision is good. In order to improve the operation efficiency,

*Corresponding author: yanke@crchi.com

most robots are equipped with large operation modules, resulting in a large overall size and heavy weight. The construction trajectory is controlled visually, but this design idea is not suitable for the narrow operating environment of tunnel lining [4, 5].

In order to solve the problem that the existing wall-climbing robot is large in size and unsuitable for tunnel working conditions, this paper develops a wall-climbing grinding robot with small size, light total weight, convenient disassembly and assembly, which can be suitable for narrow working conditions of tunnel lining.

2 DESIGN OF ROBOT BODY

In this paper, the wall-climbing robot adopts an integrated, lightweight and modular design. It can be operated by a single person to realize the grinding operation of secondary lining trolley. Meanwhile, the automatic operation of products is realized by using the difference guidance of ranging sensor, which solves the problem of low construction efficiency in visual operation.

As shown in Figure 2, the overall structure of the robot consists of an adsorption walking module, an electric control module and an operation module. The robot body structure includes adsorption walking module and electric control module, which have the functions of adsorption, walking, automatic guidance and convenient replacement of operation modules.

Figure 2. Wall-climbing grinding robot.

2.1 Design of adsorption walking module

In order to ensure the normal operation of the robot in narrow working conditions, it is necessary to carry out integrated and lightweight design on the adsorption walking module.

When the working surface of wall-climbing robot is made of magnetic material, permanent magnet adsorption is often selected. This method has simple structure and reliable adsorption, which is widely used in petrochemical industry, shipbuilding and other scenarios. The steel formwork of secondary lining trolley is made of magnetic material and has the conditions for magnetic adsorption. In this paper,

multi-point arrangement, direct adsorption and indirect adsorption are adopted to ensure the stable adsorption of the robot.

The walking modes of wall-climbing robot usually include wheeled, crawler type and foot type. Among them, the crawler type walking module has strong load capacity but slow movement speed; the foot type walking module has strong obstacle crossing ability but poor movement ability [6, 7]. The wheeled walking module has fast movement speed, flexible steering and certain load capacity. In order to ensure the operation efficiency and reliability, this paper adopts the wheeled walking mode.

2.1.1 Selection of permanent magnet material

With reference to mature products on the market, NdFeB material is selected as the raw material of magnet assembly. It has strong magnetic performance, large coercive force parameters and a wide operating temperature range. The specific grade of NdFeB is N42, and its parameters are shown in Table 1. Although there are materials with higher grades such as N50 and N52, their maximum operating temperature is only 60°C. Considering the extreme high temperatures that may be faced by field operations, it is a better choice to sacrifice some magnetic attraction force to ensure the stable operation of stable magnet assembly [8].

Table 1. Parameters and performance of N42 NdFeB.

Parameter	Value
Residual magnetic induction intensity	12.8-13.2Kgs
Intrinsic coercive force	≥12Koe
Maximum magnetic product energy	318-342kJ/m ³
Operating temperature	≤80°C

2.1.2 Design of adsorption walking module

The adsorption drive module wheel is composed of magnet, magnet housing, rubber wheel and drive motor. In order to ensure the magnetic attraction force of the chassis, the magnet is made into a circular ring as part of the drive wheel to ensure that the distance between the magnet and the working surface is small and stable as much as possible. The outer side of the magnet is wrapped by a housing, which is knurled to improve anti-skid performance.

When the magnet contacts with the working surface, since the outer diameter of the magnet housing is slightly smaller than that of the rubber wheel, under the action of magnetic attraction force, the rubber wheel is deformed and fully contacts with the adsorbed surface. The magnetic rubber wheel structure effectively controls the gap between the magnet and the adsorbed surface, so that the adsorption assembly can provide stable magnetic attraction force. In addition, the rubber wheel is deformed due to magnetic force and fully contacts with the adsorbed surface to improve the stable force of friction with magnet housing.

As shown in Figure 3, the rubber wheel is arranged adjacent to the magnet, so that the adsorption force of the magnet is close to the action point of the supporting force of drive wheel, effectively controlling the arm of force between them. In addition to bearing the weight of the robot body, the frame of the adsorption walking module does not need to bear the additional loads brought by magnetic attraction force. This structure is conducive to the lightweight design of adsorption walking module.

Figure 3. Stress analysis of adsorption walking module.

2.2 Stress analysis

When the robot works on the secondary lining trolley, there are three extreme working conditions: 1) downward sliding during facade movement; 2) overturning of the robot around its lower end during facade operation; 3) insufficient driving force during plane movement [9, 10].

As shown in Figure 4, when the wall-climbing robot is stationary at the vertical position of the lining trolley formwork, it is necessary to check two extreme working conditions: facade sliding and facade overturning.

2.2.1 Downward sliding

In order to ensure that the vertical adsorption of the wall-climbing robot is stable and does not slide down, its static friction force shall be greater than the gravity of the robot. The formula is as follows:

$$F_c = 2(F_{N1} + F_{N2}) + F_n$$

$$G \leq 2\mu(F_1 + F_2)$$

Where: F_1 is the static friction force between the front driving wheel and the working surface, and F_2 is the friction force between the rear driving wheel and the working surface. F_n is the pre-tightening force of wire brush after compression deformation. F_{N1} and F_{N2} are the supporting forces of front and rear driving wheels respectively. G is the gravity of robot, and F_c is the magnetic attraction force of adsorption module.

2.2.2 Longitudinal overturning

When the robot operation module is located above the chassis, there will be a risk of longitudinal overturning around the contact point Q at the lower end of the robot during facade running.

Figure 4. Analysis of facade stress on robot.

$$\sum M_Q = 0$$

$$F_c \cdot \frac{l}{2} - Gh - 2F_{N1}l - F_n m \geq 0$$

In order to ensure that the robot does not overturn and there is a certain safety margin, Among them, safety factor $k=1.5$, friction coefficient $\mu=0.5$, total weight of robot $G=460N$, distance from center of gravity of robot to operation $94mm$, wheel base between front and rear driving wheels $l=365mm$, pre-tightening force of wire brush $F_n=100N$, wheel base between wire brush and rear driving wheel $m=555mm$, the adsorption force F_c required by the adsorption module is $\geq 1200N$.

2.2.3 Plane drive

In order to ensure that the robot can run normally on the top of the secondary lining trolley, it is necessary to ensure that the driving force is greater than the static friction force of the chassis. The formula is as follows:

$$F_f = \mu(mg + F_c)$$

$$T = F_f \cdot r$$

The radius of the driving wheel is $r=40mm$, and there are 4 drive motors in total for the robot body, so the torque T of a single drive motor is $\geq 5N \cdot m$.

2.3 Automatic orientation

When grinding is carried out in the tunnel, it is not conducive to visual control of robot operation due to narrow environment and large height difference of temporary walking platform. In order to improve the grinding efficiency, reduce the labor intensity of operators and ensure their construction safety, the operation mode of automatic guidance is better than visual control.

Due to the narrow space, dark light, poor communication signal, heavy dust during operation and no obvious characteristics of the working surface for reference in tunnel construction by drilling and blasting method, there are obvious limitations in technical methods such as electromagnetic induction, optical detection, ultrasonic detection and coordinate detection under this working condition. This paper designs an automatic guidance technology suitable for tunnel lining.

2.3.1 Guidance technology analysis

For electromagnetic induction/optical detection technology, it is necessary to pre-lay magnetic tapes/nails or colored ribbons with stable reflectivity in the working environment, fix the traveling route of the robot, and carry electromagnetic sensor or photoelectric sensor on the robot. This method has high reliability, but it has a high requirement for flatness of working surface and large transformation of the working surface. There are many undulations on the lining window surface of the secondary lining trolley, and the walking surface is the working surface. It is necessary to polish and oil the working surface, which has the risk of damaging the reference elements. More importantly, both technologies need to transform the steel formwork surface of the secondary lining trolley, which is not conducive to on-site construction and cost control.

Ultrasonic detection uses wall or similar object to locate and guide the reflected signal of ultrasonic waves. It is not necessary to set the datum plane, controlling the guidance cost. However, during the secondary lining of tunnel, the working space is narrow and the steel formwork has no obvious characteristics, so it cannot be positioned and guided by the existing environment;

There are two methods for image recognition technology. One is to use CCD system to dynamically design the image information of the environment around the path and compare it with the image database information of the environment around the proposed operating path, so as to make decisions on subsequent operating paths. However, in practical application, there are problems such as poor real-time performance and difficulty in establishing the environment information section of operating path. The second is the image identification method of identification line, which is implemented by identifying the guide line on the path required for the robot, dynamically taking the image of identification line with a CCD system, and judging the travel deviation of the robot to determine the subsequent movement path [11, 12]. It is difficult to implement this method for the radial transformation of secondary trolley.

2.3.2 Ranging difference guidance

In this paper, the combination of laser detection technology and inertial navigation technology is used to realize automatic guidance operation under the working condition of secondary lining trolley for tunnel.

Figure 5. Schematic diagram of ranging difference guidance.

As shown in Figure 5, the distances from the two laser ranging sensors arranged in parallel to the datum plane are S_1 and S_2 respectively. When the walking path of the wall-climbing robot does not deflect, $S_1=S_2$; On the contrary, when there is an obstacle on the wall surface, the wall surface is bent or the wall-climbing robot slips, the walking path of the wall-climbing robot deviates from the movement direction of the robot, and the difference between the distances from the two laser ranging sensors to the datum plane is ΔS . The deflection angle $\alpha = \arctan(\Delta S/L)$ of the wall-climbing robot is calculated by using a trigonometric function, By detecting the deflection angle in real time, the difference algorithm is used to control the speed of left and right side wheels, so that $S_1=S_2$ and the robot can walk straight. Where, L is the distance between light outlets of two laser sensors.

By using the lane change point set on the datum plane, the ranging sensor detects a sudden change in distance and triggers the lane change program. The inertial navigation module reads the yaw angle of the robot in real time to control the steering of the robot and complete the lane change action. Through datum plane positioning, the laser ranging sensor can calibrate the absolute position of the robot from the datum plane during operation. After lane change is completed, it shall be ensured that the robot does not repeat grinding and miss the required operation area.

3 DESIGN OF OPERATION MODULE

The operation module mainly has the functions of grinding and dust collection. In this paper, the grinding and dust collection modules are effectively integrated. Meanwhile, other operation modules can be expanded through the quick-change assembly interface of the robot body (as shown in Figure 6).

Figure 6. Quick change diagram of operation module of wall-climbing robot.

3.1 Design of grinding and dust collection module

According to the grinding requirements of steel formwork, there are many commonly used methods such as high-pressure water, laser, sandblasting and mechanical grinding. High-pressure water has the problems such as easy re-rusting, need to set up high-pressure pumping station, water supply and drainage; the investment in laser grinding equipment is large, and the cables will reduce the flexibility of equipment. Shot blasting and polishing have great environmental pollution [13].

The above grinding methods have poor applicability to the narrow working environment of tunnel. The mechanical grinding is simple in structure, has high operation efficiency and little disturbance to the environment, and can effectively meet the grinding requirements of steel formwork.

The grinding module consists of base, quick-change assembly, self-adaptive adjustment assembly, grinding motor, transmission assembly and wire brush. Among them, the self-adaptive adjustment assembly consists of adjusting nut, disc spring, guide rod, damper and positioning wheel.

Grinding operation in tunnel will generate a large amount of dust, which has a great impact on the health of operators. In order to control dust and purify the working environment, it is necessary to design a dust collection module. The dust collection module is mainly composed of centrifugal fan, filter (built-in filter element), dust cover, etc. In order to ensure the service life of centrifugal fan, the filter is installed between the centrifugal fan and the integrated housing so that filtered clean air enters the fan space.

3.2 Stress analysis of wire brush

In order to clarify the influencing factors of grinding effect, calculate the theoretical load of wire brush, guide the adjustment of grinding operation parameters and complete the selection of grinding motor, the stress of wire brush is analyzed.

As shown in Figure 7, the steel wires are symmetrically distributed left and right. For convenience of calculation, the included angle from the contact surface to the disengagement of wire brush is defined as $2\theta_{\max}$, the number of steel wires within this range is

$2n$, and the maximum cutting depth is d_{\max} . The $i(1 \leq i \leq n)$ steel wire on either side of the yaxis within this range is taken as the research object, and its cutting depth is $d_i(0 \leq d_i \leq d_{\max})$, and the included angle with the yaxis is $\theta_i(0 \leq \theta_i \leq \theta_{\max})$ [14].

The analysis is as follows:

- 1) The included angle $2\theta_{\max}$ within the contact range increases with the increase of press amount a_e :

$$2\theta_{\max} = \arccos((1 - a_e)/1)$$

The number of contact steel wires increases in equal proportion with the increase of the angle within the contact range, that is, the steel wires are evenly distributed on the wire brush:

$$\frac{n_0}{\theta_{\max 0}} = \frac{n_1}{\theta_{\max 1}}$$

- 2) Maximum cutting depth d_{\max} is defined as a function which increases with the press amount a_e :

$$d_{\max} = f(a_e)$$

According to the test situation, a directly proportional relationship is temporarily taken here, where s is the proportionality coefficient:

$$f(a_e) = s \cdot a_e$$

- 3) It is assumed that the maximum cutting depth d_{\max} and included angle θ_{\max} are nequally divided by n steel wire on either side within the contact range:

$$d_i = \frac{i}{n} d_{\max}, (1 \leq i \leq n)$$

$$\theta_i = \frac{n-i}{n} \theta_{\max}, (1 \leq i \leq n)$$

To sum up, the calculation is as follows:
Contact normal force F_n :

$$F_n = \frac{4}{3} E^* \sqrt{\frac{d_f}{2}} d_i^3 = \frac{4}{3} E^* \sqrt{\frac{d_f}{2}} \left(\frac{i}{n} \cdot s \cdot a_e \right)^3$$

$$\frac{1}{E^*} = \frac{1 - \nu_e^2}{E_e} + \frac{1 - \nu_s^2}{E_s}$$

Where, E^* is the Young modulus of contact, and E_e, ν_e, E_s, ν_s are the Young modulus and Poisson's ratio of steel wire and steel formwork respectively. The corresponding relationship between the calculated press amount and the torque and grinding power is shown in Table 3:

Figure 7. Stress diagram of wire brush.

Table 2. Stress analysis parameters of wire brush.

Parameter	Value	Parameter	Value
Poisson's ratio of wire brush ν_e	0.277	Poisson's ratio of workpiece ν_s	0.3
Young modulus of wire brush E_e	207	Young modulus of workpiece E_s	206
Diameter of steel wire d_f	0.3 mm	Friction coefficient μ	0.1
Radius of wire brush l	45 mm	Coefficient of cutting depth s	13.75
Rotation speed	1000 rpm	Number of steel wires $2n$	35

Table 3. Load parameters of wire brush.

Press amount a_c (mm)	3	4	4.5	5	6
Torque T (N · m)	1.7	3.1	3.8	4.6	6.5
Power P_1 (W)	179	327	401	485	684

3.3 Self-adaptive adjustment

Due to the discontinuous variable curvature of some steel formworks for secondary lining trolley, the grinding mechanism should have a certain adaptive ability to the curved surface. In order to realize the constant force contact between the wire brush and the working surface and ensure the grinding effect, the design mode of disc spring + damper is adopted to achieve stable contact and constant force grinding between the grinding module and the steel formwork surface.

The positioning wheel is adjusted to the height of the wire brush under the preset press amount (i.e. the maximum deformation of the wire brush) to ensure that the wire brush fully contacts with the working surface under the action of disc spring pressure. The grinding down force corresponding to different press amount is calculated according to the stress model of

wire brush, and the position of the adjusting nut is adjusted with reference to the load-deformation curve until the pretightening force of the disc spring is greater than the normal force of the wire brush.

When the curvature of the working surface changes, the positioning wheel is under the action of disc spring pressure. It is closely attached to the working surface. Since the position of positioning wheel is relatively fixed to the wire brush and the pretightening force of the disc spring is greater than the normal force corresponding to the deformation of the wire brush, it can be ensured that the outer diameter of the wire brush is in close contact with the working surface and the press amount remains unchanged, thus realizing constant force grinding by the wire brush.

4 SIMULATION ANALYSIS AND ENGINEERING TEST

4.1 Simulation analysis

4.1.1 Stress analysis of main frame

The main frame of the robot consists of an adsorption walking module chassis and an operation module base. The electric control module is integrated in the electrical cabinet and installed on the adsorption walking module chassis, and the operation module base is connected with the adsorption walking module chassis through quick-change assembly. According to the preliminary scheme selection, the single magnetic attraction force of the magnetic wheel is 300N. In order to further ensure the adsorption effect, a prefabricated auxiliary magnetic device is additionally installed in the center of the chassis, with a single magnetic attraction force of 300N and a total of 600N. The normal force F_n for grinding of wire brush is rounded to 100N.

The chassis frame is made of Q345B, and the operation module frame is made of aluminum alloy 6061-T6. There are 6 simulation conditions in total, as shown in Table 4:

Table 4. List of stress calculation conditions for robot frame.

S/N	Operation status	Magnet assembly
1	Horizontal grinding	Additional installation of auxiliary magnetic device
2	Facade grinding	Additional installation of auxiliary magnetic device
3	Facade grinding and obstacle crossing	Additional installation of auxiliary magnetic device
4	Horizontal grinding and obstacle crossing	Additional installation of auxiliary magnetic device
5	Facade grinding and obstacle crossing	No additional installation of auxiliary magnetic device
6	Horizontal grinding and obstacle crossing	No additional installation of auxiliary magnetic device

Among them, the stress/displacement concentration is most obvious under working condition 3 (as shown in Figure 8) and working condition 4 (as shown in Figure 9).

Figure 8. Stress/Displacement Nephogram of robot frame under working condition 3.

Figure 9. Stress/displacement Nephogram of robot frame under working condition 4.

The simulation results show that the stress of the frame structure is less than the maximum allowable stress of the material under various working conditions, and the overall structure of the robot is reliable. It is necessary to optimize the structure in the stress concentration area. See Table 5 for specific parameters.

Table 5. Statistics and analysis of robot frame simulation results.

S/N	Maximum displacement/mm	Maximum stress/MPa	Safety margin
1	0.477	116.2	66%
2	1.237	114.5	67%
3	0.976	281.6	18%
4	0.98	255.7	26%
5	0.848	192.7	44%
6	0.985	157.3	54%

Note: 1) For Q345B material, the allowable stress is taken as 345 MPa; for aluminum alloy 6061-T6 material, the allowable stress is taken as 315 MPa. Through communication with the Designer, the safety factor has been uniformly considered in the calculation improvement provided by it.2) Safety margin = (allowable stress-calculated stress)/allowable stress × 100%

4.1.2 Operation analysis of dust collection module

In order to discuss the rationality of dust collection module, this paper analyzes it with simulation

software. As shown in Figure 10, when the dust cover and the working surface form a confined space, for the dust in an area between the dust cover and the wire brush, under the negative pressure generated by the centrifugal fan, the dust near the air inlet of the filter can quickly enter the filter to complete filtration, but the dust far away from the air inlet flows slowly or cannot move to the air inlet.

According to the results of simulation analysis, in the design of dust collection module, it is necessary to keep an effective confined space between the dust cover and the working surface during dust collection operation, and compress the space between the wire brush and the dust cover as much as possible. In addition, in order to improve the mobility of dust and ensure the dust collection effect, the wire brush is in close contact with the working surface, so that the dust has a certain initial kinetic energy under the action of wire brush, thus ensuring the operation efficiency of dust collection module.

Figure 10. Simulation analysis diagram of dust collection module.

4.2 Industrial verification

According to the actual operation requirements of drilling and blasting construction, the robot body and operation module are tested on the secondary lining construction site of tunnel. Through on-site practical operation, the wall-climbing robot body can stably walk and automatically operate on the working surface of the secondary lining trolley, and the operation module can effectively realize grinding and dust collection operations. By optimizing the grinding operation parameters, the operation effect and operation effect of the product are further improved.

4.2.1 Operation function verification of robot

The robot is absorbed onto the secondary lining trolley, and then it is controlled to complete forward/backward, left-handed rotation, right-handed rotation and other functions in the side formwork and top formwork through the remote controller. After the datum plane is arranged, the robot can carry out automatic operation according to a predetermined

trajectory. When the battery is low and the ranging sensor exceeds the limit, the buzzer will give an alarm; when the battery is insufficient, the robot stops working and automatically returns. The grinding/dust collection module is installed through the quick-change assembly. The grinding module can effectively remove the attached concrete and better adapt to the curvature change of the working surface to ensure the grinding operation effect. The dust collection module can effectively control the flying dust.

4.2.2 Operation effect test of robot

As shown in Figure 11, the wall-climbing grinding robot can effectively remove the concrete attached after secondary lining.

Figure 11. On-site operation effect of wall-climbing robot.

Combined with the stress model of wire brush, relevant variables are adjusted to test the operation effect. The main parameters are grinding speed, working walking speed, wire brush press amount and wire brush diameter.

- 1) The test results show that the higher the grinding speed, the slower the walking speed and the greater the press amount of the wire brush, the better the grinding effect (as shown in Figure 12).
- 2) For floating rust and attached concrete on the grinding surface layer, the wire brush with a wire diameter of 0.15 mm has the best operation effect and efficiency; for grinding of severe corrosion, the wire brush with a wire diameter of 0.3 mm has the best operation effect and efficiency; for grinding of set concrete, the wire brush with a wire diameter of 0.5 mm has the best operation effect and efficiency.

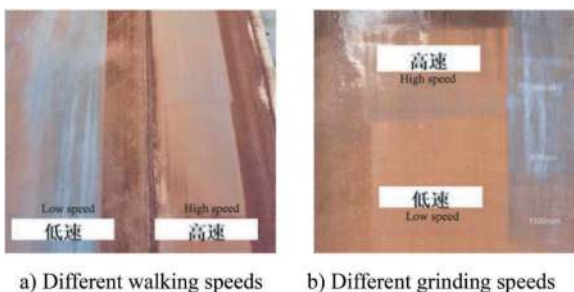

Figure 12. Operation effect after adjustment of grinding parameters.

4.2.3 Mechanical operation efficiency test

For different grinding objects such as attached concrete, floating rust, severe corrosion and set concrete, adjusting appropriate grinding parameters can effectively improve the grinding efficiency. According to the actual test, when the robot designed in this paper is used for grinding Grade C rust, the derusting grade can reach St2 (as shown in Figure 13), and the operation efficiency is 5~6 times that of manual grinding (as shown in Figure 14).

Figure 13. Steel plate derusting standard.

Figure 14. Comparison between manual operation and robot operation.

4.2.4 Summary of robot industrial verification

Through industrial verification, the robot can meet the grinding operation requirements of secondary lining trolley, effectively reducing labor intensity, controlling operation risk and improving grinding efficiency. Meanwhile, during the test, it is also found that the robot has facade turning sliding and uneven grinding effect in some areas. For the facade sliding problem, we will consider solving it from the aspects of turning algorithm control and magnetic optimization; for the uneven grinding effect, we will consider solving it from the self-adaptive adjustment structure and other aspects.

5 CONCLUSION

- (1) In view of the problem that the wall-climbing grinding robot is not suitable for narrow working conditions of tunnel secondary lining, this paper proposes an integrated, lightweight and modular wall-climbing grinding robot for rust removal and oiling. The robot is designed with adjacent magnetic drive assemblies, which ensures the stability of magnetic attraction and driving performance of the robot body and realizes continuous operation on the steel formwork surface of the secondary lining trolley.
- (2) Combined with the overall stress of the wall-climbing robot, this paper calculates the working conditions of facade sliding, overturning and insufficient plane driving force of the robot. Based on the operation requirements of secondary lining trolley, the type selection design of magnet assembly and driving assembly is completed. The structural performance of the chassis frame is checked by statics simulation, and the trial-manufactured robot realizes stable operation.
- (3) Based on the existing guidance technology, this paper proposes a guidance method with dual ranging sensor and difference algorithm to realize intelligent operation of robot. By setting up a datum plane on the secondary lining trolley, the robot realizes real-time linear deviation correction, fixed-point lane change and path planning on the working surface.
- (4) By establishing the mechanical model of wire brush grinding, the corresponding relationship between the deformation of wire brush and the power of grinding motor is obtained. The self-adaptive grinding mechanism is designed. It has been verified by test that the wire brush can better adapt to the curvature change of the working surface and ensure the grinding effect. The grinding effect and efficiency are further optimized by adjusting the parameters such as grinding speed, working walking speed and wire brush press amount.

Retrospective analysis of the design and manufacture of a case of steel fibre reinforced segmental lining in view of the actual behaviour of some rings on site

Zhuangzhi Yang* & Zonghua Gu

CRTG, China Railway Tunnel Group, Guangzhou, China

Patricio García de Haro

Tunnelconsult Engineering S.L., Barcelona, Spain

ABSTRACT: Steel fibre reinforced concrete is increasingly being used as a construction material in ring-shaped tunnels excavated by TBM. This paper examines a real case of the use of steel fibre reinforced concrete for segmental lining, where some segments, once produced, showed a different behaviour than expected. The breakage of some of them and the appearance of cracks in others required a thorough review of all the stages in the life cycle of the segments up to their final placement in the tunnel. The detailed design of the segments is being reviewed, as well as the manufacturing process, the handling and transport of the segments and the assembly of the rings.

Keywords: Steel fibre reinforced concrete (SFRC), precast segmental lining, manufacturing, behaviour, breakage, cracks, EPB

1 INTRODUCTION

This paper discusses a 2.5 km-long and 7.2 m outer diameter underground structure that was excavated and built by one of CRTG's own EPB machines.

The structure is intended to be used as a utility gallery. The tunnel has a rectilinear layout. In terms of the longitudinal profile, halfway along the alignment is the location of the maximum overburden of about 18 m, while at both entrances is the minimum overburden of about 7.0 m. The tunnel has a gradient of up to 2.50 %. The utility gallery is situated in the Middle East and was built three years ago.

While erecting and assembling the rings for tunnel construction, the SFRC segments demonstrated decreased strength, leading to the development of cracks and partial or complete breakage of the segments. The first cracks already appeared in the assembly of blind rings.

Given this scenario, it was necessary to conduct a comprehensive investigation on the life cycle of the segments, from the design to their placement inside the tunnel. This also required repairing a significant number of segments, both before and

after installed. Similarly, a considerable number of segments had to be discarded during construction.

It should be noted that in this project, the segments were supplied by the client, while CRTG was only responsible for excavating the tunnel and assembling the rings. Finally, CRTG was also contracted to carry out the necessary repairs to the rings.

The following figures illustrate some of the various segments that broke during construction, without being limiting. Otherwise, they would not have been the subject of analysis, but mere incidents of work.

In total, more than 1,600 rings of 1,500 mm length (about 9,600 segments) were produced in six and a half months.

Taking into account the days of downtime (due to breakdowns, maintenance, waiting for materials, availability of storage space, etc.) the average production was about 7.5 rings per day. In total there were 55 days of downtime, and excluding these, the average daily production was 10 rings/day. The maximum ring production reached was 19 rings per day.

During the production of the rings, while some segments were rejected, others had to be repaired due to defects. For this purpose, the defective

Figure 2. Detail of a SFRC segment that broke in half during installation.

Figure 3. Detail of another halved SFRC segment (both pieces).

segments were divided into three categories: “Minor defect”, “Major defect” and “Rejected”.

A total of 800 defective segments (8.5% of production) were recorded before transferring to the tunnel. 110 were rejected because of severe cracks, while 680 could be repaired. Of the latter, 590 segments were affected by minor cracks. The main defect was minor cracks in the area of bolt holes and sockets, less than 0.20 mm wide. When such cracks reached one of the surfaces, they became larger cracks and their width increased. If the width was greater than 0.30 mm, the segment was rejected. Micro-cracking occurred in the centre of sockets and bolt holes area due to the temperature difference between day and night and the moulds not being properly covered during curing.

Figure 4. Detail of crack traversing the entire segment face before and after repair.

2 PRECAST SEGMENTAL LINING

The segmental lining consists of a ring with an internal diameter of 6500 mm, which is 350 mm thick and 1500 mm in length. The ring, commonly known as the universal type, has a 5+1 configuration, taper of ± 20 mm, straight joints between segments (excluding key and counter keys), and bolts in both longitudinal (segment to segment) and circumferential (ring to ring) joints. The keystone is inclined at an angle of 20.5° .

The segmental lining was designed with a service life of 100 years, which is a typical duration for this type of structure. The utility gallery is situated in a hot and humid environment with high concentrations of chlorides and sulphates in the soil and groundwater.

Class C50/60 concrete (in accordance with EN 206-1:2013) was required for the precast segmental lining. A triple-bend cement type with reduced Portland cement content that can react with sulphates was identified for producing Class C50/60 concrete.

Among the permitted combinations, the triple mix was specified as OPC (35%) + GGBS (60%) + MS (5%), i.e. Portland cement, ground granulate blast furnace slag and micro silica. The water/cement ratio was restricted to a maximum of 0.40. Moreover, the minimum cementitious material content was prescribed as 380 kg/m^3 .

Figure 5. SFRC segment broken during ring assembly.

Figure 6. A different view of the broken segment shown in the previous figure.

The concrete mix included SIKA Viscocrete-TS100, a superplasticizer specifically developed for high performance concrete, as well as for precast tunnels segments and steel fibre reinforced concrete (SFRC).

The designer of the ring specified the use of steel fibres to replace steel reinforcing bars in order to minimize the risk of corrosion. This was because

“the corroding element is removed by the use of steel fibres”. He also stated that “the use of SFRC is also considered because of the demonstrated increase in ductility (strain-softening behaviour when tested in bending) in relation to unreinforced concrete and the effective elimination of spalling damage, as well as the ability to control drying shrinkage cracking”. However, despite the previous misinformed statement, the SFRC adopted had a strain-hardening behaviour, with better post-cracking behaviour and ductility than a strain-softening mixture.

HE++90/60 fibres were used. The main characteristics of the fibres were: diameter of 0.90 mm, a length of 60 mm, an aspect ratio (L/D) of 67, a wire tensile strength of 1900 N/mm² and a number of fibres per kg of 3200. A steel fibre dosage of 40 kg/m³ of concrete was established.

A 1.5 kg/m³ of polypropylene (PP) fibre was added to the concrete mix as a protective measure against thermal instability in the event of exposure to accidental fire (concrete spalling).

The following figures show some of the most commonly found defects in the tunnel segmental lining:

Figure 7. Cracking after the bolt tightening into its pocket.

All these unforeseen defects accelerate the degradation process of the structure over time.

2.1 Durability strategy during the design phase

The design for durability was based on the “Deem-to-satisfy design approach” and “Avoidance of deterioration design approach”, as outlined in the Model Code for Service Life Design by the International Federation for Structural Concrete (The fib). This approach focuses on adhering to standards/codes and using non-reactive materials to completely prevent corrosion from occurring.

The durability design considered the ground and groundwater conditions obtained from the project-

Figure 8. Crack during the installation of the next ring segments due to the thrust of the TBM jacks.

Figure 9. Cracks in the area of the bolt insert (on the upper left) and in the circumferential joint in both segments.

specific ground investigation. The appropriate parameters were then determined for the precast segmental lining to ensure minimum maintenance of the tunnel structure during its expected lifetime.

Since the tunnel was expected to remain permanently submerged, the outer face would be exposed to long-term contact with high levels of chlorides in water. Therefore, an “Aggressive” type of exposure was chosen.

The main deterioration mechanisms that could affect the long-term durability of the tunnel were thought to be chloride-induced corrosion and sulphate attacks, although other mechanisms may also contribute.

To provide corrosion protection under such severe environmental conditions, the crack width of the

Figure 10. Pocket side-face blowout after installation of the bolt.

precast segments was restricted to 0.2 mm. When the crack width is limited to this value, water that seeps through it has the potential to dissolve calcium hydroxide from the cement matrix. As a result, when the dissolved calcium hydroxide comes in contact with the atmosphere and reacts with carbon dioxide, it forms calcium carbonate, which may seal the crack.

According to the determined exposure classes and considering a concrete of C50/60, the concrete covers were set to 60 mm in the extrados surface (X3) and 70 mm in the inner and joint surfaces (X5) for the conventionally reinforced rings in singular areas on the tunnel alignment.

3 CASTING STAGES

This section briefly describes the steps involved in casting, from preparation of the moulds to stacking. Before the concrete was poured, the moulds were oiled and the socket areas were greased. The concrete was transported from the batching plant to the moulds by a truck mixer rather than a conveyor system. The use of the truck mixer system resulted in cold joints in some segments as the concrete was not poured continuously. The addition of steel fibres to the concrete mix was done manually as the plant did not have the required automatic dosing system. Vibration was carried out by a supervisor manually controlling the equipment. Once the pour was complete, the external surface was quickly cleaned and smoothed by hand. In spite of that, in order to ensure the consistent quality of the concrete produced and used on the project, both the concrete plant and the casting yard responsible for the

production of concrete and precast segments had an accredited ISO9001 quality assurance system and operating procedures.

In order to shorten time to reach minimum strength of demoulding, steam curing system was used. Once casting and covering process was over, moulds were taken to the steam curing for 10-12 hours to reach early strength level (which is 18 MPa) for demoulding.

Under no circumstances was the maximum temperature of the concrete segments allowed to exceed 70°C. To this end, thermocouple temperature sensors were used on a representative number of segments during the concrete curing process to monitor the actual temperature.

If compressive strength test requirements were fulfilled, segments were ready for demoulding. An important consideration at this point is to complete the covering process as soon as possible. Late covering causes an increase in the micro cracking percentage of the segments.

The steam curing system was used to reduce the time required to achieve the minimum demoulding strength, set at 18 MPa (cylindrical). By doing so, the concrete reached 18 MPa early strength in 8-10 hours, but the demoulding was carried out at the cubic strength value instead of the cylindrical, which is in fact about 15 MPa. The average early strength value for demoulding was 23.7 MPa (in cubic specimen). The demoulding equipment was a mobile 3-pad vacuum lifter.

During production, the segments were stored in the production hall in a concave position. All sides and the outer surface of the segments were then inspected in the same production hall. If the segments received initial approval, they were sent to the turning machine to be turned into the convex position. The segments were turned into the convex position using special equipment, one by one and after 3 days of casting.

After inspection on the internal face and approval of the repair works (if necessary), the segments were initially stacked separately for 7 days to allow the concrete to reach stacking capacity. After these 7 days, a maximum of four regular segments were stacked in their final position in the stack-yard, while the key segments were stacked separately. Transfer from the plant to the site took place a minimum of 14 days after casting.

Deliveries were planned by loading a complete ring onto a trailer and the quantities delivered were agreed on the basis of instructions from the site and the progress of the TBM, as the storage capacity on site was not very large. The average delivery was about 6.5 rings per day for almost seven months.

Taking into account that the 7-day laboratory test results 'met' the minimum strength capacity required for the concrete, a 13-day period was considered sufficient for delivery to site. The distance between the precast plant and the construction site was 75 km and the delivery of a ring took approximately one and a half hours.

4 TESTS AND INVESTIGATIONS PERFORMED BEFORE AND FOLLOWING THE SEGMENT RUPTURES

Tests were carried out on fresh concrete during the segment production phase.

In addition, following the defects observed in the rings and the first broken segments during assembly in the tunnel, tests were also carried out on cast segments, using two split segments.

4.1 Fresh concrete tests during the casting process

The fresh concrete was tested for unconfined compressive strength. Two samples for each mix (one mix is for three to four segments) to check early strength and three samples per production shift to check 7 days and 28 days were prepared.

The 7-day compressive test results were between 55-72 MPa for the cubic specimens and the 28-day results were between 70-80 MPa also for the cubic specimens. In terms of early strength, the compressive strength results vary somewhat, ranging from 18 to 28 MPa (cubic specimens).

The fresh concrete was also tested for flexural strength in groups of three specimens at 7 and 28 days according to the established test schedule. The minimum values required at 28 days were: $f_{r1k} > 4$ MPa, $f_{r1k}/f_{Lk} > 0.4$ and $f_{r3k}/f_{r1k} > 1.10$. All these requirements were met. However, tensile strength values obtained at age 7 days were not reported.

Finally, fibre washout tests were carried out on fresh concrete. Steel fibres washout tests were done three times a week on two different samples to check how much steel fibre the segments contained per m^3 . The results were between 38 kg – 44 kg per m^3 .

Figure 11. Crack that occurred when the segment was to be installed.

Figure 12. A view of the crack above, across the face of the circumferential joint.

4.2 Tests on split segments

On the other hand, the tests on the cast segments used two of the split segments.

These tests on the first segment consisted of seven core samples recovered with a Hilti machine from the segment in the presumably weakest areas. Of these, three were for fibre distribution tests, two were for uniaxial compressive strength tests and the remaining two were for tensile strength tests.

Nine core samples were taken from the second cast segment and tested as follows: five for fibre distribution, two for compressive strength and two more for tensile strength.

Figure 13. View of a segment split along the minor axis of the piece. The brown stain on the left is dirt from when it fell.

The average compressive strength values obtained were 58 MPa for one of the segments and 69 MPa for the other (all values in cylindrical specimen). For the indirect tensile tests, the values ranged from 4.7 to 7 MPa, with the minimum required by the designer being 2.6 MPa. However, 2.6 MPa was the design tensile strength of the mixture, namely the characteristic strength f_{R1k} affected by the partial factor for concrete $\gamma_c=1.5$. The requirement should have been established much higher. Fibre distribution tests were in line with requirements.

Figure 14. View of the other half of the SFRC split segment shown above, seen from the lifting sockets.

Figure 15. Detail of the concrete mass with fibres from the same splitting surface.

Figure 16. View of the positions where the cores were obtained for testing in one of the split SFRC segments.

4.3 Full scale tests

When using SFRC-based precast segmental linings, two types of full-scale segment tests are required to verify the design:

- Flexural test: aims to simulate the behaviour of the segment mainly under transient loading conditions. It allows the crack load, the load at the maximum design crack width and the ultimate load to be determined.

Figure 17. View of the positions where the cores were obtained in the other split SFRC segment under test.

- Point load test: representative of the thrust load condition of the TBM. Allows verification of shear loads. Also allows for verification of burst and burst loads and measurement of crack width.

A minimum of two segments should be tested for each type of test. The problem is that although full-scale testing is highly recommended, it requires suitable testing facilities, which are not available everywhere. For the same reason, these tests could not be performed in the present case.

Figure 18. View of some samples obtained from a split segment and its division for fibre distribution tests (left). Compressive strength test of one of the cores obtained from a split segment (right).

5 REVIEW OF THE DESIGN AND CALCULATION PHASE OF SFRC RINGS

After reviewing the manufacturing process of the segments and analysing their mechanical strength, it can be concluded that although the manufacturing process was not the most technologically advanced, the results of the strength tests carried out on specimens obtained from damaged segments met the project requirements. In concluding this, it should be noted that there is an important scale and shape factor between the laboratory specimens tested and the segments. In the light of these results, it was decided to revise the design of the rings.

The design process of the rings presents inaccuracies and some errors of importance. Firstly, the ULS load combinations considered scenarios of current groundwater conditions (ULS1), a seismic event (ULS2), high and low groundwater situation (ULS3 and ULS4) and secondary grouting (ULS5). However, despite stating that all combinations follow the prescriptions in Eurocode 2, only ULS1 load combination had the applicable factors of 1.35 for permanent loads and 1.5 for transient loads. The other four combinations were treated as “accidental combinations” with all factors set to 1.0.

Figure 19. N-M diagram for ULS2 to ULS5.

This procedure is fine for ULS2 and ULS5 (as prescribed by the ITA), but combinations ULS3 and ULS4 should have been treated as regular ULS combinations.

When observing the N-M diagrams obtained from load combinations ULS2 to ULS5 it can be seen that the sectional capacity is quite close to the limit in many cases. It should be also taken into account that the relevant partial factor for concrete is $\gamma_c=1.2$ for accidental load combinations. This design approach has a lower safety margin compared to “true” ULS combinations and may lead to potentially unconservative designs.

Secondly, another fact to take into consideration is the fact that cracking control was not performed. The designer states that the cracking moment is larger than the bending moment in SLS combinations, and therefore the crack width check is not required. However, conventionally reinforced concrete is provided with minimum reinforcement areas, which is deployed in order to ensure that the member ultimate strength is larger than the cracking moment and to avoid brittle failure after the cross-section develops a crack. In this particular case, the SFRC segments had a cracking moment $M_{cr}=125.6$ m·kN and a design ultimate strength $M_u=89.8$ m·kN. Given the post-cracking behaviour of the segment it may be advisable to perform crack control checks and consider cracked sections even if the segment should be uncracked in ideal conditions, especially in structures difficult to repair and with low structural redundancy.

Thirdly, the estimation of the tensile stresses developed at the joints due to TBM thrust is correct and

performed according to the ITA provisions, but the tensile stress values obtained are checked against the wrong parameter. Indeed, the joint bursting and spalling due to TBM ram shoe thrust are checks performed in ULS since it is the breaking of the segment that is being analysed. Instead of studying this phenomenon as a ULS scenario, the designer compares the tensile stresses obtained to f_{ctm} as if it were a SLS check and states that “SLS conditions are verified”. This assumption allows the designer to compare the maximum tensile spalling stress obtained in the circumferential joint (equal to 4.0 MPa) with the mean tensile strength of the concrete of 4.1 MPa.

Figure 20. Average spalling stresses due to TBM thrust.

However, this assumption serves only to ensure that about half of the segments will crack if the foreseen load is applied. The tensile strength that should have been used is the design residual strength of the SFRC $f_{Ftud} = 0.98 \text{ MPa}$ which is much lower.

The adoption of the design residual strength could have entailed a change in the solution such as the possible adoption of a perimetral reinforcement in order to comply with the ULS requirements. Also, through-thickness bursting stresses were checked in the same manner with tensile stress values substantially higher than the design residual strength.

Fourthly, the temporary stages of the segments were studied, which included demoulding, first stacking (2 segments per stack at age 7 days), storage (a whole ring per stack at age 28 days) and transportation (at 28 days). In spite of these clear stages the segments must follow, after 7 days of age the segments were stacked in stacks of 4, which was not foreseen in the initial design.

Finally, the seismic action was introduced as a racking deformation that distorts the circular geometry of the lining. The said deformation was not introduced accurately in the Plaxis software and the internal forces obtained may be incorrect.

6 FINAL INSPECTION AND NECESSARY REPAIRS TO SFRC SEGMENTS

After completion, the tunnel was inspected to determine what repairs were needed.

During this supervision work, several types of pathology were found in the rings. These were: dry

cracks, cracks with leakage, leakage in the joints, leakage through the secondary grouting sockets, broken edges and corners. More specifically, 45% of the rings were found to have pathologies.

The repairs consisted of epoxy resin injection for crack leaks (230 cases), smoothing filler for dry cracks (642 cases), cementitious sealing in the case of grouting socket leaks (118 cases) and PU injections for joints leaks (79 cases). The number of broken edges and corners to be repaired was nine.

Needless to say, only the defects on the intrados of the lining could be repaired. Those on the extrados remain unaddressed and unknown.

In addition, to ensure the correct stability of the lining, gap filling with secondary grouting was performed in all rings.

Figure 21. A cracked segment is repaired by injections.

7 CONCLUSIONS AND RECOMMENDATIONS

The case of a precast concrete and steel fibre segmental lining for a 6.50 m internal diameter utility tunnel, where the segments did not perform as expected, has been reviewed.

After analysing the various stages in the life cycle of the segments up to their final installation in the tunnel, it can be concluded that the detailed design phase and fabrication stages are critical in the use of this technology.

Steel fibre rings should only be used where the ground and the loads allow. The designer must have a high level of knowledge of the strength of the SFRC material and the ground of the tunnel alignment must be very well characterised in order to avoid errors in the calculations. The numerical models developed must be accurate and load combinations shall have the appropriate load combination factors.

Crack control should always be performed even if the bending moment in SLS is smaller than the cracking moment of the section, especially when the design ultimate bending strength is substantially smaller than M_{cr} and the structure is difficult to repair and presents limited structural redundancy. The catastrophic consequences of a collapse in a tunnel should be taken into consideration in the design phase, and all sections should be checked in SLS as cracked sections and no damage to the

segments should be allowed during TBM ram thrust or any other scenario.

As stated in di Prisco, M. et al., “*Fibre reinforcement is suitable for structures where diffused stresses are present. In structures with both localised and diffused stresses, which is the usual case, it is better to base the reinforcement on a combination of rebars and fibre reinforcement*”.

Steel fibre rings should never be used on the assumption that the tunnel will behave as a perfect arch subject only to axial forces. In addition to the nature of the ground, which must have suitable geo-mechanical characteristics, the thrust of the TBM may dictate the design of the segments, which is a very important localised load that is best resisted by means of conventional rebars. The design of the rings must be appropriate to each circumstance.

Steel fibres are not a universal solution (as some designers think) and therefore do not work in all cases as presented. In most cases, only rings with conventional reinforcement based on steel rebars will be suitable; in other cases, it may be necessary to combine steel fibres with conventional reinforcement in the joints in order to withstand the stresses to which the ring is subjected during assembly or in temporary stages, the bending stresses caused by the actions of handling, transport and other transient loads. In the smallest number of cases (small segments, low stresses, etc.) and after proper and truthful design, the segments may be steel fibre-based only. This is very important and should be taken into account in the design.

The designer must be completely independent of time, economic or commercial considerations in his decision to use steel fibres in the project of the tunnel.

Robustness evaluation on non-circular segmental tunnel linings: Case study on quasi-rectangular shield tunnel

Yuhang Ye

College of Civil Engineering, Tongji University, Shanghai, P.R. China

Guangzhou Metro Design Research Institute Co. Ltd., Guangzhou, P.R. China

Zhen Liu* & Xian Liu

College of Civil Engineering, Tongji University, Shanghai, P.R. China

ABSTRACT: As effective alternatives for underground construction in high density urban area, non-circular shield tunnels often face more challenges in complex surrounding environment due to their non-circular cross-sections. In order to provide theoretical guidance for the non-circular tunnels under design and service period, this paper proposes a robustness evaluation method for non-circular shield tunnels. This method is based on macro-level nonlinear structural modelling and prototype structural experiment. The elastoplastic failure process of the structure is revealed and discussed. The energy-based robustness evaluation method is proposed considering the development of structural plasticity. The robustness evaluation of the non-circular shield tunnels could then be carried out. In this study, Quasi-rectangular shield tunnel (QRST) is taken as an example for robustness evaluation. The research shows that the proposed method can effectively evaluate structural robustness of non-circular tunnels with different parameters. Considering key structural parameters such as reinforcement and bolt positions, the optimization direction of non-circular tunnels is discussed based on the robustness evaluation method. The research will lay the foundation for future application of non-circular shield tunnels.

Keywords: non-circular tunnel, energy-based robustness evaluation, Quasi-rectangular tunnel, structural optimization, bolt position

1 INTRODUCTION

During the operation period, tunnels will always face various unexpected circumstances, such as top overburden (Liu et al., 2018a), lateral unloading (Liu et al., 2016), surrounding construction (Jin et al., 2018), material deterioration (Zhang et al., 2022), etc. Therefore, for both circular and non-circular tunnel structures, an accurate prediction of the failure characteristics and robust performance of the structures under different unexpected circumstances are rather important. Relevant studies can bring an insight into how to evaluate structural performance and provide theoretical guidance for the design and maintenance of tunnels (Yuan et al., 2012).

Conducting structural failure tests is an effective way to explore the failure process of the structure and evaluate its mechanical properties at the same time. He et al. (2014) used a comprehensive loading system for the staggered assembly tunnel structure of the

Shiziyang Tunnel, and explored the failure mechanism of the structure. Based on the load-bearing process, the effective stiffness coefficient and residual bearing capacity coefficient were used to evaluate the structural performance during the failure process (Zhang et al., 2019). Liu et al. (2016) studied the mechanical behavior and failure process of the continuously jointed segmental tunnel linings under unexpected conditions of top overburden and side unloading, and defined a structural bearing capacity safety factor to evaluate the structural robustness.

Since structural failure tests are one-time and expensive, in recent years, many macroscopic nonlinear numerical models are established to simulate the structural failure process and evaluate the robust performance of the structure under unexpected conditions. Zhao et al. (2017) established a nonlinear analysis model based on the beam and rigid-plate spring model to simulate the failure process of the structure. Chen et al. (2020)

*Corresponding author: lhugospace@tongji.edu.cn

established a refined three-dimensional numerical model, verified it with full-scale tests, and analyzed the failure mechanism and failure process of the structure. The failure process of the structure under top unloading conditions were also investigated (Wu et al., 2022). Liu et al. (2022a; 2022b) established nonlinear macro-level models and carried out an explanation of the failure mechanism of RC and FRC tunnels with staggered joints. The robustness of the structure with different structural parameters are also evaluated.

Since robustness evaluation based solely on structural failure test has limitations such as insufficient monitoring methods and accidental graded loading. Existing robustness evaluations often focus on some load or deformation indicators, and do not consider the relationship between the load and deformation in the whole field. Therefore, in this study, a tunnel structure robustness evaluation process is proposed. Taking a Quasi-rectangular shield tunnel (QRST) as an example, full-scale structural tests are first carried out and referenced. A nonlinear macro-level structural model is then established and validated by the test. Then the robustness evaluation method of the structure is carried out, providing guidance for practical engineering applications.

2 NONLINEAR BEHAVIOR OF QRST

2.1 Full-scale failure test of tunnel structure

Considering the increasingly intensive urban underground space, non-circular shield tunnels with high space utilization (such as DOT tunnels and QRST tunnels) will be more and more widely utilized. The QRST shield boring machine uses three cutterheads for full-section cutting during tunnel excavation (Liu et al., 2018c). Till now, QRST tunnels have been successfully utilized in many cities such as Ningbo and Hangzhou, China.

QRST tunnel lining has an outside dimension of $11.5\text{m} \times 6.937\text{m}$. The thickness and width of the segment are 0.45m and 1.2m , respectively. The thickness and width of the interior column are 0.35m and 0.7m , respectively. A typical cross-section of the QRST lining is shown in Figure 1. The tunnel is composed of ten blocks and an interior column (LZ). Ten blocks include two T-shape block (T1 and T2), three standard blocks (B1, B2 and B3), three C blocks (C1, C2 and C3), a contiguous block (L), and a key block (F).

Liu et al. (2018a) carried out a full-scale failure test for a QRST specimen. By simulating the tunnel structure subjected to a top loading overburden condition, the weak parts and ultimate bearing performance of the structure are revealed. A photo of the test is shown in Figure 2. 30 loading points are exerted on the structure, which are divided into three groups of P1 (8 loading points), P2 (10 loading points), and P3 (12 loading points). The details of the test loading procedure are introduced by Liu et al. (2018a).

Figure 1. Schematic diagram of QRST.

Figure 2. Photo of full-scale test.

2.2 Nonlinear macro-level model

A macro-level nonlinear FEM model of QRST structure is built by LS-DYNA [LS-DYNA, 2007], which is possible to simulate material and geometric nonlinearity of the structure. For the material nonlinearity, the elasto-plastic constitutive relationship is given to the concrete, rebar and bolt in the model, in order to simulate the actual nonlinear bearing situation. For the geometric nonlinearity, the influence of the large structural deformation and the large rotation of the joint on the bearing mechanism of the whole structure is considered. An assumption is made that the degrees of freedom (DOF) are only in plane.

Figure 3. Illustration of nonlinear model.

As shown in Figure 3, the segment is simulated using a thick shell element, and the concrete and steel reinforcement are simulated in layers, all based on the results of the material properties test and Code for

Design of Concrete Structures in China (GB 50010-2010). The joints are simulated by rigid-plate-spring (RPS) model. Among the rigid plates, a number of zero-length nonlinear compression spring elements (concrete) and a nonlinear tension spring element (bolt) are used to simulate the actual compression-bending behavior of the longitudinal joint.

2.3 Comparison of test and model

The calculation results of the nonlinear macro-level model are compared with the results of the full-scale structural test to verify the numerical model. The structural convergence deformation of the long-axis and two short-axes, and the opening deformation of the longitudinal joints are selected to make comparisons, as shown in Figure 4 and Figure 5, respectively.

Figure 4. Comparison on convergence deformation of long axis and short axes between the test and the numerical model.

Figure 5. Comparison on opening deformations of joints (a) No. 4 and No. 9 joints (b) No.5 and No.8 joints.

The comparison results show that the nonlinear macro-level model fully captures the multi-stage behavior of the QRST structure. According to the convergence deformation development of the structure in Figure 4, it can be concluded that the structural deformation goes through three main stages of elasticity, elastoplasticity and plastic instability in sequence. The comparisons suggest that the nonlinear macro-level model can be used as a tool for analyzing the ultimate bearing capacity and failure process of the non-circular tunnel like QRST.

2.4 Failure mechanism of QRST

Based on the experiment campaign and the numerical model, the failure mechanism of QRST structure can be summarized. In the first elastic stage, the structure behaves linearly. When P1 reaches about 500-600 kN, the cracks induced by bending moment appear at many cross-sections of the segment, leading to the first significant decrease in the overall bearing stiffness of the structure. After entering the elastoplastic stage, the cracks on the compression side of different joints and the bolt yielded phenomenon appear sequentially, which gradually decreased the overall stiffness of the structure. It should be noted that the reinforcement of segment at T2 block near No.6 joint is also yielded. Here the plastic hinge emerges characterized by above mentioned phenomenon of joint and reinforcement. It can be found that during the failure process, plastic hinges appear at No.8 joint, No.6 joint, No.3 joint, No.5 joint, and T2 block sequentially. Along with the appearance of these plastic hinges, the internal forces of the structure are redistributed, the overall stiffness of the structure decreases, and the structural deformation continues to develop. Eventually, when the segment of T2 block near No. 6 joint is damaged subjected to bending moment and shear force, characterized by concrete spalling and hoop stirrup broken, the structure finally loses the bearing capacity and enters instability stage, leading to structural failure.

3 ROBUSTNESS EVALUATION METHOD

For tunnel structures, since different load distribution modes lead to different structural failure paths, the definition of structural robustness index using only load or deformation will not be comprehensive enough. Therefore, the evaluation of structural robustness index should be performed from the energy perspective. For the QRST structure in this study, the external load of the structure in the test is 30 point loads, and thus the external work of the structure, i.e., the internal work, can be obtained by using formula (1).

$$E_n = \sum_{i=1}^{30} \int_0^{\delta_{n,i}} F_i(\delta) d\delta \quad (1)$$

where E_n is the current calculated external work. i varies from 1 to 30. $\delta_{n,i}$ is the current displacement of the corresponding point load. $F_i(\delta)$ is the force function with respect to displacement δ of the corresponding point load.

According to formula (1), the external work of the structure is obtained through the numerical model. The external work of the structure under the design state (SLS), the state corresponding to the emergence of the first plastic hinge point, and the state corresponding to the emergence of four plastic hinges on one side of the structure, are summarized in Table 1. The ductility index and reserve index are used to

Table 1. External work and robustness indices of specimen at different states.

State	External work (J)
Design state (SLS)	2125
Emergence of first plastic hinge (Plasticity point)	23500
Emergence of four plastic hinges (Instability point)	393157
Ductility index	12.47
Reserve index	137.96

characterize the robustness performance of the structure, respectively. Where the ductility index is the ratio of the external force work at the instability point to the external force work at the plasticity point, while the reserve index is the ratio of the external force work at the instability point to the external force work at the SLS point, as listed in Table 1.

4 INVESTIGATION ON KEY STRUCTURAL PARAMETERS

For investigating the influence of key structural parameters like reinforcement and bolt position, two more cases are analyzed, to explore the optimization direction of the QRST structure. Compared with the original structure, the segment reinforcement of the second tunnel structure is increased because the designed buried depth is increased. Compared with the second structure, the bolt position of the third structure is adjusted. Here, according to the nature of positive and negative moments of the joints, the bolts are moved 50mm from the original position to the moment tension side of the joints, see Table 2. Following the same process, Zhang et al. and Liu et al. carried out relevant studies from the joint and structure levels, respectively (Zhang et al., 2021; Liu et al., 2018b).

Table 2. Differences between three structures.

State	Reinforcement ratio	Bolt position (to internal surface)	
		Positive moment joint	Negative moment joint
First structure	1.51%	200mm	200mm
Second structure	2.36%	200mm	200mm
Third structure	2.36%	150mm	250mm

The established numerical model is also compared with the structural test, in which the convergence deformation is selected to make a comparison, as shown in Figure 6, validating the applicability of the proposed model. Using the robustness indices proposed in the previous section, the three different structures are compared and the summarized results are presented in Table 3.

Figure 6. Comparison on structural convergence deformations between the test and the numerical model (a) Second structure (b) Third structure.

Table 3. External work and robustness indices of three structures.

No	First structure	Second structure	Third structure
External work (J)			
SLS	2125	5396	5332
Plasticity point	23500	23600	34111
Instability point	90778	99263	162633
Robustness indices			
Ductility index	3.86	4.21	4.77
Reserve index	42.72	18.40	30.50

Based on comparison of the external work and robustness indices between the first and the second structures. It can be found that, since the designed buried depth of the structure rises substantially with the reinforcement, the energy corresponding to the SLS point also rises. However, since the first plasticity point always occurs at joints, the increase of reinforcement has little effect on the energy of the plasticity point. Since the instability point of the structure is also governed by the segment subjected to bending moment, the elevation of reinforcement somewhat enhances the energy at the instability point. From the view of structural robustness, although the increase of reinforcement enhances the ductility of the structure to some extent, it drastically reduces the safety reserve of the structure, which is uneconomical for the structure.

Comparison of the second and third structures shows that the optimization of the bolt position, has little effect on the SLS point, however substantially affects the structural performance in the elasto-plastic stage. Since the structural test is a single-ring test, the performance of the structure is mainly determined by the joints. The optimization of the bolt position effectively improves the bending capacity of the longitudinal joints (Zhang et al., 2021), thus delays the emergence of the plastic hinges. The energy of the plasticity point and the instability point of the structure are improved, and the robustness indices also increase significantly. Compared with the first ring, the safety reserve of the third ring is still low,

indicating that the parameters of the joint and segment are still not in the optimal design, which point out the direction for future structural optimization.

5 CONCLUSIONS

In this study, a nonlinear macro-level model is established based on the full-scale failure test of the QRST. An energy-based robustness evaluation method is proposed. The optimization direction of the structure is also discussed based on test results and simulation results of three QRST structures with different segment reinforcement ratio and bolt positions. The following conclusions are drawn:

- (1) The proposed nonlinear macro-level model for QRST is established, and the model has a good accordance with the full-scale tests of structures with different parameters.
- (2) The energy-based robustness performance of the non-circular tunnel structure is more comprehensive.
- (3) The enhancement of reinforcement has less effect on the robustness of the structure, and the optimization of bolt position has a significant effect on the robustness of the structure.
- (4) The optimization of the structure should take into account the parameters of both reinforcement and bolt, which should be optimized in a better proportion to maintain high ductility and safety reserves of the structure.

The effect of polypropylene fiber on the strength and crack propagation of foam concrete

Ruibo Yin*, Qiang Li, Xianglong Zeng & Wei Qiao
School of Highway, Chang'an University, Xi'an, Shaanxi, China

ABSTRACT: Aiming at the foamed lightweight soil used in tunnel engineering, polypropylene fiber was used for modification treatment, and the influence of polypropylene fiber on foamed concrete was studied. The benchmark mixure ratio was obtained through trial test. Based on the benchmark mixure ratio, the wet weight, flow value and compressive test of foamed concrete with different the fiber ratios were carried out. SEM test was carried out to analyze the microstructure and explore the law of crack propagation. The results show that the fiber ratio has little effect on the wet weight, and the flow value decreases with the increase of the fiber ratio. When the water: cement: foam = 1:2.00:0.06 and the fiber ratio is 0.75%, the 7d unconfined compressive strength of fiber foamed concrete is the highest. The fiber foamed concrete produces short cracks under compression, and the cracks expand and connect until they are destroyed. Increasing the fiber ratio can reduce the number of cracks. When the fiber ratio reaches 1.5%, more cracks are generated locally. The microstructure analysis confirmed that the polypropylene fiber can be closely bonded to the foam concrete, and the fiber limits the cracking of the surrounding pores through the bonding force, thereby preventing the extension of the through pores and inhibiting the crack propagation.

Keywords: Fiber foamed concrete, Polypropylene fiber, 7d unconfined compressive strength, Crack propagation, Microstructure

1 INTRODUCTION

With the in-depth study of foamed lightweight soil, it has been widely used in many construction projects in recent years. Foamed lightweight soil in engineering applications mainly uses cement as a cementitious material, also known as foam concrete. Foamed concrete has been applied in frozen soil construction section, shock absorption layer and tunnel portal backfill in tunnel engineering due to its excellent thermal insulation characteristics and lightweight and high-strength porous structure.

A series of mechanical properties tests on foamed concrete were carried out by (Zhang et al., 2018). Based on the test results, the constitutive model of the material was established. According to the Galongla tunnel, the influence of different factors on the damping effect of the tunnel was explored. The uniaxial and triaxial tests on foam concrete were carried out by (Chen et al., 2011), which proved that foam concrete can be used as a reserved deformation layer material for tunnels. Based on the deep-buried soft rock tunnel of Yiba Expressway, the influence of foam concrete on its long-term stability was studied. Li (Li et al., 2022) explored the factors affecting the strength of foam concrete filled

with natural gas tunnels. (Su et al., 2016a, b, 2017) focused on the influence of wet density, curing age and cyclic loading and unloading on the mechanical properties of foamed lightweight concrete, and studied the influencing factors of its pouring effect. (Zhao et al., 2017a, b) carried out a detailed study on the influence of polypropylene fiber and alkali-resistant glass fiber on the mechanical properties of foamed lightweight concrete. (Qiu et al., 2019) analyzed the variation of unconfined compressive strength of foamed lightweight concrete under different mixure ratios from the perspective of microstructure by scanning electron microscopy. (Hu et al., 2019) carried out a detailed study on the mechanical properties of fiber foam lightweight concrete and its dynamic characteristics used in the transition section of road and bridge. (Li et al., 2013) realized the surface modification of polypropylene fiber by acrylic acid chemical grafting method, explored the mechanical properties of modified polypropylene fiber foam concrete, and analyzed the effect of modified fiber on pore structure and plastic shrinkage cracking. (Ma et al., 2012) studied the effect of apparent density and polypropylene fiber on the performance of foam concrete. This paper focuses on the influence of polypropylene fiber on the wet weight, fluidity and

*Corresponding author: 2021121122@chd.edu.cn

compressive strength of foam concrete. The influence of reinforcement on the performance of fiber foamed concrete is analyzed from the macro and micro perspectives, and the crack propagation law of compression failure is explored.

The strength of foamed concrete is mainly due to cement hardening, so the failure of foamed concrete soil tends to brittle failure after reaching the ultimate load. Only relying on internal pores to achieve strength ductility has little effect, and the strength ductility of the material is poor. This feature is a more prominent defect in the application of foamed concrete engineering. The addition of fiber materials can significantly improve the defects of brittle failure of foamed lightweight soil and improve the strength ductility of foamed concrete materials.

2 TEST MATERIAL SELECTION AND MIX DESIGN

The test raw materials of fiber foamed concrete mainly include water, cement, foam and fiber materials. The cement is ordinary Portland cement P. O.42.5 cement, the foaming agent is high concentration QW-100 cement foaming agent, and the fiber material is polypropylene short fiber. The specific information of each raw material is shown in Table 1.

Table 1. Test raw materials.

Testing material	Water	Cement	Blowing agent	Fiber material
Tupe	Tapwater	P. O.42.5 Cement	QW-100 Cement foaming agent	Polypropylene fiber(13.5mm)

3 THE BENCHMARK MIX PROPORTION DESIGN

The concept of fiber ratio is defined as the mass percentage of fiber material, that is, the fiber ratio = $[(\text{Quality of fiber material}) / (\text{Quality of foam concrete})] \times 100\%$. Compared with the quality of foam concrete, the quality of polypropylene fiber is very small, and the influence on the overall mixture ratio is relatively small. Therefore, the benchmark mixture ratio of foam concrete is preliminarily determined. On the basis of the benchmark mixture ratio, the effects of different fiber ratios on the wet weight, flow value and 7d unconfined compressive strength of foam concrete are studied.

3.1 Trial mix design calculation

Taking 1000kg/m^3 as the design wet density, the benchmark mixture ratio test was carried out. The

water-cement ratio was used as the benchmark variable, and the foam blending amount was 3.0% of the cement mixing amount. The mixture ratio of the trial test was designed and calculated according to the specification. The specific trial mixture ratio is shown in Table 2.

Table 2. Trial mix proportion of foamed concrete.

Materials	Water(kg)	Cement(kg)	Foam(kg)
Water cement ratio			
1:1.60	226.59	362.54	10.88
1:1.65	222.26	366.73	11.00
1:1.70	254.45	432.56	12.98
1:1.75	249.78	437.12	13.11
1:1.80	280.31	504.56	15.14
1:1.85	275.34	509.38	15.28
1:1.90	287.45	546.16	16.38
1:1.95	315.77	615.75	18.47
1:2.00	326.80	653.60	19.61
1:2.05	321.39	658.85	19.76
1:2.10	316.16	663.93	19.92

3.2 Trial test

3.2.1 Wet weight test

According to the Technical Specification for Design and Construction of Cast-in-place Foamed Light Soil Subgrade (TJG F10 01-2011), the wet weight of the foamed concrete should be controlled at $5\sim 11\text{kN/m}^3$, and the wet weight test should be carried out one by one for all the trial mixture ratios. The wet weight test results of foamed lightweight soil are shown in the figure.

Figure 1. Water cement ratio-wet weight curve of foamed concrete.

The correlation between the wet weight of foamed concrete and the water-cement ratio is significant, and

the wet weight gradually increases with the decrease of water-cement ratio. This is because the density of cement is significantly greater than the density of water, and the wet weight of foam concrete increases with the increase of the proportion of cement in the mixing material.

It can be seen from the figure that when the water-cement ratio reaches 1:2.00, the wet density reaches 10kN/m^3 , that is, the wet density reaches 1000kN/m^3 . Therefore, when the water-cement ratio reaches 1:2.00~1:2.10, the mixture ratio meets the design wet density requirements.

3.2.2 Flow value test

The fluidity of foamed concrete in actual construction is a key indicator, which is measured by testing its flow value. According to the Technical Specification for Design and Construction of Cast-in-place Foamed Light Soil Subgrade (TJG F1001-2011), the flow value of foam concrete should be controlled at 160~190mm. The flow value test results are shown in the figure.

Figure 2. Water cement ratio-flow value curve of foamed concrete.

The fluidity of foam concrete is mainly affected by the proportion of mixing water. The larger the water cement ratio is, the higher the proportion of mixing water is, the stronger the fluidity is, and the larger the flow value is. The flow value test curve can significantly reflect that the flow value decreases significantly with the decrease of water-cement ratio, and when the water-cement ratio is less than 1:1.70, the flow value reduce rate decreases significantly. From the flow value curve, it can be seen that the water-cement ratio in the range of 1:1.85~1:2.00 meets the requirements of the flow value range recommended by the specification.

3.2.3 Water absorption test

Water absorption refers to the ability of the material to absorb water in the soaking state, which is usually expressed by mass water absorption. There are

a large number of pores in foam concrete, which may be used as channels for water flow, and the influence of water on engineering facilities is very significant, so it is necessary to test its water absorption.

Figure 3. Water cement ratio- mass water absorption curve of foamed concrete.

The mass water absorption rate of foamed concrete decreases with the increase of cement ratio, and the water absorption rate is stable at about 36% when the water cement ratio is less than 1:1.95. When the water-cement ratio reaches 1:2.00, the corresponding mass water absorption rate is the smallest.

3.2.4 7d unconfined compressive strength test

Compressive strength is an important index to reflect the bearing capacity of materials. The bearing capacity of foam concrete is measured by unconfined compressive strength index. According to the Technical Specification for Design and Construction of Cast-in-place Foamed Light Soil Subgrade (TJG F10 01-2011), the 7d unconfined compressive strength test of foam concrete was carried out, and the sample was made by $100 \times 100 \times 100\text{mm}$ standard test mold.

Figure 4. Water cement ratio-7d unconfined compressive strength curve of foamed concrete.

When the water-cement ratio is greater than 1:1.80, the growth rate of unconfined compressive strength increases significantly with the decrease of water-cement ratio. When the water-cement ratio reaches 1:1.80, the unconfined compressive strength increases steadily with the decrease of water-cement ratio, and the compressive strength is the highest when the water-cement ratio is 1:2.00.

Based on all the test results, water: cement: foam = 1:2.00:0.06 was selected as the benchmark mixture ratio of fiber foamed concrete to carry out subsequent tests.

4 STUDY ON BASIC PHYSICAL PROPERTIES OF FIBER FOAMED CONCRETE

The fiber material is polypropylene bundle short fiber, which has high temperature resistance, high tensile strength and good chemical stability, and can be closely bonded with foam concrete. The diameter of polypropylene fiber used in the experiment is micron grade, and the fiber length is 13.5 mm, and the fiber tow itself does not have adhesion and has good dispersibility. The fiber ratio of the test ranged from 0.00% to 1.50% and was divided into 7 grades.

4.1 Effect of fiber on wet weight and fluidity

Figure 5. Fiber ratio-wet weight curve of fiber foamed concrete.

Figure 6. Fiber ratio-flow value curve of fiber foamed concrete.

The fiber ratio has little effect on the wet weight of fiber foamed concrete, and its wet weight is basically stable at 10.3 kN/m³. The flow value is significantly affected by the fiber ratio. The higher the fiber ratio, the more polypropylene fibers are dispersed inside the fiber foamed concrete, and the flow of the foam concrete is greatly inhibited.

Through the test of two basic physical performance indexes of wet weight and flow value, combined with the test data, it can be seen that the fiber reinforcement effect has no effect on the wet weight, and has a great influence on the fluidity.

4.2 Effect of fiber on compression resistance

4.2.1 Compressive strength under different fiber ratios

Figure 7. Compressive load versus displacement curve of fiber foamed concrete.

Figure 8. 7d unconfined compressive strength versus fiber ratio curve of fiber foamed concrete.

After the compressive load of non-fiber foamed concrete reaches the maximum value, the load drops sharply, and the compressive failure type tends to

brittle failure. With the increase of fiber ratio, the plastic characteristics of fiber foamed concrete are more obvious, and the compressive load gradually decreases after reaching the peak value, which proves that polypropylene fiber significantly improves the strength ductility of fiber foamed concrete, and the improvement effect is the best when the fiber ratio is 0.75%. With the increase of fiber ratio, the 7d unconfined compressive strength of fiber foamed concrete increases first and then decreases gradually, and reaches the maximum when the fiber ratio is 0.75%, so the best fiber ratio is 0.75%.

4.2.2 Comparison of compressive failure cracks

Figure 9. Non-fiber(a) and fiber(b) foamed concrete.

The compressive failure of foamed concrete produces penetrating cracks, and the small fragments at the cracks fall off directly. After reaching the peak value, the strength drops sharply and the residual strength is low. Most of the fiber foamed concrete cracks do not penetrate the whole specimen, and most of the small particles at the cracks are not directly detached due to the internal fiber traction. The integrity is strong, and the strength gradually decreases after reaching the ultimate compressive strength, and the residual strength is high.

Figure 10. Crack propagation of fiber foamed concrete.

Compared with the cracks that directly penetrate the whole specimen produced by the compression of non-fiber foamed concrete, the fiber foamed lightweight

soil produces short cracks in the compression, and then the short cracks are connected until the compression is destroyed. This is because the expansion and extension of the cracks are limited by the internal fibers.

4.2.3 Research and analysis of compression crack propagation under different fiber ratios

Figure 11. Crack propagation in compression failure of specimens with different fiber ratios.

When the fiber ratio is 0.25%, the fiber foamed concrete is compressed to produce penetrating cracks. This is due to the low fiber ratio, the internal fiber content is less, the crack propagation inhibition is limited, and the cracks are gradually connected to form cracks throughout the whole. With the increase of fiber ratio, the length and number of cracks produced by compression decrease significantly, and the development of cracks is limited, and no penetrating cracks are produced during compression failure. When the fiber ratio is increased to 1.5%, the effect of fiber on the expansion of compressive cracks is significantly reduced. During the process of compression and fracture, bulging deformation occurs along the side edge, while the fiber still has a traction effect on the cracked fragments, preventing the specimen from being crushed, so that it still has a certain residual strength.

When the fiber ratio is too high, there are a large number of fibers inside, and the fiber spacing is significantly reduced. The distribution direction of the fibers will be significantly affected by the distribution direction of the surrounding fibers, which makes the number of fibers distributed in different directions uneven, and the inhibition effect on crack propagation is significantly reduced. When there are too many internal fibers, local agglomeration of fibers will occur. The fiber agglomeration part will affect the crystal distribution produced by the hydration reaction of foam concrete, and then affects local strength and produces weak parts. The combined effect of the two factors makes the high fiber ratio foamed concrete produce more cracks under

pressure, and the fiber has a poor effect on inhibiting the crack propagation and the compressive strength is low.

From the 7d unconfined compressive strength curve and compressive crack propagation of foam concrete with different fiber ratios, it can be seen that the fiber reinforcement effect has a very significant effect on the 7d unconfined compressive strength, and the polypropylene fiber material with higher tensile strength improves the compressive strength by inhibiting the propagation and extension of cracks during compression.

5 STUDY ON THE MICROSTRUCTURE

For the specimens before and after the compression failure of fiber foamed concrete with a fiber ratio of 0.75%, SEM electron microscope scanning experiments were carried out to observe the microstructure of fiber foamed concrete and conduct qualitative description analysis.

5.1 Before compressive failure

Figure 12. Pores of fiber foamed concrete.

There are a large number of pores in foam concrete, among which the largest number are independent pores of different sizes, and there are interconnected pores. Most of the inner walls of the pores are smooth, but there are still very small pores, and holes will appear in the pore walls of a few larger pores.

Figure 13. The combination of fiber and foam concrete.

Polypropylene fiber and foam concrete can be closely bonded together, and the bonding interface is relatively complete and dense, which can give full play to the bonding force of cement cementitious materials in foam concrete.

5.2 After compressive failure

Figure 14. Microstructure of fiber foamed concrete.

In the process of compression failure of fiber foamed concrete, the larger pores are connected with each other, forming a continuously expanding crack, while the smaller pores can still maintain relatively intact. Due to the bonding force between the polypropylene fiber and the foam concrete and its excellent tensile properties, the internal polypropylene fiber limits the cracking of the surrounding pores, prevents the further development of the connected pores, and significantly inhibits the expansion and extension of the cracks. The bonding interface between fiber and foam concrete changes from dense to loose and rough.

6 CONCLUSIONS

In this paper, by adding polypropylene fiber to foam concrete, the mix ratio and strength performance of the material are studied, and the crack propagation law of compression failure is analyzed by combining macro and micro analysis. The following conclusions are obtained:

- 1) Taking the water-cement ratio as a variable, based on the design wet density of 1000kg/m^3 , the foam concrete trial test was carried out, and the benchmark mixture ratio with the lowest mass water absorption and the highest unconfined compressive strength was obtained, that is, water: cement: foam is 1:2.00:0.06.
- 2) Using polypropylene fiber as fiber material, through the wet weight and flow value test, it is concluded that the fiber ratio has no effect on the wet weight, and has a great influence on the flow value. When the fiber ratio is less than 0.25%, it has little effect on the fluidity. When it is higher than 0.25%, the fluidity decreases significantly with the increase of the fiber ratio.

- 3) The fiber reinforcement effect of polypropylene fiber can improve the 7d unconfined compressive strength of foam concrete. When the fiber ratio is 0.75%, the improvement effect is the largest, and the fiber reinforcement effect makes the strength of foam concrete gradually decrease after reaching the ultimate compressive strength.
- 4) The compression failure of non-fiber foamed concrete directly produces through cracks, while the fiber foamed concrete first produces short cracks in the compression process, and then the cracks extend to each other until the failure. When the fiber ratio is higher than 0.50%, the compression failure no longer forms through cracks. After the fiber ratio reaches 1.5%, due to the high fiber content, the fiber spacing is significantly reduced, and the fiber distribution direction is greatly affected by the fiber spacing, which makes the fiber 's inhibition effect on crack propagation worse. At the same time, there is a local fiber agglomeration phenomenon, which affects the local strength, and then makes the fiber foamed concrete produce more cracks locally when it is damaged by compression, and a large number of fibers still have the effect of delaying the further development of damage, avoiding the crushing of the specimen and maintaining its integrity.
- 5) Through the SEM electron microscope scanning experiment on the samples before and after compression failure, it is further confirmed from the microstructure level that polypropylene fiber and foam concrete can be closely bonded. The compression of fiber foamed concrete makes the internal large pores crack and extend into cracks. The internal fibers rely on the bonding force to prevent the surrounding pores from cracking, prevent the further development of the penetrating pores, and then inhibit the expansion of the cracks.
- 6) Through the above conclusions, it is confirmed that the fiber foam concrete effectively overcomes the disadvantages of brittle failure and poor strength ductility of foam concrete, and is expected to be more widely used in tunnel construction and other projects.

ABSTRACT: In response to problems such as cracking, block falling, local buckling and water leakage, tunnel load adjustment control technology has been introduced. Based on the ChangAoNong tunnel, the application of load adjustment control technology in the drilling and blasting tunnel was analysed. The results show that the application effect of load adjustment control technology in three-lane widening and four-lane tunnel is obvious, which can significantly optimize the structural force of the initial branch, improve the rationality of the internal force on the tunnel support structure, and greatly reduce the influence of bias voltage. The load adjustment control technology can greatly enhance the safety of the primary support and secondary lining, and provide a new technical direction for tunnel design optimization. Based on the regulation and control of the internal force of the tunnel lining, the optimization of the lining design parameters is realized, the consumption of labour, material and machinery in the process of tunnel construction is reduced, so as to reduce the carbon emissions in the physicochemical stage of tunnel engineering.

Keywords: load adjustment control technology, Internal force optimization, structural safety, disease prevention and control, carbon emission

1 INTRODUCTION

The stress of tunnel support structure is complex and difficult to predict, and the structural stability is poor, which is prone to lining cracking, block falling, local buckling and water leakage, structure instability and other problems(Chen, J.X., et al., 2018, Hu, C.F., et al., 2018). The essential reason for the above diseases lies in the incongruity of deformation between surrounding rock and supporting structure, and the dominant performance is that the stress distribution of supporting structure under external load is unreasonable. Therefore, it is of great practical significance to optimize the stress distribution of tunnel support structure.

With the development of modern tunnel technology, the theoretical system based on stress control is becoming more and more mature(Xu, R.X., 2000, Huang, H.Y., et al., 2019, Qiu, W.G., et al., 2017, Tian, M.J., et al., 2018). Zhang, D.L., et al. (2019) established the collaborative optimization design

method of tunnel support structure system from the essence of the interaction between tunnel surrounding rock and support structure. Peng, L.M., et al. (2001) established the optimization calculation model of tunnel reinforced concrete lining structure by applying the basic theory of inequality constrained optimization in Lagrange multiplier method. Liu, Y.H. (2002) introduced the simple complex optimization method in the structural optimization theory, and established the optimization design model of highway tunnel lining section. There are many scholars(Yang, H.X., 2022, An, H.G., 2003, Huang, D.W., et al., 2018) have optimized the design parameters of tunnel support structure from multiple angles based on the big data analysis method.

Under the support of many theoretical research results, a large number of new tunnel support structures continue to appear(LI, X.F., et al., 2017, Wang, B., et al., 2023, Sun, J., et al., 2021, Dong, B., et al., 2021). Among them, the resistance limiting and energy dissipation support structure developed by

*Corresponding author: guogangying@nbt.edu.cn

Dai, J., et al. (2022), the graded yield support structure developed by Dong, J.H., et al., the buffer layer yield support structure developed by Tian, Y., et al. (2020) and the circumferential yield support structure developed by Lei, S.X., et al. (2020) have achieved good results in application engineering.

Different from the above structures, the load adjustment control technology combines the stress control theory and prestress technology, which can not only adjust the stress distribution of the tunnel initial support structure (Ma, K., et al., 2022), but also control the deformation state of the tunnel structure, so as to effectively reduce the peak bending moment and nonuniformity of the tunnel lining. Based on the ChangAoNong tunnel, this paper introduces the principle and construction method of the load adjustment control system, analyses the application of the load regulation control system in the tunnel engineering construction, and verifies the internal force regulation effect of the primary support and secondary lining structure.

Figure 1. Load adjustment control system.

2 DESIGN OF LOAD ADJUSTMENT CONTROL SYSTEM

2.1 Principle of load adjustment control system

The load adjustment control of tunnel is divided into two stages: load adjustment and deformation control, in which load adjustment is the basis of deformation control. Load adjustment is to enhance the load adjustment ability of the arch by installing multiple load adjusters on the steel arch of the initial support, realize the long-distance transfer of the load on the arch, and make the internal force of the steel arch become clear and controllable. Deformation control is to make the steel frame produce camber by applying specific preload, so as to basically offset the linear change of the steel frame under the surrounding rock pressure, stabilize it in a linear state close to zero stress, make the steel arch in the full section compression state, and greatly reduce the peak bending moment and nonuniformity of the primary support structure. (Ying, G.G., et al., 2023).

Figure 2. Main unit.

2.2 Composition of load adjustment control system

The tunnel load adjustment control system consists of two parts: load adjuster and load applicator (Figure 1).

2.2.1 Load adjusters

The load adjuster is divided into main unit and over excavation unit. The main unit is composed of top plate, adjusting screw, adjusting nut, ejector rod, outer sleeve, piston, oil cylinder, high-strength oil pipe connecting hole, positioning hole and anchor bolt (Figure 2). The over excavation unit is composed of extended screw rod and extended nut (Figure 3).

Figure 3. Over excavation unit.

The load adjuster needs to be connected in series with high-strength oil pipes. Considering the high oil pressure in the hydraulic system, the high-strength oil pipe needs to use high-pressure steel wire braided hose. The hose is designed with five layers, consisting of a liquid resistant inner adhesive layer and an intermediate adhesive layer, two layers of steel wire braided and an outer adhesive layer with excellent corrosion resistance, as shown in Figure 4.

Figure 4. High-strength oil pipes.

After the installation of the hydraulic system, it is necessary to install the high-pressure ball valve as the interface of the hydraulic system to facilitate the subsequent pressurization adjustment.

Figure 5. High-pressure ball valve.

2.2.2 Load applicator

The load applicators include a high-pressure oil pump for oil delivery and a high-pressure oil gauge for control.

Figure 6. Portable high-pressure oil pump.

Figure 7. High-pressure oil gauge.

Considering the site construction conditions, portable high-pressure oil pump (Figure 6) is required. The maximum oil storage capacity of the oil pumps is not less than 2000cc, and the maximum pressurized load is not less than 70MPa. During oil filling, it is necessary to connect the high-pressure oil gauge (Figure 7) to accurately control the oil pressure in the hydraulic system.

2.3 Construction technology of load adjustment control system

The tunnel load adjustment control system can be installed synchronously with the steel frame. Generally, the installation of the system can be completed before the construction of the shotcrete, which will

not affect the excavation progress of the tunnel. The main construction process is as follows:

2.3.1 Installing load adjuster

Installation of adjustment unit after the erection of the steel frame, the load adjuster can be connected by welding or bolts, and the two adjacent adjustment units are installed alternately in front of and behind the steel arch frame (Figure 8).

Figure 8. Installing load adjuster.

Figure 9. Connecting high-strength oil pipes.

After the load adjuster is installed, rotate the adjusting nut to ensure that the top plate is close to the surrounding rock. If the tunnel is over excavated seriously, it is necessary to add a Over excavation unit. After all adjustment units are installed in place, connect them in series with high-strength oil pipes (Figure 9), pressurize them with oil pumps, exhaust the air in the oil circuit, and check the leakage of the oil circuit.

2.3.2 Pressurization process

According to the principle of the load adjustment control system, the pressurization process of the regulation system needs to be carried out twice. The oil pressure in the hydraulic system must be loaded to 5MPa through the oil pump 1-2 days after the completion of the initial support shotcrete construction, so as to form a regulating layer between the surrounding rock and the initial support structure.

The secondary pressurization is carried out after the steel arch is closed. At this time, the oil pressure needs to be applied to the design value, so that the steel arch has pre deformation.

Figure 10. Pressurization process.

2.3.3 Bolt anchorage

Before the construction of secondary lining, lock the piston with anchor bolt. At this time, the load adjustment stage of the load adjustment control system is over, and the prestressed provider is transferred from the hydraulic system to the anchor bolt to ensure the continuous existence of prestress.

3 ENGINEERING APPLICATION CASE ANALYSIS

In order to verify the influence of the load adjustment control system on the tunnel support structure, field comparative tests were carried out at zk18+460~zk18+480 section of the left line of ChangAoNong tunnel, in which zk18+460~zk18+470 were the regulation section and zk18+470~zk18+480 were the comparison section.

3.1 Project overview

ChangAoNong tunnel is a three-lane widened tunnel with small clear distance. The bedrock at the tunnel site is granite.

The joints are developed or relatively developed. The joints are mainly closed and lack of water. The left line of the tunnel has a total length of 885m, grade V surrounding rock is 717m, and the proportion of grade V surrounding rock is 81.02%. The right line of the tunnel has a total length of 880m, grade V surrounding rock is 613m, and the proportion of grade V surrounding rock is 69.66%. The outline of the tunnel is shown in Figure 11.

Figure 11. Outline design drawing of the tunnel.

3.2 Design of load adjustment control system

According to the design concept introduced above, the load adjustment control system of ChangAoNong tunnel is designed. Considering that the regulating load is closely related to the surrounding rock pressure of the tunnel, a proportional relationship is established between the vertical surrounding rock pressure and the regulating load of the arch wall, arch abutment and arch crown, and is named as the internal force control coefficient. Through the finite element software, the reduction of the bending moment of the tunnel vault under different internal force control coefficients is calculated. The results are shown in Table 1, and the adjustment of the bending moment is shown in Figure 12.

Table 1. Reduction of arch crown bending moment.

Internal force control coefficient	Moment reduction
1.0:1.2:0.6:0 (scheme I)	Over 90%
1.0:1.0:0.5:0 (scheme II)	Over 70%
1.0:0.8:0.4:0 (scheme III)	Over 50%

Figure 12. Comparison of bending moment distribution.

Considering the economy of the scheme, the internal force control coefficient in scheme II is adopted for the load adjustment control system applied in ChangAoNong tunnel, and the bending moment reduction is expected to reach more than 70%. The tunnel secondary lining is optimized based on the adjusted bending moment, and the design structure is shown in Table 2.

Compared with the design of the section of the comparison section, the load adjustment device is installed in the primary support structure of the adjusting section, and the concrete thickness of the secondary lining arch ring is reduced by 10cm.

3.3 Application effect analysis

In order to analyse the application of load adjustment control system in ChangAoNong tunnel, monitoring sections were set up at zk18+465 and zk18+478 sections to monitor the internal force of tunnel structure.

Table 2. Lining design of experimental section.

Section	initial support				Secondary lining		
	advanced support	bolt	Shotcrete	Steel arch	Load Adjusting unit	arch ring	inverted arch
Adjusting section	Φ42×5mm advanced small pipe	Φ22-5 hollow grouting anchor rod	31cm C25 shotcrete	I25a section steel, spacing 0.75m	15, evenly divided by arch ring	55cm C40 reinforced concrete	65cm C40 reinforced concrete
Contrast section	Φ42×5mm advanced small pipe	Φ22-5 hollow grouting anchor rod	31cm C25 shotcrete	I25a section steel, spacing 0.75m	/	65cm C40 reinforced concrete	65cm C40 reinforced concrete

3.3.1 Bending moment adjustment effect of initial support

According to the action mechanism of the tunnel, combined with the design parameters of the tunnel structure and the strain monitoring data, the bending moment of the tunnel structure can be calculated. Take zk18+478 section as the contrast section, and compare it with zk18+465 section of the adjusting section. The bending moment distribution is shown in Figure 13:

Figure 13. Distribution of tunnel bending moments.

Observe the change of bending moment at each measuring point of the structure and draw an image. The change of tunnel bending moment is shown in the Figure 14.

Figure 14. Diagram of extreme changes in tunnel bending moment.

Figure 15. Diagram of tunnel moment distribution change.

According to Figure 14, the bending moment at the extreme point of the original positive bending moment decreased from 27.093KN·m to 7.82KN·m, a decrease of 71.14%, and the bending moment at the extreme point of the original negative bending moment decreased from -43.367KN·m to -1.335KN·m, a decrease of 96.92%. The position of the maximum positive bending moment remained unchanged, and the size decreased from 27.093KN·m to 7.82KN·m, a decrease of 71.14%. The position of the maximum negative bending moment shifted from the right arch waist to the arch crown, and the size decreased from -43.367KN·m to -18.807KN·m, a decrease of 56.63%. It can be seen that after the application of the load regulation system, the load acting on the structure has been transferred and the stress has been redistributed. According to the goal, the rationality of the bending moment distribution has been significantly improved.

According to Figure 15, the unevenness of bending moment before and after adjustment is reduced by 61.23%, and the bias of bending moment is relieved by 78.36%. It can be seen that after the application of the load regulation system, the stress concentration phenomenon of the structure is obviously improved, and the influence of load bias on the structure is basically eliminated

3.3.2 Safety of secondary lining

Since the secondary lining of the regulation section is optimized according to the design, it is necessary

to check the safety factor of the lining of this section. According to the field measured data and the calculation method in the specification, the safety factors of the secondary lining in the comparison section and the secondary lining with the load adjustment control system before and after optimization are calculated respectively, and the calculation results are shown in Figure 16.

Figure 16. Tunnel second lining safety factor.

The safety factor of the secondary lining of the regulation control section was increased from 5.558 to 8.927, indicating that the application of the load adjustment control system can greatly enhance the safety of the secondary lining. After the application of the optimal design, the thickness of the secondary lining is reduced by 10cm, and the safety factor of the secondary lining is reduced from 8.927 to 6.162, which is still about 11% higher than the safety factor of 5.558 before adjustment, which shows that the optimal design of the secondary lining is reasonable from the perspective of safety.

3.3.3 Analysis of emission reduction effect

The manufacturing, transportation and installation of the load adjustment control system will bring additional carbon emissions to the tunnel construction, and the optimal design of the secondary lining can effectively reduce the carbon dioxide emissions during the tunnel construction stage. In order to

clarify the emission reduction effect of the load adjustment control system, it is necessary to calculate the carbon emissions of the two schemes respectively.

In this study, the tunnel construction steps are divided into 12 construction results, including advanced small conduit, surrounding rock excavation, anchor rod, reinforcement mesh, steel arch, load adjustment device, connecting reinforcement, anchor rod, shotcrete, secondary lining reinforcement, inverted arch concrete, and arch wall concrete. The carbon emissions generated in each construction result can be divided into four parts: building material production, building material transportation, construction machinery and equipment, and construction personnel. According to the *JTG/T 3832-2018 highway engineering budget quota* and the calculation table of the quantities of ChangAoNong tunnel, the construction results are converted into the carbon emissions of materials and machinery shifts for calculation and summary. The calculation results are shown in Figure 17:

It can be seen from Figure 17 that the carbon emissions generated by the construction results of surrounding rock excavation, steel arch frame, shotcrete, secondary lining reinforcement and arch wall concrete decreased by 719.6 kg CO_{2eq}, 1306.0 kg CO_{2eq}, 982.0 kg CO_{2eq}, 2772.4 kg CO_{2eq} and 6281.4 kg CO_{2eq} respectively. The installation of load regulating device increased the carbon emissions by 2968.5 kg CO_{2eq} in the physicochemical phase of the project, and the other steps had no significant impact. To sum up, the application of the load adjustment control system has reduced the carbon emissions of the ChangAoNong tunnel project in the physicochemical phase by 9092.9 kg CO_{2eq}, i.e., 909.29 kg CO_{2eq} /m.

4 CONCLUSIONS

According to the application of load adjustment control system in ChangAoNong tunnel in this study, the following four conclusions can be summarized:

Figure 17. Calculation results of engineering carbon emissions in the test section.

1. The main function of the load adjustment control system is to adjust the surrounding rock pressure of the tunnel initial support structure, control and reduce the peak bending moment and unevenness of the tunnel lining, so as to realize the optimization of the tunnel lining structure design. The engineering verification shows that the application effect is obvious in three-lane widening and four-lane tunnel.
2. The application of the load adjustment control system reduced the maximum positive and negative bending moment of the primary support by 71.14% and 96.92%, the unevenness of bending moment by 61.23%, and the bias degree by 78.36%, which shows that the load adjustment control system can significantly optimize the structural stress of the primary support, improve the rationality of the internal force of the tunnel structure, and greatly alleviate the bias effect.
3. According to the monitoring results of ChangAo-Nong tunnel, after the adjustment and optimization of the primary support stress, the minimum safety factor of the secondary lining is still slightly greater than that of the secondary lining in the comparison section after the thickness is reduced, which verifies the rationality and scientificity of the secondary lining optimization method, and provides a new technical direction for the safety and economy of tunnel design optimization.
4. Based on the adjustment and control of the internal force of the tunnel lining, the optimization of the lining design parameters is realized, which can reduce the material and energy consumption in the process of tunnel construction, and reduce the carbon emission of the tunnel in the physico-chemical phase by about 909.29kg CO_{2eq}/m, which provides a new technical direction for the green and low-carbon tunnel design optimization.

ABSTRACT: In mountain tunnel constructions, there is a concern that the large overburden at vulnerable fault zones may cause deformations due to the large ground load, leading to an instability of the tunnel structure. In such cases, to ensure stable excavation and support construction, a rigid multiple support structure that can withstand the load can be used. Another method is the drift advancing tunnel construction method that can be used to release initial stresses in the ground before constructing the main tunnel support. In the Aokuzuretōge Tunnel, a two-lane road tunnel, the total length is 4,998m while the maximum overburden is 610m. The geology of the Nagano side of the tunnel is mainly mylonite, a metamorphic rock, and the area around the fault is soft. In this construction section, the problematic large overburden section was only about 100m long. Although, the implementation of the drift advancing tunnel construction method was considered as a countermeasure, since this method required separate procurement of machinery to construct the drift, it was believed to be disadvantageous in terms of the cost and the construction period. Therefore, we adopted the double-support construction method, which is still very rarely used in Japan. In addition, ultra-high-strength sprayed concrete with a design standard strength of 54 N/mm² was applied to the section with the largest overburden to ensure the stability of the tunnel. This paper describes the design concept and construction results of the countermeasures that were taken to reduce the displacement due to the large overburden.

1 INTRODUCTION

The Sanen-Nanshin Expressway starts the Chuo Expressway from Iida City in Nagano Prefecture to Inasa-cho in Shizuoka Prefecture, a high-standard arterial road of approximately 100km in length. The Aokuzuretōge Tunnel is a two-lane road tunnel totaling 4,998m located on the border of Nagano Prefecture and Shizuoka Prefecture in this Expressway.

The tunnel is located about 500m west of the Median Tectonic Line. Based on the excavation of the previous investigation shafts, the main geological feature is thought to be mottled mylonite, a fault rock has undergone plastic flow under high temperature, pressure, and dynamic metamorphism.

The Nagano construction side of the tunnel is 2,854m, and the excavation began in April 2019 (Figure 1, Table 1). The displacement and deformation

Construction site	Minamishinano, Iida City, Nagano Prefecture, Japan
Length of construction section	2,854m from the Nagano side mouth of the 4,998m
Inner cross section	63m ² (standard part at the time of completion)
Excavation cross section	124m ² (shoring pattern EdI-aF)
Construction period	August 9, 2018 to November 30, 2024
Construction method	NATM (Full Face Method With Auxiliary Bench Cut)
Excavation method	Blasting excavation (sliding: tire method)

after excavation of about 2730m from the start were relatively small since the geology was mainly composed of mottled mylonite, and the tunnel stability was ensured with the DI Support Pattern.

However, after the excavation distance of 2,730m, which passed the hypothetical fault F15, the displacement and deformation increased after the tunnel excavation. Cracking of the shotcrete, buckling of the steel arch supports, deformation of the rock bolt plates, and bolt breakages were confirmed (Figure 2).

The overburden of the section from 2,730m excavation distance on the Nagano construction side to 2,854m at the end of the construction area increased sharply from 530m to 610m. Based on this, it was determined that a support structure and a construction method that can withstand extremely large ground loads would be necessary for Subsequent tunnel excavation, and a study was conducted. As a result, it was decided to apply double supports using ultra-high-strength shotcrete with a design strength of 54 N/mm² for the section and to apply a tunnel shape close to a perfect circle.

This paper reports the process of application of double support using ultra-high-strength shotcrete in this section and the construction results.

2 GEOGRAPHY AND GEOLOGICAL OVERVIEW

2.1 Topography overview

Figure 3 shows the geological profile of the Nagano construction side of the Aokuzuretōge Tunnel. This

tunnel is planned in a steep mountainous area with an altitude of about 590m to 1,260m. The overburden is 1.5D (D is the tunnel excavation diameter) at about 31m from the Nagano Side entrance and beyond that point, the overburden increases as the tunnel is excavated.

In the section approximately 440m from the tunnel entrance at the Nagano construction side to the construction zone boundary, it was impossible to apply standard supports based on the design method because the overburden is over 500m. The maximum is 610m on the Nagano construction side, about 58m from the boundary of the construction area (Japan Road Association, 2023).

2.2 Geological overview

As a result of the investigation pit excavation conducted prior to the excavation of the main pit (Motoki et al., 2020), the geology mainly was patchy mylonite found in the section of about 2,600m from the tunnel entrance on the Nagano construction side. The displacement and deformation after excavation of the survey pit were relatively small because the patchy mylonite was relatively stiff.

However, it was confirmed that the fine-grained mylonite and muddy mylonite were distributed in the section after 2,600m, which was far away from the tunnel entrance on the Nagano construction side, and the displacement and deformation after tunnel excavation increased. In addition, since the displacement and deformation after excavation will continue for an extended period in the evacuation tunnels, the cross-sectional shape is made close to a perfect circle, and double support is applied.

Figure 2. Deformation situation of the support which occurred.

3 DEFORMATION HISTORY OF SUPPORT MEMBERS

From the Nagano construction side entrance to around 2,740m, the support pattern DI-b shown in Figure 4 was applied except for the support pattern DIII at the

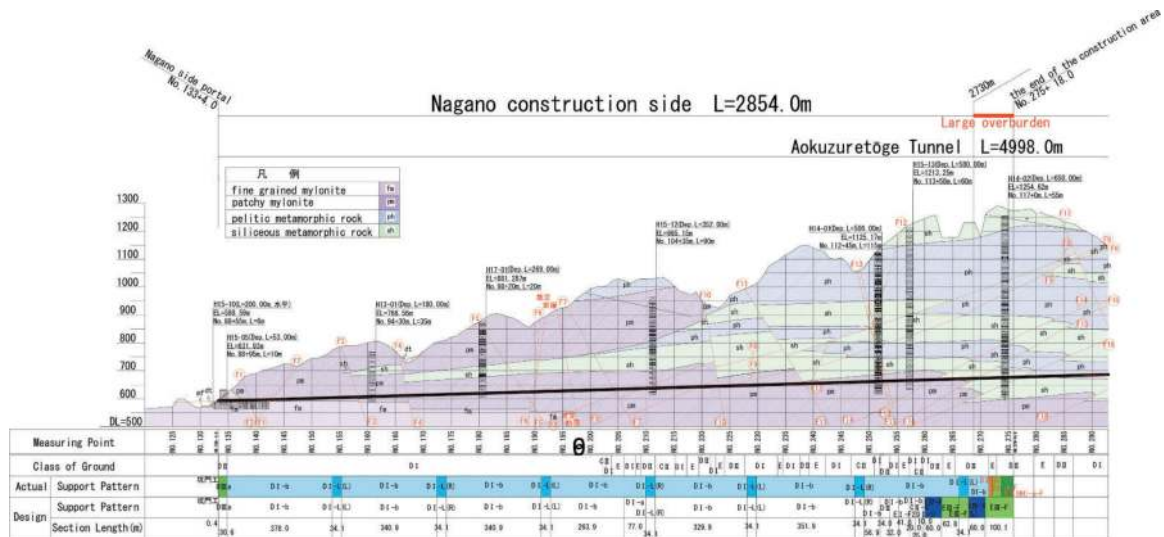

Figure 3. Geological profile.

tunnel entrance. In this section, the convergence and crown settlement were comparatively small, about 1 to 2 cm at maximum, and a convergence tendency was confirmed at a distance of 2D from the tunnel face.

However, after passing through F15, shown in Figure 3, the rock types that appeared at the tunnel face included black shale. Cracks in the shotcrete and steel cracks appeared at the top of the tunnel, and the steel arch support buckled, as shown in Figure 2. In addition, the deformation of the plate of the rock bolt and its breakage was confirmed in the rock bolt on the side wall. For this reason, in the section where the deformation occurred, additional rock bolts were installed, and additional shotcrete with a thickness of 10 cm was applied to ensure the stability of the tunnel and the safety of construction.

4 EXAMINATION OF TUNNEL STRUCTURE AND CONSTRUCTION METHOD

4.1 Mechanism of deformation generation

Figure 5 shows the convergence and crown settlement measurement results in the section where the support deformation occurred. This figure shows that both the convergence and crown settlement were increased, and the displacement and deformation trend of the shotcrete increased to the face distance of 20m (about 1.0D). In particular, the displacement and deformation rates are significant, and the convergence is larger than the crown settlement after the tunnel excavation.

From the above, in this deformed section, the deformation of the supporting element occurred due to displacement and deformation at an early stage about the distance of 4m to the tunnel. These results coincided with the time when underground observation confirmed the deformation.

From these results, it was considered that the deformation occurred in the support member due to displacement and deformation in the early stage after

excavation when the strength of the shotcrete was not sufficiently developed.

4.2 Consideration of countermeasures

From the tunnel observation and measurement results, it was considered that deformation occurred

Figure 4. Support Pattern DI-b.

Figure 5. Measurement results of displacement and deformation in the deformation occurrence section.

Figure 6. Considered support structure.

in the steel arch support and the shotcrete at a face distance of about 4m. As shown in Figure 2, the shotcrete at the top of the tunnel has cracks in the longitudinal direction, and it is thought that horizontal displacement and deformation are the causes of deformation.

In many cases, early closure using supportive inverts effectively suppresses horizontal displacement and deformation (Susumu et al., 2019). However, considering that deformation occurs at a face distance of 4 m in this tunnel, it is necessary to complete closing at a face distance of 3 m or less. It was considered difficult to apply the method because closing the full cross-section face of about 124m² near the face needs to include the operating range of the construction machine, and it was challenging to ensure the safety of the work. Based on the above about the support structure behind the deformation-occurring section, the use of a high-rigidity support structure based on the construction results of the adjacent Shizuoka construction section was examined.

Specifically, the double support structure shown in Figure 6 was adopted. For the top heading and bench, high-strength steel HH-200 (ss540) was used for the high-arch support, and high-strength shotcrete with a design strength of 36 N/mm² was used. At that time, the shotcrete thickness of the first support was set at 35 cm, and the shotcrete thickness of the second support was set at 25 cm. As for the rock bolts, only the first support was applied, and high-strength bolts with a yield strength of 290kN for a length of 4 m were applied.

As for the shape of the invert, the tunnel's center was 1m deeper than the usual cross-section so that the radius was reduced, and the high-strength steel HH-200 (ss540) invert supports were used for the early closure. At that time, high-strength shotcrete with a design strength of 36N/mm² shall be applied for the shotcrete of the invert, and the thickness shall be 60cm, equivalent to the total thickness of the primary and second support in the top heading and bench. However, to ensure the construction's safety, the closing distance was approximately 6 to 8 m from the top heading face.

In addition, for the 40m section from No.273+18 to No.275+18, which has the maximum overburden, it is assumed that the initial stress of the ground will increase further, therefore ultra-high strength shotcrete with a design strength of 54N/mm² was applied (Hazama Ando Corporation, 2023).

5 EFFECTS OF COUNTERMEASURES

After the deformation occurred, countermeasures were considered, materials such as steel arch support were procured, and double-supported tunnel excavation was resumed.

First, an auxiliary construction method, the injection Steel pipe forepiling, shown in Figure 6, was constructed. The top heading was excavated using blasting and installing the first support. After that, the bench was excavated, and the first support was installed. The second support was installed 6-7m behind the top heading face, and early closure was performed by inverting the support about 10m behind.

5.1 Displacement and deformation

Figures 8(a) and (b) show the convergence and crown settlement measurement results at No.273+05, where the overburden is 609m. In the figure, initial values are set at the time of the first and second support construction and arranged by the tunnel face distance.

In addition, this figure also shows the convergence and crown settlement in the section where ultra-high strength shotcrete was applied, which will be described later.

This figure confirmed that both the convergence and crown settlement increased during the period from the construction of the first support to the construction of the second support. In particular, a comparatively large value of about 90mm was obtained for the convergence, but no deformation

Figure 7. Construction status of double support section.

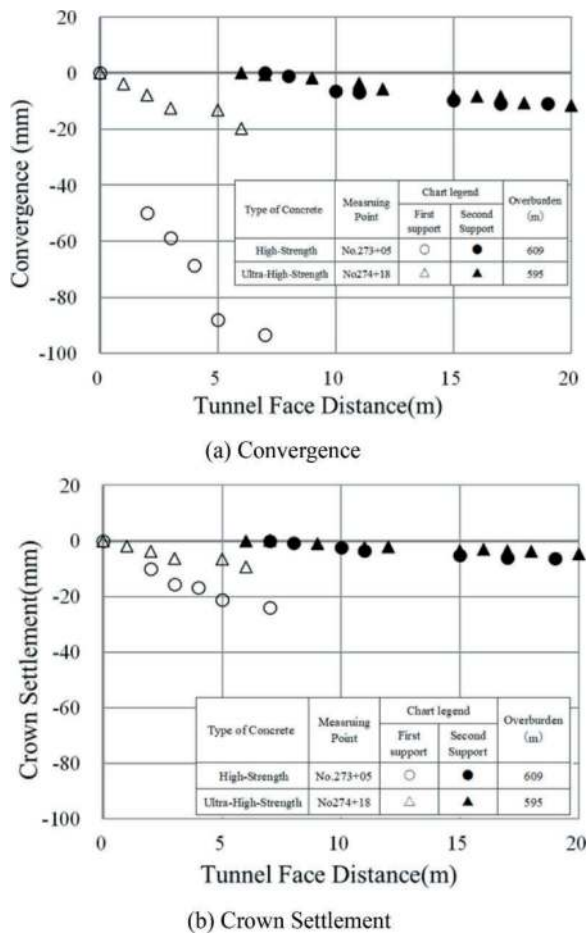

Figure 8. Measurement results of the convergence and crown settlement.

was confirmed in the shotcrete, steel arch supports, and rock bolts.

After that, it was found that by installing the second support, both the convergence and crown settlement were reduced to about 10mm, and the rate of increase in displacement and deformation also decreased.

Therefore, the first support with high-strength concrete, high tensile steel arch support, and high-strength rock was not found to cause any deformations in the supports because the material strength increased along with the stiffness of the support. Although displacement and deformation could not be sufficiently controlled at the first support stage, secondary support and early closure with supported inverts ensured that subsequent displacements and deformations were controlled.

5.2 Effects of ultra-high-strength shotcrete

In the 40m section from No.273+18 to No.275+18, which is the construction zone boundary, the maximum overburden is 610m, so the ultra-high strength shotcrete with a design strength of 54N/mm² was applied. In this case, ordinary high-strength shotcrete was used for the steel arch support. The thickness of

the shotcrete was 35cm for the first support and 25cm for the second support. The same high-strength bolts were also applied to the rock bolts.

Figures 8(a) and (b) show the convergence and crown settlement when ultra-high-strength shotcrete is applied compared to the case when normal high-strength shotcrete is applied.

This figure shows that the application of ultra-high-strength shotcrete can reduce the convergence and crown settlement at the construction stage of the first support to approximately 1/6 to 1/3. On the other hand, there was no significant difference in the convergence and crown settlement after the construction of the second support.

Based on the above, when the double support structure is applied, the displacement and deformation of the tunnel after the construction of the first support are not significantly different from those of the standard single support. However, it was found that the displacement and deformation after the construction of the second support were small and stabilized in an early stage. In addition, although the application of ultra-high-strength shotcrete can suppress the displacement and deformation after the construction of the first support, it is considered that there is no significant difference in the suppression effect of the displacement and deformation after the construction of the second support.

6 VERIFICATION OF EFFECTIVENESS

Numerical analysis was conducted to verify the effect of double supports applied in the Nagano section of the Aokuzuretōge Tunnel.

6.1 Analysis method

The effect of the applied double support was verified using numerical analysis. The analysis code used for verification was FLAC3D by the finite difference method. The ground was assumed to be an elastoplastic body according to the Mohr-Coulomb failure criteria, and the support members were assumed to be a composite shell by the steel arch supports and shotcrete.

The support effect of the rock bolts was sufficiently small and therefore, that it was not considered to model and did not consider the auxiliary construction method.

6.2 Analysis model and input physical property values

Figure 9 shows the analytical model, and Table 2 shows the input physical property values of the ground and supports.

Based on the *Tunnel Numerical Analysis Manual* of the Japan Highway Public Corporation Test Research Institute (Nihon Doro Kodan Research Institute, 2002), the analysis area was set to 60m to the

left and 70m to the right of the tunnel's center and 120m to the longitudinal direction. The area below the invert was about 3.75D (D: tunnel excavation diameter) of 45m, and the overburden was 500m (about 40D). In order to reproduce the maximum overburden of 610m, a distributed load of $2.7 \times 10^2 \text{ kN/m}^2$ was applied in the initial ground analysis.

Among the input physical property values used in the analysis, the ground's modulus of elasticity was assumed to reproduce the displacement and deformation in the support pattern DI, where deformation occurred in this tunnel.

Regarding the modulus of elasticity of the shotcrete at the stage of tunnel excavation, the value of general construction steel was used in the research

Figure 9. Analysis model.

results of Tsuchiya (1985). In addition, the second support was constructed when the tunnel face distance was 8 m, changing the composite shell's elastic modulus from the first support to the second support.

6.3 Analysis result

Figure 10(a) and (b) compare the analysis results and measurement results when double support using high-strength shotcrete with a design strength of 36 N/m^2 is applied. Figure 11(a) and (b) compare the analysis and measurement results when applying ultra-high-strength shotcrete with a design strength of 54 N/m^2 .

In this context, (a) is the convergence, and (b) is the crown settlement. The horizontal axis is the tunnel face distance, while the vertical axis represents convergence and crown settlement.

However, from Figure 10, the convergence in (a) shows that the measurement results greatly exceeded the analysis results at the first support stage. At the stage of the second support in (a) and the crown settlement shown in (b) at the stage of the first support and the second support, the analysis and measurement results were in general agreement. From this, the numerical analysis could not reproduce the significant convergence immediately after constructing the first support. However, the convergence at the second support stage and crown settlement at the first and second support stages can be reproduced by changing the rigidity of the first and second support.

Figure 11(a) and (b) show that analysis results and measurement results of the convergence and crown settlement when the double support structure with ultra-high strength shotcrete was used generally agreed with each other. In addition, compared with the double support using high-strength shotcrete with a design standard strength of 36 N/mm^2 shown in Figure 10(a) and (b), the measurements using ultra-high-strength shotcrete suppresses the amount of convergence and crown settlement.

7 CONCLUSION

In the construction section on the Nagano side of the Aokuzuretoke Tunnel, a large ground load caused deformation of the support members, so double support was applied to the 76m section from No.272+02 to the boundary of the construction section. At that time, ultra-high-strength shotcrete with a design strength of 54N/mm² was used instead of the standard high-strength shotcrete for the section from No. 273+18 to the boundary of the construction zone, where the overburden was particularly large.

As a result, there was no deformation of the support after excavation, and it was considered that the stability of the tunnel was secured. In addition, applying ultra-high strength shotcrete when double support is applied under construction conditions with significant overburden, displacement and deformation after tunnel excavation can be suppressed. The effect of suppressing this displacement and deformation was also confirmed by numerical analysis in which the rigidities of the primary and second support composite shells were changed.

ABSTRACT: In the subsea tunnel built by drilling and blasting method, the section steel frame of primary support is corroded by long-term ions, and the bearing capacity and degradation mechanism of the primary support after corrosion are the key to long-term safety evaluation of the tunnel. Based on the stress characteristic state of a subsea tunnel, eccentric concrete components with section steel frame were constructed. First, eccentric concrete components with steel frame sections that had varying rates of corrosion were obtained using an electric acceleration test. A handmade counterforce mechanism was then used to enhance eccentric loading. This paper investigates the bearing capacity and law of failure form of corroded primary support that vary with the eccentricity distance and corrosion rate. It also determines the critical corrosion rate for the primary support with section steel frame that satisfies the plane cross-section assumption. Ultimately, the evolution process of the primary support's mechanical deterioration under the section steel frame's corrosion influence was uncovered using numerical simulation. This attenuation of primary support bearing capacity was caused by the following factors: the geometric and mechanical parameters of the section steel frame, which contributed between 32.69% and 37.75%; the attenuation of concrete mechanical parameters, which contributed between 18.36% and 20.8%; and the bond-slip degradation, which contributed between 43.09% and 46.58%.

Keywords: Subsea tunnel, Primary support, Section steel frame corrosion, Corrosion degradation test, Mechanical evolution mechanism

1 INTRODUCTION

A tunnel is an underground structure with a complicated operating environment and surrounding geological conditions. The operation safety of the tunnel is gravely threatened by a number of degradation characteristics that will undoubtedly arise with longer operating times. These characteristics include lining cracking, water leakage, block failure in extreme circumstances, tunnel floor uplift or slurry rising, etc (Liu et al., 2021). This is because the materials of the tunnel support structure, like steel and concrete, are deteriorating to varying degrees, and the surrounding rock of the tunnel has deteriorated because of its own geological conditions, groundwater conditions, or construction factors.

The environment within subsea tunnels is more special than that of ordinary tunnels; saltwater has a high concentration of ions such as sulfate (SO_4^{2-}) and chloride (Cl^-), and high water pressure encourages ion transport (Jin et al., 2013; Wang et al., 2019). The steel in the supporting structure system is easily depassivated and corroded by ion erosion, resulting in the weakening of its mechanical parameters and the degradation of the bond strength (Zhang et al., 2022), which ultimately has an impact on the tunnel's supporting structure system bearing capacity and safety. The subsea tunnel designed based on NATM theory often has poor surrounding rock conditions in the section with section steel frame, where the primary support will bear a large load. The section steel frame's corrosion not only

*Corresponding author: zytzytlvzq@163.com

causes the corrosion expansive force but also breaks down the bond between the section steel frame and the shotcrete, allowing slippage to occur. Because the section steel frame and the shotcrete are unable to work together, the bearing capacity of the primary support is significantly reduced. The decay law and degradation mechanism of the primary support bearing capacity after the section steel frame corrosion have become the key to the long-term safety evaluation of operational tunnels.

Based on the stress characteristics of the primary support at a particular site, and taking into consideration two factors: the loading eccentricity and the corrosion rate of the section steel frame, twelve sets of section steel frame concrete eccentric components were made in order to reflect the influence of corrosion on the bearing capacity of section steel frame corrosion from a macro perspective. Different eccentricity was taken into consideration to load the components after performing accelerated electrolytic corrosion experiments to determine different corrosion rates. The failure form and bearing capacity of the primary support with corrosion rate and eccentricity were investigated, and the critical corrosion rate of primary support with section steel frame that meets the plane cross-section assumption has been obtained. Finally, the decay of geometrical and mechanical parameters of steel frame corrosion, the decay of mechanical parameters of concrete caused by corrosion expansion, and the degradation of bond-slip between section steel frame and concrete caused by corrosion respectively contribute to the decay of primary supporting capacity is revealed.

2 TEST METHOD FOR CORROSION DEGRADATION OF SECTION STEEL FRAME IN PRIMARY SUPPORT

2.1 The methods of loading and ion-accelerated corrosion

The primary support structure is a ring shape in practice, and the idea of “straight instead of curved” is adopted to simulate the stress characteristics of the primary support (Feng et al., 2021), and straight beams with equal sections are selected to replace the primary support curved beam members to carry out research on the characteristics of the primary support bearing capacity under erosion environment indoors (Figure 1). Since the primary support is an eccentric compression member, the test will be equipped with a bull leg under the straight beam to achieve eccentric loading (Figure 2).

Affected by water pressure and drainage methods, the primary support of the subsea tunnel is immersed in seawater, so the primary support components are eroded by chloride ions everywhere., which has the characteristics of global corrosion and deterioration. Consequently, in order to imitate the project’s real circumstances, the primary support members in this

Figure 1. Schematic diagram of “straight instead of curved” equivalence principle.

Figure 2. Eccentric loading form.

test were completely immersed in NaCl solution, and then the section steel frames in the primary support were corroded by electrical acceleration test.

2.2 Deterioration test device and measuring system

Using the weathering capsule trough portion of a subsea highway tunnel as an example, the primary support section was made of NO. 22b I-shaped steel, and the concrete was made of C25 shotcrete with a 32cm thickness. Therefore, the cross-section width b and height h of the columns of eccentric members were determined to be 32cm×32cm, and the bull legs of the members were employed for test loading, as shown in Figure 3.

Figure 3. Dimensions of the specimen (unit: cm).

The experiment constructed a total of 12 steel reinforced concrete eccentric compression components, primarily examining the effects of varying eccentricity and corrosion rate on the eccentric components’ bearing capacities. The test conditions are shown in Table 1.

Table 1. Eccentric member test conditions.

Specimen number	Eccentricity	Target corrosion rate/%
B-1-1	6.4cm (Relative	0
B-1-2	eccentricity	3
B-1-3	$e=0.2)$	6
B-1-4		9
B-2-1	11.2cm (Relative	0
B-2-2	eccentricity	3
B-2-3	$e=0.35)$	6
B-2-4		9
B-3-1	16cm (Relative	0
B-3-2	eccentricity	3
B-3-3	$e=0.5)$	6
B-3-4		9

The main steps involved in producing eccentric compression components are cutting I-shaped steel, welding brackets, pasting and waterproofing I-shaped steel strain gauges, making molds, injecting I-shaped steel and connecting wires, pouring concrete, demoulding components, curing, and forming, etc. The formed components are shown in Figure 4.

Figure 4. Eccentric member.

2.2.1 Electric accelerated corrosion test

This test uses an electric accelerated corrosion test method, which is based on Faraday's law (Hou et al., 2019), to accelerate the corrosion of I-shaped steel. This accelerated electrolysis test mainly adopts an electrolytic cell composed of DC power supply, wire, 5% NaCl solution, stainless steel, steel pipe frame, tarpaulin and wooden pad, as shown in Figure 5.

Test steps: Prepare a 5% concentration NaCl solution in the electrolytic cell, immerse the component in it for more than 7 days, and allow the salt water to slowly penetrate into the interior of the component, in contact with the I-shaped steel inside; Connect the electrolysis circuit according to Figure 5, turn on the power, adjust the current, and control the current to 1A; Maintain a constant flow and turn the power on at the target time that was initially intended and determined using Faraday's principle..

2.2.2 Loading device

In the test, the static loading method was used, and a homemade reaction frame (Figure 6) was

(a) Outdoor accelerated electrolytic corrosion test

(b) DC power supply equipment

Figure 5. Electric accelerated corrosion test.

employed. Its internal dimensions were 2.5m long \times 1.5m wide.

Figure 6. Homemade counterforce frame device.

2.2.3 Measuring system

The majority of the tests involve deformation tests of eccentric compression components and strain tests on I-shaped steel and concrete surfaces.

(1) Strain testing of I-shaped steel

Strain gauges are pasted on both sides of the web and flange of the I-shaped steel, and the arrangement of measuring points is shown in Figure 7. The number of I-shaped steel strain gauges is shown in Figure 8. The A and C sides are the flange side of the I-shaped steel, and the B and D sides are the web side of the I-shaped steel.

(2) Strain testing of concrete surface

Thirteen concrete surface strain test sites in total are positioned at the eccentric compression member's mid-span location; five monitoring points are situated on surfaces ② and ③, and three monitoring points are situated on surface ①. The location of strain measurement points on the concrete surface is shown in Figure 9.

Figure 7. Measurement point for I-shaped steel strain.

Figure 8. Schematic diagram of I-shaped steel strain gauge pasting position.

Figure 9. Measurement points for concrete surface strain.

(3) Deformation test of eccentric compression components

Each eccentrically compressed component is equipped with 4 displacement test points. Two displacement meters, ① and ②, are respectively arranged on the compression and tension sides of the span. Two displacement meters, ③ and ④, are symmetrically arranged on both ends of the tension side. The specific arrangement of displacement test points is shown in Figure 10.

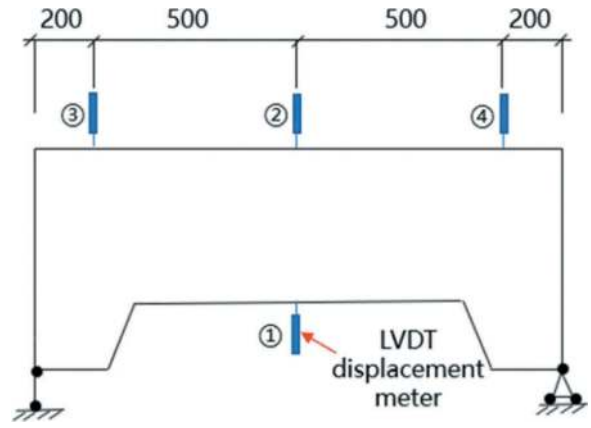

Figure 10. Displacement meter layout measuring point.

3 MECHANICAL EVOLUTION OF PRIMARY SUPPORT UNDER SECTION STEEL FRAME CORROSION

3.1 Failure mode of primary support with corroded section steel frame

The loading failure of steel reinforced concrete eccentric members has experienced elastic, concrete cracking, crack development, concrete spalling in compression zone, steel bending and other stress processes, but the failure process is different, and the influence of eccentricity plays a dominant role.

3.1.1 Failure mode when relative eccentricity $e=0.2$

When the relative eccentricity $e=0.2$, the failure process of specimens with different corrosion rates is roughly the same: when the initial load is less than the initial cracking load, both concrete and steel are in the elastic stage, and at this time, the deflection and strain values are small and the development trend is slow; When the load is about 45% -50% of the ultimate load, there is a slight cracking sound inside the specimen, and in the specimen's center control section, a first longitudinal discontinuous fine cracking emerges. As the load increases, the longitudinal crack gradually widens and extends. When the load reaches about 95% of the ultimate load, the section steel flange in the compression zone begins to yield, longitudinal cracks and deflections increase sharply, and the concrete begins to peel off. When the load reaches the ultimate load, the section steel undergoes compression buckling, and the concrete at the longitudinal crack of the concrete component collapses. Lateral cracks also occur on the smaller side of the compression zone. The typical failure of B-1-4 components is shown in Figure 11.

3.1.2 Failure mode when relative eccentricity $e=0.35$

For the test component with relative eccentricity $e=0.35$, the component is in the elastic stage before cracking. When the load reaches about 45% of the ultimate load, several transverse cracks appear in the

Figure 11. Typical failure mode of B-1-4 member.

central control section of concrete. With the further increase of the load, the width of the transverse crack of the central section increases, and the transverse crack of the surrounding section also begins to appear. When the load is increased to about 98% of the ultimate load, the compression side of the I-shaped steel flange side yields. When loading to the ultimate load, the flange side of the I-shaped steel in the tension zone yields, the tensile crack of concrete intensifies, and the deflection increases sharply. Finally, the concrete in the compression zone of the central section of the specimen collapses and falls off, and the I-shaped steel appears buckling phenomenon, which is the failure of large eccentric compression. Typical failure of B-2-4 components is shown in Figure 12.

3.1.3 Failure mode when relative eccentricity $e=0.50$

For the test component with relative eccentricity $e=0.5$, the component is in the elastic stage before cracking. When loading to about 25% of the ultimate load, several transverse cracks appear in the central section of concrete. With the further increase of the load, the width of the tension transverse crack of the central section increases, and several transverse tension cracks begin to appear in the surrounding section. When the

Figure 12. Typical failure mode of B-2-4 member.

load is increased to about 85% of the ultimate load, the flange of the I-shaped steel on the tension side yields, and the crack at the central section widens abruptly. When loading to the ultimate load, the I-shaped steel flange on the compression side yields, the tensile crack of concrete intensifies, and the deflection increases sharply. Finally, the concrete in the compression zone of the central section of the specimen collapses and falls off, and the I-shaped steel appears buckling phenomenon, which is the failure of large eccentric compression. Typical damage of B-3-4 components is shown in Figure 13.

3.2 Influence of corrosion on primary support capacity

The test primarily recorded three characteristic values: the ultimate load, the residual load, and the cracking load. Table 2 displays the recording results.

When the eccentricity is fixed, the relationship curves between different corrosion rates and the bearing capacity of the component can be obtained, as shown in Figure 14.

The load characteristic values fall almost linearly as the corrosion rate increases (from 0% to 9%) while the eccentricity remains constant. The

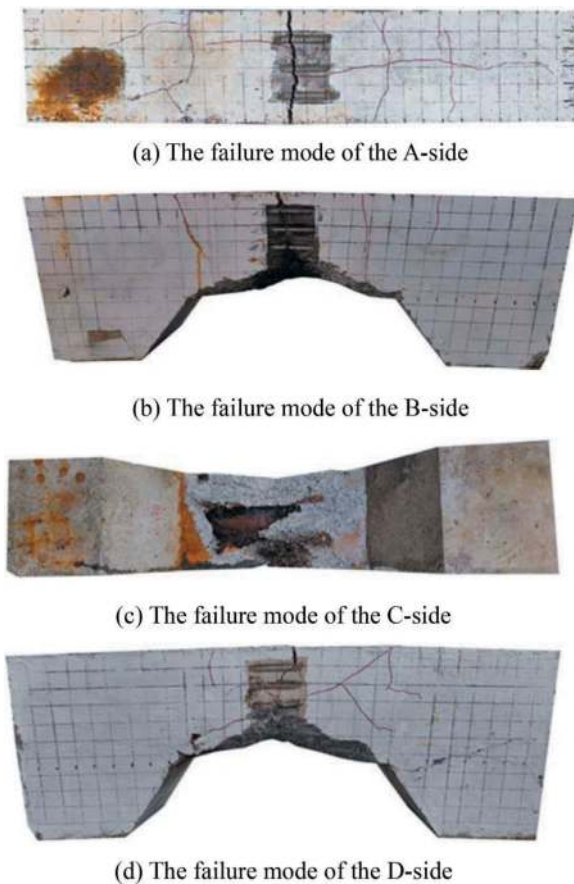

Figure 13. Typical failure mode of B-3-4 member.

reduction in the cracking load is from 27.8% to 33.9%, the reduction in the ultimate load is from 23.9% to 26.7%, and the reduction in the residual load is from 32.8% to 34.0% when the corrosion rate is between 0% and 9%. The synergistic effect between the two is reduced as a result of corrosion destroying the bond between I-shaped steel and concrete. The load shared by I-shaped steel decreases with increasing corrosion degree, lowering the bearing capacity of core concrete.

Table 2. Load characteristic values of eccentric members.

Specimen number	Relative eccentricity e	Corrosion rate/%	Cracking load /kN	Ultimate load /kN	Residual load /kN
B-1-1	0.20	0	1371	2688	1439
B-1-2		3	1211	2522	1271
B-1-3		6	1091	2321	1145
B-1-4		9	920	2045	966
B-2-1	0.35	0	865	1765	908
B-2-2		3	776	1650	814
B-2-3		6	680	1512	714
B-2-4		9	571	1328	600
B-3-1	0.50	0	617	1542	648
B-3-2		3	542	1425	596
B-3-3		6	488	1318	536
B-3-4		9	407	1130	468

3.3 Influence of corrosion on primary support deformation

Based on the mechanical analysis, the component's central control section has the highest internal force and deflection, making it the most dangerous section. The test component's deflection curve varies with load as seen in Figure 15. The only deflection of the component before the ultimate load is attained, limited by the test techniques.

When the eccentricity is constant, the component's ultimate deflection rises as the corrosion rate increases. The rationale is that more corrosion means a higher rust expansion force produced by the I-shaped steel within the specimen, resulting in the more severe initial defects of the specimen. At the same time, the bond between I-shaped steel and concrete weakens, resulting in poor coordinated deformation. Under the combined action, the stiffness of the component decreases. When the corrosion rate is constant, the component's ultimate deflection rises as the eccentricity increases. The rationale is that the specimen's tensile component proportion increases with eccentricity, and the deflection at the centre section increases correspondingly.

3.4 Plane cross-section assumption analysis

Due to the slip caused by the interface bond degradation between corroded section steel and concrete, the section of steel and concrete does not meet the plane cross-section assumption. The critical corrosion rate of different eccentric components meeting the assumption of plain section is obtained by comparing the strain distribution of central section steel and concrete in the loading test. Figure 16 shows the strain of I-shaped steel and concrete at the central section, where the applied load is 50% of the ultimate load (i.e. $50\%P_u$).

When the relative eccentricity is $e=0.20$ (small eccentric member) and the corrosion rate of I-shaped steel $\rho \leq 3\%$, the strain distribution difference

(a) Relative eccentricity $e=0.2$

(b) Relative eccentricity $e=0.35$

(c) Relative eccentricity $e=0.5$

(b) B-2-1

(c) B-3-1

Figure 16. Strain distribution of I-shaped steel and concrete (Only part).

between I-steel and concrete is small, and the cross-section strain conforms to the plane cross-section assumption. When the relative eccentricity is $e=0.20$ (small eccentric member) and the corrosion rate $\rho>3\%$, the strain distribution between I-shaped steel and concrete is different, and the cross-section strain does not conform to the plane cross-section assumption. When the relative eccentricity is $e=0.35$ and 0.50 (large eccentric members), the external load reaches $50\%P_u$, the strain distribution between the

I-shaped steel and the concrete is quite different from the beginning, and the cross-section strain does not conform to the plane cross-section assumption.

4 DECAY MECHANISM OF PRIMARY SUPPORT BEARING CAPACITY

The decrease of geometry and mechanical parameters of the section steel frame under corrosion, the decrease of concrete mechanical parameters caused by rust expansion, and the degradation of the bond between the section steel frame and concrete caused by corrosion will directly lead to the attenuation of the primary supporting capacity. In order to reflect the influence of the three factors on the bearing capacity attenuation, the finite element ANSYS numerical simulation method is used here to analyze the contribution of each factor to the bearing capacity attenuation. The final ANSYS model is shown in Figure 17.

Figure 17. Numerical calculation model of the eccentric member.

By studying the impact of each of the three factors on bearing capacity, as shown in Figure 18. The contribution rate of geometric and mechanical parameters of the section steel frame caused by corrosion to the primary support bearing capacity attenuation is $32.69\%\sim 37.75\%$, the contribution rate of concrete mechanical parameters attenuation caused by rust expansion is $18.36\%\sim 20.8\%$, and the contribution rate of bond slip degradation between the section steel frame and concrete caused by corrosion is $43.09\%\sim 46.58\%$. The degradation of bond slip between the three has the greatest contribution to the attenuation of bearing capacity, while the degradation of concrete parameters caused by rust expansion has the smallest contribution to the attenuation of bearing capacity. In practical engineering, to prevent a significant decrease in the primary support bearing capacity due to bond slip degradation, connectors can be installed between the section steel frame and concrete to enhance the bond between the section steel frame and concrete.

5 CONCLUSIONS

Firstly, the primary support of section steel frame with different corrosion rates was obtained through

Figure 18. Percentage contribution of primary support bearing capacity decay.

electric acceleration testing, and then the mechanical degradation law of the primary support with corroded section steel frames was obtained through eccentric loading. Finally, numerical simulation was used to reveal the mechanism of corrosion on bearing capacity attenuation. The following conclusions could be drawn.

- (1) When the corrosion rate of the section steel frame is 0%~9%, the failure mode characteristics of the primary support during corrosion are mainly determined by the eccentricity. The small eccentricity failure sign is concrete

crushing, and the large eccentricity failure sign is the steel yield failure under tension.

- (2) When the corrosion rate ranges from 0% to 9%, the reduction in cracking load ranges from 27.8% to 33.9%, the reduction in ultimate load ranges from 23.9% to 26.7%, and the reduction in residual load ranges from 32.8% to 34.0%.
- (3) Based on the strain development law of concrete and I-shaped steel in eccentric component tests, the critical corrosion rate of the primary support of the section steel frame meeting the plane cross-section assumption was obtained.
- (4) The contribution rate of geometric and mechanical parameters of the section steel frame caused by corrosion to the primary support bearing capacity attenuation is 32.69%~37.75%, the contribution rate of concrete mechanical parameters attenuation caused by rust expansion is 18.36%~20.8%, and the contribution rate of bond slip degradation between the section steel frame and concrete caused by corrosion is 43.09%~46.58%.

Effect of excavation on the pipe roof deformation under the action of the pipe roof-beam support system

Wen Zhao, Qian Bai* & Dongli Pi

School of Resources and Civil Engineering, Northeastern University, Shenyang, China

ABSTRACT: The pipe roof method can significantly reduce the deformation resulting from excavation and is widely used in the construction of underground spaces. Based on Shifu Road station of Shenyang Metro Line 4, this paper studies a new support system for constructing ultra-shallow buried subway stations, named pipe roof - beam support system. Firstly, the influence of large section excavation on pipe roof deformation under different parameters such as beam spacing, transverse span, burial depth and steel pipe diameter was analysed by numerical simulation. Then, according to the linear regression model, the effect degree of the key parameters on the pipe roof deformation was investigated. Finally, based on the elastic foundation beam theory, a calculation model of pipe roof deformation was established and compared with the numerical simulation results. The results show that: The pipe roof deformation due to excavation is linearly increasing in relation to the beam spacing and exponentially increasing in relation to the transverse span. Increasing the diameter of the steel pipe can effectively reduce the pipe roof deformation due to the increased beam spacing. The influence on the pipe roof deformation is in descending order of magnitude: transverse span, beam spacing, steel pipe diameter and burial depth. The results of the pipe roof deformation at different pipe diameters calculated according to the Pasternak double-parameter elastic foundation beam theory are in good agreement with the numerical simulation results.

Keywords: Subway station, Pipe roof method, Excavation, Pipe roof deformation, Numerical simulation, Theoretical model

1 INTRODUCTION

Subway is generally in the prosperous area, with the continuous development of underground space, the environment of underground engineering is increasingly complex, which is difficult to construct using double-side heading method, pile-beam-arch method and other traditional tunnelling method, and it is difficult to ensure the safety of construction (Fang et al., 2011). To reduce the surface settlement caused by the excavation construction of subway station, a pipe-roof method is increasingly popular to use (Xie et al., 2019; Lunardi, 1990). To solve the problem, low bearing capacity and flexural stiffness, of traditional pipe-roof structure, the steel tube slab (STS) method (Jia et al., 2018; 2020; Lu et al., 2023) and the small pipe-roof-beam method (Bai et al., 2023) were proposed, which are successful in minimizing the soil disturbance caused by the excavation construction of subway station.

Jin et al. (2011) explored the surface settlement mechanism and structural forces of the NTR method under different construction conditions using a combination of numerical simulation and site monitoring, and investigated the damage mode and flexural performance of the rib-beam structure of the NTR pipe-roof structure through laboratory tests.

Lu et al. (2022a) studied the deformation characteristics of SSCP structure by numerical simulation, and analysed the effect of parameters such as longitudinal spacing of steel support, size of transverse steel support and vertical steel support on the deformation of steel support and surface settlement, and obtained the optimal parameter combination of steel support for SSCP structure. Subsequently, the wall thickness and chord height ratio of a single steel pipe in the pipe-roof structure were studied, and it was concluded that the change of wall thickness and chord height ratio had significantly impact on the bearing capacity of the pipe-roof structure (Lu et al., 2022b).

*Corresponding author: baiqianneu@163.com

Jia et al. (2019) conducted laboratory tests and numerical simulation to study the bending performance and damage mode of STS structure, and the results showed that the STS method can improve the transverse stiffness of the pipe-roof structure. Subsequently, the surface settlement mechanism caused by STS structure deformation using a combination of numerical and monitoring investigation, indicating that the STS structure as a kind of pre-support system has significant advantages.

In summary, many investigations have conducted on the support mechanism of pipe-roof, soil deformation caused by excavation under pipe-roof support. However, the diameter of the steel pipe for the new pipe-roof structure has not yet been systematically studied. Steel pipe is an important component of the pipe-roof structure, and its diameter can affect the mechanical properties of the structure and the surface settlement. Hence, it is critical for the design and construction of pipe-roof to determine the relationship between steel pipe diameter and other parameters. It has an important practical significance of guidance that study effect of different steel pipe diameter on the structural deformation mechanism, summarize the deformation characteristics of the main structure and surrounding soil with different pipe-roof diameters and different parameters, and a reasonable choice of the pipe diameter of the pipe roof structure.

2 NUMERICAL SIMULATION MODELING

In the practical construction of tunnel engineering, the deformation control standards for the pipe-roof-beam structure are extremely strict. Therefore, researching the deformation characteristics of the pipe-roof-beam structure is of significant importance. In this investigation, a three-dimensional numerical model was established using Midas GTS NX software. Based on previous finite element models, a numerical analysis model of the pipe-roof-beam structure under soil pressure is calibrated, using the same material properties, element types, component contact forms, and meshing methods. To emphasize the variable of steel pipe diameter, simplifications are made to the overall station structure and excavation method. The side piles are simplified as diaphragm walls following the principle of equivalent stiffness, while considering the case without temporary support. The deformation patterns of station excavation under the most unfavorable conditions are studied, and the soil excavation method employs the benching tunnelling method. Along the longitudinal direction of the steel pipe, the analysis is conducted over one span of the pipe-roof-beam structure. A schematic representation of the finite element model of the pipe-roof-span structure is shown in Figure 1. Subsequently, the research investigates the influence of different beam spacing, transverse span, burial depth, and

other parameters on the deformation performance of the pipe-roof-beam structure with varying steel pipe diameters.

Figure 1. Schematic diagram of finite element model of the pipe-roof structure.

2.1 Calculation basic assumptions

- (1) Surface settlement caused by pipe-roof construction can be controlled through grouting between the pipes to achieve zero settlement or controlled pre-uplift before excavation. Therefore, this paper's simulation did not take into account surface settlement caused by pipe jacking.
- (2) The subway station has undergone dewatering treatment of the surrounding soil prior to construction. Hence, the impact of groundwater is not considered.
- (3) In underground engineering simulations, the majority of soil models use the Mohr-Coulomb model. However, the traditional Mohr-Coulomb model does not consider the impact of the soil's second principal stress yield conditions and neglects the effects of soil unloading, resulting in significant disparities between simulation results and reality. To ensure the accuracy of numerical simulations, this paper employs the Modified Mohr-Coulomb constitutive solid element model to better simulate the soil unloading process. Soil calculations are conducted using the Modified Mohr-Coulomb constitutive model, assuming homogeneity and isotropy within the same soil.
- (4) The structures, including pipe-roof, station linings, beams, columns, and slabs, are treated as homogeneous and isotropic materials and are modeled using an elastic constitutive model.

2.2 Parameter selection

The primary geological stratum on the project site consists predominantly of sandy soil. Based on geological conditions, it is known that only a small amount of miscellaneous fill soil exists at the top of the stratum. The pipe-roof structure as a whole is situated within the sandy soil stratum, and the physical and mechanical properties of these sandy soil layers are very similar. Therefore, the stratum is simplified to homogeneous sandy soil for analysis in the model. Detailed structural parameters can be found in Table 1.

Table 1. Indexes of stratum mechanics parameters.

soil	γ / kN·m ⁻³	c / kPa	ϕ / °	E / MPa	E_u / MPa	μ
medium-coarse sand	20	2	34	31.6	252.8	0.25

Notes: γ is volumetric weight; c is cohesive forces; ϕ is internal friction angle; E is Elastic Modulus; E_u is unloading modulus; μ is Poisson ratio.

The subway station primarily consists of a composite structure composed of arches, beams, side walls, and steel columns to collectively bear loads. In order to better describe the deformation characteristics and mechanical properties of each structural component, solid elements were employed to simulate the arches, beams, bottom slab, side walls, and grouting between arches, while beam elements were used to simulate the intermediate columns. The beam elements are considered isotropic and yield-free linear elastic materials, approximated as ideal elastic bodies. It is assumed that the vertical displacements between the soil and intermediate columns were negligible. The main structural parameters were determined based on the actual engineering design data and the ‘Code for Design of Concrete Structures’ (GB50010-2010, 2010). Specific values for the main structural components are provided in Table 2.

Table 2. Parameters of structural materials.

Components	γ /kN·m ⁻³	E /MPa	μ
Pipe-roof	30.0	61000	0.25
Bottom slab	25.0	40000	0.20
Beams	26.0	45000	0.20
Side walls	30.0	61000	0.25
Intermediate columns	25.0	69000	0.25
Grouting between arches	20.0	500	0.30
Second lining	24.0	20000	0.20

2.3 Network segmentation

Using the Midas GTS NX finite element analysis software, a three-dimensional finite element model was constructed for nonlinear construction stage analysis, as depicted in Figure 2. According to the Saint-Venant principle (Xia, 2021), the stress and strain resulting from tunnelling excavation only affect the region within a maximum excavation span of 3 to 5 times the pit’s centerline distance. Along this boundary, it is assumed that the displacements caused by excavation were negligible. To minimize the influence of boundary constraints on the calculation results, the model dimensions were set as follows: 140 m in the horizontal direction, 75 m in the vertical direction, and one span length in the

longitudinal excavation direction. In the model, the positive X-axis pointed horizontally to the right, the positive Y-axis was aligned with the station excavation direction, and the positive Z-axis extended vertically upward from the ground.

Figure 2. Schematic diagram of finite element calculation model.

3 EFFECT OF PARAMETERS ON PIPE-ROOF DEFORMATION

3.1 Steel pipe diameter

To analyze the deformation of the pipe-roof in a cross-support system with steel pipes of different diameters within various ranges, seven different steel pipe diameters were selected for investigation: 300, 600, 900, 1200, 1500, 1800, and 2100 mm. The remaining computational parameters were as follows: beam spacing (L) is 8 m, transverse span (S) is 20 m, and the burial depth of the overlying soil (H) is 5 m.

Figure 3 illustrates the lateral deformation curves of the station’s pipe-roof structure after excavation with different diameter steel pipe support. It can be obtained that under varying steel pipe diameters, the deformation trend of the pipe-roof structure is fundamentally consistent. The overall arch structure exhibits a sinking tendency, and the deformation curve closely approximates a parabolic shape. Deformation values on both sides of the pipe-roof structure are relatively small, gradually increasing as they approach the midpoint, where they reach their maximum values. Simultaneously, the end sections of the pipe-roof structures with different steel pipe diameters show a slightly larger deformation value than 0 mm, indicating an upward deformation at the ends. This can be attributed to the upward support exerted by the side walls at the ends of the pipe-roof structure. The deformation values at the mid-span of the pipe-roof decrease as the steel pipe diameter increases. For steel pipe diameters ranging from 300 mm to 2100 mm, the corresponding maximum deformation values of the arch structure are 19.5 mm, 14.1 mm, 11.8 mm, 11.2 mm, 10.2 mm, 9.7 mm, and 8.5 mm, respectively. Compared to

a steel pipe diameter of 300 mm, increasing the steel pipe diameter from 600 mm to 2100 mm results in a reduction of 27.7%, 39.5%, 42.6%, 47.7%, 50.3%, and 56.4% in the maximum pipe-roof deformation values. The increase in steel pipe diameter leads to an increase in the pipe-roof structure's flexural stiffness, subsequently reducing the deformation values. Thus, it can be concluded that within the range of different steel pipe diameters for the pipe-roof, the variation in steel pipe diameter significantly influences the maximum pipe-roof deformation values.

Figure 3. Deformation curve of pipe-roof in the cross section of station span.

3.2 Spacing between beams

The vertical deformation values at the mid-span position of the 900 mm diameter pipe-roof structure were extracted under five different beam spacing conditions, as depicted in Figure 4. It can be observed that under varying beam spacing, the deformation trend of the pipe-roof structure remains largely consistent. The pipe-roof structure, as a whole, exhibits a sinking trend, with the deformation curve closely resembling a parabolic shape. Deformation values at both sides of the pipe-roof structure are relatively small, gradually increasing as they approach the mid-span position, where they reach their maximum values. Simultaneously, the end sections of the pipe-roof structures with different beam spacing exhibit identical deformation values, slightly greater than 0 mm, indicating upward deformation at the ends. This is attributed to the upward support exerted by the side walls at the ends of the pipe-roof structure. The deformation values at the mid-span of the pipe-roof increase with an increase in beam spacing. The corresponding maximum deformation values of the pipe-roof structure are 11.8 mm, 18.8 mm, 31.3 mm, 47.4 mm, and 61.8 mm for beam spacings of 4 m, 8 m, 12 m, 16 m, and 20 m, respectively. For each 4 m increase in beam spacing, the maximum pipe-roof deformation values increase by 7.0 mm, 12.5 mm, 16.1 mm, and 14.4 mm, with growth rates of 59.3%, 66.5%,

51.4%, and 30.4%, respectively. From a beam spacing of 6 m to 24 m, the difference in maximum deformation values is 50.0 mm, with a growth rate of 423.7%. Increasing beam spacing similarly leads to a significant increase in arch structure deformation.

Figure 4. Deformation curves of 900 mm diameter pipe-roof structure under different beam spacing.

3.3 Transverse span

Taking the 900 mm diameter pipe-roof structure as an example, the extracted vertical deformation values at the mid-span position of the pipe-roof structure are shown in Figure 5 under five different transverse span conditions. It can be obtained that under varying transverse spans, the deformation trend of the pipe-roof structure remains fundamentally consistent. The pipe-roof structure, as a whole, exhibits a sinking trend, and the deformation curve closely approximates a 'bowl' shaped parabola. Deformation values at both sides of the pipe-roof structure are close to 0 mm. As one moves from the sides towards the mid-span position, the deformation values gradually increase and reach their maximum at the mid-span. The mid-span pipe-roof deformation values increase with an increase in transverse span. The corresponding maximum deformation values of the pipe-roof structure are 11.8 mm, 21.0 mm, 31.8 mm, 44.3 mm, and 56.5 mm for transverse spans of 20 m, 22.5 m, 25 m, 27.5 m, and 30 m, respectively. When the transverse span increases from 20 m to 30 m, with each 2.5 m increment, the maximum pipe-roof deformation values increase by 9.2 mm, 10.8 mm, 12.5 mm, and 12.3 mm, with growth rates of 77.9%, 51.4%, 39.3%, and 27.8%, respectively. While the pipe-roof deformation gradually increases with larger transverse spans, the growth rates progressively decrease. The difference in maximum deformation values for the pipe-roof structure's transverse spans from 20 m to 30 m is 44.7 mm, with a growth rate of 378.8%. Therefore, an increase in the transverse span of the pipe-roof structure similarly leads to a significant increase in pipe-roof structure deformation.

Figure 5. Surface settlement curve of 900 mm diameter pipe curtain at different lateral spans.

3.4 Soil burial depth

Taking the 900 mm diameter pipe-roof structure as an example, the extracted vertical deformation values at the mid-span position of the pipe-roof structure under five different burial depth conditions are shown in Figure 6. It can be observed that under varying burial depths, the deformation trend of the pipe-roof structure remains fundamentally consistent. The pipe-roof structure, as a whole, exhibits a sinking trend, and the deformation curve closely approximates a ‘bowl’ shaped parabola. As one moves from the sides towards the mid-span position, the deformation values of the pipe-roof structure gradually increase and reach their maximum at the mid-span. The mid-span pipe-roof deformation values increase with an increase in burial depth. When the burial depth increases from 3 m to 11 m, with each 2 m increment, the growth rates of pipe-roof deformation are 77.96%, 51.42%, 39.30%, and 27.53%, respectively. As burial depth increases, the growth rate of pipe-roof deformation gradually decreases. Therefore, it can be concluded that burial depth has a relatively minor impact on pipe-roof deformation.

Figure 6. Deformation curve of 900 mm diameter pipe curtain under different burial depth of soil.

4 EFFECT MAGNITUDE

To investigate the pipe-roof deformation caused by soil excavation under pipe-roof structure support, a multi-variate linear regression analysis was conducted using SPSS software. In this analysis, the pipe-roof diameter was treated as the independent variable, while three factors, namely beam spacing, transverse span, and burial depth, were set as independent variables. The pipe-roof deformation was defined as the dependent variable.

4.1 Steel pipe diameter and beam spacing

From Figures 7 and 8, it can be obtained that the histogram of pipe-roof deformation exhibits an overall favorable pattern of normal distribution. In the cumulative probability plot of standardized residuals, the residuals closely adhere to the vicinity of the straight line, indicating a pronounced adherence to the normal distribution pattern.

Figure 7. Histogram of surface settlement residuals for pipe-roof structures.

Figure 8. Cumulative probability map of standardized residuals of surface settlement of pipe-roof structures.

4.2 Steel pipe diameter and transverse span

Figures 9 and 10 reveal that the histogram of pipe-roof deformation generally follows a well-defined pattern of normal distribution. In the cumulative probability plot of standardized residuals, the residuals closely align with the vicinity of the straight line, indicating a clear adherence to the normal distribution pattern.

Figure 9. Histogram of surface settlement residuals for pipe-roof structures.

Figure 10. Cumulative probability map of standardized residuals of surface settlement of pipe-roof structures.

4.3 Steel pipe diameter and soil burial depth

Figures 11 and 12 illustrate that the histogram of pipe-roof deformation generally exhibits a strong pattern of normal distribution. In the cumulative probability plot of standardized residuals, the residuals closely adhere to the vicinity of the straight line, indicating a clear adherence to the normal distribution pattern.

Figure 11. Histogram of surface settlement residuals for pipe-roof structures.

Figure 12. Cumulative probability map of standardized residuals of surface settlement of pipe-roof structures.

Through multivariate linear regression analysis conducted in SPSS software, a high level of fit was obtained for the relationship between pipe-roof deformation caused by soil excavation under pipe-roof structure support with different steel pipe diameters and parameters such as beam spacing, transverse span, and burial depth. This demonstrates a strong linear relationship between pipe-roof deformation and these parameters. A regression equation for burial depth was derived from the software analysis. Additionally, the overall frequency histogram of standardized residuals exhibits a favorable pattern of normal distribution, and in the cumulative probability plot of standardized residuals, the residuals are predominantly distributed near the straight line, confirming the accuracy of the regression equation. Based on the magnitude of the absolute values of the standardized regression coefficients, the influence magnitude on pipe-roof

deformation can be ranked as follows: transverse span > beam spacing > steel pipe diameter > burial depth. Therefore, the parameter with the greatest impact on pipe-roof deformation displacement is the transverse span of the pipe-roof structure, followed by beam spacing, then steel pipe diameter, and the parameter with the least impact is burial depth.

5 CALCULATION MODEL OF DEFORMATION

Based on the Pasternak elastic foundation beam theory, this study focuses on single steel pipe concrete structures used in pipe-roof construction. It aims to establish deformation calculation model for these structures and analyze the excavation-induced deformation patterns under various steel pipe diameters.

The Pasternak elastic foundation beam model assumes the presence of a shear layer between the foundation and the beam, where the shear layer can only undergo lateral shear deformation (Liu, 2021). This introduces interacting shear forces between independent springs to mitigate foundation discontinuities [67]. Based on the Pasternak elastic foundation beam theory, this study focuses on single steel pipe concrete structures within pipe-roof construction, with its simplified model shown in Figure 13.

Figure 13. Schematic diagram of the Pasternak calculation model.

This paper employs a semi-infinite elastic foundation beam analysis for the mechanical model of the pipe-roof. The construction of the pipe-roof's mechanical model during the excavation of the tunnel is illustrated in Figure 14.

Figure 14. Pasternak-based two-parameter elastic foundation beam tunnel construction pipe-roof force calculation diagram.

5.1 Governing differential equations

Under the action of the soil pressure $q(x)$ from the soil, the relationship between the foundation reaction $p(x)$ and the displacement $\omega(x)$ in the Pasternak dual-parameter elastic foundation beam model is expressed as follows:

$$p(x) = k\omega(x) - G_p \frac{d^2\omega(x)}{dx^2} \quad (1)$$

where k is coefficient of subgrade reaction, and G_p is the shear modulus of the foundation, associated with the foundation's shear deformation.

When the overburden pressure $q(x) = q_0$ and the foundation reaction $p(x) = 0$ in section BC, the governing equation for section BC is:

$$EI \frac{d\omega^4(x)}{dx^4} = b_0 q_0 \quad (2)$$

When the overburden pressure $q(x) = q_0$ and the foundation reaction is given by equation (1) in section CD, the governing equation for section CD is:

$$EI \frac{d\omega^4(x)}{dx^4} - G_p b^* \frac{d\omega^2(x)}{dx^2} + kb^* \omega(x) = b_0 q_0 \quad (3)$$

When the overburden pressure $q(x) = 0$ and the foundation reaction is given by equation (1) in section DE, the governing equation for section DE is:

$$EI \frac{d\omega^4(x)}{dx^4} - G_p b^* \frac{d\omega^2(x)}{dx^2} + kb^* \omega(x) = 0 \quad (4)$$

where b^* represents the equivalent width of the beam, and b_0 is the width of the elastic foundation beam, i.e., the steel pipe diameter.

$$b^* = b_0 + (G_p/k)^{1/2} \quad (5)$$

5.2 Solution of the governing differential equations

The solution to the governing equation for section BC is:

$$\omega_1(x) = \frac{b_0 q_0}{24EI} x^4 + A_1 x^3 + A_2 x^2 + A_3 x + A_4 \quad (6)$$

The solution to the governing equation for section CD is:

$$\omega_2(x) = e^{\alpha x} (B_1 \cos \beta x + B_2 \sin \beta x) + e^{-\alpha x} (B_3 \cos \beta x + B_4 \sin \beta x) + \frac{q_0}{kb^*} [1 - ch\beta(x-s-d) \cos \beta(x-s-d)] \quad (7)$$

The solution to the governing equation for section DE is:

$$\omega_3(x) = e^{\alpha x}(B_1 \cos \beta x + B_2 \sin \beta x) + e^{-\alpha x}(B_3 \cos \beta x + B_4 \sin \beta x) \quad (8)$$

5.3 Deformation of pipe-roof with different diameters

The maximum pipe-roof deformations were extracted for steel pipe diameters of 300 mm, 600 mm, 900 mm, 1200 mm, 1500 mm, 1800 mm, and 2100 mm in numerical simulations, and these values were compared with the theoretical calculations as shown in Figure 15. Overall, the two approaches yield relatively close pipe-roof deformation results. It is worth noting that the deformations calculated based on the Pasternak model theory are consistently greater than the numerical simulation results, indicating a conservative tendency in the theoretical formulas proposed in this study.

Figure 15. Comparison of theoretical and numerical simulation values of pipe-roof deformation.

The comparative results between theoretical calculations and numerical simulations for different steel pipe diameters are presented in Table 3. After computation, it is observed that the average error between theoretical calculations and numerical simulations for various steel pipe diameters is 18.95%. Thus, there is a good consistency between the theoretical calculations and numerical simulation results. The reason for the theoretical calculations yielding larger pipe-roof deformation values compared to numerical simulations can be attributed to the actual dense arrangement of steel pipes, which results in a favorable synergistic effect between the pipes, effectively restraining soil deformation and relaxation. In contrast, the calculations only consider the stress on individual steel pipes

without considering the combined effects between them, leading to larger deformation values.

6 CONCLUSIONS

This study investigated the effect of parameters including beam spacing, transverse span of pipe-roof structure and burial depth on the deformation mechanism of pipe-roof structure is through numerical simulation. Subsequently, the deformation calculation model of pipe-roof structure with different diameters is established, as well as the influence of different parameters on the selection of reasonable diameter of steel pipe was explored. The following conclusions are drawn:

- (1) The pipe-roof structure and beams are arranged crosswise to bear the upper load together, which effectively control the surface settlement. The diameter of the steel pipe has a significant effect on the deformation characteristics of the pipe-roof structure. The trend of surface settlement groove is to gradually gather to the center of the surface, which is constant with pipe-roof deformation, showing a “basin”-shaped settlement curve.
- (2) The maximum value of pipe-roof deformation has a linear relationship with the spacing of beams, and the increasing pipe-roof deformation due to the increase of spacing of beams can be effectively reduced by increasing the diameter of steel pipes; the maximum value of pipe-roof deformation has an exponential relationship with the transverse span.
- (3) The regression equations regarding the pipe-roof deformation between the steel pipe diameter and the parameters of beam spacing, transverse span, and burial depth, respectively, were obtained, and the accuracy of the regression equations was verified by standardized residual frequency histograms.
- (4) The deformation calculation model of pipe-roof structure of different diameters based on Pasternak’s elastic foundation beam theory is obtained, and the theoretical calculated values are in good agreement with the numerical simulation results, with an average error of 18.95%.

ABSTRACT: The reasonable application of backfill grouting pressure is very important for the design of tunnel lining and the control of surface settlement. In order to explore the influence of grouting pressure on the earth pressure of segment, the model test of earth pressure of segment considering the effect of backfill grouting was carried out. On this basis, a numerical analysis model considering the influence of grouting pressure was established, and the distribution law of earth pressure of segment under different grouting pressure and different buried depth was obtained. The results show that: 1) The distribution rules of numerical simulation and model test results are basically the same. With the increase of burial depth, the more uniform the earth pressure distribution of the whole circumferential segment is. 2) the vertical earth pressure and horizontal earth pressure acting on the segment show a parabola distribution of large in the middle and small on both sides. 3) The grouting pressure has a significant effect on the earth pressure of the segment, but has little influence on the ground reaction and the coefficient of ground reaction. The earth pressure of the segment increases linearly with the increase of grouting pressure. 4) When the buried depth of the tunnel is shallow, the lateral earth pressure coefficient is suggested to be 0.07-0.13 higher than the coefficient of earth pressure at rest. When the buried depth is deeper, the lateral earth pressure coefficient is suggested to be 0.1-0.2 higher than the coefficient of earth pressure at rest.

Keywords: shield tunnel, backfill grouting, horizontal earth pressure, lateral earth pressure coefficient, ground reaction

1 INTRODUCTION

Shield tunneling method has become the mainstream construction method of shield tunnel construction because of its advantages of convenient construction, little impact on the surrounding environment, safety and efficiency (Hong and Feng, 2020; Editorial department of china journal of highway and transport, 2022; Zhu and Chen, 2001). Backwall grouting is an important means to control the surface settlement during shield tunneling, and the grouting quality after the wall is determined by the grouting quantity and grouting pressure. Too large or too small grouting pressure will affect the ground around the tunnel, and affect the force of the segment to a certain extent.

Attention has been paid to the influence of backfill grouting of shield tail segment on the earth pressure. Many scholars have carried out theoretical analysis and model tests. Koyama et al (1998,2003) studied

the effect of backfill grouting on the earth pressure of tunnel segment through model test. The results show that when the grouting pressure is low, the earth pressure is low and uniformly distributed, and when the grouting pressure is high, the earth pressure on the segment is high and uneven. Liu et al (2020) studied the effect of grouting on the surrounding ground and the filling process of grouting through small-scale model tests. The results show that the distribution of grouting pressure in the space at the tail of the shield is uneven, and the earth pressure of the segment is more sensitive to the quantity of grouting than the suspension and start-up of the grouting operation. Qin et al (2004) based on the pressure filtration diffusion mode of backfill grouting put forward by fractal theory, considered that the segment pressure increases linearly with the increase of grouting pressure. Ye et al (2009) draw the same conclusion.

*Corresponding author: Jian-ling Zhong 2073969912@qq.com

In the field measurement studies, Bezuijen et al (2004) studied and analyzed the field monitoring data of backfill grouting pressure of Sophia tunnel, and considered that the grouting pressure has an effect on the earth pressure of the segment during construction, and the earth pressure acting on the segment after the final setting of the slurry is mainly water pressure. Li et al (2014, 2022) is based on a large number of field measured earth pressure, which shows that the backfill grouting pressure has an obvious effect on the earth pressure of the segment, and the smaller grouting pressure is beneficial to the long-term stability of the earth pressure acting on the segment. Wang and Hao (2018) by collecting the measured data of 52 typical earth pressure monitoring sections of 35 shield tunnels, the results show that the earth pressure on the segment is uniformly distributed along the circumferential direction, and the lateral earth pressure coefficient ranges from 0.5-2.3. Hashimoto et al (2006) collates and analyzes the field measured data of the earth pressure of the shield tunnel segment, and thinks that in the soft clay stratum, the grouting pressure has little influence on the segment earth pressure, in the hard clay stratum, the earth pressure is mainly affected by the grouting pressure, and in the sand stratum, the distribution of the segment earth pressure considering the grouting pressure is relatively uniform.

In the numerical simulations, Zhu et al (2000) through finite element analysis, the grouting pressure has a great influence on the internal force of the segment, and when the grouting pressure is unevenly distributed, the simulated earth pressure of the segment is closer to the measured value. Kaspere and Meschke (2006) through finite element analysis, the grouting pressure has a great influence on the internal force of the segment, and when the grouting pressure is unevenly distributed, the simulated earth pressure of the segment is closer to the measured value. Wei (2007) obtained the distribution and pattern of the earth pressure in different construction stages by numerical simulation, and the top vertical earth pressure is greater than the horizontal diameter. Ji (2004) used a variable rigid body to simulate the change of slurry properties with time in shield tunnel construction, and the effects of slurry thickness, soil properties, segment stiffness and tunnel buried depth on the earth pressure of the segment are analyzed. the results show that the earth pressure on the segment increases gradually with the construction process, and the deeper the tunnel is buried, the more uniform the earth pressure acting on the segment is.

From the above research, it can be seen that the research on the earth pressure of the segment considering the grouting pressure is mainly on the magnitude, distribution pattern and surrounding stratum deformation. There are few detailed studies on the

vertical earth pressure, horizontal earth pressure, ground reaction and the variation of lateral earth pressure coefficient of the tunnel under the action of grouting pressure. Therefore, this paper carries out the segment earth pressure model test under the influence of backfill grouting. Based on this, establishes a numerical analysis model considering the influence of backfill grouting pressure, in order to obtain the variation law of earth pressure on the segment under different burial depth and different grouting pressure.

2 ESTABLISHMENT OF NUMERICAL MODEL

2.1 Numerical model establishment and material parameters determination

Establish 3D finite element model with size of 60 m×40 m×1 m (length×height×width). The buried depth of shield tunnel is 6 m (15 m), the outer diameter of the segment is 6 m, and the segment thickness is 0.3 m. Due to it is difficult to quantify the grouting layer respectively, it is equivalent to a homogeneous and equal thickness layer, and the main component of the equivalent circle zone is a mixture of soil and slurry, and its elastic modulus and Poisson's ratio are between soil and slurry (Zhang et al, 2002), The thickness is 0.2 m. The values of the finite element model parameters are shown in Table 1.

Mohr Coulomb is used in soil. The tunnel lining and grout layer are simulated by linear elasticity. The tunnel lining is simulated by shell element and its elastic modulus is reduced to a certain extent. The horizontal displacement constraint is applied on the left and right sides of the model, and the vertical displacement constraint is imposed on the bottom.

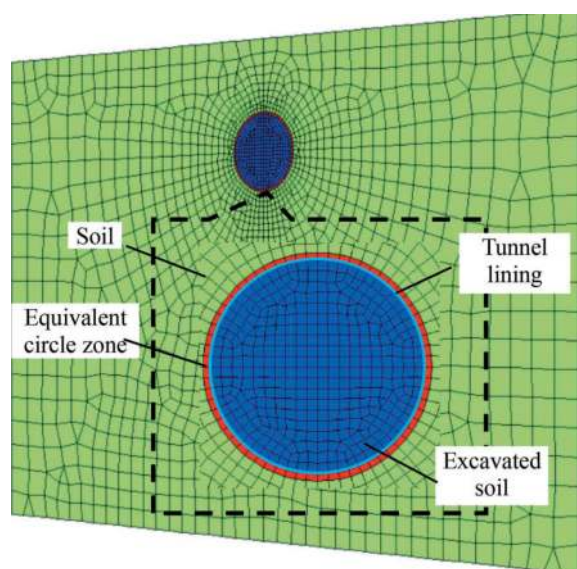

Figure 1. Finite element model of shield tail backfill grouting.

Table 1. Finite element calculation parameter.

Materials \ Properties	Density γ (kN/m ³)	Young's modulus E (MPa)	Shear modulus G (MPa)	Bulk modulus K (MPa)	Poisson's ratio ν	Friction angle φ (°)	Cohesion c (kPa)	Coefficient of earth pressure at rest K_0
Soil	19.00	-	11.54	25.00	0.30	20	22	0.5
Tunnel lining	25.00	2.58E4	-	-	0.167	-	-	-
Equivalent circle zone	21.00	-	1.67	2.22	0.30	-	-	-

2.2 Model condition setting and simulation steps

In this paper, the effects of different grouting pressures on the earth pressure of segments under 6 m and 15 m burial depths are considered. The grouting pressure is considered according to the uneven distribution, as shown in Figure 2, the pressure gradient is 15 kPa/m, and the grouting pressure mentioned below refers to the pressure value at the top. The grouting pressure of 6 m buried depth is 50 kPa, 70 kPa, 90 kPa, 110 kPa, 130 kPa, 150 kPa. The grouting pressure of 15 m buried depth is 220 kPa, 240 kPa, 260 kPa, 280 kPa, 300 kPa, 320 kPa and 340 kPa respectively.

Figure 2. Grouting pressure distribution pattern.

After establishing the finite element model with appropriate parameters, the numerical simulation steps are as follows:

- (a) Initial ground stress balance: calculate the gravity stress balance to complete the formation of the initial ground stress field.
- (b) Tunnel excavation: kill the soil element, shell element, grouting and other soil element in the range of the core cylinder of tunnel excavation, and apply grouting pressure.
- (c) Backfill grouting construction: release the grouting pressure, activate the grouting layer and shell unit, and set the material parameters to complete the segment and grouting operation.
- (d) Calculation of shield tunnel construction.
- (e) Data collation and analysis.

2.3 Validation of the numerical model for its effectiveness

In the numerical simulation process, medium equivalent circle zone parameter reduction, boundary condition setting and load step setting have a great influence on the numerical calculation results. Therefore for the accuracy of the numerical calculation results should be verified.

In the early stage, the test equipment was developed and the indoor model test was carried out (Zhong et al, 2023). The influence of construction factors such as different buried depth, different backfill grouting density, segment attitude and grouting filling rate on the segment earth pressure of shield tunnel. The schematic diagram of the test device is shown in Figure 3. The test device is composed of pressure supply system, construction simulation system, data acquisition system and grouting system. The tunnel lining is simulated by plexiglass with outer diameter of 15 cm, inner diameter of 14 cm and thickness of 0.5 cm with a density of 1.18 g/cm³. The elastic modulus is 2300 MPa, and the Poisson's ratio is about 0.2. In the tank, the layered filled sand simulation formation, the density of sand is 1.59 g/cm³, The elastic modulus is 30 MPa, the internal friction angle is measured at 32.1° according to the straight shear test, and the cohesive force is 0. The earth pressure of the segment is collected by setting 8 groups of strain miniature earth pressure gauges equidistant from the circumferential direction of the plexiglass segment.

Establish a numerical model with the same size and the same material parameters as the model test done in the previous stage. Mohr Coulomb is used for the soil, the tunnel and grout layers are calculated by linear elasticity. The equivalent circle zone parameters are same as the Table 1. The boundary condition setting is the same as section 1.1. The finite element model is shown in Figure 4, and the calculation results of the comparison are shown in Figure 5.

From the comparison of earth pressure results, the distribution law of numerical simulation and model test results is basically the same. The deviation of the two results is 4.88%, and the earth pressure distribution of the whole peripheral segment is relatively uniform. It is considered that the simplified analysis method calculated in this paper is feasible.

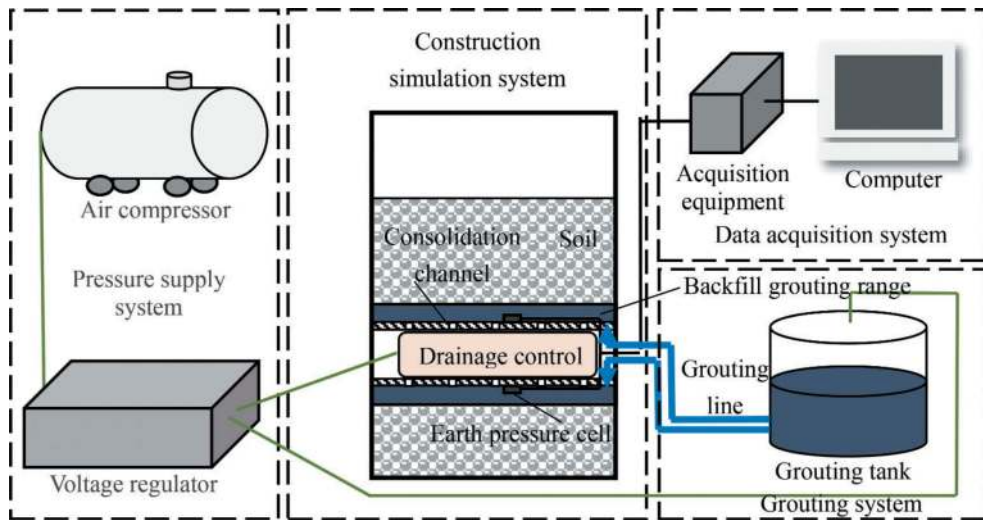

Figure 3. Simplified diagram of laboratory model test device.

Figure 4. Finite element model of shield tail backfill grouting in laboratory test.

3 ANALYSIS OF EARTH PRESSURE DISTRIBUTION

According to the modified routine method, in addition to the vertical earth pressure on the segment structure, the difference between the horizontal earth pressure and the vertical earth pressure will also determine the force bending moment in the segment. This paper mainly discusses the horizontal earth pressure and ground reaction of the segment to provide reference for the segment structure design.

In the numerical calculation, the stiffness of the tunnel segment is increased by 1000 times, at this time, the elliptic deformation of the segment can be

Figure 5. Comparison of earth pressure results.

ignored, and the horizontal earth pressure of the segment will no longer include the ground reaction. The magnitude and distribution range of the ground reaction can be obtained by subtracting the horizontal earth pressure including the ground reaction and the horizontal earth pressure excluding the ground reaction. Figure 6 shows the numerical calculation of the earth pressure distribution pattern of the segment when the buried depth is 6 m and the grouting pressure is 110kPa.

As can be seen from Figure 6, the vertical earth pressure of the segment is parabolic distribution, which the earth pressure at the top and bottom of the segment is large and small on both sides. This is related to the deformation of the stratum, that is, the relative dislocation of the soil particles. The greater the relative dislocation of the soil particles, the more obvious the decrease of the earth pressure. The relative dislocation of soil particles in

the spandrel is the largest, and the relative dislocation of soil particles in the crown is the smallest, thus forming a parabolic distribution of large in the middle and small at both ends (Zhong et al, 2006).

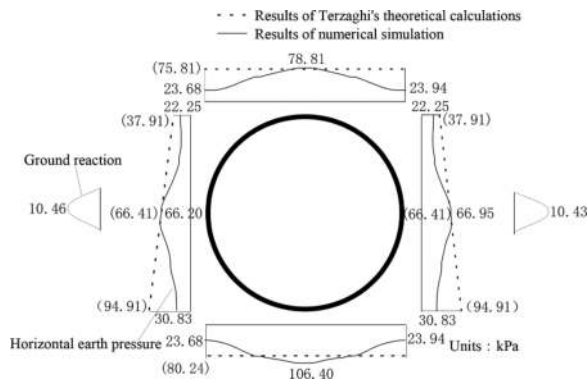

Figure 6. The earth pressure distribution of the segment.

The horizontal earth pressure distribution of the segment is not strictly trapezoidal distribution, but a approximate parabolic distribution. This is because the shield tunneling ring and complete the backfill grouting, slurry is consolidated under the surrounding rock pressure. The initial stress state of the soil layer is that the vertical earth pressure is greater than the horizontal earth pressure, that is, the vertical consolidation deformation of the tunnel is larger than the horizontal consolidation deformation, as shown in Figure 7. Vertical relaxation degree is greater than the horizontal, until the earth pressure is relatively close. From the above analysis, it can be seen that the soil mass at the spandrel is relatively large, and the final performance is that the earth pressure at the spandrel is close to or reaches the active earth pressure state, while the earth pressure at the arch waist changes less. The above analysis results can be obtained from literature (Zheng et al, 2013). According to the resulting tunnel failure mode, the tunnel plastic failure surface is shown in Figure 8. In addition to the arch forming a pressure arch, the horizontal direction also forms an obvious pressure arch.

Figure 7. Vector diagram of soil deformation around tunnel.

(a) Destruction of shallow buried tunnel

(b) Destruction of deep buried tunnel

Figure 8. Numerical simulation of tunnel failure surface.

4 EFFECT OF GROUTING PRESSURE ON EARTH PRESSURE

4.1 Earth pressure of segment

The distribution of earth pressure of segments under two buried depths is shown in Figure 9. Where p represents the backfill grouting pressure (the same below). Where $p = 50 \text{ kPa} \sim 70 \text{ kPa}$ is under 6 m buried depth, and $p = 220 \text{ kPa} \sim 340 \text{ kPa}$ is 15 m buried depth. It can be seen from Figure 8 that the ratio of earth pressure to crown earth pressure at each position of the segment is between 0.78 and 1.46 at 6 m depth, and between 0.96 and 1.27 at 15 m depth. That is, the distribution of earth pressure acting on the segment tends to be more uniform when the buried depth of the tunnel is deeper.

Under 6 m buried depth, the Terzaghi loose earth pressure of the tunnel crown is 75.81 kPa, and the 15 m buried depth is 147.13 kPa. It can be seen from Figure 10 that with the increase of grouting pressure, the earth pressure at each position of the segment increases linearly, and the earth pressure on the tunnel crown gradually exceeds the Terzaghi loose earth pressure. This is because the increase of grouting pressure can effectively reduce the surface settlement, and the loose deformation of the soil around the tunnel decreases, then the earth pressure acting on the segment gradually changes to the overburden soil weight.

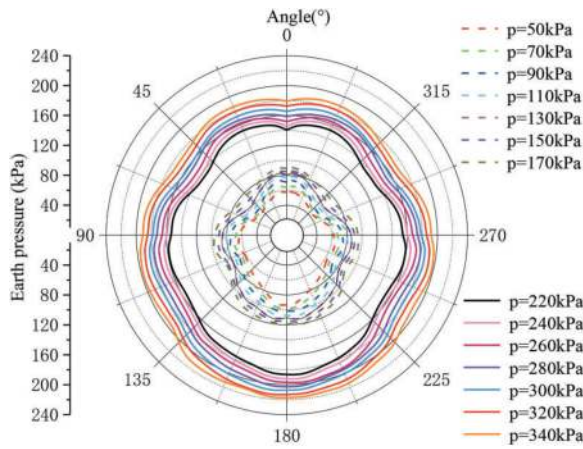

Figure 9. Distribution of segment earth pressure under different grouting pressure in 6 m and 15 m buried depth.

Figure 10. Variation of earth pressure at each position of segment.

During shield construction, the grouting pressure not only affects the pressure on the lining segment, which is also an important aspect of surface settlement. According to Figure 11, when the tunnel buried depth is shallow, the grouting pressure increases and the surface settlement deformation is more sensitive. When the grouting pressure fluctuates the overburden weight by 20 kPa, the ground deformation is controlled within 10 mm. Excessive grouting pressure will lead to surface uplift. When the tunnel is deep, the grouting pressure has less influence on the ground deformation. When the grouting pressure is greater than the weight of the overburden, the ground deformation can meet the settlement requirements of 10 mm.

4.2 Lateral earth pressure coefficient

The lateral earth pressure coefficients at each position on the side of the segment can be calculated by obtaining the horizontal earth pressure and vertical

(a) Surface settlement under different grouting pressures at 6 m buried depth

(b) Surface settlement under different grouting pressures at 15 m buried depth

Figure 11. Surface settlement under different burial depths and different grouting pressures.

earth pressure of the segment. As can be seen from Figure 12, in the two cases of deep burial and shallow burial, the grouting pressure basically has no effect on the lateral earth pressure coefficient, and the lateral earth pressure coefficient varies around the coefficient of earth pressure at rest, ranging from 0.28 to 2.98, which is similar to the conclusion that the lateral earth pressure coefficient measured by Wang and Hao (2018). According to the deformation state of the soil around the tunnel, the change of lateral earth pressure coefficient can be divided into two areas: when $K < K_0$ is the I zone. The horizontal dislocation deformation of the soil particles at the spandrel is larger but the vertical dislocation deformation is small, so that the decrease of the lateral earth pressure is much larger than that of the vertical earth pressure, so the lateral earth pressure coefficient is smaller than the coefficient of earth pressure at rest. when $K_0 < K$ is the II zone The horizontal dislocation deformation of soil particles is small but the vertical dislocation deformation is large. So the decrease of vertical earth pressure is much larger than that of horizontal earth pressure, and the coefficient of lateral earth pressure of segment is larger than that earth pressure at rest, and the maximum is 2.98.

Figure 12. Effect of different grouting pressures on lateral earth pressure coefficient of segment under two kinds of burial depth.

Figure 13. Variation of overall lateral earth pressure coefficient of segment under different burial depth and grouting pressures.

By comparing the sum of the horizontal earth pressure acting on the segment to the sum of the vertical earth pressure, the lateral earth pressure coefficient of the segment ring can be obtained. It can be seen that the lateral earth pressure coefficient of the whole segment is larger than the initial coefficient of earth pressure at rest(0.5). At 6 m buried depth, the entirety lateral earth pressure coefficient varies greatly under different grouting pressure, and when the grouting pressure increases from 50kPa to 170kPa, the entirety lateral earth pressure coefficient increases by 0.13. However, when the buried depth is 15 m, the change of grouting pressure has little influence on the entirety lateral earth pressure coefficient, which is maintained at about 0.6, and the variation range is not more than 0.1.

When the buried depth of the tunnel is shallow, the coefficient of lateral earth pressure is suggest 0.07-0.13 higher than that of coefficient of earth pressure at rest. When the buried depth of tunnel is deeper, it is suggested that the coefficient of lateral earth pressure is 0.1-0.2 higher than earth pressure at rest. This is

consistent with the conclusion drawn by Han (2017) that the actual lateral earth pressure coefficient of the segment considering the effect of synchronous grouting at the shield tail is 0.1-0.2 higher than the recommended value of geological prospecting.

4.3 Ground reaction and the coefficient of ground reaction

Deep buried or shallow buried grouting pressure has little influence on the ground reaction and the coefficient of ground reaction. When the tunnel buried depth is certain, the ground reaction decreases with the increase of grouting pressure, and the coefficient of ground reaction increases with the increase of grouting pressure. Although the grouting pressure increases and the earth pressure on the segment also increases, the overall distribution of the earth pressure on the segment is uniform, so the deformation of the segment under the uniform pressure is small, resulting in the reverse ground reaction caused by the displacement of the segment to the soil.

Figure 14. Change of ground reaction under different grouting pressures.

Figure 15. Change of the coefficient of ground reaction under different grouting pressures.

5 CONCLUSION

From the above study, the following conclusions can be obtained:

- (1) The influence of the backfill grouting pressure on the segment earth pressure simulated by the equivalent circle zone method based on the concept of gap parameters is basically consistent with the results of the previous model test, which shows that the simplified analysis method calculated in this paper is feasible.
- (2) Considering the influence of backfill grouting, the vertical earth pressure and horizontal earth pressure of the segment show a parabola distribution of large in the middle and small on both sides.
- (3) The earth pressure of the segment increases linearly with the increase of grouting pressure, and with the depth of the tunnel, the earth pressure acting on the segment is more uniform.
- (4) The lateral earth pressure coefficient varies around the coefficient of earth pressure at rest, ranging from 0.28 to 2.98. When the buried depth of the tunnel is shallow, the lateral earth pressure coefficient is suggested to be 0.07-0.13 higher than the coefficient of earth pressure at rest. When the buried depth is deeper, the lateral earth pressure coefficient is suggested to be 0.1-0.2 higher than the coefficient of earth pressure at rest.
- (5) The grouting pressure has little influence on the ground reaction and the coefficient of ground reaction.

Impact of base rock deterioration on the mechanical characteristics of loess-expansive mudstone tunnel lining structure

Haoyan Zhu*

School of Highway, Chang'an University, Xi'an, China

ABSTRACT: In order to study the stress characteristics and displacement deformation law of the secondary lining structure of the loess-expansive mudstone binary structure tunnel under the expansion and softening of the surrounding rock of the tunnel basement, the nonlinear finite element numerical simulation method was used to carry out different degrees of deterioration of the basement under different water contents. The influence of the secondary lining structure of the tunnel with different thicknesses of loess and mudstone (i.e., different spatial position relationships) was analyzed to obtain the variation law of the displacement of the surrounding rock of the tunnel and the stress and strain characteristics of the secondary lining structure of the tunnel. The results show that with the increase of the water content of the surrounding rock of the tunnel (that is, the degree of deterioration is deepened), the vault settlement and the tunnel bottom uplift of the tunnel lining structure show an increasing trend, and the degree of deterioration has little effect on the vault settlement and has a great influence on the tunnel bottom uplift. When there is loess layer in the overlying surrounding rock, the maximum principal stress distribution of the secondary lining structure unit shows a large change in the force at the arch waist, and the value increases with the deepening of the deterioration, while the minimum principal stress changes more obviously at the inverted arch. The vault settlement of the lining and the uplift of the tunnel bottom decrease slightly with the decrease of the thickness of the overlying loess layer, but the growth rate is consistent. The research results can provide a theoretical reference for the deterioration mechanism of tunnel lining structure performance under variable loads during the operation period of loess-expansive mudstone dual structure tunnel.

1 INTRODUCTION

Mudstone is a special geological body between soil and rock mass. Its engineering properties are extremely complex and changeable. Water expansion and disintegration are the main engineering geological characteristics of mudstone (Um et al., 2009; Gautam et al., 2016). The argillaceous rock series is widely distributed in China and the world (Guangzhi, 2018; Lichuan et al., 2014). Among the many diseases that occur in tunnels in mudstone areas, the inverted arch floor heave is particularly significant, which even seriously affects the stability of tunnel structure and the comfort and safety of driving. The inverted arch floor heave of mudstone tunnel brings great trouble to the construction and research of engineering. The surrounding rock of inverted arch base may produce mechanical effects such as expansion, softening and rheology due to the change of groundwater storage environment, which is an important cause of inverted arch floor heave disease (Xiong et al., 2020).

There are many factors that cause the uplift of the tunnel bottom and the mechanism is extremely complicated. The failure of the tunnel inverted arch floor heave is related to geological structure, geological environment, load conditions, type design and construction quality, and the failure forms of the tunnel floor heave are also different (Mingqing et al., 2019; Zeng et al., 2014). Erfeng et al. (2013) described the engineering geological characteristics of Liangjiashan mudstone by classifying and geochemical analysis of the mudstone of Liangjiashan tunnel in Tianshui. Through the field monitoring and numerical simulation of the surrounding rock pressure of the mudstone flint, Qinpeng et al. (2016) showed that the mudstone was softened after saturation and caused uneven stress, resulting in obvious uplift failure of the inverted arch. Through monitoring measurement and numerical simulation, Dongdong et al. (2016) discussed the mechanical properties of the inverted arch of the tunnel after the soft flow of mudstone in water.

*Corresponding author: zhuhaoyan068@gmail.com

At present, the expansion pressure of the basement surrounding rock is equivalent to the uniform load in the design of the tunnel structure (Wilson, 1980; Chuntan et al., 2019), and the influence of the change of the water content of the basement surrounding rock on the stress of the tunnel and the floor heave of the inverted arch is not well considered, especially the simulation of the expansion and softening process caused by different water content. Therefore, it is particularly important to study the stress of the mudstone tunnel and the deformation and failure mechanism of the inverted arch under the action of basement expansion and softening. In view of this, based on the equivalent relationship of expansion theory caused by temperature deformation and humidity change, ABAQUS thermal plate is introduced, and the volume expansion caused by mudstone material heating is used to equivalent the volume expansion caused by mudstone water absorption. The analysis of base swelling effect is carried out to study the influence of swelling characteristics on the stress of tunnel structure and inverted arch deformation under different water content conditions, so as to provide theoretical basis for the deterioration mechanism of tunnel lining structure performance under variable load during operation period of tunnel in loess-mudstone area.

2 NUMERICAL SIMULATION OF SURROUNDING ROCK DETERIORATION OF TUNNEL BASE

2.1 Establishment of the model

According to the Saint Venant Principle, the actual influence width of surrounding rock stress redistribution after tunnel excavation is generally 3-5 times the distance around the center of the cavern. The change of surrounding rock stress at 3 times the excavation width is generally not more than 10 %, and the change of surrounding rock stress at 5 times the excavation width is generally not more than 3 %. Therefore, in order to reduce the influence of tunnel excavation and the simulation of expansion and softening of surrounding rock on the boundary effect, the left, right and lower sides of the cross-section size of the model are selected about 4 times the diameter of the excavation section. The established soil layer calculation model includes 247464 grids. The C3D8R hexahedral element is selected for the surrounding rock, the primary support and the secondary lining. The finite element mesh extracted from the finite element software is shown (Figure 1). In this paper, the initial support of the model adopts C25 shotcrete with a thickness of 0.28 m, and the secondary lining adopts C30 concrete with a thickness of 0.5 m. The tunnel section is 80 km/h highway tunnel standard section, the tunnel span is 12.76 m, and the height is 10.36 m. The thickness of the overlying soil on the top of the tunnel is

40 m (the overlying loess layer is reduced from 30 m to 0 along the excavation direction, and the thickness of the mudstone layer is increased from 10 m to 40). The distance between the tunnel arch bottom and the lower boundary is 37.64 m. The cross-sectional size of the model is 90×90 m, the longitudinal length along the tunnel axis is 24 m, and the excavation footage is 2 m. The ABAQUS model change method is used to complete the excavation and lining arrangement of the tunnel, and then the field variables are used to control the change of the surrounding rock parameters of the base, and the influence of the water expansion and softening of the expansive mudstone of the tunnel base on the tunnel structure is simulated.

Figure 1. The ABAQUS model of the tunnel.

There are contacts between the tunnel surrounding rock and the primary support, the primary support and the secondary lining. By defining the contact surface, the deformation coordination between the various structures of the model can be ensured. The contact surfaces are set between the tunnel surrounding rock and the primary support, and between the primary support and the secondary lining, so that the effective combination of the surrounding rock, the primary support and the secondary lining together constitute a relatively coordinated bearing body. The bottom interface of the formation calculation model is set with fixed constraints. The left, right, front and rear interfaces of the model are set with normal constraints, and the upper interface is free constraint.

2.2 Basic assumptions of the model

In the actual tunnel construction, due to the complex and changeable geological conditions, numerical simulation is difficult to simulate the actual engineering conditions. Therefore, this paper combines the relevant data to simplify the numerical simulation. The assumptions are as follows: (1) Assuming that the surrounding rock is isotropic, uniform and continuous material; (2) The natural stress field of surrounding rock only considers the effect of self-weight stress, and does not consider the complex stress such as tectonic stress which is difficult to be

expressed by formula; (3) The change of stress and strain of surrounding rock is always in the elastic-plastic range. The numerical simulation adopts Mohr-Coulomb yield criterion, and the numerical simulation of supporting structure material adopts linear elastic constitutive relation; (4) The stress and strain of the simplified humidity field are linear elastic relationship. The water absorption and expansion thermodynamic model of surrounding rock is isotropic heat conduction model. It is assumed that the specific heat, thermal conductivity and thermal expansion coefficient of the surrounding rock material do not change with temperature; (5) The material parameters of the primary support, secondary lining and excavation part of the tunnel are not affected by the change of temperature field. The interface between the primary support and the surrounding rock is adiabatic boundary, that is, the expansion only occurs in the surrounding rock, and the model boundary is adiabatic boundary.

2.3 Theoretical basis of temperature field simulation humidity field

From a macro perspective, the expansion process of expansive mudstone is the volume expansion of surrounding rock caused by the change of water content. By controlling the water content, the stress-strain and displacement changes of tunnel lining structure caused by expansive mudstone can be reflected. The built-in temperature field program of ABAQUS software changes the temperature change field controlled by heat conduction by controlling the temperature conditions, and then analyzes the stress change of the component. According to the basic theory of humidity stress field, the conversion formula of temperature expansion coefficient and humidity expansion coefficient is deduced, and the expansion effect of mudstone after water absorption is realized by temperature analogy method. Therefore, this paper uses ABAQUS built-in temperature field to simulate the expansion of expansive mudstone.

When the water content of mudstone is less than the saturated water content, the flow differential equation can be simplified as follows:

$$\frac{\partial}{\partial x} \left(k_x \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial y} \left(k_y \frac{\partial u}{\partial y} \right) + \frac{\partial}{\partial z} \left(k_z \frac{\partial u}{\partial z} \right) = C_w \frac{\partial u}{\partial t} \quad (1)$$

Where, k_x, k_y, k_z are the permeability coefficient (m/d); u is the head value of matric suction (m). $u = -u_w/(\rho_w g)$, where u_w is the matric suction (Pa); ρ_w is the density of water (kg/m^3). t is time (d); C_w is the specific water bulk density (1/m), which indicates the change value of the water content of the mudstone when the matrix suction of the unit volume mudstone changes by a unit head.

The heat conduction differential equation of the material is as follows:

$$\frac{\partial}{\partial x} \left(\lambda_x \frac{\partial T}{\partial x} \right) + \frac{\partial}{\partial y} \left(\lambda_y \frac{\partial T}{\partial y} \right) + \frac{\partial}{\partial z} \left(\lambda_z \frac{\partial T}{\partial z} \right) = \rho C_v \frac{\partial T}{\partial t} \quad (2)$$

Where, $\lambda_x, \lambda_y, \lambda_z$ are thermal conductivity ($\text{W}/(\text{kg} \cdot ^\circ\text{C})$); T is temperature ($^\circ\text{C}$); ρ is material density (kg/m^3); C_v represents the specific heat capacity ($\text{J}/(\text{kg} \cdot ^\circ\text{C})$).

Comparing the above unsaturated flow differential equation with the heat conduction differential equation, it is found that the two are basically the same in form. Therefore, the corresponding parameters in the seepage differential equation and the heat conduction equation can be exchanged. It is considered that solving the temperature field T parameter is to solve the matrix suction u of the expansive mudstone in the humidity field, so that the volume change of water in the unit volume mudstone can be calculated as $\Delta w = C_w \Delta u$. The strain increment caused by temperature change and the strain increment caused by humidity change are as follows:

$$\Delta \varepsilon_T = \alpha \Delta T \quad (3)$$

$$\Delta \varepsilon_w = \beta \Delta w \quad (4)$$

Where, α and β are temperature expansion coefficient and humidity expansion coefficient respectively. Let the above two formulas be equal, then:

$$\alpha = \frac{\beta \Delta w}{\Delta T} = \frac{\beta C_w \Delta u}{\Delta T} \quad (5)$$

Based on the above theory and formula analysis, the differential equation of expansive mudstone seepage problem is similar to the differential equation of heat conduction of temperature field material in mathematical expression. Through equivalent conversion, the seepage field of surrounding rock can be simulated by means of temperature field. Therefore, the volume expansion caused by water absorption of expansive mudstone can be approximated as the volume expansion caused by temperature change of mudstone material for equivalent conversion.

2.4 Model parameters

According to the specification, combined with the grade V surrounding rock of a mudstone tunnel and the geological survey data of similar projects, the physical and mechanical parameters of the model surrounding rock and supporting structure are given in Table 1.

According to the description of the basic theory of expansion in the previous section, the indoor test of mudstone and the reference, the following parameters are obtained: the initial water content is 12%, the void ratio e is 0.65, and the relative density G_s of mudstone is 2.71. It is assumed that the water content of mudstone in the surrounding rock of the project is 24%. According to the relationship between expansion force and temperature in numerical calculation: $\Delta P_s = 3\alpha K \Delta T$ ($\Delta P_s, K$ are the expansion force

Table 1. Physical and mechanical parameters of model materials.

Material	Density/ (kg/m ³)	Elastic		Cohesion/ kPa	Internal Friction Angle
		Modulus/ GPa	Poisson Ratio		
Loess	1820	0.15	0.39	32	26
Mudstone	2200	1.30	0.35	260	30
Initial Support	2400	28.00	0.20		
Secondary Lining	2360	30.00	0.20		

increment and bulk modulus of mudstone respectively). The temperature field is used to simulate the humidity field. At this time, the change of water content can be expressed as $C_w \Delta T(1 + e)/G_s$, and the water content can be calculated according to the following formula:

$$w = \frac{C_w \Delta T(1 + e)}{G_s} + w_0 \quad (6)$$

Fredlund et al. (1993) used the laboratory test to obtain the value of C_w is about 0.0846m^{-1} . The initial moisture content of mudstone is 12 % humidified to different moisture contents. The initial moisture content corresponds to $T_1 = 0$, and the final moisture content corresponds to temperature $T_2 = 2.330 \text{ }^\circ\text{C}$. The thermal calculation parameters of mudstone with different water content are calculated, as shown in the following Table 2.

Table 2. Thermal parameters of mudstone under different water content conditions.

Water Content/%	Temperature Expansion Coefficient $\alpha/10^{-5}$	Temperature Load $\Delta T/^\circ\text{C}$
12		0 ~ 2.330
16	2.0	0 ~ 2.330
20	3.9	0 ~ 2.330
24	8.5	0 ~ 2.330

Table 3. Physical and mechanical parameters of softened mudstone.

Softening Grade	Density/ (kg/m ³)	Elastic		Cohesion/ kPa	Internal Friction Angle
		Modulus/ GPa	Poisson Ratio		
Not	2200	1.30	0.35	260	30
Weak	2020	0.90	0.35	100	28
Moderate	1930	0.35	0.35	50	26
Strong	1840	0.13	0.35	25	22

Aydan summarized the material parameters of Tertiary soft rock such as a large number of mudstone,

and obtained the empirical relationship between the unit weight, Poisson 's ratio, elastic modulus and internal friction angle of mudstone and the uniaxial compressive strength, and calculated the parameters of mudstone after softening. After calculation, the physical and mechanical parameters of softened mudstone are listed in the following Table 3.

2.5 Simulation condition setting of tunnel surrounding rock expansion and softening

In order to better simulate the influence of water expansion and softening of surrounding rock on the tunnel during the operation of the tunnel, the excavation simulation of the three-dimensional dynamic construction stage of the tunnel is considered first. Expansive mudstone is a V-level weak surrounding rock, and the step-by-step excavation method is generally used to achieve the purpose of controlling stress and deformation. In this paper, the three-step method is used to construct the tunnel. The excavation footage of the tunnel is unified to 2m, the initial support is delayed by 2m, and the second lining is constructed after the end of the initial support. In this way, the displacement, deformation and stress distribution characteristics after excavation and support can be obtained. Then, based on the predefined field and temperature variable field in ABAQUS to control the change of surrounding rock parameters, the finite element analysis of expansion and softening simulation under different water content of surrounding rock is carried out, and the mechanical properties of tunnel structure caused by volume expansion and softening of surrounding rock are calculated. The deterioration area set in this paper is the 2m depth area at the bottom of the tunnel, which is the expansion and deterioration area of surrounding rock.

3 ANALYSIS OF CALCULATION RESULTS OF EXPANSION AND SOFTENING OF SURROUNDING ROCK AT TUNNEL BASE

3.1 Analysis of surrounding rock displacement

In order to compare and analyze the vertical displacement of surrounding rock with the change of excavation cloth, the curves of vault settlement and tunnel bottom uplift of monitoring sections (A, B, C, D) at 1m, 8m, 16m and 24m during tunnel excavation are drawn, as shown in the Figures 2 and 3.

It can be seen from the figure that in the tunnel excavation stage, the vault settlement value and the tunnel bottom uplift value are in the order of 1m to 24m from large to small. The main reason is that the vertical displacement of the surrounding rock has different degrees of influence with the excavation process. At the same time, in the expansion and softening stage of the substrate, the displacement value also increases with the increase of the water content in the substrate deterioration area (that is, the degree of deterioration deepens).

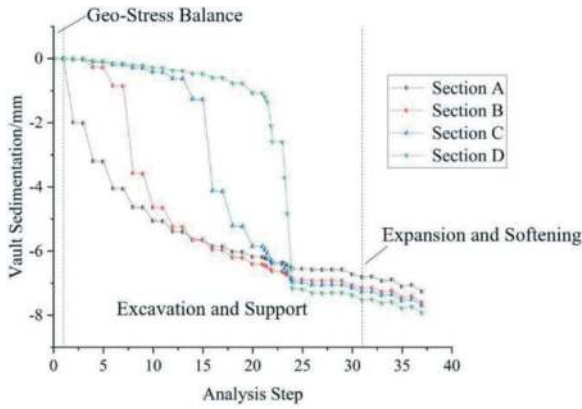

Figure 2. The curve of vault sedimentation with analysis step.

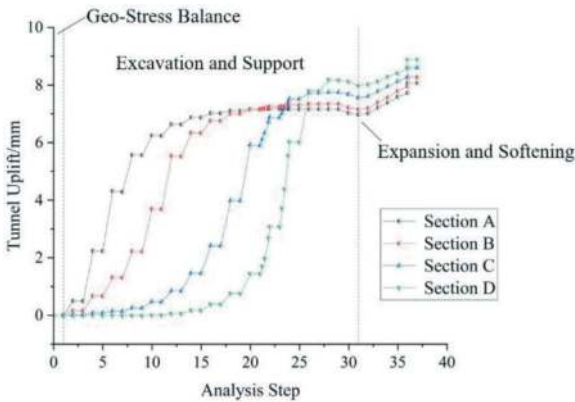

Figure 3. The curve of tunnel uplift with analysis step.

The vertical displacement cloud diagram of the whole tunnel model after construction and under the action of strong deterioration is shown in the Figures 4 and 5.

Figure 4. Undeteriorated vertical displacement after tunnel construction.

In order to analyze the change of displacement distribution of tunnel surrounding rock under the condition of different degrees of base deterioration, the vertical displacement values of representative nodes

Figure 5. Vertical displacement of tunnel base under strong deterioration of surrounding rock.

of four sections of lining vault and arch bottom are extracted, and the vertical displacement values of vault settlement and arch bottom uplift of four different monitoring sections are drawn. The relationship curves between water content and expansion and softening stages are shown in the Figures 6 and 7.

Figure 6. The relationship curve between vault sedimentation and water content.

It can be seen from the figure that under the action of expansion and softening of the basement surrounding rock, the maximum settlement value and uplift value appear in the monitoring section D of the inverted arch surrounding rock. The maximum settlement value of the tunnel vault is 7.92 mm, and the change after construction is 5.37%. The maximum uplift value of the inverted arch bottom is 8.88 mm, and the change after construction is 7.66%. The arch bottom heave increases with the increase of the water content of the basement surrounding rock and the process of gradual expansion and softening. With the increase of water content, the settlement value of the vault decreases slightly under the action of each level of expansion, and increases continuously under the

Figure 7. The relationship curve between tunnel uplift and water content.

action of each level of softening. It can be seen that the water absorption and expansion of the surrounding rock at the bottom of the tunnel can have a certain inhibitory effect on the settlement of the tunnel vault.

3.2 Lining stress analysis

The section of the secondary lining support structure at section A is taken for analysis. The maximum principal stress and minimum principal stress cloud diagram of the lining support structure under the strong deterioration of the basement surrounding rock are shown in the Figures 8 and 9.

Figure 8. The maximum principal stress cloud diagram of strong deterioration surrounding rock lining structure.

In order to analyze the variation of the maximum and minimum principal stress distribution of the tunnel secondary lining along the circumferential direction, the maximum and minimum principal stress distribution curves of the tunnel lining unit under different water content conditions are drawn, as shown in the Figures 10 and 11.

From the diagram, it can be seen that after the tunnel excavation is completed, with the increase of the water content of the surrounding rock, the

Figure 9. The minimum principal stress cloud diagram of strong deterioration surrounding rock lining structure.

Figure 10. The variation curve of maximum principal stress of lining.

Figure 11. The minimum principal stress change curve of inverted arch.

maximum principal stress at the inverted arch position gradually becomes larger, and the stress concentration phenomenon occurs at the arch waist. The minimum principal stress of the ring unit of the inverted arch lining is negative, that is, the compressive stress. The

compressive stress of the inverted arch unit increases with the increase of water content. The minimum principal stress at the arch bottom is relatively larger than that at the vault, and the stress concentration occurs at the arch foot.

The stress variation curve of the inverted arch is basically axisymmetric. The maximum principal stress σ_1 of the inverted arch is positive, the minimum principal stress σ_3 is negative, and the absolute value of σ_3 is greater than σ_1 . With the increase of water content, that is, the deepening of mudstone expansion and softening, the maximum principal stress at the arch waist and the minimum principal stress at the arch foot show an increasing trend. The problem of concrete cracking caused by excessive tensile stress at the arch bottom of the tunnel invert should be considered emphatically.

4 CONCLUSIONS

Based on the temperature field simulation humidity field theory of ABAQUS and the softening effect theory of surrounding rock, this paper analyzes the influence of different expansion and softening effects on the stress and deformation of loess-mudstone tunnel lining structure through numerical simulation. The following conclusions are obtained:

- (1) With the increase of the water content of the surrounding rock of the basement, the uplift of the arch bottom and the settlement of the vault increase continuously. The expansion effect has little effect on the settlement of the vault, while the softening effect has a relatively large effect on the settlement of the vault. The water absorption expansion of the surrounding rock at the bottom of the tunnel can have a certain inhibitory effect on the settlement of the tunnel vault.
- (2) With the enhancement of the deterioration of the basement surrounding rock, the maximum principal stress and the minimum principal stress of the inverted arch waist and the arch foot show an increasing trend. The concrete tensile deformation and failure caused by the excessive tensile stress at the inverted arch position of the tunnel should be considered.
- (3) The range of the deterioration area of the basement surrounding rock, the stress and deformation of the tunnel lining structure at the top of the tunnel section and the deterioration of the surrounding rock on the left and right sides

should be further considered, and the stability of the lining structure under different surrounding rock deterioration can be completely analyzed.

ABSTRACT: The construction industry, particularly tunnel construction, exposes workers to respirable crystalline silica (RCS), which can cause incurable illnesses such as silicosis and lung cancer. Despite a range of control measures being implemented, these measures do not completely remove the potential risk of RCS. This research aimed to identify the barriers and challenges hindering the implementation of effective controls and the adoption of safe work practices to protect workers from RCS exposure in tunnelling. A mixed-method approach was employed for this research. Tunnel construction workers were observed, surveyed and interviewed to gauge their knowledge and attitudes and understand their challenges in reducing RCS exposure. The preliminary analysis of the data reveals a diverse array of sociotechnical factors interacting to influence RCS exposure. It is noteworthy that participants consistently emphasised the project as the most exemplary one they have been involved in, although there is room for improvement. Although there is a notable proficiency in understanding RCS exposure and management in tunnelling, there appears to be a noticeable deficiency in perceived contentment regarding dust control. Several factors were identified as interacting to prevent the effective management of dust. These include perceived time pressure, absence of on-tool dust controls for some equipment, and low risk perceptions among workers, and inadequate enforcement of controls. Moreover, participants highlighted communication and heat-related challenges as hindrances to the continuous wearing of respirators. This research highlights the need for a paradigm shift in tunnel construction to address the barriers associated with RCS exposure reduction. It emphasises the importance of collaboration among various stakeholders, advocating for more effective controls, enforcement strategies and enhanced worker education through knowledge sharing.

1 INTRODUCTION

Tunnelling, or the creation of underground passages or openings, supports water, sewer, and utility systems and significantly helps to move thousands of people through road and railway lines to reduce congestion and create more connected communities. In Australia, tunnels are being constructed in Melbourne, Brisbane, and Sydney, like other major cities worldwide. For example, the Metro Tunnel project, led by the Victorian Government (2023), is actively constructing twin 9km rails that will have five new underground stations, connecting Sunbury in the west to Cranbourne/Pakenham in the southeast of Melbourne.

Several tunnelling projects must be completed to achieve these train services. Completing these tunnelling projects involves excavation, material removal and boring or cutting through different rock formations that contain quartz (ATS 2018; WHSQ 2013). The process of tunnelling through quartz-bearing rocks produces dust containing harmful tiny particles known as crystalline silica within the dust, exposing workers to respirable crystalline silica (RCS) if left uncontrolled (Bakke et al. 2014).

Although several interventions like foam (Guo et al. 2019), air curtains (Cai et al. 2020), press-in ventilation (Guo et al. 2020) and water misting (Sun et al. 2023) are available, hazardous exposure to RCS is still an

*Corresponding author: faka857@uowmail.edu.au

ongoing risk in tunnelling (Leite et al. 2023; WHSQ 2013). These exposures may lead to silicosis (Leung et al. 2012) and other illnesses like lung cancer (IARC 1997), chronic obstructive pulmonary disease (Rushton 2007) and kidney disease (Vupputuri et al. 2012).

Given these risks, examining tunnelling operations to gain a deeper understanding of the practices and challenges related to dust controls has become essential. Previous studies investigating workplace dust control practices have predominantly focused on construction rather than tunnelling.

Research on tunnelling dust control practices, include a survey conducted among Australian Institute of Occupational Hygienists that identified challenges hindering exposure reduction. These challenges include a lack of management commitment, financial constraints, employer prioritization of other concerns over worker health protection, over-reliance on personal protective equipment, and a lack of knowledge-sharing (Cole et al. 2023). Cole (2016) also identified best practices across several countries rather than challenges faced by workers and management in using dust control measures.

In construction, a study by Xing et al. (2018) identified practices employed by the Chinese government to reduce dust emissions on construction sites. The practices were categorised into technological, economic, supervisory, organisational, and assessment-based measures. They further noted that the government is more inclined to use technologies and organisational measures to encourage dust exposure reduction. Similarly, Zuo et al. (2017) found that construction site managers with personal experience in dust pollution employed by companies committed to dust control or working for larger firms tended to demonstrate greater awareness of dust exposure consequences, potentially resulting in increased self-responsibility for controlling dust. Kaluarachchi et al. (2021) revealed that workers' awareness of dust pollution consequences and their sense of responsibility positively affected personal norms, subsequently influencing their behaviour in dust control management.

Beyond the construction sector, a study by Haas et al. (2016) noted that US miners paid more attention to RCS exposure and silicosis risks when they first started working. However, this vigilance waned as they became more comfortable with their job responsibilities. This decrease in attention does not appear to be related to knowledge, as Sifanu et al. (2023) discovered that knowledge does not significantly influence the attitudes and behaviours required to reduce respirable dust exposure among copper miners. Furthermore, Utuk and Atulomah (2023) also observed that negative attitudes towards dust control exist even among workers with adequate knowledge of exposure risk in a cement factory.

When these factors are considered alongside the limited protection provided by engineered dust controls, even when they are highly efficient (Anlimah et al. 2023), work practices and associated barriers contribute to RCS overexposure reported in the

literature (Leite et al. 2023). Therefore, the current study seeks to contribute to the body of knowledge by providing evidence of the practices and challenges associated with effective dust control in tunnelling.

2 METHOD

A mixed research approach involving an online survey, site observations and interviews was adopted for the study.

2.1 Data collection instrument

A customised version of the Safety Attitudes Questionnaire (SAQ) developed by Sexton et al. (2006) was utilised to understand the knowledge and attitudes related to dust control in tunnelling. The SAQ has been used in various medical facilities in the USA, Sweden and Cyprus, as reported by Al Malki et al. (2018) and Alayed et al. (2014) and is suitable for understanding the safety attitudes of workers.

The lead author initiated the modified questionnaire, which the co-authors reviewed independently. Necessary revisions were discussed and implemented. Subsequently, professionals from the tunnelling industry assessed the questionnaire for its suitability. The questionnaire evaluated five domains: teamwork climate, awareness and control of dust, dust control satisfaction, stress recognition and working conditions. Table 1 highlights the number of items under each domain.

Table 1. The five domains evaluated by the questionnaire.

Scale	Definition	N° of Items
Team Climate	Quality of collaboration among workers to control dust	6
Awareness and control of dust	Creation of awareness about the risk and control measures for RCS	10
Dust control satisfaction	Positivity about dust control practices	5
Stress recognition	Acknowledgement of how excessive dust impacts work performance	3
Work condition	Perceived quality of dust control practices and logistical support, including staffing and equipment	5

In addition to the survey, semi-structured interviews were conducted to delve deeper into the knowledge, attitudes, and challenges associated with managing dust on the project. Site observations were conducted during multiple site visits between August 2022 and September 2023.

2.2 Study sites

The research was conducted at a tunnelling project managed by a principal contractor in Australia. Various dust-generating tools and equipment were utilised on

the project including excavators, rock hammers, rock saws, surface miners and roadheaders. The roadheaders were used to excavate crossover caverns. The tunnels are being bored by two double-shield, hard rock tunnel boring machines (TBM), which were launched at the dive site and will be retrieved later at the extraction site.

2.3 Participant selection

Employees at each site were informed about the purpose and goals of the study during their weekly toolbox meetings. Those interested in participating accessed the online study by scanning a QR code. Follow-up interactions took place throughout the four-week survey period. Interviews were conducted after the survey had concluded and occurred face-to-face for each participant, except for two, where it was conducted online. One author conducted the interviews. All interviews were recorded with consent.

2.4 Data analysis

Data were analysed using Jamovi (2023) computer statistical software package for MacBook (version 2.3.19). Demographic information was presented through frequencies and percentages. Calculations of the sub-domain values in the survey were based on the instructions of Sexton et al. (2006) with minor adjustments due to the use of a 4-point Likert scale. To convert scores to a 100-point scale, 100/3 was used instead of the original 25. Respondents with a mean score of 75 or higher on the 100-point scale were classified as having a positive attitude towards a specific domain. Interview responses were thematically analysed in NVivo.

2.5 Ethical consideration

The research protocol received approval from the Human Research Ethics Committee of the University of Wollongong (Protocol Number: 2021/280).

3 RESULTS

3.1 Demographic information

The survey included 174 employees who were either frontline workers or leaders such as leading hands, engineers, supervisors, safety advisors, superintendents and managers. Participants were from diverse age groups and work backgrounds. Respondents were relatively young to middle-aged workers. The largest age group was 25 to 34 years, comprising 49% (n = 85) of the participants, while the smallest group (n = 2; 1%) consisted of workers over 54 years, as shown in Figure 1.

Survey respondents brought diverse work experiences across various industries to the study. About

29% (n = 50) had 11 to 20 years of experience, followed by 25% (n = 43) with 6 to 10 years and 16% (n = 27) with 3 to 5 years. However, most participants had limited experience in tunnelling projects, with participants with less than a year of experience accounting for 32% (n = 56) of the sample, as highlighted in Figure 2.

Figure 1. Age distribution of respondents.

Figure 2. Work experience of participants.

Furthermore, 54% (n = 94) of the participants held no supervisory role, while the remaining 46% (n = 80) did. Among the 40 employees interviewed, 40% (n = 16) were workers, whereas 60% (n = 24) held supervisory roles.

3.2 Reliability assessment

The overall Cronbach's alpha value for the survey was 0.912, with a mean of 3.27 (SD = 0.352), while that of the five domains was between 0.761 and 0.895. The questionnaire therefore had high internal consistency.

3.3 Factor structure and multi-level modelling

A five-factor confirmatory factor analysis was conducted to evaluate the tool's validity by comparing it against observed data. The fit of the final model, which retained 29 items, was generally satisfactory: $\chi^2(619) = 367$, $p < 0.001$; CFI = 0.92; TLI = 0.0911; RMSEA = 0.0628; SRMR = 0.0701. Factor

estimates are detailed in Table 2 (all estimates are $p < 0.05$ except values marked with *).

Table 2. Factor estimates for the attitudes domain.

	Team Climate	RCS Awareness	Dust control satisfaction	Stress recognition	Work condition
Team Climate	1.000	0.380	0.873	0.175	0.847
Awareness and control of dust		1.000	0.242	0.402	0.391
Dust control satisfaction			1.000	0.107*	0.872
Stress recognition				1.000	0.143*
Work condition					1.000

An independent samples T-test revealed no statistically significant difference in employment levels (supervisor or not) across domains. Similarly, an ANOVA analysis showed no significant differences in attitudes based on age, work or tunnelling experience ($p > 0.05$). Further analysis illustrates interrelationships among the domains, with Teamwork significantly linked to Awareness and Control of Dust ($r = 0.284$, $p < 0.001$) and Dust Control Satisfaction ($r = 0.786$, $p < 0.001$). For additional correlations, refer to Table 3 below.

Table 3. Correlation matrix for dust control attitude. (r = Pearson's r and p = p-value).

	Teamwork	Awareness and Control of Dust	Dust Control Satisfaction	Stress Recognition	Work Condition	Age	Experience in Tunnelling	Supervisor or not
Teamwork	—							
Awareness and Control	r 0.284	—						
	p < .001	—						
Dust Control Satisfaction	r 0.786	0.130	—					
	p < .001	0.088	—					
Stress Recognition	r 0.124	0.315	0.055	—				
	p 0.103	< .001	0.474	—				
Work Condition	r 0.732	0.298	0.813	0.071	—			
	p < .001	< .001	< .001	0.353	—			
Age	r 0.003	-0.018	0.094	-0.097	0.005	—		
	p 0.963	0.818	0.955	0.207	0.953	—		
Experience in Tunnelling	r -0.099	0.139	-0.141	0.14	-0.108	0.396	—	
	p 0.193	0.067	0.063	0.066	0.156	< .001	—	
Supervisor or not	r 0.069	-0.07	0.085	-0.131	0.01	-0.114	-0.201	—
	p 0.365	0.355	0.268	0.085	0.698	0.134	0.098	—

3.4 Attitudes towards dust control

A positive domain score of 76 for Awareness and Control of Dust demonstrates a good attitude towards efforts to raise awareness about RCS exposure and control. However, similar positive attitudes are not observed in the other domains. The results suggest that excessive dust impacts the work output of workers, evidenced by the negative score of 60 for Stress Recognition, as illustrated in Figure 3.

93% of participants positively perceive that they receive adequate information regarding the impacts and effects of dust, as well as strategies for reducing dust levels. Site observations align with these findings, supporting awareness creation and implementation of various dust control measures, including on-tool water spray systems, the establishment of

exclusion zones, sprinklers around the work area and ventilation systems.

Figure 3. Attitudes towards dust control.

Additionally, the project is required to adhere to strict client RCS exposure control requirements. This includes specific measures such as the prohibition of dry sweeping and the use of handheld water sprays to control dust. Moreover, the client has representatives on the project to monitor compliance. A third-party conducts monthly monitoring of personal RCS exposure. In case of recorded overexposures, thorough investigations are conducted to determine the root cause. The outcomes of these personal exposure monitoring efforts are displayed on notice boards and communicated during toolbox meetings. Furthermore, matters concerning dust exposure are actively discussed in safety committee meetings.

These efforts may be a contributing factor to many interviewed participants quick to point out that when compared to other tunnelling projects they have worked on, the research site stood out as one of the best in dust control.

3.5 Dust control challenges

3.5.1 Technical and operational factors

However, when dust control is inadequate, or there is no engineered control for an activity, workers may adopt unauthorised methods to minimise their exposure. For example, while dust-generating tools like hammers, twin headers, and rock saws have on-tool controls, applying these measures to equipment such as an excavator with a bucket for scraping the floor or a dozer for stripping proves challenging. In such circumstances, there is reliance on water sprinklers installed above ground around the work area or air-assisted water spray systems. While these controls reduce dust, installing irrigation-type sprinklers with a spray distance between 5 - 30m raises concerns about understanding factors influencing dust control.

Additionally, factors like wind, space restrictions and vehicle (equipment) movement limit the effective use of air-assisted spray mist. Consequently,

workers sometimes resort to handheld dust suppressions, although the practice is prohibited on the project. Similarly, in the TBM tunnel, where outby workers deal with residual dust, management has experimented with different approaches, such as consulting experts and testing sprinkler systems. However, because they have not identified a fully effective solution, workers use water hoses to clean their work areas.

Furthermore, the challenge of ensuring that ventilation systems adequately remove dust is also encountered when excavating with a roadheader, especially when transitioning between different phases of excavation.

Participants highlighted multiple reasons for non-compliance with dust control measures at the worker level. This includes the type of activity, time factor, laziness and indifference on the part of workers.

3.5.2 Organisational factors

Inadequate enforcement compounds challenges faced in exposure reduction, evidenced by some observed hammer drilling activities that did not use any on-tool extraction. Also, using prohibited dust control methods, such as handheld dust suppression in some situations, lends to the theme.

3.5.3 Challenges with the use of respirators

Compliance issues are not restricted to engineering controls but are also associated with using respirators or dust masks.

Three types of respirators are used on the project: the P2-rated mask, half face mask (rubber mask) and one brand of powered air purifying respirator (PAPR). While it is mandatory for every worker to wear a respirator before entering the work area, the continuous use of respirators poses a challenge. Reasons cited for frequently removing masks include discomfort caused by hot weather conditions, the need to drink water, wipe their face or communicate with others.

In a restricted work environment with multiple activities and several vehicle movements, communication among the work teams is important for worker safety and discussions about the work process. However, workers often find it necessary to compromise their respiratory protection to have these conversations. While participants acknowledged the challenge of speaking in the P2 mask, the difficulty was more severe with the half-face mask and the PAPR. However, participants noted that the PAPR used on the project was more comfortable than the P2 and half-face mask.

In addition to these challenges, there is resistance among some workers to comply with the shaving requirement for the use of P2 and half-face masks despite the provision of shaving tools in some washrooms. The main reason is rooted in personal lifestyle choices.

Presently, only a specific group of workers on the project receives PAPR, which does not require a clean-shaven face. Most participants advocated for

the use of only the PAPR on the project. Irrespective of these challenges with the continuous use of mask, participants rate compliance as high.

3.5.4 Dust risk perception

These compliance related issues were mainly attributed to the low dust-risk perception of workers, as the severity of dust-related problems is not immediate. Moreover, dust has only recently emerged as a significant concern for workers, possibly heightened by the nationwide awareness of RCS exposure in the engineered benchtop industry (SafeWork SA 2023).

The project's reliance on construction contractors, who may typically operate in environments with less strict dust control measures, further contributes to a lack of awareness of dust control requirements and compliance. This low dust risk perception makes some workers complacent, especially when they do not see dust in the work area.

3.5.5 Addressing dust control challenges

Across the participants, a strong consensus was the need for more education, particularly emphasising the consequences of RCS exposure. This can be done by using silicosis patients to share their experiences or having medical professionals and experienced tunnellers share their knowledge.

Furthermore, participants stressed the importance of enhanced collaboration between tunnel clients, government entities, and regulatory bodies to reduce dust exposure. Regular visits by regulators were advocated to ensure compliance. To enhance collaboration, they recommended the establishment of a dedicated learning team to champion research efforts to find effective solutions and share best practices across Australian tunnelling projects.

Participants also believed that having competent professionals or more hygienists among the work teams to help translate the dust control and ventilation plans into practice would enhance dust control practices.

One participant proposed a solution to address concerns about cost optimisation potentially affecting dust controls. The participant suggested that the cost for dust control should be predetermined and fixed for all bidding firms to eliminate variability and ensure a consistent commitment to effective dust control measures across tunnelling projects.

4 DISCUSSION

The study employed a survey, site observations, and interviews to understand practices and challenges in reducing RCS exposure during tunnelling. The results indicate the survey effectively identifies dust control knowledge and attitudes among tunnellers, allowing for detailed exploration through interviews. Positive factor loadings in the survey's five domains suggest a favourable relationship between observed variables and respective latent factors. The generally satisfactory

fit model of the survey indicates further scale refinement would result in stronger factor loadings and a better fitting model.

The study emphasised a positive attitude toward Awareness and Control of Dust on the project, while other domains mainly received negative ratings. The score for Dust Control Satisfaction as shown in Figure 3 demonstrate there is room for improvement in reducing dust exposure on the project despite participants praising the project's dust control measures when compared to their previous experiences. The negative ratings may be due to instances where the supervisory team had to step in to stop the dust generating activity to rectify the cause. Positive correlations between Teamwork and Awareness and Control of Dust, and between Teamwork and Dust Control Satisfaction, suggest opportunities for practical interventions. Improving one domain is likely to influence the others positively.

Some of the challenges faced in tunnelling are similar to ones faced in general construction such as cost, inadequate risk perception of dust, and worker attitudes (Abas et al. 2021). The study findings are consistent with the results of Utuk and Atulomah (2023) that negative attitudes towards dust control exist even among workers with adequate knowledge of exposure risk. Additionally, findings about heat affecting compliance for dust masks in underground tunnels align with ATS (2018). Thus, their recommendation for a "worker respite station" in tunnelling where workers can cool down or have a drink is highly seconded.

The study further indicates that when workers perceive controls as inadequate, they prioritise alternative approaches to complete the job, even if unsafe. This highlights that workers focus on getting the job done rather than prioritising safety. Hence, when assigning tasks, supervisors should emphasise the necessary dust controls. Additionally, interactions among work teams can adopt coaching conversations, as explained by Long (2021).

Calls for collaboration are consistent with the current cooperation between industry and Australian regulators termed the Air Quality Working Group (AQWG) (ATS 2020). The partnership has led to the publication of several reference materials to help improve occupational health outcomes, including RCS exposure reduction.

The need for increased education is highlighted by limited formal academic education specific to tunnelling, unlike mining. These efforts will enhance engineers' understanding of factors influencing the effectiveness of dust controls in the design of work activities. Moreover, the decade-old guide for tunnelling in Australia (SWA 2013) lacks comprehensive information on dust control, although it is understood to be under review by the collaborative working group.

The insights from the study highlight the complexities of implementing dust control measures and the need for ongoing attention to equipment, employee compliance, and the dynamic nature of tunnelling. Addressing these challenges requires

effective collaboration, equipment design, training, and enforcement of controls.

Limitations to consider when interpreting the study results include that although the sample size aligns with qualitative research methods and objectives (Dworkin 2012), it is crucial to note that these findings may not represent all tunnelling projects in Australia or globally. Additionally, the results presented are based on a preliminary research data analysis.

5 CONCLUSIONS

This research aimed to identify the barriers and challenges hindering the implementation of adequate controls and the adoption of safe work practices to protect workers from RCS exposure in tunnelling. It demonstrates the feasibility of reliably and meaningfully measuring tunnellers' dust control knowledge and attitudes. The study reveals a complex interplay of organisational, operational, technical, environmental and individual factors influencing dust exposure on tunnelling sites. Furthermore, the study highlights that despite advancements in dust control in tunnelling, continued improvement requires collaboration, strict enforcement, technological advances in dust control, and enhanced respiratory protection.

The study demonstrates that the level of knowledge and attitudes towards dust control in tunnelling can be measured. The study supports the recommendation to standardise the cost aspect of dust control for all bidding firms, thereby eliminating variability and ensuring a consistent commitment to dust control from tunnelling companies. It advocates for stricter enforcement of standards, urging tunnelling clients and governments to allocate funds for research addressing identified gaps and facilitating opportunities for sharing best practices among tunnel contractors. Knowledge sharing should include experiences from experienced tunnellers, medical professionals, and silicosis-diagnosed patients with workers to help raise workers' risk perception. Furthermore, the study calls for more focused formal studies on tunnelling dust control.

There is a need for focused research to address identified gaps, such as the absence of on-tool controls for excavators or dozers. Solutions for eliminating residual dust in tunnels merit increased research attention, including improvements in communication when using respirators.

ACKNOWLEDGEMENTS

This research constituted an independent study in the Centre of Occupational Public and Environmental Research in Safety and Health (COPERSH) supported by a doctoral scholarship funded by the Occupational Safety and Health Research Alliance (OSHRA). Gratitude goes to Leanne Treadwell for her feedback on the interview questions and reading through the manuscript.

ABSTRACT: The City Rail Link (CRL) is a major railway construction project underway in Auckland, New Zealand. The project includes the design and construction of two underground rail stations, the redevelopment of an existing surface rail station, two new rail tunnels and the connection to an existing line. This paper presents the design and construction optimisation of the Karanga-a-Hape Station Mined Tunnels and the Bored Tunnel Cross passages on the project. Karanga-a-Hape Station is a 32m-deep mined underground, twin platform station with four cross passages along the bored tunnel alignment. An overview of the design of the elements is presented with particular focus on the construction optimisation of the secondary linings during detailed design, the programme and implications for methods. The secondary lining formwork selection process is described along with formwork systems and shape optimisation. Lessons learnt from design and construction are presented along with future opportunities for optimisation.

Keywords: Tunnelling, Secondary Lining, Tunnel Formworks

1 INTRODUCTION

1.1 Project overview

The City Rail Link (CRL) is New Zealand's largest transport infrastructure project ever to be constructed. CRL is a 3.45km twin-tunnel underground rail link up to 42 metres below the city centre transforming the downtown Waitemata Station (Britomart) into a two-way through-station that better connects the city's rail network.

It includes a redeveloped Maungawhau Station, where the CRL connects with the North Auckland (Western Line) and new underground stations - one midtown underneath Albert Street called Te Waihorotiu Station and Karanga-a-Hape Station just off Karangahape Road with entrances at both Mercury Lane and Beresford Square.

The Link Alliance is delivering the main works including three new stations, twin tunnels, rail systems and work at the existing Waitemata Station (Britomart) to accommodate the new rail connection. Link Alliance comprises City Rail Link Limited, Vinci

1.2 Karanga-a-Hape station tunnels

Karanga-a-Hape Station is a 32m-deep mined underground, twin platform station. A temporary access

*Corresponding author: Pierre.daudibertieres@vinci-construction.com; Vinno.Bala@aurecongroup.com

shaft was constructed halfway along the Adit 1 alignment (Figure 2) and served as the only access and egress point during the construction of both the primary and secondary linings.

Figure 2. Station shaft and tunnels layout.

The tunnels were excavated through the East Coast Bays Formation, a sandstone that varies from very weak to strong interbedded layers across the project alignment. However, there were channelised sandstones present at Karanga-a- Hape along with a possible fault that contained a broken zone.

The tunnels were constructed with road headers and the primary lining comprised shotcrete followed by a geotextile and a PVC sheet waterproofing membrane.

The secondary lining sections varied to account for ventilation requirements. The secondary lining sections were split into platform tunnel (PT) and adit (AD) sections.

Corbels are present in all the PT sections but were optioneered out of the AD sections to aid formwork construction and operation in the smaller cross sections.

All tunnel profiles are effectively at grade except for Adit 1 which has a 6.9% slope. Section geometry, thicknesses and profile lengths are presented in Table 1.

2 KARANGA-A-HAPE TUNNEL SECONDARY LINING DESIGN

2.1 Design team organisation

The design team comprised both local and international based firms to leverage both local geological expertise and broader metro and large span tunnel design experience.

2.2 Lining design

2.2.1 Design philosophy

The detailed design was based on an unreinforced drained tunnel with reinforcement only provided at

Table 1. Secondary lining profile summary.

Tunnel Section	Profile (length)	Width x Height at intrados	Max thickness
Platform tunnel MC30	PT-1 (186m)	9.0m x 7.9m	400 mm
Platform Sub-Zone MC31	PT-2 (20m)	10.3m x 7.9m	550 mm
Platform Sub-Zone MC32	PT-2 (8m) PT-4 (13m)	10.3m x 7.9m 10.9m x 9.0m	550 mm 800 mm
Platform tunnel MC20	PT-1 (123m)	9.0m x 7.9m	400 mm
Platform Sub-Zone MC21	PT-5 (32m)	13.4m x 9.6m	900 mm
Adit 1	AD-2 (30m)	7.9m x 6.7m	350 mm
Adit 2	AD-1 (12m)	7.9m x 7.2m	350 mm
Adit 3	AD-1 (32m)	7.9m x 7.2m	350 mm
Adit 4	AD-3 (21m)	10.3m x 6.7m	400 mm
Adit 5	AD-2 (27m)	7.9m x 6.7m	350 mm

the corbels and the junctions with the adits. The design itself was carried out by long established methods such as the use of bedded beam models documented extensively in published literature.

2.2.2 Early contractor input

The alliance delivery model facilitated early contractor input with regular co-ordination between the contractor's methods team and the designers. Specifically, the design was able to facilitate the preferred formwork transition strategy (4.2.1). The tunnel geometry was frozen early in the detailed design to facilitate procurement discussions with formwork suppliers.

2.3 Lessons learnt

The reinforcement detailing was carried out by the steel supplier based on detailed design intent drawings. The drawings and schedules were checked by project engineers and the designer's representative on site but there were inevitable issues with the supplier interpreting the design intent drawings. As such, in house production of the construction drawings and schedules would have led to the removal of an additional quality assurance process and potentially reduced lead times for reinforcement supply.

The transitions between platform tunnels and the sub-zones (MC30 to MC31) necessitated two

formwork transformations for relatively short sections. Each transformation took 2 to 3 weeks and was both logistically and labour intensive. As such, the need for shorter unique sections could be reappraised for similar projects in the future where there is safe scope for an extended larger initial excavation for the primary lining.

The design of the interfaces with the headwalls were initially based on concrete-to-concrete bearing connections with the secondary lining. However, during construction it became apparent that this was not possible at the largest section (MC32- PT-4). The secondary lining had to be built before the headwall was completed and it would not be possible to safely install a stop end along the circumferential face of the

Figure 3. Headwall stitched to secondary lining.

tunnel. As such, a stitch detail was provided to connect the headwall to the secondary lining (Figure 3).

3 CONSTRUCTION

3.1 Concrete mix design and performance

3.1.1 Concrete mix specifications

The main concrete design requirements were as follows:

- Compressive strength at 28d: 40MPa
- Flexural tensile strength at 28d: 3.8MPa
- Drying shrinkage at 56d under 1000 μ strain
- Maximum W/C ratio of 0.45
- Fire resistance to the RABT-ZTV (car) curve
- Minimum of 20% of Pulverised Fly Ash (PFA) in the binder, to satisfy the project's minimum cementitious replacement targets (no other cementitious replacement materials – such as ground granulated blast furnace slags, metakaolins etc.- were available in New Zealand during the CRL construction)
- Maximum core temperature of hardening concrete: 75°C

- Maximum temperature differential between core and skin during concrete hardening following an evolutive criterion depending on concrete maturity, as per CIRIA C766
- 10MPa at formwork striking time

In addition, the mix design needed to satisfy the following constructability requirements:

- 100m pumpability
- Slumpflow of 500mm +/-50mm with workability retention of 3h

It was decided to proceed with a flowable mix rather than a self-compacting mix, in order to increase its robustness and limit quality issues linked to batching variability. Vibration was provided with skin vibrators fixed to the formwork (Figure 8). The fire resistance was provided by the inclusion of polypropylene microfibres. 6mm long, and 18 μ m diameter fibres were selected. The fibre content was optimized to 0.9kg/m³ following a series of furnace tests on 1200x1200mm concrete panels.

Two mixes were used:

- Mix A: 40MPa concrete with 30% PFA
- Mix B: 40MPa concrete with 40% PFA, designed to limit detrimental thermal effects on larger section pours

3.1.2 Strength and temperature predictive modelling, and implementation of site-based maturity strength and temperature controls

To refine striking times and optimize construction cycles, and to remain in control of thermal issues such as early age cracking and delayed ettringite formation, we implemented a program of thermo-numerical predictive calculations and site based concrete maturity controls.

Determining the correct striking times was paramount for the large pours of unreinforced concrete, to avoid detrimental cracking, and meet programme targets.

We performed semi-adiabatic calorimetry tests as per the EN 196-9 (2010) test methods on the proposed binders, to determine their heat release properties. Along with general constituents' properties, formwork and shotcrete thermal exchange properties, and sample-based calibration, this allowed us to build an accurate thermo-numerical model to study and predict strength gain, and temperature developments in the structures, depending on fresh concrete and ambient temperatures.

This work drew on over 15 years' experience of the Alliance partners, including several PhDs and extensive site implementation, on thermo-numerical calculations for concrete structures.

This was used to determine which mix to use based on the lining thickness, and current temperature conditions, and when to strike the forms.

Figure 4. Expected temperature and differential within 0.9m thick section with Mix A in spring.

Table 1 shows the predicted striking times at 10MPa, along with maximal authorized fresh concrete temperature to prevent thermal issues, for various lining thicknesses poured with Mix A:

Table 2. Mix A pouring guidelines.

Tunnel final lining thickness	Max allowed concrete temperature at delivery	Expected time (from the end of pour) to achieve 10 MPa within the tunnel lining
≤700mm	32°C	13 hours
>700mm	28°C	15 hours
≤900mm	28°C	15 hours
>900mm	23°C	17 hours
≤1100mm	23°C	17 hours

These results were compiled in a thermal study report shared with the construction teams and used as a planning tool for the pours on site.

For the actual construction phase a maturity calculation tool was built, based on a preliminary equivalent age/strength calibration phase. The construction teams were trained to use the tool, which would allow them to determine their striking time.

Initial monitoring of the pours was implemented with thermocouples placed at the core and at 50-100mm of the surface, to control peak core temperature and temperature differential, and to determine surface concrete strength for striking with the maturity tool.

After validation of the predictive modelling for core temperature and temperature differential, only surface temperature was monitored on subsequent pours for the site teams to determine exact striking time at 10MPa, to enable construction cycles optimizations.

The maturity tool formulas calibration was verified every 6 months by crushing cylinders kept at specific temperatures, at various ages.

3.2 Tunnel formworks

The construction of the Karanga-a-Hape station tunnels secondary lining necessitated the use of four

different sets of formwork. Different types of formwork were specified depending on the geometrical and logistical constraints as well as the number of pours and performance expected in the different tunnel sections. These four sets are summarised in Table 2 and described in the following sections.

Table 3. Summary of formworks sets.

Tunnel Section	Description	No.	Manufacturer
Platforms MC20 & MC30	Pre-stressed full section	1 unit + 3 junctions.	Tunnel Formworks International
Platform MC21	Crown	1 unit + 1 junction.	Liando Tianjin
Adits A1, A2, A3 & A5	Separated Crown and Sidewalls	2 sets	Liando Tianjin
Adit A4	Separated Crown and Sidewalls	1 set + 1 junction.	Liando Tianjin

3.2.1 Platforms formwork

A single formwork system was designed to build all the platform tunnels and adapt to the 3 different sections existing along the alignment. This was only possible due to the early involvement of the construction team in the design process which allowed the tunnel sections geometry to be refined so to optimise the need for formworks.

The basic principle was to keep the geometry of the sidewalls unchanged and to extend the section by inserting straight extension pieces in the crown (Figure 5).

Figure 5. Platform tunnel sections.

The key elements which had to be considered were:

- The total length of the formwork: This was dictated by the width of the junctions with the connection adits as the junction must be poured in one go. This meant the initial 10m maximum pour length considered in the design had to be increased to 11.5m.
- The interface with the headwalls: This meant the whole gantry system had to sit within the extent

of the formwork and the end access platforms had to be easily removable.

- The assembly constraints: The maximum size and weight that can be transported to site, lifted down the shaft, transferred to and from the assembly location and lifted in place had to be determined early in the formwork design process.
- The transformation methodology: The design of the system had to take into account all the temporary stages so the assembly was stable throughout the transformation process. Due consideration also had to be given to the size and weight of the elements in relation to the space and handling constraints at the time of their installation and removal. The elements involved in a transition are shown in Figure 6 and Figure 7
- The minimum traffic gauge: The minimum gauge through the gantry to allow site traffic and services.
- The position of the concrete ports and vibrators: The concrete windows and ports were spaced so to ensure the maximum concrete drop would not exceed 2.0m (Figure 8). The compressed air vibrators were placed according to their radius of influence and the thickness of the lining.
- The desired performance: Since the main formwork was due to build approximately 350lm of tunnel lining in 33no. bays, the cycle time required to strike, tram and reset the system was of prime importance to achieve the construction programme. To make this process as efficient as possible, all the movements were operated hydraulically. This included:

- Bogies on rails
- Hydraulic legs for vertical adjustment
- Horizontal rams for horizontal of the whole form structure on the gantry
- Hydraulic rams to operate the corbel shutters
- Hydraulic props to operate the side skins
- Hydraulic pins to lock the props in place
- Pre-stressing jacks at the end of the props

Figure 6. Platform tunnel formwork exploded view.

Figure 7. PT form during transition (central section about to be inserted).

Figure 8. Developed view of skin vibrators and windows.

3.2.2 Junctions formworks

The formworks add-on required to form the junction of the main tunnels with connection adits were included into the same scope to ensure the best compatibility of the systems. Although efforts were made to standardise the junctions as much as possible, the different section types and levels meant that 3 junction formwork types were required to build the five junctions (Figure 9).

3.2.3 MC21 cavern formwork

The formwork of the MC21 cavern was developed giving attention to the same consideration as described in 3.2.1, however the solution was very different as the constraints were different. The main differences were:

- **The length of the cavern:** The cavern was only 33m long and took only 3 pours and did not need any reconfiguration. This meant the design was kept as basic and economic as possible with no hydraulics involved. All the skin movements were operated manually using turnbuckle props.

Figure 9. Junction formwork.

This resulted in longer cycle times during construction but was balanced by the reduced assembly and commissioning time required.

- **The assembly constraints:** Due to the large 14m wide section of the cavern to be built, the space available for the assembly was less of a constraint, meaning larger individual elements could be handled which sped up the assembly.

Figure 10. MC21 formwork.

3.2.4 Adits formworks

The station comprises 5 connection adit tunnels (Figure 11), relatively short in length and with some distinct features such as junctions and corners (Table 4).

During the design phase, the section profiles AD1 and AD2 were optimised so they use the same radii and only differed in height. This allowed the development of a set of formworks which could be used in 4 of the 5 adits. However, it was not possible to rationalise the section of Adit A4 and so a specific set of formworks had to be procured for this location.

Figure 11.3D. View of adit A3, A4 and A5.

Table 4. Summary of tunnel adits sections.

Adit	Section	Length	Unique feature (s)
A1	AD2	34m	-
A2	AD1	11m	-
A3	AD2	30m	Junction with A4
A4	AD3	15m	Corner and junction with. A3
A5	AD2	20m	Corner

Figure 12. Adit sections AD1 and AD2 geometry.

The key elements considered during the procurement of the adit formworks were:

- **Mobility:** Since the adits were relatively short, it was identified that an important part of the effort would be spent in assembling, transferring and transforming the formwork elements.
- **Repeatability:** The formworks' design aimed at reusing the same parts as much as possible, minimising the need for special single use pieces.
- **Durability:** The system had to be simple and robust so it could be used for a number of pours over several months with minimum maintenance.

With these considerations in mind, it was decided to use steel formwork and to split the pours between sidewalls and crowns, resulting in smaller formwork elements that could be pre-assembled at the surface and transferred between adits.

The sidewalls were cast in 4m-long bays using 2m-long modules connected. The reaction frame allowed the skin to tilt to adjust to the different tunnel profiles. Two specific corner pieces were designed to build the corner in Adit A5.

Figure 13. 4m Sidewall Formwork.

Figure 14. Sidewall formwork reconfigured in inner (top) and outer (bottom) corners using insert pieces.

Figure 15. Junction between adits A3 and A4.

For the crown, two 5m-long formworks were procured. They featured a hydraulically operated gantry which allowed tramming as well as vertical and lateral adjustments.

The two modules were designed with a triangular removable section which allowed the system to be reconfigured in a corner setup with minimal need to extra components as shown on Figure 7. All the skin pieces were reused and only a few specific supporting beams had to be manufactured. These removable sections were broken down into small elements to help with the handling in constrained spaces during the reconfigurations.

Figure 16. Crown formwork reconfiguration.

A dedicated set of formworks were developed for adit A4 following the same principle. Junction additions were also designed to build the junction between adits A3 and A4.

Figure 17. Adit A4 Crown formwork skin during manufacture with corner and junction piece.

4 CROSS-PASSAGES DESIGN

4.1 Primary and secondary lining design

The primary lining comprised a 125mm shotcrete shell (sprayed in two passes) and the secondary

Figure 18. Adit A4.

lining was a 300mm thick traditional concrete section. Similar, to the typical cross sections away from the junction in the station tunnels both layers were designed as unreinforced concrete sections using well documented methods.

4.2 Collar design

A relative innovation in the collar design and construction was the removal of the need to temporarily support the cross passage openings with lintels. This was achieved by reinforcing the first stage concrete in front of the cross passages and anchoring it to the bored tunnel segments.

Figure 19. Reinforcement for first stage concrete and cross passage opening without lintel.

5 CROSS-PASSAGES CONSTRUCTION

An overview of the cross passage construction sequence is as follows:

1. Probe drilling
2. Saw cutting the segments
3. Removing the segments

4. Excavating in 2m steps
5. Shotcreting
6. Secondary lining pour
7. Collar reinforcement placement
8. Collar pour.

The collars were fixed at 90 degrees from the bored tunnel intrados and the secondary lining formwork only allowed for perpendicular stop ends. As such, additional concrete sections were required between the collar and the secondary lining to fill the gap (Figure 20). The collar formwork and stop ends could comfortably be adjusted to create the angles created (Figure 7).

Figure 20. Collar and secondary lining arrangement.

Figure 21. Collar form meeting cast secondary lining section.

6 CONCLUSIONS

Early contractor involvement during the detailed design of the secondary linings facilitated a formwork selection process that sped up construction. This was mainly due to formwork that could be enlarged on site to form different profiles. Whilst the adaptation of formwork on site can be logistically and labour intensive it is preferable to having bespoke formwork for each tunnel profile.

The use of BIM to produce 3D sequencing drawings was commonplace on this project and was

a valuable tool in conveying construction methods to everyone involved in the operations.

Cross passage openings are typically formed with lintels above and below the opening and jambs either side. This typically involves lifting and fixing steel sections in a confined working environment. However, reinforcing the first stage concrete in front of the cross passages removes this risk. Moreover, in this instance a separate team could carry out this task whilst the mining team was utilised elsewhere.

Experiences during tunnelling in extreme ground conditions in the Himalayas - Excavation of Rohtang Tunnel, India

Radek Bernard*

SG-Geotechnika a.s., Prague, The Czech Republic

ABSTRACT: The 9,02 km long, single tube, two-lane bi-directional Rohtang Highway Tunnel through the Himalayas was finally opened on the October 2020. It was constructed at an elevation near 3.100 m above the sea level. This tunnel, which is still one of the longest highway tunnel of the World at such altitude, is also known by its complex and challenging geotechnical conditions, which unfortunately caused significant delays for the completion of the construction. Finally construction works takes approx. 10 years from the start of 2010 till the end - autumn 2020. Rohtang tunnel shortens the Manali–Leh Highway (NH 21) by about 50 km and should provide a route between Himachal Pradesh State and the union territories in Jammu and Kashmir over the whole year in the future, once further tunnels on this route will be completed.

Keywords: Drill & Blast, long tunnel, high overburden

1 INTRODUCTION

The Rohtang Tunnel (after opening new name added – The Atal Tunnel) is a highway tunnel located in the eastern part of Himalayas in the North Indian state of Himachal Pradesh. The tunnel was excavated from both directions by the Drill and Blast method with application of the NATM philosophy. From the South Portal, near to Manali, practically all-round year and from the North Portal, between Sissu and Khoksar (Lahaul & Spiti Valley) only approx. half year (summer season).

The project was constructed by FIDIC principles according to the Red book. The Contract was awarded to a joint venture of AFCONS, an Indian construction company and STRABAG (Austria). The design of the tunnel was provided by a Design Consultant SMEC International (Australia) and proof checked by a joint venture of 3G (Austria) and VAYAMTECH (India). Construction supervision was ensured by a joint venture of D2 Consult International (Austria) and ICT-PEMS (India) acting as an Engineer. Author of this article worked at this organization as a Leader of supervision party that time. The Rohtang tunnel is single tube as shown at Figure 1, with two 4 m wide bi-directional lanes, walkways and emergency egress channel located below the road structure 3,6 m wide and 2.25 m high precast escape channel, which connects both portal areas is accessible every 500 m through a stairs in niches.

The tunnel is horseshoe shaped with completed regular cross section of 75.9 m², and increased at the section of Seri Nallah fault zone constructed with deep invert (587.5 m long). Separated smoke duct is located at tunnel crown area allowing emergency ventilation. The tunnel lining is double shell with intermediate waterproofing membrane installed only in Seri Nallah section. The rest of the tunnel is sealed within construction joints by swelling tapes. Groundwater is collected by longitudinal drainage pipes. Primary support consists of shotcrete lining with wire meshes and lattice girders or steel fibre-reinforced shotcrete lining with lattice girders (in technological classes I. to III. without lattice girders). Self-drilling and/or Swellex rock bolts were used for radial rock bolting, spiles in the crown area as required. Final lining was made of cast-in-situ plain concrete, except Seri Nallah section and locations around large niches, where reinforced concrete was used.

1.1 Basic features of the project

Basic features of the project you can see on Table 1.

2 GEOLOGICAL SITUATION

The Rohtang tunnel is located in Higher Himalaya and about 100 km south of Indus Suture Zone (Indus

*Corresponding author: radek.bernard@geotechnika.cz

Figure1. Cross section of Rohtang highway tunnel.

Table 1. Main characteristics of the project.

Part of the Tunnel	Characteristic
Invert elevation at SP	3.060 m asl.
Invert elevation at NP	3.085 m asl.
Regular cross sectional area	75.9 m ²
General slope	0.5%, ascending from both portals
Finished dimension	Approx. 12 m wide at tunnel road level
Tunnel shape	Modified horse shoe
Concrete final lining	Cast in situ concrete
Smoke duct	At tunnel crown, above carriageway
Drainage system	Collect seepage water on side walls
Roadway	8 m wide with two lanes (1 m walkway)

Tsangpo Ophiolite belt). The project is situated in Rohtang Axial zone, which has a NW-SE trend, which divides the drainage system of Chandra river in the north and river Beas in the south with following tectonic features. The major tectonic feature separate the Lahaul-Spiti segment of the Spiti-Zanskar basin from the Tandi basin and also the Chamba-Bhadarwah basin and represents crystalline core with doubly plunging disposition.

This zone has the elements of mantled gneiss exhibiting anataxis and migmatization and underlies the Infra cambrian sediments. The overlying sedimentary sequence and its metamorphosed basal part are welded to the crystalline basement and it forms the root zone area of the Salkhala Nappe. The area is always covered by snow on the top with valleys and valley slopes having thick cover of vegetation. Seri Nalla is a significant stream which crosses the alignment and joins Beas Kund nala at about 1.8 km downstream of the South portal site. The general drainage pattern of the area encompassing the project site is sub-parallel and is structurally controlled. The South and North portal of tunnels are at elevation 3060 m and 3085 m respectively. The general strike of foliation of

these folded and faulted mountains is NW-SE. In general the average trend of dip direction and amount of foliation of these rocks is 220/350° along with three major joints and one random joint. The main lithological rock units are Phyllitic quartzite, Quartzitic Phyllite, Migmatitic gneiss, Phyllites and Biotite Mica Schist. Geological profile is shown at Figure 2.

Figure 2. Longitudinal geological profile from design.

In general, the average trend of dip direction is 220° and plunge of foliation of these rocks is 350° along with three dominant joints planes and one random joint plane. Maximum overburden of the tunnel reaches 1860 m near chainage 6+000. The most complex and complicated geological condition was found in Seri Nallah fault zone within chainage 1+900 to 2+450 with maximum overburden 300 m located under small river valley as written above. The tunnel drive of Rohtang Tunnel was divided by design into six segments, based on the overburden depth primarily for the support system, see Table 2.

Table 2. Classification of tunnel based on overburden depth.

Segment	Overburden Depth (m)
I	0 to 300
II	301 to 600
III	601 to 900
IV	901 to 1.200
V	1.201 to 1.500
VI	> 1.500

3 TUNNELLING WORKS

The tunnel was excavated with horizontal excavation sequence. Tunnel face was divided into top heading and bench. To reach breakthrough of the tunnel as soon as possible, the highest priority was given to the top heading excavation. Therefore, in case of any machinery or labour reduction, all available resources were shifted to the top heading face, even at the cost of interruption benching works. That is why bench was excavated after breakthrough more than 1 km behind the top heading from both directions. Taking

into account the total length of almost 9 km accessible only from two portals, it was clear that proper planning and organization of all tunnelling works together with effective logistic was a key factor for construction schedule of the tunnel. Construction site on the South portal you can see on the next Figure 3.

Figure 3. Rohtang's construction site at the South portal – more than 3000 m above the see.

That means independent working areas for all tunnelling main works throughout the tunnel, which included top heading excavation, half sided bench excavation, main tunnel drainage and concreting of base slab, concreting of first kicker (lower part of final lining slightly above the road level), installation of pre-cast emergency egress structure, concreting of second kicker and backfilling works up to the road level, installation of cable ducts and concreting of walkways, concreting of final arch lining, reinforcement and concreting of ventilation slab. In addition, there were other independent works on tunnel niches and on both tunnel portals. Construction of road structure and E&M works had to be completed afterwards. The Rohtang tunnel breakthrough was finally reached after 7 years from beginning of works on 15th of October 2017, directly at chainage 5+000 m. Breakthrough of the top heading brought many advantages for the rest of tunnelling works, especially with respect to a considerable length of the tunnel and limited access to the North portal. Firstly, all north portal works became accessible through the tunnel from south, which enabled in case of need direct material supply from large construction site near the South portal. It must be noted that south portal was more accessible and less affected by weather/climate condition than north portal. This logistic connection was successfully used mainly during winter period when operation of north portal construction site was significantly limited. It means breakthrough finally enabled to continue concreting works in full swing during winter period. On the other hand, considerable increasing of the traffic inside the tunnel was disturbing the rest of tunnelling works, mainly in Seri Nallah fault zone and benching

stretches. Very positive impact to the all construction steps had the fact, that after the breakthrough natural tunnel ventilation was created, so all tunnel ventilation ducts could be removed. It enabled start of all re-profiling works and further excavation works in Seri Nallah fault zone, where huge ventilation ducts occupied almost all cross section. Moreover, due to natural ventilation, temperature inside the tunnel dropped from 36°C at the tunnel face to nearly natural temperature from outside.

3.1 Tunnel excavation from South Portal in detail

Tunnel construction from the South portal started by top heading excavation in August 2010, using mentioned Drill and Blast method. Top heading excavation had more than 1.000 m advance to bench at the beginning. Predominantly quarzitic schists with bands of phyllitic quartzites and phyllites with occasional seams of carbonaceous phyllites were encountered till chainage 1+900 during the first 18 months. No major problems occurred during initial drive from the South portal to Ch. 1+900, except for minor dripping of water and occasional wedge failures, which were easily managed by the Contractor. When tunnel excavation reached approx. Ch. 1+900, adverse shear zone, consisting of clay with minor rectangular fragments of quarzitic schists, charged with water was encountered 10° oblique to the tunnel axis from western side of excavated face at beginning of year 2012. Initial water inflow of 2 – 2.5 l/s was recorded. The fact of that shear, later very big fault zone called Seri Nallah, was confirmed for several hundred meters. The Q value of rock excavated determination was only around 0.5 indicating “Very Poor” rock condition. Accordingly, the rock support was immediately changed from more favourable rock classes to RC 6, later to RC 7 (the worst designed RC). You can see in Table 3 how Q values were divided and proposed RC at this project according design.

Table 3. Classification of tunnel based on Q value according design.

Serial No.	Condition	In situ “Q” - value	Excavation RC
1.	Good	> 10	1
2.	Fair	4 – 10	2
3.	Poor	1 – 4	3
4.	Very Poor	0.4 - 1	4
5.	Very Poor	0.1 – 0.4	5
6.	Exceptionally Poor	0.001 – 0.01	6 or 7

From Ch. 1+911 to Ch. 1+918 large deformation of primary support system was observed. Within 24 hours significant cracks were developed in the shotcrete of the primary lining, widths between 50 mm

and 300 mm were noticed. Deformations of primary lining also sharply increased and exceeded the amount of 500 mm. Immediately necessary measures were taken to prevent the collapse of the primary lining. From Ch. 1+904 to Ch. 2+049, the encountered rock condition featured highly jointed and sheared variously weathered quartzitic phyllites with a number of shear seams along and across the bedding planes. With ongoing excavation, geology slowly changed along the tunnel profile from rock to highly fractured, loose rock, (nearly soil condition). Rock condition changed from RC 1 with Q value ~ 20 (as determined/predicted in the tender document) to RC 6 (or 7) with Q value distinctly less than 1.

As already mentioned, the most difficult part of south drive was overcoming of the Seri Nallah fault zone with many large water inflows and frequent ingresses of loose river borne material inside the tunnel. Several types of remedial actions were implemented: dewatering pipes installation, single and multistage grouting using rock bolts, sequential excavation with top heading division into small panels and immediate support using shotcrete, wire meshes and rock bolts, single/double pipe roofing, temporary invert of top heading. Pilot tunnel and PU grouting were also used with no success. A total of 42 pipe roof umbrellas with single or double rows and length with 9, 12 or 15 m were installed within the Seri Nallah fault zone. These pipe roof umbrellas had dia firstly 87 mm, then only 114 mm. In April 2012, at Ch. 2+049, a sudden heavy inflow of water was observed at the centre of the face. The initial discharge was estimated with approx. 5 l/s and during the coming four hours, water inflow increased to 30 l/s that time. That rapid increase of water flow was then followed by a blowout of material from the crown area. The washed out material consisted of pieces of rock, rectangular in shape ranging in size from 1 to 5 cm. This washout resulted in the formation of a cavity/loose zone on right side of the crown of tunnel profile. The volume of slurry washed out was estimated with up to 300 m³. As per the predictions of the geological studies and reports of the project should most probably have crossed the Seri Nallah Fault Zone near Ch. 2+200. However, these predictions also indicated that extensions of the fault zone could be expected. And further that due to the very shallow dipping angle of geological formations and the fault zone itself, earlier influence on the tunnel construction could be assumed. The surface study of the geological features and their correlations with geological features encountered at tunnel level (Ch. 2+049) indicated that this problem was not related only to the Seri Nallah fault, but was reflected especially due to another lineament crossing the tunnel alignment at this location. This statement is also in agreement with the fact that as per studies undertaken earlier, the Seri Nallah fault is the contact between quartzitic/phyllitic schist and the magmatic rocks. The Seri Nalla itself is one of the minor tributaries of Beas River, which is joined by several other

small perennial cross drainages in the vicinity of the tunnel alignment at the surface. After stabilisation of the tunnel face, another major blowout occurred during tunnel construction at Ch. 2+076 on 7th September of 2012. Crushed material mixed with water and slurry of about 1.000 m³ filled the tunnel from the crown area, creating another cavity/loose zone. The geological profile of that section indicated that the surrounding rock massif was heterogeneous in nature and mainly consisting of alternating bands of moderately to thinly jointed with a number of shear zones varying in thickness from 0.1 to 2 m. To stabilise the area, contact and cavity grouting was executed at Ch. 2+048 to Ch. 2+071 with 6 m long self-drilling rock bolts around the tunnel periphery (between 10 to 2 o'clock). The total grout consume was about 135 tons. After tunnel face stabilization, core drilling was carried out by using a diamond core drilling machine (4 boreholes 15 to 30 m long). Interpretation of core drilling indicated that the zone of dilated rock mass was created above the tunnel by the intersection of shear zone, which together with the high amount of water resulted by flowing conditions of the rock material. No major cavity was found during that investigation. After passing the tunnel section between Ch. 2+049 to Ch. 2+085 with heavy support by double pipe roof umbrellas, tunnelling conditions continued to be still difficult. Construction of the upcoming 406 m tunnel meters (between Ch. 2+049 and Ch. 2+455) took more than 3 and half years. The presence of this weak and water bearing Seri Nala zone in highly sheared rock resulted in the formation of dilated material zone above the crown of the tunnel, which was slowly shifting to the left side the further tunnel excavation continued. In summer 2014 water inflow to tunnel profile increased approx. to 85 l/s and beginning of year 2015 the total water inflow reached 100 l/s, resulting in a lot of material wash out occurred at the tunnel face, which had to be solved by mentioned remedy actions. Also, a change of material composition was noticed. The highly fractured and shared material that was encountered in the beginning of the Seri Nallah stretch slowly gave way to so called river borne material (RBM), at least partially rounded rock fragments of different origin not necessarily related to the rock at/ or close to the tunnel face. Figure 4 shows the situation at Ch. 2+390. That day huge volume of loose material with water came to the tunnel by excavation from left side of the Top heading.

To stabilise the crown area and left side firstly 76 mm dia, then 89 mm dia pipe roofing were carried out, which unfortunately could not undertake the load of disturbed rock massif and it failed. Then 114 mm dia pipe roofing installed and it has also failed at some pipe roof stretches. Finally double layer skin to skin pipe roof 114 mm dia, 15 m long perforated pipes, including 76 mm dia drainage pipes up to length 24 m were installed at critical area from Ch. 2+413 till Ch. 2+445 as shown on the Figure 5. Perforated pipes were of course used for

Figure 4. Material wash out at top heading in ch. 2+390 dated 30/08/2014.

optimal grouting procedures of surrounding massif. The highest inflow 102 l/s of water was observed from Ch. 2+403 onwards till passing the Seri Nalla Fault Zone. At the start of the year 2016 regular rock massif was finally encountered.

Figure 5. Installation of double pipe roof umbrella with dia 114 mm at the stretch of 2+413 to 2+445.

3.2 Tunnel excavation from North Portal in detail

Tunnel excavation from North Portal (NP) was found much different compared to the South. The overburden was much higher and tunnel drive went through hard rock formation for the most part of that stretch. Weather conditions allowed working during procedure max. 6 to 7 months per year, depending on the snowfall. North drive included rock bursting and squeezing condition during excavation with overburden reaching almost 1.9 km, caused large convergences over 20 cm and extensive cracks of primary lining. Due to delayed release of rock mass stress, convergences were decreasing very slowly till stabilization of profile usually more than 100 m behind the tunnel face. Proper timing of rock bolting was very important as well. Additional rock bolting (Swellex) perpendicular to the rock foliation was regularly used

immediately after application first layer of primary lining to reduce convergences. Primary lining showed significantly cracking, while excavating through subhorizontally laid migmatite gneisses with alternate bands of thinly foliated mica schist, dipping in tunnel drive direction with high overburden. Slots as one optional solution were used at this part of the project. The reason was that shotcrete cracking in the primary lining developed behind the tunnel face of the Top Heading with a delay of approx. 10-15 m in the crown, between 12 o'clock and 1 o'clock position. The monitoring profiles were stabilized approx. 100 to 130 m behind the tunnel face. To overcome the difficult stress conditions, mentioned slots were predominantly used with positive reaction of the primary lining. Slots are actually gaps of a primary lining with width of approx. 50 cm, with only 1 layer of wire mesh and thin layer of shotcrete. This tool enabled the rock mass to release stress by allowing deformations through closing of the gap and preventing damages of the primary lining. Having slots to get stress release had nevertheless negative effect on lattice girders, which were kinked and have distorted the integrity of the shotcrete shell. Consequently, the shotcrete shell got also cracking accordingly same time. Such negative effect accompanied by an increased deformation behavior of the primary lining was usually eliminated by using another tool of our Himalayan tunneling. So, when above mentioned slots did not ensure sufficient primary lining, the Engineer instructed to use lining stress controllers (LSC), which could ensure the shotcrete shell integrity, but it was more expensive instrument. One row of the Slot in the primary lining located approximately at 1 o'clock is shown on Figure 6. Successful utilization of two rows LSC under overburden about 1.800 m can be seen at Figure 7.

According to Table 3, tunnelling condition were usually classified as "Fair" or "Poor" there and the rock formations composed of high grade of metamorphic migmatite. The variation of migmatite

Figure 6. One row of slot in the primary lining behind tunnel face of the top heading, NP at July of 2017.

Figure 7. Two rows of LSC, then 1 row of LSC close to tunnel face of top heading, NP at July of 2015.

includes micaceous gneiss, magmatic schist or phyllites with a significant proportion of quartzite.

Following chart on Figure 8 summarizes yearly progress of top heading excavation from both portals till the breakthrough. After 10 years of hard-won progress, the completed tunnel was opened to the traffic on 3rd October of 2020. The South Portal of the tunnel one day prior opening can be seen on Figure 9.

4 CONCLUSIONS

The young Himalayan Mountains with their complex geology and such geotechnical conditions do always

hold surprises during tunnel construction. From the examples of Rohtang Tunnel shown in this article, it is clear that not only careful and as detailed as possible geological investigations are required prior and during the execution of the project, but the same also needs to be done with concentrated attention of all parties involved in the project, namely Contractor, Engineer, Designer and Client. Only combined efforts throughout all different project stages (Feasibility study, Design, Execution and Implementation) will provide the necessary flexibility of the construction process that allows instant and immediate reaction to changing geological and geotechnical conditions. The all parties of this project are definitely happy that Rohtang/Atal Tunnel was finally opened approx.. after 10 years in the Autumn 2020. The following fact added a certain prestige and uniqueness to this project. In conclusion, the author can note with great pleasure and pride that this project was awarded in the category “Outstanding Large Project of the Year” on the global conference of the international organization FIDIC, held in Geneva from 11th to 13th September of 2022.

ACKNOWLEDGMENTS

The author thanks to the Employer and especially to the client for possibility to work on such challenging project in Himalaya and also thanks for consent to publish this article at international congress - WTC.

The impact of ramp width on tunnel face stability during ramp excavation

Qi Chen* & Ying Cui

Yokohama National University, Yokohama, Japan

ABSTRACT: When excavating a tunnel using the short bench cut method of NATM, the top heading of the tunnel cross-section is excavated first; then, the bench simultaneously follows several to tens of meters behind. A ramp is maintained to access the top heading from the bench. Tunnel failure has been reported during ramp excavation, with the unsterilized side wall of the ramp being considered one of the contributing factors. Additionally, the width of the ramp is a significant factor that influences the stability of the tunnel face. Hence, a comprehensive investigation into the influence of the ramp excavation on the stability of the tunnel and the surrounding ground, as well as the impact of ramp width, was conducted through a combination of two-dimensional experiments and corresponding DEM analysis.

An experimental setup involving an aluminum laminate apparatus was employed to visually observe the response of the surrounding ground during tunnel excavation. A semi-circular acrylic cylinder was used to simulate the support for the top section of the tunnel. The excavation was modeled by directly removing the aluminum rods. After maintaining the unchanged conditions following the excavation of the top heading, the ramp was excavated with various widths to investigate their effects on the ground and the support system. Furthermore, corresponding DEM analysis was conducted to investigate the mechanisms underlying the results obtained from the model experiment.

Both experimental and analytical results indicate that the failure mode during ramp excavation is recognized as the bearing capacity failure due to the loosening of the surrounding ground with the ramp excavation. Further, this result indicates significant deformation occurring at a shallower depth for a wider ramp compared to other cases.

1 INTRODUCTION

Various tunneling techniques presently employed encompass conventional mining methods, the New Austrian Tunnelling Method (NATM) (Takasaki, 1996), the tunnel boring machine (TBM) method, and the cut-and-cover method. The selection of a specific tunneling method is contingent upon diverse factors, including the thickness and strength of the surrounding rock, groundwater conditions, and construction constraints. In the context of mountainous highway construction, the unpredictable presence of unidentified obstacles and intricate geological conditions frequently necessitate prompt adjustments during excavation. Mining methods are commonly utilized in mountain tunnel excavation owing to their ability to provide real-time geological information from the excavation surface. Moreover, the New Austrian Tunnel Mining (NATM) method, categorized as a mining method, leverages the mechanical properties of the soil to withstand external soil pressures. This methodology facilitates the implementation of suitable excavation and

support techniques, presenting substantial economic advantages. Consequently, the widespread adoption of the NATM method is observed in tunnel construction projects situated in mountainous regions.

In mountain tunnels constructed using the NATM method, the step excavation technique is commonly employed for both excavation and tunnel support. This method entails dividing the tunnel into upper and lower sections, which are systematically excavated in stages, creating a distinct separation known as a “bench.” In scenarios where the surrounding rock exhibits considerable strength, a longer step length may be utilized to facilitate the operation of construction machinery. However, challenges arise during the excavation of the upper section, particularly when encountering loose soil, leading to the generation of earth pressure (Akutagawa et al., 1998). This pressure can induce deformation and settling of the tunnel support structure. Consequently, when confronted with weak rock strength or expansive soils, it is preferable to adopt shorter step lengths. This approach aids in minimizing the risk of tunnel support

*Corresponding author: chen-qi-yp@ynu.jp

deformation, particularly in the upper section of the tunnel (Nakano et al., 2010). To address the transportation of excavated soil and waste materials from the upper section and facilitate the movement of construction machinery, a connecting passage or ramp is typically excavated between the upper and lower sections. Notably, instances of tunnel collapse or support damage in the ramp section are prevalent in tunnel construction, as evidenced in the construction of the Hokuriku Shinkansen, as reported by JR TT (2017).

The influence of the width of the ramp connecting the upper and lower sections on tunnel support remains unclear. Therefore, gaining a comprehensive understanding of the impact of ramp construction and its width on geological conditions and support is imperative for designing an appropriate tunnel excavation method.

In this study, two-dimensional simulation experiments were carried out for upper excavation and ramp excavation of a specific soil section with short steps in a tunnel using aluminum bar aggregate and an acrylic tunnel lining model. Discrete element numerical simulations were also used. The aim was to investigate the effect of ramp excavation on tunnel support and geological conditions, as well as the effect of ramp width. Regarding established studies, many researchers have conducted simulation experiments on excavated tunnels in soft, unconsolidated strata.

Murayama et al. (1971) conducted trapdoor experiments using laminated aluminum rods to explain and discuss the arching effect of tunnel earth pressure. Kikumoto (2005) also conducted trapdoor experiments using laminated aluminum rods. They found that the earth pressure acting on the tunnel support foot (around the trapdoor) converged to a constant value after excavation.

Adachi et al. (1985) buried a variable-diameter metal cylinder in layered aluminum bars and gradually reduced its diameter to simulate ground loosening during tunnel excavation. They investigated the effect of ramp excavation, which couldn't be simulated by trapdoor experiments. They addressed the drawback of trapdoor experiments, where the discontinuous contact point with the fixed plate becomes a singularity. Their conclusions were as follows: the loosening zone develops rapidly above the upper edge and eventually extends below the spring line. The loosening zone reaches the surface when the soil cover is shallow but decreases as the soil cover increases.

Sakurai et al. (1994) reproduced the soil loosening phenomenon by placing an airbag in stacked aluminum rods and reducing the pressure inside the airbag. They assumed the pressure inside the air pocket to be the minimum support pressure required to sustain the mountain's deformation, and they measured the loosening load. They elucidated the discontinuous surface of the stacked aluminum rods where abrupt changes occurred inside.

In Koike's experiment (2020), a semicircular tunnel lining model was embedded in stacked aluminum rods with a hollow interior of the support, and

a small number of aluminum rods were withdrawn from the ground below the lining model to obtain ground settlement and deformation of the support structure. The following conclusions were drawn from the experiment: a) Continuous removal of aluminum rods in the ramp results in the formation of a slip line between the support foot and the excavation position, leading to tunnel settlement. b) Among different excavation widths, wider excavation is more likely to cause settlement than narrower excavation.

This study delves into a spectrum of ground behaviors, extending from upper excavation to ramp excavation, a subject hitherto unexplored in the existing literature. Diverging from Koike's research, our study incorporates a novel approach to upper-section excavation, integrating the burial and removal of aluminum rods within the support structure. Furthermore, in alignment with insights from prior research, this study interprets soil damage around the tunnel as a discontinuity problem. Consequently, we employ the Discrete Element Method (DEM) for numerical analysis, recognizing its suitability for simulating model tests in this context.

2 MODEL TEST

2.1 *Laboratory model test*

In this study, experiments were conducted utilizing a model featuring a half-cylinder buried within laminated aluminum rods. The primary objective was to elucidate the behaviors of the ground in two distinct phases: the excavation of the upper section of the tunnel and the subsequent excavation of the ramp. Notably, this research delves into the discussion of the influence of the ramp's width, maintaining consistent testing conditions across all cases during the upper-section excavation phase.

2.1.1 *Soil particles for surrounding ground*

This experiment simulates the tunnel excavation in loose sandy soil. Aluminum rods have a close density with sand soil. The length of the aluminum rods is 50 mm, and they were piled up to create a ground with a two-dimensional plane strain state. Two types of aluminum rods with diameters of 1.6 mm and 3.0 mm were combined in a 3:2 weight ratio and compacted to maintain a constant density across the entire area.

The unit weight of the aluminum rod laminate area was set to 21 kN/m³, referring to the previous research that used the same aluminum rods (Kikumoto, 2005).

2.1.2 *Lining model*

Figure 1 illustrates a schematic diagram of the acrylic lining model employed in this experiment. The front of the lining model is marked with colors to facilitate the measurement of the deformation of the lining. Load cells were positioned within the foot recesses to measure the vertical loads exerted on the individual support foot of the lining.

Figure 1. Schematic view of the lining model.

Figure 2. Two-dimensional trapdoor apparatus.

2.1.3 Experimental setup

Figure 2 represents an overview of the experimental setup. The base comprises 40 aluminum blocks, each 24.5 mm wide, arranged at 0.5 mm intervals. Ball bearings between adjacent blocks minimize vertical friction from block collapse. Load cells attached to the bottom of each aluminum block measure the vertical load. A tripod-mounted video camera captures images of tunnel and ground behavior during excavation.

Figure 3. Experiment process.

2.1.4 Experiment procedure

Figure 3 illustrates the experimental process. Initial values of foot load and bottom load are measured before loading. To achieve the specified unit weight, the required weight of aluminum rods per 50 mm stacking is calculated, and the specimen is leveled and compacted after each 50 mm stacking. After reaching a model foundation height of 100 mm, the acrylic lining model is placed, ensuring that both foot of the lining model are at the same height. Accumulation

continues until the depth of aluminum rods covering the upper part of the lining model reaches 200 mm, the same as one time the diameter of tunnel lining, as shown in Figure 3a. Table 1 shows the parameters of the model ground and aluminium rods.

Table 1. Aluminum bars' particle parameter.

Porosity	Density of particles [kg/m ³]	PSD(diameter)
0.22	2700	1.6mm:3mm = 3:2

The excavation process is modeled by removing the aluminum rods manually. Figure 3b shows the condition after the top section excavation. The top-section excavation involves removing aluminum rods from the top edge to simulate the excavation process, ensuring the inner surface of the model remains consistently horizontal. For every 40 grams of aluminum rod removed in the initial half of the excavation, ground load, and foot load are measured and documented through photography.

During ramp excavation, as depicted in Figure 3c, a photograph is taken for every 5 grams of aluminum rod removal, and bottom load and foot load measurements are conducted until the lining model's foot settles approximately 20 mm from its initial position. Despite settlement causing deformation in the width of the excavation ramp, the aluminum rod removal area is maintained within the pre-deformation width for the duration of the experiment.

To study the effect of ramp width in the lower section of the tunnel, experiments were conducted using the three conditions shown in Figure 4. All experimental conditions were kept consistent in the upper half until the end of the excavation. The experiments were grouped as follows in Table 2. During the excavation process, the ground bottom and foot load are collected for each step.

Table 2. Experiment cases.

Figure 4. Ramp excavation.

2.2 Outline of the DEM simulation

This study incorporates DEM to analyze the various behaviors of soil particles and tunnel models due to ramp excavation.

2.2.1 Simulation process

The DEM resolution process aligns with the model test, as illustrated in Figure 5. Initially, a soil body with the tunnel model is generated, and subsequent excavation is performed by removing particles. Excavation simulations are conducted separately for various ramp widths. Table 3 provides an overview of the simulation groupings for DEM. Unlike the experiment, the DEM simulations do not use a single removal of weight. For upper excavation, the process is divided into four steps, as depicted in Figure 5a, involving the removal of particles from the interior of the tunnel at 15%, 40%, 67.5%, and 100%. Ramp excavation, as shown in Figure 5b for DEM case 1, involves removing particles within a limited width of the interior tunnel surface at the end of the upper excavation, within a depth range of 0.5 cm, 1 cm, 1.5 cm, and so forth. In DEM case 2 and DEM case 3, particles within a limited width and depth range are removed in increments of 0.3 cm, 0.6 cm, 0.9 cm, and so on.

Figure 5. DEM simulation process.

Since the DEM depends on the parameters of the particles, it is necessary to calibrate the parameters of the two unintelligible materials. (Itasca, 2019)

2.2.2 Soil particle parameter

For calibrating soil particle parameters. In this study, a fitted biaxial compression experiment was used for calibration. The sketch of the experiment is shown in Figure 6 below. The biaxial compression experiment was carried out using an aluminum rod with a peripheral pressure of 19.6 Kpa and simulated. After several trials and errors, the parameters are shown in Table 4, and the fitting results as stress ratio (σ_1/σ_3) and void ratio are shown in Figure 7.

Figure 6. Bi-axial compression test equipment sketch.

Figure 7. Bi-axial compression test results comparison.

2.2.3 Lining particle parameters

Regarding the calibration of the tunnel model parameters, the cantilever beam compression and bending experiments and their simulations, as well as the uniaxial compression test simulations, were used. The sketch of the cantilever beam compression experiment is shown in Figure 8a, and the bending experiment and its numerical simulation were performed on an acrylic plate with the parameters shown in Table 5. The simulation of the uniaxial compression experiment is shown in Figure 8b, and the parameters are shown in Table 6. The results obtained after coupling these two experiments and simulations are shown in Table 7, Figure 9, and Figure 10. The difference in the results of the uniaxial compression test in 10 is neglected

because of the small stresses in this experiment and the fact that the axial direction of the tunnel model is mainly considered for force transfer rather than deformation.

3 RESULTS AND DISCUSSION

3.1 Verification of the simulation results for 4 cm width

3.1.1 Upper-section excavation

Since there is no variable in the upper excavation of each group, all the experimental results in this study should theoretically behave the same way at the end of the upper excavation. In the DEM, since there is no variable in the numerical simulation, only one set of results of the upper excavation process is taken for comparison with the experimental results. Figure 11 shows the stresses on the tunnel footing as the upper excavation proceeds.

Figure 11. Foot-load during upper excavation.

It can be seen from the figure:

- In the experiment and simulation, although the initial particle distribution is different, resulting in different forces on the left and right feet of the tunnel model, the initial average force on the left and right feet is the same.
- In both experiments and simulations, the force acting on the feet of the tunnel model increases and then decreases as the excavation proceeds.
- In the experiments, the average force acting on the tunnel feet before and after the upper excavation did not change significantly, reproducing the conclusion of Kikumoto (2005).
- In the simulation, the force acting on the foot after the end of the upper excavation is relatively large compared with the experiment, which may be due to the uneven distribution of particles in the numerical simulation.

During the upper excavation, the experimental case2 and numerical simulation results showed a slight foot settlement, as shown in Figure 12. This may be due to the uneven distribution of particles.

Figure 12. Foot settlement during upper excavation.

3.1.2 Ramp excavation

Figures 13 and 14 below show the force on the foot of the tunnel model during the excavation of a ramp with a width of 4cm and the variation of the settlement of the tunnel foot with the depth of excavation, respectively.

Figure 13. Foot load during ramp excavation [case2(4cm)].

Figure 14. Foot settlement during ramp excavation [case2 (4cm)].

The following tendency can be seen in the figure:

- Transient settlement damage occurred in the experiment when the excavation was up to 2.3 cm, and there was a sudden change in the force on the foot when the settlement occurred. Whereas in the numerical simulation, the settlement occurred with continuity. But the final settlement is consistent.
- Although the force on the foot changes when settlement occurs, it remains stable overall.

3.1.3 Discussion

The results of the DEM simulations are specifically analyzed in the next section. Figure 15 below shows the forced settlement at the toe of the tunnel and the change in porosity of the particles below the toe of the

tunnel during the tunnel ramp excavation. The porosity increased before the tunnel settlement occurred. The extent of porosity monitoring is shown in Figure 16. Figure 17 shows the contact force distribution of the soil around the tunnel at different stages. Considering the conclusions above, the damage mechanism of tunnel settlement can be concluded: due to the excavation of the inclined shaft, the porosity of the loose soil at the bottom of the tunnel increases, leading to a decrease in the supporting force (Terzaghi, 1943), and the development of a shear zone at the foot of the tunnel support eventually leads to damage.

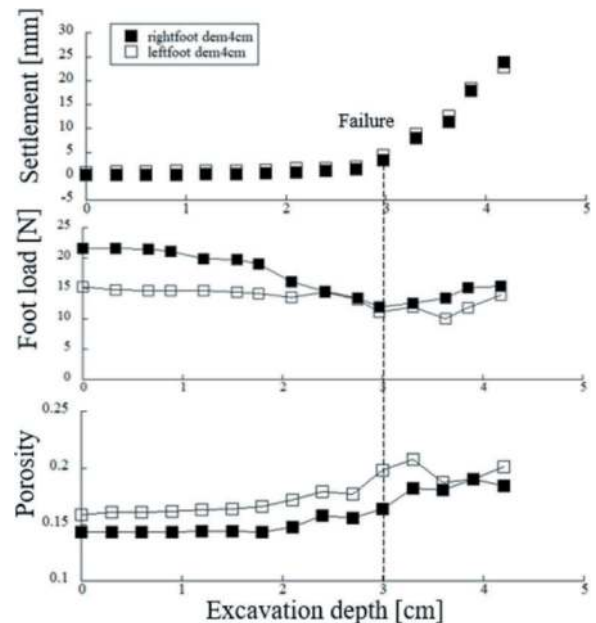

Figure 15. DEM results discussion of DEM case2.

Figure 16. Porosity analysis area.

Figure 17. Progress of the contact force (width 4 cm) a. initial state, b. after upper-section excavation, c. before failure, d. after failure.

3.2 Effect of ramp width

Figure 18 shows the changes in forces on the foot of the tunnel model, settlement, and porosity of the soil underneath it as excavation proceeds for each ramp width in the DEM numerical simulation result.

Table 8. Contact force for various width.

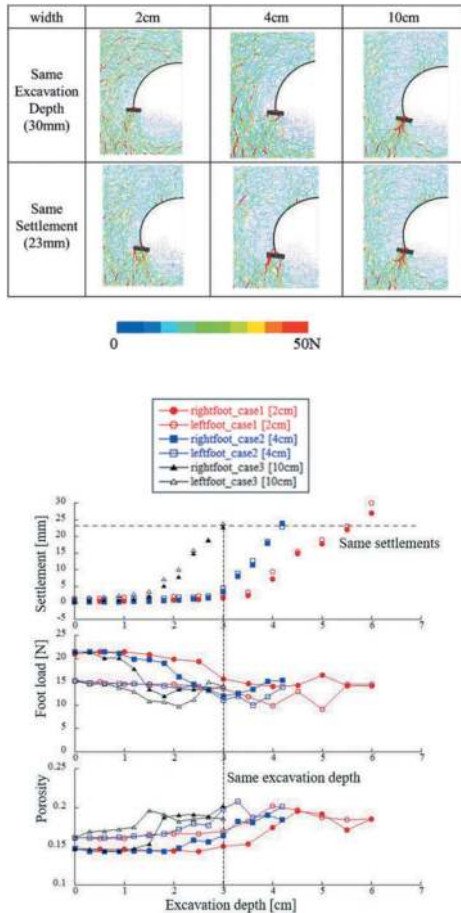

Figure 18. DEM results for various ramp width.

It is clear from the figure that the wider the ramp, the smaller the excavation depth. Table 8 compares the soil contact forces for the same excavation depth (30mm) and the same lining settlement (23 mm). It can be found that:

- For the same depth of excavation as 30mm. Although settlement damage to the soil occurred in both the ramp width 4 cm and 10 cm excavation conditions, there was no significant reduction in contact force after damage occurred in the ramp width 4 cm case.
- For the same lining settlement as 23mm, there was no significant difference in the force chain of each case.

4 CONCLUSIONS

The following conclusions were obtained in this study.

- The suitability of the DEM for the ramp excavation issue was verified. The DEM analysis effectively simulated the ground failure patterns, enabling a clear observation of settlement and soil loosening caused by ramp excavation.
- The mechanism of ground failure during ramp excavation was elucidated. Throughout the excavation process, the load acting on the foot of the tunnel support remained relatively constant. However, constraints between soil particles decreased, leading to increased porosity and, subsequently, reduced bearing capacity.
- The influence of the excavation width of the ramp on excavation stability was investigated. Both experimental and numerical simulation results supported the finding that the larger the excavation width, the shallower the soil layer that can be excavated, corroborating findings from Koike's experiment (2020). Additionally, the DEM analysis indicated that, under the conditions of this study, there is minimal variation in the contact force distribution within the ground after damage, regardless of different ramp widths.

Deep underground mined cavern excavations in Auckland city centre, New Zealand

Thomas Cheung*, Wataru Okada & Shu Fan Chau
City Rail Link, Link Alliance, Auckland, New Zealand

ABSTRACT: This paper presents the application of the latest technology in tunnel engineering during the detailed design process and construction of Karanga-a-Hape (KHP) Station for the City Rail Link (CRL), the largest transport infrastructure project in New Zealand. KHP Station is the deepest mined underground station in the Auckland city centre. This is the first time a deep station has been excavated in East Coast Bays Formation (ECBF). Comprehensive ground investigation has been carried out and the data used to assist engineering geologists and geotechnical engineers to interpret and build up a comprehensive 3D ground model for efficient planning, design and construction.

Building Information Modelling (BIM) is mandatory for both temporary support and permanent structure designs in this project. The proposed primary supports are designed based on the 2D analysis and empirical formula and are optimized by using 3D analysis, particularly at the junction and tunnel-shaft interface. The process helps the tunnel engineers to understand the overall picture of the studied area and to predict the impacts to the stakeholders. The tunnel excavation was started from the temporary access shaft in September 2020. The tunnel deformation and ground movement has been kept well under control with no adverse impacts on the nearby structures. In mid 2023, the mined section has been fully lined with permanent concrete and successfully handed over to the rail systems and track team.

1 INTRODUCTION

The City Rail Link (CRL) Project in Auckland is the largest transport infrastructure project ever in New Zealand (NZ) and will help Auckland cater for the demands of population growth over the next 30 years.

The C3 (main stations and tunnels) contract is the largest of all the CRL contract packages. It consists of the construction of a 3.5 km long twin rail tunnel underneath Auckland's city centre, between Waitematā Station (Britomart) and Maungawhau Station (Figure 1 and Figure 2). Two new architecturally-designed stations with underground platforms will be built on Albert Street – Te Waihorotiu Station (entrances at Victoria Street and Wellesley Street) and Karangahape Road – Karanga-a-Hape (KHP) Station (entrances at Mercury Lane and Beresford Square) – providing new transport connections.

The reference design is undertaken by a Principal Technical Advisor (PTA) consortium led by Aurecon and including Jasmax, Grimshaw, Mott MacDonald, Golder, and Arup.

In July 2019 City Rail Link Limited signed a contract for the C3 works with Link Alliance,

comprising City Rail Link Ltd (CRL), Vinci Construction Grands Projets S.A.S., Downer NZ Ltd, Soletanche Bachy International NZ Limited, WSP (NZ) Limited, AECOM NZ Limited and Tonkin + Taylor Limited. The client, construction contractors and design firms all work together and share their expertise to deliver the Project. The alliance model promotes innovation and flexibility and helps achieve value for money.

Karanga-a-Hape Station is a 32m-deep mined underground, twin platform station, with access shafts, platforms, lifts, escalators, and equipment rooms housing station, tunnel services, and plants. The entrances of the station are from both Mercury Lane and Beresford Square. It will be the deepest station of the CRL project (Figure 3).

2 KARANGA-A-HAPE STATION DESCRIPTION

Karanga-a-Hape Station comprises two station shafts, one at Mercury Lane and one at Beresford Square, platform tunnels and five connection adits. The twoplatform

Figure 1. Plan of CRL's alignment.

Figure 2. Section of CRL's alignment.

Figure 3. KHP station at construction stage.

tunnels (MC20 and MC30) and adits have been mined using sequential excavation method (SEM).

The total length of mined platform tunnels (MC20 and MC30) is about 219m and 228m respectively, with an active platform length of 203m to accommodate nine-car trains at the station.

Two stub tunnels each 10.2m long are assigned at the northern end of the station to facilitate the re-launch of the Tunnel Boring Machine (TBM).

The general tunnel layout of the station is shown in Figure 4. The excavated span is from 7m to about 13m and the diagonal span can be up to about 20m at the connection between platform tunnel and adit tunnel to facilitate different construction stages. The tunnel construction sequence requires that the TBM is able to transit through the platform tunnels (MC30 and later MC20) from the south to north. For the MC30 platform tunnel, the transit occurs with only primary lining installed whereas for MC20 the transit occurs after installation of secondary (permanent) lining. Within 21m at each end of the platform tunnels, the cavern profiles are widened. The widening

is required to allow sufficient length for the TBM transit alignment to shift towards the middle of the station and clear the walls of the typical section.

Figure 4. General tunnel layout of Karangahape Station.

3 APPLICATION OF BUILDING INFORMATION MODELLING (BIM) IN DESIGN

BIM is a process focused on the development, usage, and transference of a digital information model to improve the design, construction, and operations of a project.

The objective of BIM in CRL is to achieve a single source of truth and long-term cost savings through the following BIM benefits:

- Single source of truth: To improve collaboration and reduce errors.
- Data interoperability: To improve project delivery and collaboration.
- Visualization: To improve safety and reduce risk in design and construction by clash analysis and 3D coordination of integrated disciplines.
- Integrate asset data: To increase collaboration between different parties in Link Alliance and quick access to accurate information.

The application of BIM in Project and Operational and Maintenance (O&M) lifecycle management helps to form and enhance the whole lifecycle management in CRL.

The BIM modellers extract the latest information from the 3D model (Figure 5) for the tunnel engineer to use in their design modelling and analysis. In addition, clash analysis is carried out for each submission to ensure that the conflicts between each design parties have been solved.

Figure 5. Isometric view in BIM of KHP station.

4 APPLICATION OF 3D GEOLOGICAL MODEL IN DESIGN

Extensive existing boreholes data available from Auckland Council records and a total of more than 195 specific CRL boreholes confirmed the geological conditions along the CRL alignment. In-situ tests, including dilatometer and pressuremeter testing, and televiewer surveys of structure, were undertaken along with a comprehensive suite of laboratory tests to determine geotechnical design parameters.

3D geological model was created by CRL by using Leapfrog Works software. Link Alliance has developed this model and mapped a combination of geological and geological units. Boreholes and corresponding data drilled after starting of the Project are also uploaded for use (Figure 6).

Using the geotechnical digital transformation, the engineers and geologists can easily access the data from a single source and review all the data in 3D view (Figure 7 and Figure 8). The geological section along the tunnel is much easier to be generated, which enhance the work efficiency.

Figure 6. Geotechnical database soilcloud.

Figure 7. 3D geological model imported into BIM.

Figure 8. Cross section in BIM (Combined Model).

5 GEOLOGY AT KARANGA-A-HAPE STATION

The station area extends from Mercury Plaza to Beresford Square. Fill is generally 1 to 2m thick but is up to 4m thick at the south of the ridge crest at Karangahape Road and is mostly comprised of pavements with granular sub-grades.

Local deposits of Pleistocene age Tauranga Group Alluvium (TA) infill the heads of paleo-tributary gullies.

A variable thickness of weathered well-cemented, moderately strong sandstone, East Coast Bays Formation (ECBF). Bedding in this layer is horizontal or sub-horizontal. The unit drops in level from the north to south of the station. A narrow fault zone is inferred to be intersected in the vicinity of the Mercury Lane Shaft.

Tunnel excavation is predominately within massive EUs3 and EUg3 (slightly to unweathered weak to moderately strong ECBF, the unit is also referred as “channelized sandstone”) materials. The Unconfined Compressive Strength (UCS) is about 10 to 25 MPa with a Geological Strength Index (GSI) of 60 to 85. On top of EU3 is the slightly to unweathered very weak ECBF (EU2) with, an UCS of about 1 to 3 MPa and a GSI of 55 to 80 and highly to moderately weathered ECBF (EW). The general geological profile along the MC30 platform tunnel is presented in Figure 9. It is found that the rockhead level is less than a tunnel diameter at some locations with broken rock masses across the station (Figure 10).

Figure 9. General geological section along MC30 platform tunnel.

Figure 10. Anticipated broken rock masses across KHP station.

6 TUNNELLING DESIGN

6.1 Ground relaxation of tunnelling

Numerical analyses are carried out to confirm the ground reaction curves (GRCs) to assess the three-dimensional nature of an advancing tunnel face using two-dimensional methods. The adopted theory is the Convergence Confinement Method (AFTES, 2001 and Almog et al, 2015). The GRCs are plotted using numerical models to determine the degree of ground relaxation and load on tunnel lining from an empirical relationship and longitudinal deformation profile (LDP).

6.2 Numerical analysis

Finite Element Method (FEM) analysis using PLAXIS 2D (Figure 11) and 3D (Figure 12) have been carried out, taking into account the tunnel geometry (shape, span, height), geological conditions, shotcrete stiffness development, and temporary support requirements with existing building loadings and shaft excavation. A steady-state seepage analysis has been also undertaken to determine groundwater pressure distribution in the ground.

Although the modelling technology is advanced, the analytical methods developed by past experience in the tunnelling industry are still invaluable. For example, the proposed advance length is first verified from the empirical ground stand-up time, within which the ground is able to stand prior to application of the primary support system. An advance length assessment has been carried out using the methodology provided in Lee and Schubert (2008) and Lauffer's chart ('Lauffer, H. (1988)).

Figure 11. PLAXIS 2D analysis at KHP.

Figure 12. PLAXIS 3D analysis at beresford square shaft and Adit A5 & MC20 stub tunnels.

6.3 Optimisation of design

To increase the efficiency of construction, the tunnelling design has been further optimized after obtaining more site data from the excavation.

The initial design has considered the effects of joints to the excavation and proposed primary supports based on boreholes logs, photos, and televiewers. The data is limited by the borehole spacing, drilling direction, and drillhole size. The geological mapping records obtained from the excavated tunnel section (Figure 13) have been referenced to update the RS2 analysis modelling to reflect the actual site conditions (Figure 14) and to optimize the design (Figure 15).

For example, the original primary support design at MC30 Subzone 31 junction consists of split heading and a temporary central wall due to uncertainty of rock cover, which introduces construction complexity (Figure 14). Removal of the central wall and lapping of mesh may result in longer construction time and potential quality issues. The new boreholes have confirmed over the junction the EU3 thickness at the junction is about 1.2 m to 1.5 m, and the overall rock cover (EU2 & EU3) is about 4.0 m in total, which is roughly half of the tunnel span. All data is reassessed in the 3D model (Figure 16) and cross-checked with the 2D model. The analysis has demonstrated that split heading excavation is not required and full-face top heading excavation is technically feasible. The excavation of this portion had been successfully completed in late 2020 (Figure 17). The accumulated ground settlement at MC30 Subzone 31 junction is about 2.8 mm to 5.0 mm which is well under the limit (i.e. 21 mm).

Figure 13. Geological mapping.

Figure 14. RS2 analysis at KHP.

Figure 15. FLAC3D analysis at KHP (Split Top Heading Excavation).

Figure 16. RS3 analysis at KHP (Full Top Heading Excavation).

7 TUNNEL CONSTRUCTION

Top heading and bench excavation sequence were adopted for the Karanga-a-Hape Station platform tunnels and adits. The tunnel was excavated in a full-width top-heading along the tunnels. Rock dowels and Polypropylene Fibre Reinforced Shotcrete (PFRS) with the full thickness of the primary support arch built up in layers were applied for the top-heading. The bench of the tunnel excavated afterwards.

Excavator was used for all excavation with the operator's cabin under supported ground conditions. All tunnels were constructed without any personnel

Figure 17. Excavation at KHP Adit A1.

entry under unsupported ground conditions at all times. For the installation of rock bolts, an automated carousel bolter was used. First, a safety shotcrete layer was applied within the same shift and at the end of each excavation advance to protect the excavation surface against deterioration and prevented localised slabbing failures. Temporary support rock bolts were subsequently installed, and a second layer of shotcrete was then applied. Upon completion of the excavation, the temporary support was installed, and remote shotcreting was adopted by using the shotcrete robot.

Figure 18. TBM breakthrough at KHP station MC30 cavern.

Figure 19. TBM in the KHP MC30 mined stub tunnel.

The mined excavation at MC30 was completed successfully before the first TBM broke into the cavern on 17 Oct 2021 (Figure 18) and TBM was then relaunched in the mined stub tunnel (Figure 19).

The second TBM transition was also completed in July of 2022 as shown in Figure 20.

Figure 20. TBM transition in KHP MC20 mined tunnel with permanent lining.

Figure 21. A zephir rail vehicle delivering tracks for installation at Karanga-a-Hape Station.

8 CONCLUSIONS

With the advanced technology in digitalization and modelling, the tunnel excavation and primary support can be studied in detail and results can be graphically presented. Optimization on the design can be

carried out by adopting the latest site excavation and mapping information.

For the overall performance of mined tunnel excavation at Karanga-a-Hape Station, the ground movements are kept under well control and there are no adverse effects on the nearby structures. The permanent lining of KHP Station has been completed by the time of preparing this conference paper (Figure 21).

ACKNOWLEDGMENTS

The paper is published with the permission of the City Rail Link Limited and Link Alliance for which the authors would like to gratefully acknowledge. The design and construction of the project is currently undertaken by Link Alliance.

ABSTRACT: Girgaon station lies amidst residential and commercial establishments in congested bustling downtown marketplace in Mumbai, India. Construction of this station, one of the 26 underground stations on the 33.5 Km long Colaba-Bandra-Seepz (Line 3), has been an engineering feat. There were 139 buildings in the Zone of Influence of Station Box. Fourteen building housing 560 PAPs were demolished to make space for station. Critical buildings were supported and repaired prior to construction. Impacts on day-to-day life were handled with care and consultations. Pre-Construction Building Condition Survey, Instrumentation and Monitoring and structural audit reports helped in alleviating apprehensions during construction. PAPs will be rehabilitated later in-situ to preserve their lively-hood and social fabric under a unique rehabilitation scheme. Steel decking was provided for space and traffic management plans. Acquisition of land and rehabilitation of PAPs in the congested Girgaon locality was a major influencing factor in project execution. This was handled with public consultations and special policies by the State Government for Rehabilitation and Resettlement. Station plans were modified to accommodate these requirements. The station is now 71 % complete. The paper will delve into these technical, social, and logical challenges successfully dealt in construction of this station as a case study of undertaking a mega urban project in a socially responsive manner.

Keywords: cut & cover, conventional tunnelling, social and technical challenges

1 INTRODUCTION

As cities grow and expand, the demand for efficient transportation systems becomes increasingly critical. Tunnels offer an effective solution for providing underground transportation infrastructure, but the implementation of tunnelling projects in congested urban areas presents numerous challenges. Traditional tunnelling methods, such as the Cut & Cover technique, can cause significant disruption to the urban fabric, affecting businesses, communities, and the environment. On the other hand, Conventional Tunnelling techniques may be more suitable for

sensitive urban areas but come with their own set of social and technical challenges.

As urbanization continues to intensify, cities face increasing challenges in expanding and upgrading their transportation infrastructure to meet the demands of a growing population. Tunnelling plays a crucial role in addressing this urbanization with limited problems posed to the residents in terms of limited space, environmental concerns, and social implications. By analysing case studies, best practices, and lessons learned, this study aims to provide insights into effective strategies for mitigating the adverse effects of tunnelling and cut & cover

*Corresponding author: shantaram.dalvi@mmrcl.com

excavations on urban communities while ensuring efficient and sustainable project outcomes.

Mumbai Metro line-3 is a 33.5 km long underground corridor running along Colaba – Bandra - Seepz. The dense and historic urban environment of Mumbai on the narrow north-south peninsular region, necessitated for underground alignment of this metro line. Line-3 is the first underground metro line for Mumbai as the current public transport system are overcrowded and the road transport network is congested. To decongest the existing public transport and increase mobility across the region, Mumbai Metro Line-3 was planned as an underground metro. The corridor is marked with 27 key stations out of which 26 will be underground and only 1 station is at grade. This project is twin tunnel project with adequate cross passages throughout the network. Mumbai Metro Line-3 (MML-3) project joins South Mumbai and Central Mumbai and has several interchanges with Indian Railways Suburban network and Mumbai Metro Line-1.

MML-3 Project has a standard gauge (1435 mm) and maximum permissible speed is 85 km/h. There are 8 coaches rolling stock for each train with a total passenger capacity of 2406 and axle load of each coach is kept at 17 Tons. Length of one metro train will be 22.60 m. Power supply for metro trains will be through the overhead 25 kV AC traction supply and the propulsion system will be a 3-phase drive system.

Integration of Line 3 will provide a faster, effective, dependable mode of public transport and will also become a key factor in increasing public transit usage reducing the carbon footprints. As planned, construction of underground metro rail corridor is carried out using Tunnel Boring Machines (TBM's), Conventional tunnel excavation and Cut & Cover station boxes. This paper presents a mix of social and technical challenges in congested Urban Environment during Construction of Girgaon Station of Mumbai Metro Line – 3, through a combination of cut & cover and conventional tunnelling.

2 GIRGAON STATION - LOCATION

The upcoming Girgaon Metro Station is located in a densely inhabited locality in old Mumbai. Building structures under which the tunnel passes and in the vicinity of the cut and cover station box are mostly dilapidated. The narrow streets are congested with heavy traffic at all times. The location of the station was decided, basis the social importance of the place with places of worship and business avenues in the vicinity.

Land acquisition, dilapidated structures in the zone of influence, traffic congestion due to limited space availability, adverse mixed geological conditions and water ingress due to proximity to the sea were the primary challenges which were overcome efficiently, some prior to start of construction works and some during the course of construction of this station box.

Figure 1. Location of Girgaon Metro Station.

Figure 2. Redevelopment plan of Girgaon Metro Station.

This paper details the measures undertaken and at times the changes adopted to overcome these social and technical challenges and the successful completion of the Girgaon metro Station.

3 CHALLENGES IN GIRGAON METRO STATION CONSTRUCTION

3.1 Land acquisition

Land Acquisition was a major challenge from the very inception of the project, this being the most densely populated area with a high congestion of the structures

and no open tracts of land available. Structures were identified to be demolished for in-situ rehabilitation (Figure 2) of PAP's (Project Affected Persons). The displaced residents would be reinstated in the reconstructed buildings at the same location after the completion of the station.

A series of public hearings were conducted firstly to explain the importance of the upcoming Metro Station in the area and finally to convince them for the land to be acquired and their rehabilitation and settlement. In the process the Rehabilitation schemes were also explained. Coordination was done between various Government bodies to verify the Ownership and tenancy rights of the displaced residents.

Despite a number of public hearings and other in-situ redevelopment plans developed, a minor section of the residents/owners remained unconvinced for the urban development of the area and denied handing over the structures for the works to start. This accounted for a delay in the start of the cut and cover excavation works for the station.

As a consequence of the refusal of land, a general re-sizing of the station box was done to accommodate the station in the available space. The original layout and the modified layout are depicted in Figure 2.

Figure 3. Original & modified layout of Girgaon Metro Station.

Girgaon Station had a reduction in length after tender stage, length was reduced to 244.675 m from 289.6 m. Reduction in length was undertaken to mitigate impacts of delay in land acquisitions and space constraints at site. The profile of land change extensively as alternative land was made available by the authorities instead of initially conceived land plans.

This resulted into modification in construction methods. Further, extensive R&R and property development works were planned in the available land pocket, with a component of the works overlapping the underground station structure. Structural provisions of these R&R and PD works, as well as space planning within station area had to be suitably changed to accommodate structure needs of multi-storeyed R&R and PD structure above ground.

3.2 Dilapidated structures in the zone of influence

Details of the Damage Category assigned to structures in the Zone of Influence of the Girgaon Station Box excavation are shown in Table 1 as below:

Out of a total of 140 structures in the Zone of Influence (ZOI) of the Girgaon Station Box, 35 structures were in a dilapidated condition. It was of prime importance to minimize construction induced settlements in order to prevent the loss of property and life. Stringent measures in consultation with the Detailed Design Engineer, General Consultant and the Client were adopted in terms of supporting the dilapidated structures, structural repairs and monitoring of all the structures in the ZOI.

Prior to the start of the TBM mining operations under these structures, a detailed Building Condition Survey was undertaken and structural Audits for critical structures undertaken upon the Damage Classification. Structural repairs and supports were provided to the structures as per the recommendations of the Structural Audit Reports.

Instrumentation and Monitoring formed an integral part of the project. Structures were monitored for tilt, cracks, vibration and settlement. Real-Time monitoring was carried out during the TBM mining as well as during the station excavation through conventional tunnelling.

Precautionary measures were in place in case some settlements were noticed.

3.3 Congestion due to Limited Space Availability

Girgaon Metro station is planned on the Jagannath Shankar Seth Road (JSS); located on the central verge along 12 m wide road. The station is about

Table 1. Damage category assigned to structures in ZOI.

Station/ Tunnel	Total No of Structures within ZOI	Heritage Structures	NOCReceived (Structures Surveyed)	Damage Category						Structural Audit Completed	NOC Refused (Structures Not Surveyed)
				Very Severe	Severe	Moderate	Slight	Very Slight	Negligible		
Girgaon Station Phase-1 (0 to 25m)											
Station	80	1	76	0	20	39	17	0	0	18	4
Girgaon Station Phase-2 (26 to 50m)											
Station	59		53	4	11	26	10	2	0	3	6

0.73 km away from the Kalbadevi Metro station. The entry and exit of the station are planned on both sides of the road. This station is being built in one of the busiest and densely populated residential areas of South Mumbai.

Girgaon is one of the very congested and populous locations in this stretch of MML3 Project. Due to the limited availability of land, part of the Station box was designed under the existing road and to manage the traffic congestion, steel decking was placed for uninterrupted traffic movement.

An efficient traffic management was put to place and the lane was transformed to a one way lane. Traffic Marshals manned the major junctions for managing a smooth flow of traffic.

Excavation for the cut and cover station box commenced with space constraints at the surface with limited heavy equipment and at times specialized equipment to cater to the limited space available. Consequent to the excavation up to the base slab, widening of the bored tunnel was taken up through conventional means. Special temporary openings to accommodate the muck transport from the tunnel widening were made use of. Construction sequencing of the cut and cover station box modified and re-modified at times due to space constraints and in order to ease workability at Girgaon station. Same is explained in the series of Figures below:

Once the casting of the base slab up to desired level was accomplished, walls up to the Mezzanine slab were casted and subsequently the mezzanine slab. Widening of the bored tunnel was taken up immediately upon casting of the mezzanine slab. Since the excavation could not be done by blasting, mechanical breaking of the rock was proceeded with which was another cause of the prolonged excavation regime.

Following are the models for the Girgaon station from the Building Information Modelling Software (BIM).

3.4 Adverse geological conditions – mixed ground

Figure 6 is a representation of the Geological Profile of Girgaon Station. As is evident, it represents a mixed geology of hard and soft Breccia in general and a small patch of hard, compact, fresh Basalt. This patch of Basalt extended from the up line tunnel to the right portion of the Station Box and pinched out prior to reaching the down Line tunnel.

The secant piles drilled prior to the start of excavation of the station box could not be socketed into the hard and compact basalt which posed problems of water ingress and excavation when the excavation reached that particular level. Corrective measures in the form of raker piles were taken up which resulted in delay in excavation works. Mechanical breaking of this hard basalt was also challenging since blasting could not be taken up in the midst of this densely populated location.

Figure 4. Stages of construction for cut & cover at Girgaon.

3.5 Water ingress - Girgaon station in close proximity to sea

The Girgaon Station is placed in close proximity to the sea (Figure 7) with a very high ground water table. Excavation started with all precautionary measures in place for anticipated high water ingress into the excavation.

Figure 5. BIM model for Girgaon station.

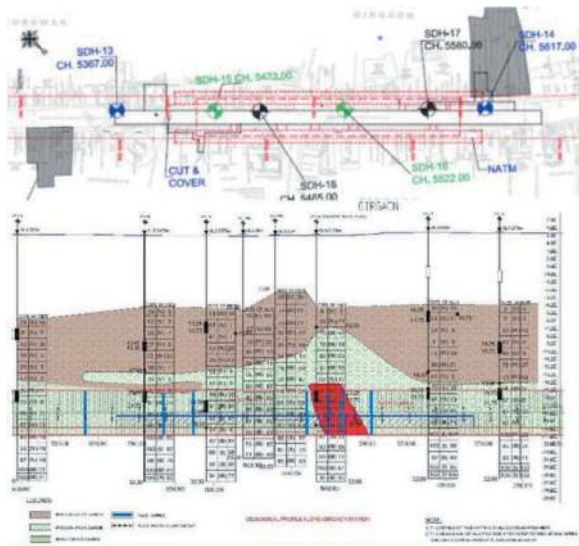

Figure 6. Geological profile of Girgaon.

Figure 7. Location of Girgaon Station in close proximity to the sea.

High water ingress was observed at a number of places during the excavation of the station box which was overcome by grouting measures. The materials used for grouting the walls of the station box were Cement, Sodium Silicate and in extreme cases Polyurethane Grout (both single and double component). No major incidents of settlements in the Zone of Influence were reported barring a few minor ones which were taken up on priority and amicable solutions were provided.

4 INSTRUMENTATION & MONITORING

Extensive Instrumentation and Monitoring regime was enforced for all the structures in the Zone of Influence of Girgaon Station to counter any unforeseen situations during the course of the excavation. Monitoring was carried out for Vibration levels, settlement, cracks and tilt. Real-time monitoring for 3-D deflections in buildings across the alignment through prisms was also carried out. Water levels in existing wells and additionally installed Standpipes were monitored throughout the stretch on a daily basis and with increased frequency of monitoring when the need arose in case of any noted abnormal changes in readings.

The data collected from the instruments was thoroughly analysed at different levels by the Instrumentation Engineers, by detailed design consultants and finally by the General Consultants and a final report formulated and circulated on a daily, weekly and monthly basis. No major adverse effects in the form of settlement, draw down of ground water table or tilting of structures were evident barring a few minor settlements to the tune of 6 to 8mm.

5 SIGNIFICANT ADVANTAGES

1. The station construction work was converted into cut & cover which made construction work easier than the previously proposed conventional method.
2. A portion of work got shifted off-road and reduced inconvenience to the public by appropriate segregation of pedestrian and vehicle movement.
3. Station box shortened by approximately 60m which reduced the scope of secant pile and assisted in the early completion of piling activity.
4. Reassessment in station box size eliminated the construction of secant pile work in front of one of the dilapidated structures of concern.
5. Width of concourse got significantly increased as a result and ease the movement of passengers facilitated for operation of Line-3.
6. Fruitful utilization of land pockets above ground to meet the integration requirements of metro station and property redevelopment in accordance with the approved plan.

7. Ancillary building occupies one compact location and rest of the area made available for redevelopment of property for rehabilitation of PAP's.
8. During an emergency, a greater number of evacuation routes shall be available to the public.

Girgaon Metro Station – 3D Model

9. Tunnel ventilation system and fan room will be ideally located on wide cut and cover box closer to the platform end.

6 CONCLUSION

Despite all odds and what seemed to be a gigantic task, excavation for the Girgaon Metro Station was accomplished with efficacy. Assessment of all work fronts were made at different levels on priority and timely interventions for appropriate and adequate changes wherever required were adapted for a successful and timely completion of various activities at Girgaon Metro Station.

Construction activities, in one of Mumbai's busiest market places with limited space and congested streets amidst a dense network of dilapidated structures was completed in the face of adversity through sheer grit, determination and adaptation to the latest technical knowhow in the construction industry.

Challenges in the conventional tunnel mixed-face execution

ABSTRACT: The construction of tunnels by the sequential method (NATM, SEM, SCL) has as one of its fundamental principles, the contribution of the massif that surrounds the executed section, through the redistribution of tensions in the excavated region (arching), which, added to the treatment applied in the work area, it keeps the displacements in balance, enabling underground construction. Predicting the behavior of tunnels excavated in heterogeneous masses is additionally difficult, since the heterogeneity of materials can occur in an incalculable number of directions, formats, positions in the section, dimensions and type of formation. Sections excavated in this region, usually called Mixed Section, have a robust treatment, closer to the treatments adopted for sections in Soil, which in theory would be the worst case scenario. For the project contractor, the uncertainties regarding the deadline and cost of the work increase as, even with robust sounding campaigns, there remains a possibility of significant variation in these sections in relation to the theoretical compartmentalization of the project. This variation has a very large impact on project costs and deadlines, as well as on the acquisition of construction insurance. Taking as a basis the tunnels executed in the Florianópolis ring road, the transition sections between the soil regions at the entrances of the tunnels and the rock region inside the mountain, a large proportion of tunnels excavated in heterogeneous environments is shown, the so-called mixed classes, with the most diverse characteristics possible. Of the 6.700 m excavated, around 1.100 m (14%) took place in mixed-class massif regions. This article aims to report the difficulties in the conception, design and execution of tunnels excavated in mixed classes, as well as the view of contractors for work of this nature, considering the execution of the 4 (four) tunnels, which took place between Jan/21 and Oct/23.

Keywords: Tunnelling, NATM; SCL, Mixed-face, Tunnel Design, Ring road

1 INTRODUCTION

The Florianópolis Road Ring is a new road section that is being implemented in compliance with the obligations set out in the road concession contract signed by Autopista Litoral Sul. Its main objective is to divert long-distance traffic distance from the metropolitan region of Greater Florianópolis, in the south of Brazil, South America.

The route passes through municipalities of Governador Celso Ramos, Biguaçu, São José and Palhoça. The project presented refers to part of the South Section, specifically between the Km 220+396 and Km 228+310, which foresees the construction of 4 double tunnels. (ANTT, 2018).

Figure 1. Florianópolis ring road location. ANTT, 2018.

The tunnels are situated along the ring road, as showed in Figure 2.

2 MIXED SECTION - DEFINITION

Tunnel excavation using the sequential method (NATM, SEM, SCL), has as its principle, taking advantage of the natural behavior of homogeneous masses, in the redistribution of tensions when excavated, seeking balance with the smallest possible displacement.

In general, mixed sections are present in the transition range between homogeneous masses, which naturally forms a heterogeneous region. Considering the layout of the tunnel, the formation found in the excavated section and its surroundings, will go through an incalculable range of compositions, making it impossible to characterize each one of them in the project, nor to predict construction methodologies and customized treatments for each situation, causing difficulties from the conception from the project until its execution.

By characteristic, definitions of mixed sections bring inaccuracy, with impacts on the project, economic viability and execution. Example of idealized mixed section is showed in Figure 3.

Figure 3. Mixed section, in center, an intermediate situation between soil (left) and rock (right). Source: Authors.

And these mixed sections, found as the excavation progresses, also raise concerns about the stability of the excavation front. As highlighted by LUNARDI, 2008, the stability of the face plays a fundamental role in maintaining tunnel deformations at acceptable levels, and for the short and long-term stability of the excavation. It is in the face (or transition) zone that the design engineer must intervene to regulate and control the deformation response.

Furthermore, mixed-face conditions, if not properly characterized in advance, can lead to contractual

impasses (Attewell, 1995, p. 32), overriding issues inherent to the design or execution technique.

Mixed face situations, as highlighted by Rodriguez Ortiz, 2006, p. 121, based on a series of occurrences in Spanish road tunnel works, bring with them a probable incidence of unwanted overbreaks, which is an example of both a technical and economic problem.

2.1 Difficulties

After defining the best route for a tunnel, be it for adduction, road, rail or for any other purpose, the next step is to estimate a theoretical geological compartmentation throughout the future construction.

This compartmentalization will be the basis for a project that must be created within a search for economic and executive viability. As what is sought is safety, in addition to precision in the demand for construction and financial resources for the project, depending on the length of the mixed section stretches, this search becomes an exercise almost in futurology.

Even if the investigations are of good quality, the behavior of the mass/structure set in mixed-class regions is difficult to be precise. The risk of geological accidents and/or costs due to unforeseen variations become a point of attention in the project, often leading to changes in layout or unfeasibility of construction.

2.1.1 From the tunnel designer's point of view

The construction of tunnels in mixed sections involves additional risks compared to tunnels entirely in soil or rock.

In a mixed tunnel with soil on the roof and/or in a considerable part of the excavation section, the main precautions related to a tunnel built entirely in soil are necessary, such as controlled advancement and the need for treatments for roof and/or front stability.

However, there is an additional stage in the excavation cycle of a mixed face tunnel similar to a rock tunnel, which is the fire blasting stage. Carrying out rock blasting with explosives in mixed tunnels, in addition to the fact that productivity is affected, by adding an additional step to the cycle (compared to the soil tunnel), brings a new risk, which is a greater difficulty in controlling advance distance.

If the blast generates greater progress than expected, the actions (and efforts) in the temporary support systems will be greater (and consequently the risks). On the other hand, if the blast operation does not remove enough to install a steel ribs at the design spacing, it is usually decided to install the steel ribs at a lower spacing (in favor of safety), which impacts productivity.

For the design of a mixed section, a more unfavorable condition is generally accepted in terms of efforts in the coating, in which there is a predominance of soil in most of the section and with the rocky top in the lower part of the section (Figure 4a).

Figure 4. Mixed section, idealized condition, and other possibilities. Source: Authors.

The section idealized for design, however, has a limited occurrence in terms of extension. In practice, until there is complete certainty about the rock cover conditions of a tunnel, sufficient for greater advances to be made and tie rods to be used (usual solution for rock tunnels), the mixed section is used, which is much closer to a tunnel in the ground than a tunnel in rock.

Thus, the mixed section can be used in the most diverse interface conditions between soil and rock, some of which are shown in Figure 4b, c and d.

Certain conditions, despite not being the most unfavorable from the point of view of sizing the support and/or covering, are terrible in terms of execution, such as 2b, c and d.

Scenarios containing transition zones on the roof (2b), in which the behavior is closer to the soil behavior, but containing little altered rock blocks (boulders) bring difficulty both in the execution of treatments (forepoling and nailing) and in the controlled dismantling of the rocky part, as shown in Figure 5.

Figure 5. Forepoling and Nailing in mixed section with longitudinal variation of the rock. Source: Authors.

Even an excavation front completely in rock may not be favourable in terms of execution, as for example in the case of a small rock cover, or one that has a large longitudinal variation, where the treatment alternately intercept soil and rock along the perforations. In this condition, the tunnel is constantly susceptible to intersecting soil at the excavation front. It is common for accidents to occur when the reduction and/or removal of treatments (filling) is anticipated due to the presence of rock on the excavated face.

Faced with the uncertainty and risks involving excavations in these conditions, the designer normally opts for conservative solutions, maintaining the roof treatment (albeit in smaller quantities) and support closer to a ground tunnel, with the use of steel ribs and short advances (~ 1m).

These two scenarios in particular, when they occur over large areas, tend to have a significant negative impact on the progress of the construction.

2.1.2 From the project financier's point of view

Underground constructions such as tunnels are considered expensive and usually adopted as a last solution among other engineering role of possibilities.

Part of this scenario is due to the difficulty related to predict the real costs of a tunnel that may have significant variations in the geological conditions.

Although a good investigation campaign is important and necessary, depending on the massif peculiarities, much uncertainty related to proportion between soil, rock and mixed tunnels extensions remains for the construction phase, which will – inevitably – raise economic and deadline risks.

Hence, the viability of a tunnel often will be granted by the length of the tunnel that will require a mixed face solution. The economic contingency necessary to cover a significative variation of mixed class might be extremally high compared to the cost of the project.

The Project Financier has the challenge to format the best contractual model for this kind of project, in a way that it is financially safe and attractive for constructors. The main question in this aspect is to supply safety to the constructors that unpredicted variations in the project will not have a financial impact in the contract. Even in cases where the is expected to have a geological uncertainty, having a good project design and a qualified constructor reduce the chance of the variation of costs when facing these uncertainties.

2.1.3 From the contractor's point of view

When contracting the execution of a project, the contractor specializing in underground excavations will mobilize the best composition of resources (Equipment and Labor), considering the approved schedule, based on construction processes and with appropriate costs.

For excavations and supports in regions generally characterized by the homogenous presence of soil, resources will be dimensioned with a focus on pre-supports such as forepolings, CCPh, pre-injections, face nailing, sub-horizontal drains, among others. The progress of excavation is carried out conventionally

with cutters, mechanized and manual breakers, as well as conventional excavators themselves.

When it comes to excavations in rock masses, the resources are different. It focuses on an adjusted cycle of rock drilling, use of explosives, cleaning of detonated material and supports defined in the project.

Considering the general characteristics of excavation in soil or rock, some resources are coincident, but with significant adjustments in their quantity and functionality.

When it comes to the execution of tunnels in mixed sections, pre-support resources tend to be used for excavation in soil and also those for excavation and support in rock. Productivity is, in general, lower than that of excavations in competent soil, but with demand for a varied line of resources with a high degree of unproductivity.

From the transition from a tunnel excavated completely in the ground, to a classification for rock, depending on the types and levels of weathering suffered, there is an incalculable variety of soil/rock compositions “faced”.

The photos shown in Figure 6 are of the evolution of a mass over the course of a week of progress, in Tunnel 1 of the Florianópolis road contour, the Tunnel with the largest presence of mixed sections in the project. This evolution exemplifies how vast the portfolio of resources and expertise must be to maintain the productivity and safety of the project. The four sections illustrated in the photos were mapped as a mixed section, however under very different conditions.

Figure 6. Mixed faces with different aspects, in the same tunnel and same week. Source: Authors.

Figure 7. Different locations where mixed face support was applied in the same tunnel. Source: Authors.

In the Figure 7, another set of photos, in the same tunnel.

The presence of rock in the lower, upper or lateral portion of the section brings many differences in the construction sequence and risks to workers. Furthermore, tools are generally sized for best performance in rock or soil; Hybrid tools tend to bring greater cost and unproductivity.

As they are regions of contact between materials, they tend to have a greater presence of water, creating more difficulty for the executor. Masses with the presence of water, when exposed during excavation, tend to be carried by infiltrations and behave with a shorter stand-up time of the excavated material. Hence the demand for a consistent contingency plan.

As these are regions with a higher risk of geological accidents, the technical teams that define which project section to use tend to be more conservative, naturally leading to an increase in the section considered a mixed section.

The Figure 8 demonstrates, based on the drilling reports, the proportion of soil/rock in the mixed class excavation region in Tunnel 1, on the Florianópolis ring road. For safe execution, the presence of a multidisciplinary team and technical support capable of identifying the best construction sequences, using the best equipment and tool resources, is essential.

Figure 8. Drilling reports, Florianopolis ring road Tunnel 1. Source: Authors.

2.1.4 Data from Florianópolis Ring Road

The Florianópolis Ring Road were built in the Granite massif. Of the 4 (four) tunnels built, two of them had a very short soil-to-rock transition, thus contributing to the accuracy of expected costs and deadlines. On the other hand, tunnels 1 and 2, present in

Table 1. Tunnels data (extensions).

	Soil	Mixed	Rock
Foreseen	515.23	1,438.08	5,130.71
Realized	917.02	1,045.20	5,121.79
Difference	+ 401.79	- 392.88	-8.92

the massif of the Pedra Branca region, had extensive mixed class portions.

The consequence of the greater presence of mixed classes were variations in cost and time, as shown in the Table 1.

4 CONCLUSIONS

The execution of conventional tunnels in mixed-face zones requires a high level of attention, due to their technical and economic sensitivity. Projects must pay special attention to these sectors, in order to predict, in the best possible way, the condition that will be found on site, in terms of behavior and extent. The builder, in turn, must foresee countermeasures for the executive phase, if the extent and behavior of the mixed-face zone are worse than the initial prediction.

In the works on the Florianópolis Road Ring, the mixed-face zones were found to have smaller extensions under construction than the project forecast.

ABSTRACT: Taking the Siding Extra Long Tunnel, the longest highway tunnel in Guangxi, China, as the engineering background, the key technology research for the construction of green highway extra long tunnels in karst peak cluster areas was carried out. BIM technology was applied to analyze the light environment of tunnel portal buildings such as sunlight analysis and glare analysis, and a hollow-bamboo-cut tunnel portal structure was proposed; In response to the geological characteristics of tunnels in karst peak cluster landform areas, a joint detection technology of “single hole radar-cross hole radar-hole surface radar” geological advance prediction has been developed, forming a method for predicting and treating karst caves in extra long highway tunnels in karst peak cluster areas; We have developed a water stop that combines drainage and anti karst crystallization functions, and proposed a treatment structure for water and mud inrush and arch top karst cavities in highway tunnels in karst peak cluster areas. The research results have ensured the safety and quality of tunnel construction, saved construction time, created direct economic benefits of 36.75 million RMB, improved the quality of tunnel engineering, reflected the concept of green highway construction, and achieved significant economic and social benefits.

1 INTRODUCTION

By end of 2022, there are 24850 highway tunnels with a length of 26.7843 million linear meters totally nationwide in China. In 2022, an increase of 1582 highway tunnels with a total length of 2.0854 million linear meters totally. Among them, there are 1752 extra long tunnels with a length of 7.9511 million linear meters totally, and 6715 long tunnels with a length of 11.7282 million linear meters totally^[1]. China has become the country with the largest number of highway tunnels and the fastest growing tunnel scale in the world. The mainstream trend of tunnel

engineering technology development is moving towards safer, more economical, greener, and more artistic directions^[2].

The distribution of karst areas in China is extensive, with three contiguous areas of special poverty concentrated in karst areas. The transportation construction in karst areas is significant for poverty alleviation and transportation power. The karst peak cluster area is widely distributed in Yunnan, Guizhou, Sichuan, Chongqing, southwestern part of Hunan, northern part of Guangdong and other areas. Its unique geological structure has formed many scenic spots such as Guilin mountains and rivers,

*Corresponding author: 11607775@qq.com

however, it also brings new challenges to tunnel construction.

The tunnel portal is not only the “face” of tunnel, but also the “throat” of tunnel. The “black hole” and “white hole” effects at the tunnel portal area have a great impact on driving safety. A large amount of research has been conducted domestically and internationally on the impact of the lighting environment and portal type at the tunnel portal. The differences and measured values of the brightness outside the tunnel between the bamboo-cut portal and end-wall portal types are explained in the detailed design rules for highway tunnel lighting^[3], however, the separation between the civil design of tunnel portal and the design of light environment is a common phenomenon. How to comprehensively consider the coupling of tunnel opening geography, terrain, geological conditions and the design of light environment, fully apply new technologies such as BIM, and create tunnel portal buildings with beautiful landscapes, low energy consumption, and safe driving is an important manifestation of actively practicing the development concept of “green highways”.

2 RESEARCH ON THE DESIGN OF LIGHT ENVIRONMENT AT THE PORTAL OF GREEN HIGHWAY TUNNEL

2.1 Characteristics of light environment at tunnel portal

Highway tunnel is an extremely special road traffic operating environment, characterized by significant differences in the light environment inside and outside the tunnel, and low brightness levels in the middle section. Entering the tunnel, adapting from a bright environment to a dark environment is dark adaptation; Drive out of the tunnel and adjust from a dark environment to a bright environment is light adaptation. The visual adaptation curve is shown in Figure 1. According to research on the light environment and physiological effects to light^[4], the visual requirements for driving at tunnel entrances are not only brightness, but also transition time, color temperature, etc., especially in the portal section. At the same time, the tunnel portal section is located at the junction of light and dark adaptation, and there are also optical issues such as glare and stroboscopic effects.

2.2 BIM simulation analysis of tunnel luminance

The application of BIM technology in tunnel engineering is receiving increasing attention. This project has established a Revit-Dynamo-Excel modeling solution to digitize and program tunnel BIM models. At the same time, Insight 360 is used to achieve functions such as sunlight analysis, interactive sunlight path simulation, and glare analysis^{[5]-[6]}.

Creating three types of tunnel portal (end-wall, bamboo-cut, and hollow-bamboo-cut) simulation models by Revit software, as shown in Figures 2-4.

Figure 1. Visual adaptation curve.

Figure 2. End-wall portal tunnel simulation model.

Figure 3. Cut-bamboo portal tunnel simulation model.

Figure 4. Hollow-cut-bamboo portal tunnel simulation model.

The Revit Insight 360 Sunlight Factor Analysis type was selected, which used the Sunlight Factor (DF) sky model. In the field of architecture, daylight factor refers to the percentage ratio of the internal and external luminance levels of a building (structure) under CIE full overcast sky conditions, expressed as:

$$DF = (E_i/E_0) \times 100\% \quad (1)$$

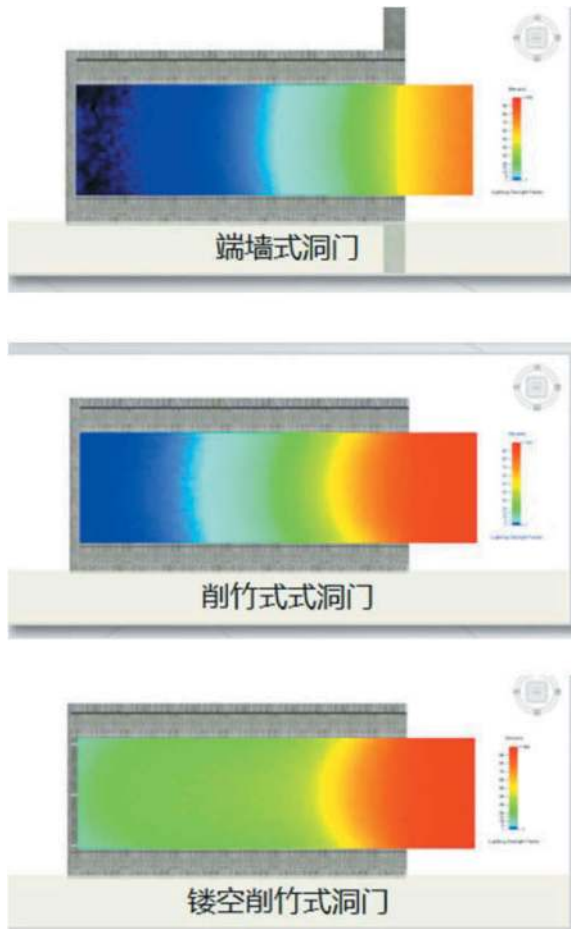

Figure 5. Comparison of solar factor distribution scale in different portal types.

Among them, E_i is the sunlight illuminance value at a certain point on the indoor analysis plane, and E_o is the illuminance value on the outdoor unobstructed horizontal plane at the same time.

The variation law of sunlight factor in the simulation analysis of three types of tunnel portal is shown in Figure 5.

Figure 6. Comparison of daylight factor simulation results of different portal types.

The operating conditions and BIM simulation analysis results of different portal structure types indicate that the changes in road surface illumination inside the

hollow-bamboo-cut portal tunnel are smoother, and the transition of the lighting environment is more humanized, which can effectively improve the driver's visual comfort and have a good dimming effect.

2.3 BIM simulation analysis of tunnel glare

The generation of solar glare is not only related to the height and position of the sun, but also to the geographical location of the tunnel, the direction of the tunnel, and the direction of vehicle travel. Through observation, it was found that the direct glare generated by the sun has the greatest impact on the driver. It usually occurs during the early morning when the sun has just risen and the evening when the sun gradually sets. The glare generated during other periods is indirect glare or refracted and reflected light.

In order to study the distribution characteristics of sunlight glare at tunnel exits with different directions, four typical directions of east, west, south, and north were selected. In Revit, models were created for the east exit (for eastbound vehicles driving out), west exit (for westbound vehicles driving out), south exit (for southbound vehicles driving out), and north exit (for northbound vehicles driving out). Revit software integrates interactive sun path tools that support visualizing sunlight. In addition to any specified geographic location, it can also be used to create solar studies at any time, studying the impact of natural light and shadows on the internal and external aspects of a project.

To evaluate the distribution characteristics of solar glare at tunnel exits with different orientations throughout the year, four representative dates in astronomy were selected, namely the spring equinox (March 20th), summer solstice (June 21st), autumn equinox (September 23rd), and winter solstice (December 21st). The spring equinox, summer solstice, autumn equinox, and winter solstice are the four solar terms that reflect the return movement of direct sunlight. Based on the BIM model, a roaming tool was used to simulate the process of vehicles driving out of the tunnel exit from four different directions. The distribution of sunlight glare at the tunnel exit from different directions was obtained at the spring equinox, summer solstice, autumn equinox, and winter solstice. The results are shown in Figure 7. When the sun appears in the driver's field of view simulated by the camera, it indicates the occurrence of solar glare.

Figure 7. Simulation of sunlight glare in east portal.

The solar glare at the east exit occurs in the morning, without considering the obstruction of surrounding objects. The sunrise time is considered as the start time of the solar glare, and the end time of the glare can be obtained through Revit simulation. The distribution of solar glare at the east exit is shown in Table 1. The maximum glare duration at the east exit of the tunnel occurs at the summer solstice, which is 2 hours and 17 minutes, but there is no significant difference in glare duration compared to the spring and autumn equinoxes, The minimum duration of glare occurs during the winter solstice.

Table 1. Distribution time and duration of solar glare at the east portal.

Date	Glare Starting Time	Glare Ending Time	Glare duration
Spring Equinox (March 20th)	06:51	09:05	2h 14min
Summer Solstice (June 21st)	06:03	08:20	2h 17min
Autumn Equinox (Sep 23rd)	06:35	08:50	2h 15min
Winter solstice (December 21st)	07:23	08:30	1h 7min

The sunlight glare at the west exit occurs in the evening, and the distribution time and duration pattern were similar to those at the east exit.

Based on the BIM model simulation, it was found through roaming analysis that there will be no sunlight glare at the south and north exit.

The simulation of glare and lighting environment at the exit of different tunnel portal types are shown in Figure 8 below.

By simulating and comparing the light environment of different tunnel exit types, and using the environmental diagram method^[7] for calculation, the driver's view brightness at a distance of 48.66m from the tunnel exit was increased by 70.76% compared to the end-wall tunnel portal exit. The use of hollow-bamboo-cut tunnel portal achieved a humanized transition of brightness inside and outside the tunnel, increasing the driver's visual brightness at the tunnel exit section. Due to the adaptation of human vision to changes in the brightness of the tunnel entrance, The driver's resistance to solar glare is enhanced, which can effectively prevent glare and improve driving safety.

3 RESEARCH ON GEOLOGICAL PREDICTION TECHNIQUES IN KARST PEAK CLUSTER AREAS

3.1 Geological characteristics of karst peak cluster areas

From the process of occurrence, development, and evolution, karst peak cluster landforms belong to the

(1)End-wall Portal

(2)Bamboo-cut Portal

(3) Hollow-bamboo-cut Portal

Figure 8. Light environment simulation diagram in different portal types.

middle age of the development process of karst landforms. Further development of peak clusters can form peak forests and isolated peak landforms. The hydrological system within the peak cluster depression can be summarized as a binary structure, lacking a river water system on the surface and only forming a surface karst system; Underground caves and pipelines often form a dense underground drainage network system.

The tunnel engineering in karst peak cluster areas has problems and characteristics such as large depth fluctuations, long tunnel length, strong karst development, and high risk of water and mud inrush in tunnels.

3.2 Advance prediction technology of drilling radar

Drilling radar is a geophysical method in the well that emits high-frequency electromagnetic waves into the stratum, utilizing the propagation characteristics of electromagnetic waves in the stratum to obtain stratum information and interpret unfavorable geological bodies underground. It has high resolution and a large detection range. There are three measurement methods for drilling radar: single hole reflection measurement, cross hole measurement, and hole to ground measurement. In order to verify the effectiveness of the drilling radar method in advanced geological prediction of tunnels, this project adopted a combination of single hole, cross hole, and hole ground methods, and conducted experimental work relying on tunnel engineering.

The geological advance prediction method for tunnels has been developed for karst peak cluster landform areas based on advanced drilling, drilling radar, and ground radar technology, which combines “single hole-cross hole-hole surface” and “three hole combination”. The method has been verified through exploration in the Siding extra long tunnel, and the prediction results are very consistent with actual exploration, improving the accuracy of advance prediction, overcoming the shortcomings of single hole’s unable to locate karst and multiple holes’ affecting construction duration.

Figure 9. Photos of drilling radar on-site testing.

3.3 BIM simulation analysis of tunnel water inflow

Prediction of water inflow in karst tunnels is a prerequisite and foundation for tunnel design and construction. At present, the method of tunnel water inflow prediction includes rainfall infiltration method, groundwater dynamics method, groundwater runoff

Figure 10. Technical process of “three hole combination method”.

Figure 11. Test and verification of aperture surface combined with radar.

modulus method, and depression infiltration method. BIM technology plays a significant role in improving the accuracy of tunnel water inflow by improving the calculation of catchment area using rainfall infiltration method and determining the location of water inflow.

Figure 12. Watershed analysis (red lines indicate regional boundaries).

The achievements of civil engineering 3D design and a series of functions of Map 3D have been expanded and achieved by Civil 3D effectively, which can handle geographic information, planning, and engineering decision-making. Building a BIM model by using Civil 3D can quickly perform watershed analysis and water drop analysis.

Creating terrain surfaces and conducting watershed and surface runoff analysis through Civil 3D, combined with hydro-geological and engineering geological analysis, possible development channels and directions of underground karst can be effectively inferred, providing reference and reference for karst prediction during tunnel construction in karst areas.

Figure 13. Water drop analysis (blue line indicates the direction of the drop).

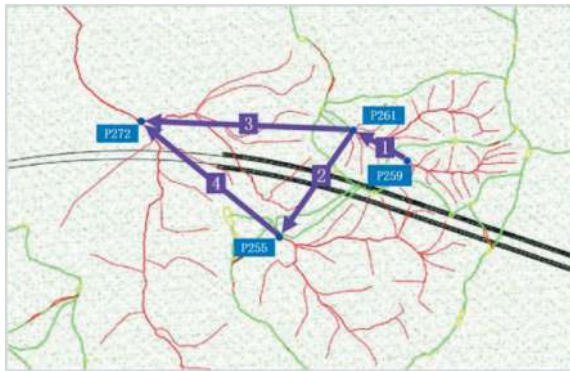

Figure 14. Underground runoff path and direction of surface water collection in watershed depressions.

4 RESEARCH ON TUNNEL STRUCTURE AND WATERPROOF & DRAINAGE TECHNOLOGY IN KARST PEAK CLUSTER AREAS

4.1 Hydrological characteristics of karst peak cluster areas

The vertical zoning of groundwater hydrodynamics in karst peak cluster areas can be divided into four zones: vertical infiltration zone, seasonal alternation zone, saturated zone, and slow flow zone. Vertical infiltration zone refers to the zone above the groundwater level during the rainy season; The seasonal alternation zone refers to the zone between the groundwater levels during the high and low water periods; The saturated zone refers to the zone between the groundwater level during the dry season and the local erosion drainage benchmark.

Due to the large terrain fluctuations in karst peak areas and the long length of tunnels, a tunnel may cross multiple vertical zones of groundwater hydrodynamic forces in a longitudinal direction. The tunnel faces a great risk of mud and water inrush. In addition to the pressure of surrounding rock, the tunnel structure also needs to withstand complex and variable groundwater pressure.

The lithology of the karst peak cluster area is mostly composed of soluble rock masses such as limestone and dolomite. The surrounding rock is severely corroded, and the groundwater hardness is relatively high. Crystallization is very common in the tunnel drainage system, with prominent crystal blockage at construction joints. And the construction joint is the weak point of tunnel waterproofing and drainage, and the difficulty of construction quality control. Once the waterproof and drainage facilities in the tunnel fail, it is easy to form seepage, water gushing, and water curtains, seriously affecting driving safety.

Figure 15. Water curtain disease formed at construction joints.

4.2 Optimization of tunnel support structure in gushing water section

The design of general anti water pressure lining mainly involves increasing the thickness of the tunnel secondary lining and improving the compressive capacity of the tunnel section to bear groundwater loads. Based on the research and analysis of vertical zoning of groundwater in karst peak cluster areas, a double-layer initial support system was proposed for tunnels located in the vertical infiltration zone to seasonal alternation zone. The parameters of the tunnel support system were optimized, and grouting+double-layer initial support system was adopted to achieve drainage limit conditions. The bearing capacity of the initial support was increased and part of the water pressure was borne, the thickness of the secondary lining was reduced, the cost of template trolley transformation was saved, the construction difficulty was reduced, the construction period was accelerated.

4.3 Research and application of anti crystallization waterstop

In response to the widespread problem of crystallization in the drainage system of tunnels in karst peak cluster areas, a waterstop with both drainage and anti crystallization functions has been developed and applied to tunnel construction joints and settlement joints.

Figure 16. Optimization section of tunnel support structure in gushing water section.

Figure 17. Waterstop with drainage and anti crystallization functions.

The application of waterstop with drainage and anti crystallization functions prevents crystallization blockage in the drainage channel, ensures smooth drainage of the channel, reduces water pressure on the tunnel structure, improves the durability of drainage waterstop, and enriches the types of tunnel waterstop.

5 ENGINEERING APPLICATION ANALYSIS

5.1 Overview of tunnel

The Siding Extra Long Tunnel, located in the Guilin-Liucheng Highway in Guangxi, was

Figure 18. Photos of siding extra long tunnel.

completed and opened in December 2021. It was the longest highway tunnel in Guangxi at that time.

The starting and ending chainage of the left tunnel were ZK61+220~ZK66+860, with a length of 5640m. The starting and ending chainage of the right tunnel were K61+192~K66+839, with a length of 5647m. The maximum burial depth of the tunnel was about 301m. The construction clearance of a single tunnel was 11.0m×5.0m (width×High). The azimuth angle of the entrance direction of the tunnel axis was about 262°(8° due east by south), the azimuth angle of the tunnel body section was about 289°, and the azimuth angle of the exit direction is about 282° (12° due west by north). The left and right entrance and exit doors are all equipped with new hollow-bamboo-cut type portals.

5.2 Analysis of social and economic benefits

New technologies and products such as the light environment design technology for green highway tunnel portal, hollow-bamboo-cut portal, drilling geological radar prediction technology in karst peak cluster areas, BIM simulation analysis technology for tunnel water inflow, and waterstop with drainage and anti crystallization functions have been successfully applied to the Siding extra long tunnel. The landscape effect of the tunnel portal has been improved by the key technology, especially, the “white hole” and “black hole” effects of the tunnel portal have been effectively solved, glare has been effectively prevented, the driving comfort and safety of the tunnel portal have been improved, and the energy consumption of tunnel lighting has been reduced, saving 75.1 tons of energy conversion standard coal annually. BIM technology has been used to simulate and predict tunnel water inflow. advanced geological prediction methods such as single hole reflection measurement, cross hole measurement, and hole ground measurement have been proposed to evaluate and analyze the environmental impact of tunnels in karst peak cluster areas. The concept and construction method of “connecting first, prevention, drainage, blockage, and interception combined, adapting to local conditions, protecting ecology, and comprehensive management” have been proposed. The construction methods for tunnel disaster prevention and ecological protection in karst peak cluster landform areas have been formed. The new type of waterstop with drainage and anti crystallization functions can be applied to tunnel construction joints and settlement joints. It’s functions such as waterproofing, drainage, and anti crystallization, effectively solving the problems of water leakage in tunnel construction joints and settlement joints, as well as crystal blockage of drainage facilities. According to calculations, a direct economic benefit of 36.75 million RMB has been created, the quality of tunnel engineering has been improved, and the concept of green highway construction were reflected. The economic and social benefits are very significant.

6 CONCLUSION

Through theoretical analysis, simulation, on-site testing, and engineering applications, a systematic study was conducted on the key technologies for the construction of extra long green highway tunnels in karst peak cluster areas. Based on the above, the main achievements and conclusions can be drawn as follows:

- (1) BIM technology has been applied to the study and analysis of the light environment of tunnel portal for the first time, such as sunlight analysis and glare analysis. Innovative proposals have been made for the structural type of hollow-bamboo-cut portal, and the construction process and method of hollow-bamboo-cut portal has been formed
- (2) Based on the geological characteristics of tunnels in karst peak cluster landform areas, BIM technology has been applied to establish a prediction method for tunnel water inflow, and a joint detection technology of “single hole radar-cross hole radar-hole surface radar” geological advance prediction has been developed
- (3) A waterstop, combined drainage and anti karst crystallization functions, has been developed. The problems of water leakage from tunnel construction joints and settlement joints, and crystal blockage of drainage facilities have been effectively solved

The research results of this article have been promoted and applied to multiple highway projects in China. However, further research is needed to address issues such as the construction of tunnel clusters, and the impact on water environment during tunnel operation in karst peak cluster areas.

ABSTRACT: Bhutan is a small mountainous kingdom located in the eastern part of the Himalayas between China in the north and India in the east, west and south. There exist several major rivers throughout Bhutan that provide excellent opportunities for hydropower development that have been constructed since the 1980's. To date, more than 100 km of long (6-23 km) and medium to large size (6-12 m) low pressure headrace tunnels have been constructed by traditional drill and blast methods via multiple adits along the tunnel alignments and finished with concrete linings. The headrace tunnels have been constructed within both the Lesser and Greater Himalaya geological environments where challenging geotechnical conditions have been experienced including major geological faults with running ground and collapses, large volume and high-pressure groundwater inflows, appreciable overbreak, abrasive rock conditions, and in some cases the need to re-align the tunnel. Traditional and innovative mitigation measures including pre-support forepoling, sequential excavation, and pre-drainage have been successfully implemented to allow the completion of the headrace tunnels and operations of the multiple hydropower plants.

Keywords: Lessons Learned, long tunnels, drill and, blast excavation, hydropower

1 INTRODUCTION

Bhutan is a small mountainous kingdom of less than 40,000 km² and about 750,000 inhabitants and located in the eastern part of the Himalayas between China in the north and India in the east, west and south. There exist several major rivers throughout Bhutan where excellent opportunities for hydropower development have been completed since 1985 with glacial meltwater from the northern part and relatively high precipitation especially during the monsoon season. To date, more than 100 km of long (6-23 km) and medium to large size (6-12 m) low pressure headrace tunnels (HRTs) have been constructed by traditional drill and blast methods via multiple adits along the tunnel alignments and finished with concrete linings. Despite the headrace tunnels being sited within the lower Himalaya geological environment, challenging geotechnical conditions have been experienced including major geological faults with running ground, large volume and high-pressure groundwater inflows, appreciable

overbreak, abrasive rock conditions, and in some cases the need to re-align the tunnel. Traditional and innovative mitigation measures have been successfully implemented to allow the completion of the headrace tunnels and operations of the multiple hydropower plants. Significant associated underground excavations have also been constructed in Bhutan as part of these hydropower projects including large powerhouse caverns and long pressure and surge shafts. Figure 1 presents a typical large and steep valley where hydropower projects have been planned and constructed in Bhutan.

2 PAST, RECENT AND CURRENT PROJECTS

Table 1 presents the past and recently completed major tunnels along with current major tunnels. All of the hydropower tunnels in Bhutan can be recognized as major tunnels as part of large hydropower developments with installed generation capacities varying from 120 MW to 1200 MW. One of the

*Corresponding author: t.dorjee2167@drukgreen.bt

projects is currently in construction and two of the projects have experienced exceptional circumstances that has prevented them from being commissioned and these unique challenges are discussed later.

3 DESIGN AND CONSTRUCTION APPROACH

3.1 Tunnel design

All of the tunnels have been designed as high elevation, low gradient pressure tunnels aligned sub-parallel to the major valleys that typically transect multiple cross valleys. Horseshoe, circular, and D-shaped cross-sectional geometry has been adopted with full (100%) concrete linings for long-term low maintenance hydropower operations.

Limited geotechnical investigations were completed at most projects given the very difficult access along the steep terrain and densely vegetated topography. Geotechnical drilling was typically limited to the dam and powerhouse locations with only short holes along the tunnel alignments that was sometime supplemented with geophysical surveys. Exploration adits were typically excavated at most dams and powerhouses that provided good insight into the main bedrock types as well as for in situ testing of rock

mass deformability. Table 2 presents a summary of the key investigations completed for the tunnels.

Table 2. Summary of Key Investigations for the Tunnels.

Project	Total Drilling, m	Drift Length, m
Chhukha	?	?
Tala	?	580
Dagachhu	980	N/A
Punatsangchhu 1	1129	550
Punatsangchhu 2	1640	N/A
Mangdechhu	638	452
Nikachhu	1946	727
Kholongchhu	1420	808

3.2 Tunnel construction

Traditional drill and blast methods have been used for the construction of all of the hydropower tunnels to date using multiple adits parallel to valley with individual camps and spoil sites at each adit location. The smaller size tunnels, typically less than 6.8 m have been excavated full face while the larger tunnels were excavated by top heading and bench stages. Some of the major tunnels have experienced significant geological overbreak during construction given the highly fractured nature of the bedrock at some projects. Traditional components of rock support including pattern rock bolts, mesh, shotcrete, and steel ribs with forepoling/spiling for adverse geological occurrences (AGO's) formed the various tunnel support classes that were evaluated based on face mapping after each blast. Most of the construction adits were sealed with concrete plugs following completion but at least two (2) adits were completed with hydraulic pressure doors for future access and inspections. Finally, most of the tunnels were constructed under design-build (EPC) type of contracts, with the most recent including a Geotechnical Baseline Report (GBR) for risk sharing of the encountered geotechnical conditions. The increasing number of future major tunnelling projects in Bhutan with long and deep tunnels with challenging access and increasing environmental impacts has led to the scope for the consideration for the use of tunnel boring machines (TBMs) as has been recently and successfully used in neighbouring Nepal and again being used in India. The construction of several of the major tunnels in Bhutan have resulted in contractual disputes. Bonaventura et al. (2015) have reported that 55% of claims associated with long and major tunnels in Bhutan have been due to differing site conditions (with 49% due to adverse geotechnical conditions) which have resulted in appreciable delays in the completion of construction for dispute resolution.

4 ENCOUNTERED GEOTECHNICAL CONDITIONS

4.1 Regional and local geology

The majority of the major hydropower tunnels constructed to date in Bhutan have been sited within the Lower Himalayan geological region where the bedrock formations have been only subjected to very limited distortion and tilting unlike that associated with the central and upper Himalayan geological regions. Typically, bedrock formations include mixtures of gneiss, phyllite, mica-schist and quartzite of variable rock mass quality and degree of fracturing. The quartzite bedrock is particularly very strong with rock strengths varying from 250 MPa to 350 MPa. Figure 2 presents a typical example of a major outcrop of quartzite in Bhutan. Major shear zones of low quality and non-durable phyllite are often intermixed within the more competent and durable quartzite.

Figure 2. Major outcrop of quartzite.

4.2 Groundwater conditions

All of the tunnel alignments are aligned sub-parallel to major valleys with elevated topography and with the significant groundwater recharge from annual monsoon rains there is appreciable groundwater resources in the project areas. Extensive permeability testing has been performed as part of geotechnical investigations for dam sites that has indicated Lugeon values generally ranging from $Lu=1$ to $Lu=10$ for shallow depths to 100 m and Lugeon values generally less than $Lu=3$ for depths greater than 200 m. Large groundwater inflows have been experienced during the excavation of most of the HRT's with short-term dissipation of inflows. Major and continuous inflows of more than 125 l/s at Nikachhu HRT.

4.3 In situ stresses

Hydro-fracturing testing has been typically carried out at the powerhouse locations primarily for the evaluation of low in situ stresses for steel lining

design of the pressure shaft. Hydro-fracturing testing results can however also offer insight into the possible maximum in situ stresses for the powerhouse cavern stability and rock support requirements. The powerhouse caverns and pressure shafts of most of the hydropower projects in Bhutan have been sited at the intersection of a main valley and that of a cross valley where a topographic “nose” exists with limited lateral cover. These areas are commonly associated with low confining in situ stresses or are de-stressed as a result of intersection geological faults associated with the topographic valleys. Multiple geotechnical drillholes have been completed as part of the powerhouse cavern and pressure shaft designs and hydro-fracturing testing have been performed at varying depths of such drillholes to provide multiple testing results and greater confidence in the prevailing in situ stresses in these important project areas.

Figure 3. Hydrofracturing testing results at powerhouses.

Figure 3 presents the results from several campaigns of hydro-fracturing testing at the powerhouse and pressure shaft sites of various projects in Bhutan.

5 MAJOR HYDROPOWER TUNNELS

5.1 Chhukha

The Chhukha hydropower project that included a 6.5 km, 5 m HRT was the first major project constructed in Bhutan starting in 1979, and with the commissioning of the plant in 1986. Madhavan et al,

(1987) and Shukla (2016) report that during the excavation of the downstream section of the D-shaped HRT a saturated sand seam was unexpectedly intersected after 565 m that resulted in a sudden in-rush up to 50 m³/s of flowing ground with failure of steel rib support and fatalities and a delay of six months before construction resumed with a re-aligned section. Subsequent drilling investigations confirmed the presence of a deep slide area above the tunnel of water saturated fluvial terrace deposits with very limited cover. No probe drilling ahead of the tunnel face was performed during excavation and this represented a key technical shortcoming. Unwatered inspections of the Chhukha tunnel were performed in 2011 and again in 2021 using a remote operated vehicle (ROV) and no signs of any form of distress were observed of the concrete lining after a total of 35 years of operations.

5.2 Tala

The construction of the Tala hydroelectric project commenced in late 1997 and the construction of the HRT was completed in November 2004 with the first generating unit commissioned in 2006 and with the final unit commissioned in 2007. The 23 km long HRT was constructed as a 6.8 m internal diameter of horseshoe-shape using traditional drill and blast methods from a total of 5 adits with 11 working faces with a layout as presented in the plan and profile layout of Figure 4. The maximum cover along the HRT was about 1000 m. The alignment of the HRT includes six (6) bends. The total length of HRT was divided into four packages as indicated in Figure 4. Package C-1 comprised of 6.5 km length of initial reach of HRT from desilting chambers side. Package C-2 consisted of 5.0 km length of HRT. Package C-3 comprised of 4.4 km length of HRT. Package C-4 with a length of 7.2 km was the most typical package with regards to the difficult tunnelling conditions.

Construction of the HRT was delayed by approximately one year due to challenging geological conditions with nearly 30% of the geological conditions classified as poor to very poor and there were large variations in the originally anticipated rock mass conditions as per the contract and as actually encountered rock mass conditions in the HRT excavation (Singh and Khazanchi, 2010). For the HRT, 75% was expected to be excavated through class I to class III (very good to fair tunnelling medium) and 25% in class IV and in class V (poor to very poor tunnelling medium). However, about 27% of tunnel length was excavated in class III and 74 % was excavated in class IV, V, VI and in exceptionally poor tunnelling conditions.

Table 3 presents the summary of the originally anticipated geotechnical conditions versus the actual geotechnical conditions and the increase if poorer conditions of a total of 48%. It is particularly noted from Dev et al. (2013) that concrete grade M15A20 was used as backfilling between the steel arch ribs for tunnel support classes IV, V, and VI for the poorest of geotechnical conditions and that the internal diameter

Figure 4. Layout and re-alignment for tala headrace tunnel.

of the HRT was reduced to 6.5 m along these sections. Very difficult tunnelling conditions were experienced at a shear zone downstream of the Mirchingchhu adit where the HRT was re-aligned under deep cover over a length of about 1190 m and special tunnel support was installed. Despite this a major failure of the high-capacity support occurred as shown in Figure 5.

Table 3. Anticipated and actual geotechnical conditions.

Rock Class	Anticipated %	Actual %	Increase %
1	0%	0%	
2	6%	0%	
3	69%	27%	
4	21%	41%	20%
5	4%	21%	17%
6	0%	6%	6%
7-AGO	0%	5%	5%
Totals	100%	100%	48%

Finally, the Tala tunnel experienced problems after 13 years of operations with the loss of appreciable pieces of concrete lining along a 35 m section along the upstream section as a result of ongoing instability as squeezing due to insufficient support at this section that was aligned sub-parallel to a major lineament and cross valley creek. The instability was detected and identified from an unwatered inspection in 2021 using a remotely operated vehicle (ROV) and repairs of this section were performed over a 3-month period in 2022 (Brox et al, 2023).

5.3 Dagachhu

The construction of the 7.7 km HRT for the Dagachhu hydropower project commenced in 2009 and was commissioned in 2015. The HRT was constructed through

Figure 5. Failure of high-capacity tunnel support.

a mixed sequence of gneiss and mica-schist with a maximum cover of about 630 m. The tunnel transected two main valleys where open aerial pipeline bridge sections were constructed of lengths 600 m and 100 m. The rate of progress of excavation with initial support was limited due to the poor encountered conditions and generally ranged from 1.25 m/day to 1.5 m/day and rate of progress of the final concrete lining generally ranged from 3 m/day to 6 m/day. Groundwater inflows were generally very limited below 1 l/s but with only five locations of elevated inflows from of 3 l/s to 11 l/s. Figure 6 presents the longitudinal and statistical distributions of installed tunnel support for northern 4 km section of the tunnel that indicates that mainly Classes 2 and 3 were installed. Minor squeezing conditions were experienced during construction under the maximum cover section over a length of 640 m with cracking of the initial support shotcrete and minor buckling of the lattice girders that required the installation of additional initial support comprising mesh reinforcement followed by a final concrete lining that required an additional 2.5 months.

Figure 6. Distribution of installed tunnel support.

The Dagachhu HRT experienced some very challenging conditions along the northern low cover section whereby a 15 m high cavity formed during excavation with flowing ground and high groundwater inflows. Pipe umbrella support had to be installed along this section without blasting and excavation by excavator only of suspected geological fault materials as

presented in Figure 7. A portion of this section of the HRT resulted in misalignment and in order to provide an acceptable final lining solution a 160 m long section of steel lining was required to be installed.

Figure 7. Pipe umbrella support in Dagachhu HRT.

5.4 Punatsangchhu 1

The Punatsangchhu 1 headrace tunnel was the first large size (10 m) tunnel constructed using top heading and bench methods from December 2009 to December 2012 and was completed under two contracts for the upstream 7.5 km and the downstream 1.5 km and using only two intermediate access adits. The 9 km HRT parallels the left bank of the valley under a maximum cover of 500 m. The achieved progress of excavation was consistent with what was planned as 65 m of top heading in 25 days for an average of about 2.6 m/day and about 60 m of benching in 5 days for an average of about 12 m/day. There were no good quality rock conditions anticipated along the HRT and the installed distribution of tunnel support was Class 3 (52%), Class 4 without ribs (37%), Class 4 with ribs (10%), and Class 5 (< 1%).

While preparing for the casting of the kerb concrete along a 105 m upstream section of the HRT, movement in the 250 mm steel rib supports occurred that resulted in the significant dislodging of steel ribs and the detachment of large rock blocks. At this location it was observed that a thick clay shear zone was present and was highly saturated that caused the instability as shown in Figure 8.

5.5 Punatsangchhu 2

The 8.6 km Punatsangchhu 2 HRT was the second largest size (11 m) tunnel constructed using top heading and bench methods and was contracted in 2 packages, included excavation utilizing two intermediate access adits, and was constructed from late 2012 to October 2018. At the time, it was the largest HRT constructed in Asia.

Figure 9 illustrates the HRT. The HRT parallels the right bank of the valley under a maximum cover of about 560 m.

Figure 8. Dislodging of Steel Ribs at Shear Zone.

The maximum cover along the alignment was 580 m. Average progress rate of excavation for the top heading was 3.3 m/day, and 6.9 m/day for benching. Difficulties were encountered along both access adits due to the intersection of major shear zones necessitating re-alignments of the access adits to the intersection of the main HRT. Rock support comprised a series of classes from a minimum pattern rock bolts of 6 m length through to 250 mm steel ribs with variable spacings from 400 mm to 750 mm with 125 mm shotcrete. While an average or typical overbreak of 1.5 m was realized, which represents an appreciable amount for backfilling, there were a limited number of locations for major overbreak as much as 12-14 m occurred that was associated with the intersection of very poor conditions and where more than 1100 bags of concrete was backfilled.

Figure 9. Top heading and Benching in Punatsangchuu 2.

A major collapse occurred during the excavation of intermediate adit 2 and the junction with the main tunnel whereby a low dipping shear zone was intersected. Despite the installation of high-capacity support of steel ribs, rock bolts, fibre-reinforced shotcrete with forepoling and channels to support the crown from detachment as a precautionary measure, several large blocks became dislodged and caused distortion of the installed support as shown in Figure 10.

In addition to challenges with the excavation of the HRT, a major collapse occurred in the powerhouse. On

March 3, 2016, a massive roof fall of approximately 100,000 m³ occurred in the downstream surge gallery (cavern) which halted the operations in the major caverns and required additional strengthening measures.

Figure 10. Distortion of high-capacity tunnel.

The collapse extended up to 100 m upwards into the overlying deep overburden above the powerhouse. Prior to concluding anything on the treatment measures for the muck dislodged into the cavern and the cavity formed over the crown of the downstream surge chamber, there was a strong need to determine the extent of the resulting cavity. Even to understand the influence of cavity formation on the adjacent transformer cavern, the cavity needed to be delineated. Therefore, the project client adopted several techniques to decipher the shape and dimensions of the cavity including, cavity monitoring surveying, geophysical, cross-hole tomography seismic surveys, borehole scanning, and exploratory drilling. In 2022, a major stabilization program was initiated with the backfilling of cavern, placement of reinforced concrete walls, and the installation of nearly 20,000 m of 100-ton tie-back strand anchors (Roberti, 2023).

5.6 Mangdechhu

The construction of the 13.5 HRT of the 720 MW Mangdechhu project parallels the left bank of the Mangdechhu valley commenced in early 2012 and was completed in 63 months using five (5) intermediate access adits. The maximum cover along the HRT was about 900 m. A design change completed during the early stage of the HRT was the size of the intermediate access adits from 6.5 m to 7.5 m to better facilitate ventilation, services, and mucking as requested by the contractor. The distribution of anticipated and actual tunnel classes is presented in Table 4 which indicates a minor increase in poorer than expected ground in comparison to the construction of other HRT's.

In addition, tunnel excavation experienced challenges with a major fallout at the intersection of Adit 3 and the HRT as depicted in the graphic of Figure 11.

Finally, squeezing conditions with buckling of steel ribs occurred with deformation as much as 560 mm along an upstream section of the HRT with mica schists, quartzitic schists and quartz biotite gneiss

under a cover varying from 750 m to 1000 m as presented in Figure 12. In addition, post-excavation slabbing due to dilation to a depth of 1.5 m.

Table 4. Anticipated and actual tunnel classes.

Rock Class	Anticipated %	Actual %	Increase %
1	0%	0%	
2	25%	6%	
3	50%	71%	21%
4	20%	22%	2%
5	5%	1%	
6	0%	0%	
7-AGO	0%	0%	
Totals	100%	100%	23%

Figure 11. Major fallout of ground at intersection of HRT.

Figure 12. Squeezing conditions and buckling of steel ribs.

5.7 Nikachhu

The 9 km HRT for the Nikachhu power plant is the most recently completed major tunnel and was constructed using four (4) intermediate access adits through mixed rock conditions of mica schist, quartzitic schist and quartz biotite gneiss. Tunnel excavation experienced multiple challenges including the intersection of large unstable wedges, major shear zones with

squeezing conditions with a maximum convergence of over 550 mm, slabbing and rockbursting under high cover section of 700 m to 1000 m and large groundwater inflows up to 125 l/s as presented in Figure 13. Mitigation for some of these challenges included stress relief holes were provided for release of stresses, split heading excavation with top heading and benching, and curved invert struts for the squeezing conditions poor rock mass.

After the completion of the project, the Nikachhu hydropower plant will provide additional water to the Mangdechhu Hydropower Plant (MHP) to enhance power generation during lean seasons as the water discharged from its tailrace tunnel is spilled directly into the dam of Mangdechhu.

Figure 13. Very Large groundwater inflows.

5.8 Kholongchhu

The 15.8 km HRT for the Kholongchhu hydropower plant started construction in April 2021 utilizing six (6) intermediate access adits. The HRT parallels the right bank of the north-south oriented valley and the maximum cover along tunnel is about 560 m and there exist two cross valleys where the minimum cover is less than about 75 m and 45 m where steel lining sections will be required as part of the design to prevent leakage during operations. A total of eleven (11) lineaments have been identified to transect the HRT with 2 described as minor, 4 as intermediate, and 5 as major lineaments. Most of lineaments are oriented mainly

Figure 14. Adit construction at Kholongchhu.

north-easterly but the major lineaments are oriented east-west and southeasterly. The main rock types anticipated to be encountered during construction are gneiss with bands of quartzites, amphibolites, schist and intrusions of porphyritic granite of variable thickness. The anticipated distribution of tunnel classes has been estimated to be Class 2 (8%), Class 3 (77%), Class 4 (8%), and Class 5 (7%). The construction of the project is on hold since mid-2022 due to restructuring of the project ownership and is expected to resume construction by the end of 2023. Since April 2021 until mid-2022, some progress in development of HRT portals have been made as shown in Figure 14.

5.9 Future tunnel – Dorjilung

A major new tunnel is currently planned as part of Dorjilung hydropower project and comprises a 15 km, 11 m size tunnel aligned sub-parallel to the Kirichhu valley in eastern Bhutan. Maximum cover along the tunnel is about 800 m over a relatively short section and about a 500 m length of cover over 500 m. The geology along the tunnel alignment comprises mainly very strong but closely spaced fractured quartzite (~70%) and phyllites (~30%).

The tunnel alignment passes below two major valleys with cover of about 100 m and where geological faults or fractured zones are anticipated and where steel lining sections will be required unless re-aligned. Drill and blast methods of excavation with a total of 6 intermediate adits represent the base case for studies to date. The highly fractured nature of the quartzite has been recognized as a key risk for excessive overbreak, even for top heading and bench stages of excavation given previous limited controlled drilling and blasting practices where significant overbreak was experienced.

Accordingly, this tunnel is the first major tunnel in Bhutan where the use of a tunnel boring machine (TBM) is being contemplated. Based on a preliminary schedule comparison there is a possible 18-month savings with the use of a TBM with concurrent pre-cast concrete segmental lining. The use of a TBM is considered to be technically viable for this tunnel regarding the geotechnical conditions and key environmental advantages of the TBM option are available power from a nearby hydropower plant located immediately downstream as well as the elimination of the multiple intermediate access adits and the associated logistics of camps, spoil sites and traffic. Accordingly, the TBM option will be further evaluated holistically in terms of logistics, overall project timeline, cost-benefit to the project and risks associated with the use of a TBM for the site-specific geotechnical conditions of the HRT.

6 UNIQUE CHALLENGES OF OTHER COMPONENTS

The hydropower projects in Bhutan have experienced unique challenges associated with other major components of the projects which has

prevented the commissioning of some of the projects. A major landslide is present along the right bank at the Punatsangchhu 1 project preventing the construction of the dam. A significant collapse has occurred within the downstream surge cavern of the Punatsangchhu 2 project which is under rehabilitation. At Tala there has been the ongoing failure of rock bolts in the powerhouse after several years of operations.

7 KEY CHALLENGES AND LESSONS LEARNED

The following challenges and key lessons learned from the past 100 km of hydropower tunnels in Bhutan are:

- Unanticipated adverse geotechnical conditions were encountered that caused appreciable delays in the absence of comprehensive geotechnical investigations;
- Large instabilities have generally been experienced with the construction of large size tunnels;
- Greater attempts are to be made for deep geotechnical drillholes along all long and deep headrace tunnels as well for all key components such as surge and pressure shafts;
- Greater geotechnical testing should be conducted especially for very strong and abrasive bedrock;
- Improved evaluation of main lineaments along the tunnel alignments and their geological characterization;
- Detailed geotechnical models are required to be developed for main project components based on improved investigations to be attempted despite the challenging mountainous terrain;
- Improved estimates should be developed for anticipated groundwater inflows;
- Geotechnical Baseline Reports (GBRs) should be prepared in accordance with the format and content of the ASCE guidelines for all new major tunnels to attempt to limit claims and avoid confusion of presenting factual and interpretative geotechnical information that should be contained in their respective reports (GIR and GDR);
- Improved practices to be included in technical specifications for controlled drilling and blasting possibly with computerized jumbos to limit overbreak, and;
- The option of tunnel boring machines (TBMs) in conjunction with pre-cast concrete segmental linings should be thoroughly evaluated and considered for construction of new major tunnels subject to acceptable geotechnical conditions and logistical requirements.

ABSTRACT: The design and construction of underground cross passages are one of the challenging tasks in soft ground tunnelling in urban areas. According to the construction of MRT Orange Line (East Section) Project in Bangkok, two cross passages between an intervention shaft and a segmental tunnel lining are designed and constructed to serve emergency egress for commuters and ventilation purpose. The application of New Austrian Tunnelling Method for tunnel construction is employed for cross passages. Special measures of ground improvement by jet grouting and pre-support techniques are employed prior to excavation. In addition, the application of special segments for bored tunnel and the use of temporary steel ring to support the opened ring of the bored tunnel are utilized to effectively enhance safety and stability. This paper presents an introduction to the project, specific site constraints and requirements on the design and construction. It also provides the design process and key considerations on the construction of cross passages work which contribute to the successful implementation of the tunnelling works.

Keywords: Tunnelling, Cross passage, Primary lining, NATM, Final lining

1 INTRODUCTION

In the last few decades, the expansion of congested urban areas has rapidly increased the demand for underground structures, particularly metro tunnels. Owing to a tunnelling work, it is undeniable that a design and construction of cross passages are considered to be one of the most challenging tasks for tunnelling in soft ground conditions. This is due to the complicated construction sequence and high proportion of ground-structure interaction. It also involves difficult technical challenges in supporting the tunnel face, excavation profile, and existing bored tunnel lining (Kuyt, 2015).

The MRT Orange Line (East Section) project – Contract E2, an intervention shaft is designed to be typically positioned at every 750 m between two underground stations along the tunnel alignment to provide a means of emergency escape and

ventilation system in accordance with NFPA 130. Due to restrictions of the construction area, a top – down construction by using diaphragm walls for an intervention shaft 14 (IVS14) to cover the tunnel is restricted in very dense areas. Thus, a cross passage is proposed to tackle this issue as shown in Figure 1.

Three aspects of cross passage design and construction generally require structural and geotechnical considerations including excavation and support installation of primary lining, support of running bored tunnel during construction, and permanent lining of the cross passage.

A primary support typically involves a shotcrete lining, also known as a sprayed concrete lining, with additional reinforcements as required. Excavation and support installation of the primary lining play an essential role in maintain stability and controlling the level of ground movements which is particularly in

*Corresponding author: ochok_d@gfe.co.th

urban areas. During the excavation and opening for cross passage, the forces in tunnel lining can be distributed and transferred to the adjacent fully enclosed tunnel rings (Lee and Choi, 2014). Consequently, support of bored tunnel is required to transfer of the excessive loads from tunnel lining and mitigate lining ovalization resulted from tunnel opening and mined adit excavation. The final lining is the main permanent structural support element of cross passages which include cast-in-place reinforced concrete, connecting concrete collar and waterproofing system.

In this paper, the design methodology and construction of the cross passage for the MRT Orange Line Project is presented.

2 PROJECT DESCRIPTION

Mass Rapid Transit Authority of Thailand (MRTA) has implemented the MRT Orange Line (East section) project to proceed a comprehensive rail system in Bangkok, Thailand. CKST Joint Venture is awarded to carry out the design and construction. AGATE consortium is commissioned by CKST as their designer for this contract. The MRT Orange Line Project – Contract E2 has four underground stations, three intervention shafts and 3.68 km of twin bored tunnels. In this contract, a cross passage connected between the intervention shaft no.14 (IVS14) and Westbound (WB) tunnel is required to serve two primary purposes namely, ventilation works and emergency egress work. A longitudinal section of cross passage is shown in Figure 2.

2.1 Geological conditions

The geological condition of Bangkok subsoil is relatively uniform throughout the area. The uppermost 2.0 m thick layer is the fill material, which is underlain by an 8.0 to 15.0 m thick of soft clay layer. A medium

Figure 1. IVS14 and cross passage.

stiff clay layer is found at a depth of approximately 10.0 m from the surface with a thickness of about 2.0 to 3.0 m. Below this layer is 1st stiff clay in which the thickness is about 6.0 to 10.0 m. The 1st sand layer is generally found at a depth of 25 to 30 m. The piezometric pressure head observed during the construction is about 13 m below the ground surface level.

The cross passage is designed to be positioned in the firm soil stratum of the 1st stiff layer and to avoid groundwater issues as depicted in Figure 3. Depth of ground surface level to the springline of tunnel is approximately 17 m.

3 CROSS PASSAGE SYSTEMS

Two adit tunnels connected between IVS14 and the WB tunnel are required to provide a ventilation purpose and evacuation of passengers. The requirement of minimum dimensions for ventilation adit tunnel is 3.9 m high and 3.4 m wide, whereas egress tunnel is required for 2.1 m high and 2.4 m wide. Figure 4 shows a typical section of adit tunnel where the total

Figure 2. Typical longitudinal section of cross passage.

Figure 3. Soil profile and cross passage position.

excavation area of ventilation adit and egress adit are 27.91 m² and 21.74 m², respectively. Main components of this structural system are described in the following sections.

3.1 Ground improvement

In the area of the cross passage, the WB tunnel connected to the adit tunnels is partially situated in the medium stiff clay and 1st stiff clay layers. To stabilize the surrounding ground during construction of cross passages and opening of the bored tunnel as well as to mitigate the potential impacts on the existing structures, ground improvement is proposed to be applied by jet grouting techniques. The minimum required strength of the ground improvement in the medium stiff clay layer is 1.0 MPa.

3.2 Pre-support

Canopy tubes, also known as a pipe roof method, are adopted as pre-support to be installed ahead of the tunnel face to improve the tunnel stability, stand-up time of the ground, and to allow safe excavation. A perforated steel pipe is 12 m long with an outer diameter of 114.3 mm and a wall thickness of 5.6 mm. The steel grade of the pipe is SS400 which is equivalent to a yield strength of 245 MPa.

The pipes are designed as longitudinal beams carrying the imposed load from surrounding grounds. The pipe span is taken as 1.5 times the length of the round length (John and Mattle, 2003). The section properties of the pipe are used in conjunction with the induced bending moment to calculate the maximum stress in the pipe.

3.3 Primary lining

The primary lining or shotcrete lining is typically designed to sustain the ground loads, controls the

deformations during tunnel construction, secures safe working conditions, and provide support until the final lining is completely installed. The primary lining of cross passages involves a shotcrete lining in combination with wire mesh and lattice girder.

3.3.1 Shotcrete

Shotcrete is applied as the primary support to provide the stability of the tunnel excavation. Shotcrete lining is designed to be 250 mm thick with a minimum compressive strength of 25 MPa at 28-day strength. The early strength development of shotcrete has to conform to Class J2 according to the Austrian Guideline for Sprayed Concrete.

3.3.2 Wire mesh

Welded wire mesh of 6 mm diameter bars at 100 mm spacing in both circumferential and longitudinal directions is applied into two layers. This material is used to strengthen the structural capacity of the shotcrete lining.

3.3.3 Lattice girders

Lattice Girders are installed in conjunction with shotcrete to provide immediate support and to maintain the designed shape of the tunnel excavation. A three-bar type (G105-25-32) of lattice girders with steel grade GR.75 equivalent to a yield strength of 520 MPa is proposed to be installed at every 1.0 m spacing.

3.3.4 Excavation sequence

Excavation sequence is a major influence on the stability of mined adit tunnel and ground movements in a soft ground condition. For the excavation of mined adit tunnels, the New Austrian Tunnelling method (NATM) also referred as Sequential Excavation method (SEM) is proposed to be applied for tunnel construction. The concept of NATM in soft ground is to provide the immediate tunnel support by closing the invert quickly to prevent the excessive ground movements (Mostafa et al., 2013).

Tunnel excavation is designed to sequentially perform into three stages; top heading, bench and invert as illustrated in Figure 5. A round length of 1.0 m is typically utilized for top heading and bench, whereas 2.0 m is employed for invert excavation.

In addition, further criteria are considered for the design and construction of cross passages as follows:

- The cross-sectional profile should be as smooth as possible in order to prevent stress concentration.
- Ring closure of the invert should be done behind the tunnel face as quickly as possible to create a load support ring.
- A 50 mm thick flashcrete layer is installed at the face and covered all other exposed ground surface immediately after completion of each excavation round.
- Elephant's foot was also provided at the bottom of the top heading to increase its stability.

Figure 4. Typical cross section of primary lining.

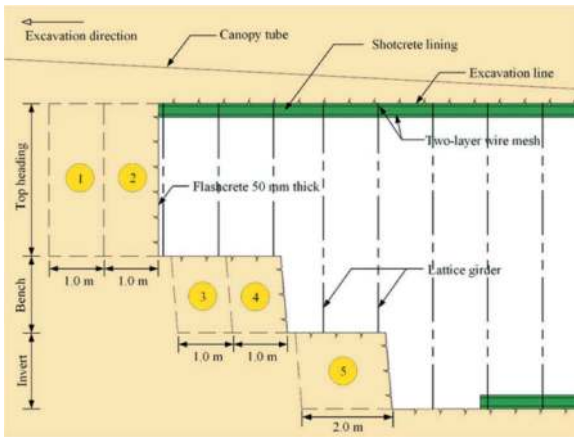

Figure 5. Excavation sequence for adit tunnels.

3.3.5 Analysis of primary lining

A two-dimensional (2D) finite element (FE) software RS2 by Rocscience is utilised for the analyses and simulation of ground conditions, loads acting on the primary lining, ground responses to the tunnel excavation and structural forces induced in the lining. The bottom boundary of the FE mesh was assigned at a depth of 50 m below the ground surface, while a width of the model was 100 m. For the displacement boundary a fixed constraint was applied only for the modelling bottom, whereas the movement was restrained in the horizontal direction for the two side boundaries. The boundary of ground surface was set as a free displacement in all directions. The FE simulation of the NATM tunnel is represented in Figure 6.

The primary lining was simulated as beam elements for both ventilation tunnel and emergency egress tunnel. In finite element stability analyses of mined tunnel, an equivalent stiffness is generally assigned to the shotcrete lining to account for hardening during application of the load as well as creep and shrinkage. Consequently, a modulus of $E = 15,000$ GPa is applied as the equivalent of the primary lining according to John and Mattle

(2003). Soils are modelled as an elastic-plastic material using the Mohr-Coulomb failure criteria.

The simulation for the primary lining design utilises a multi-staged modeling approach. An initial stage describing the in-situ stress state of the soil prior to tunnelling. The modeling stages are established to assess the individual construction stages. Top heading excavation is modelled by reduction the stress within the excavation area to simulate the excavation and prior to installation of the support and it is followed by support installation. The modelling sequence is concluded with bench and invert excavation and installation of the shotcrete lining. The amount of relaxation to be applied is derived from the ground reaction curve (GRC) corresponding to the longitudinal displacement profile (LDP) of tunnel excavation. The LDP can be generated by using axis-symmetrical analysis as shown in Figure 7.

The shotcrete lining is checked for its integrity. The capacity of the shotcrete lining is determined in accordance with BS8110.

3.4 Support systems for opening

In accordance with the requirements of the project, where openings are to be formed in the running tunnel lining, temporary internal support to the running tunnel shall be provided. These supports shall adequately restrain the lining such that, on completion of the cross passage and removal of the temporary supports.

Figure 6. 2D Finite element analysis.

3.4.1 Bored tunnel and steel segments

A precast concrete structure is utilised for twin bored tunnel. The internal diameter of precast concrete tunnel lining is 5.7 m with a thickness of 0.3 m. The width of the segment is 1.4 m. Each tunnel consists of three ordinary segments, two counter key segments, and one key segment (5+1).

To allow for openings at the cross passage, five rings are partially replaced by steel segments. The removeable fabricated steel segments are installed at

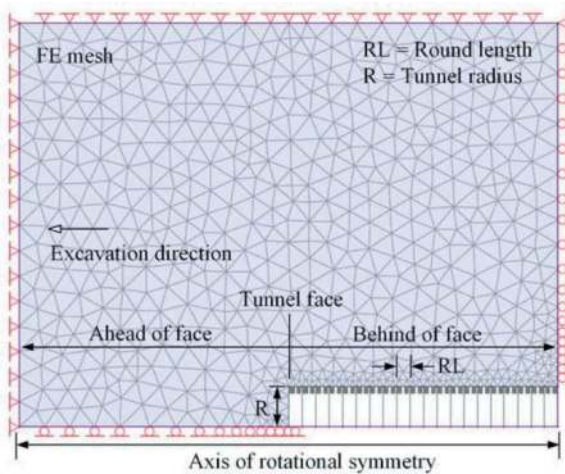

Figure 7. Axisymmetric analysis.

the opening areas for ventilation tunnel and emergency egress tunnel as illustrated in Figure 8.

3.4.2 Temporary ring support

A temporary internal support system of full moon type is utilised as presented in Figure 9. This system is capable in dealing with the heavier loads, which provides support for a full 360 degrees of the tunnel. The structural steel frame consists of a series of rigid ring beam, vertical steel props and cross beams to potentially support the opened tunnel rings and transferred the loads around the opening. A gap between the temporary ring support and the segments are filled by non-shrink grout with equivalent strength of concrete so that the loads can effectively transfer between two structures.

3.4.3 Analysis of temporary steel support

According to the requirement of the project specification, the maximum allowable deflection on radius of the running tunnel is 15 mm. A three-dimensional finite element analysis by using Plaxis3D is preliminary employed to investigate the effects of adit tunnels excavation on the TBM tunnel. As a results, it is found that 16 rings of the tunnel lining are

Figure 8. Steel segments for opening.

Figure 9. Temporary steel support.

necessarily to be required to mitigate large ovalisation and overstress of the structural system.

A structural system of 3D shell spring model constitutes 16 rings of the tunnel lining associated with a temporary steel support were then taken into consideration. The tunnel linings are modelled as curved beam elements defined by the cross-sectional properties. The inner steel ring is modelled as curved beam element whereas column and longitudinal beam are modelled by straight beam element. Connection between the tunnel linings and the inner steel rings is simulated by radial springs. Coupling between adjacent rings is simulated by shear springs. Interaction between ground and the lining is modeled by springs in radial and tangential directions. For more detailed information about the analysis procedure and related results, it can be found in the previous study (Jayasiri et al., 2022).

3.5 Final lining

In this project, the permanent lining followed the same oval shape profile as the primary lining as shown in

Figure 10. Idealized simulation of shell spring model.

Figure 11. This shape generally requires less excavation area, thickness of final lining and quantity of reinforcements. Once the excavation of adit tunnels was completed and temporary steel supports inside the bored tunnel are still active, a permanent reinforced concrete lining is then constructed so that the loads from the segmental tunnel are able to transfer to this stiffed section after removal of the steel ring supports.

The junction was designed to fully support the running tunnel lining at the opening together with the ground and groundwater loads on the junction itself and maintained the specified watertightness of the tunnels. The final lining was also analysed using the finite element code RS2. For these analyses the following loads on the final lining were taken into account: full overburden pressure, different water pressures with groundwater at current level and surface level and a surcharge load of 50 kPa. The concrete collar section was also designed to carry the entire loads from the surrounding soils as well as the loads transferred from segmental tunnel lining at the opening areas. It should be noted that the primary shotcrete lining was assumed to be fully degradable in the long-term condition, thus the property of shotcrete material was not taken into account in the simulation of permanent tunnel lining.

Characteristic concrete cube strength at 28-day of 40 MPa and a steel grade of SD50 (yield strength = 490 MPa) were employed for the construction of the permanent lining. A concrete cover to all reinforcement types of 50 mm was proposed for the final lining subject to the requirements of the exposure condition and 4-hour fire resistance. To transfer a load from segmental lining to the collar section, shear dowels are installed.

The structural capacity in terms of Ultimate Limit State (ULS) of the final lining is determined in accordance with BS8110. Furthermore, verification of Serviceability Limit State (SLS) is performed to satisfy the allowable crack width of 0.3 mm for the final lining.

4 CONSTRUCTION

This section aims to briefly present the construction sequences of the cross passage to connect between the running tunnel and IVS14. Work sequences can be described as follows:

- Construct and complete IVS14.
- Carry out ground improvement at the medium stiff clay layer.
- Excavate and construct WB tunnel. In this project, an earth pressure balance shield machine is employed to tunnel lining conduction.
- Install the temporary steel support within the WB tunnel prior to mined adit excavation.
- Verify geological condition and effectiveness of ground treatment. Both vertical and horizontal probes are conducted in this stage.
- Install pre-support using a drill rig. For each adit tunnel, 16 steel pipes are provided.
- After completion of the canopy tubes installation, demolish the diaphragm wall.

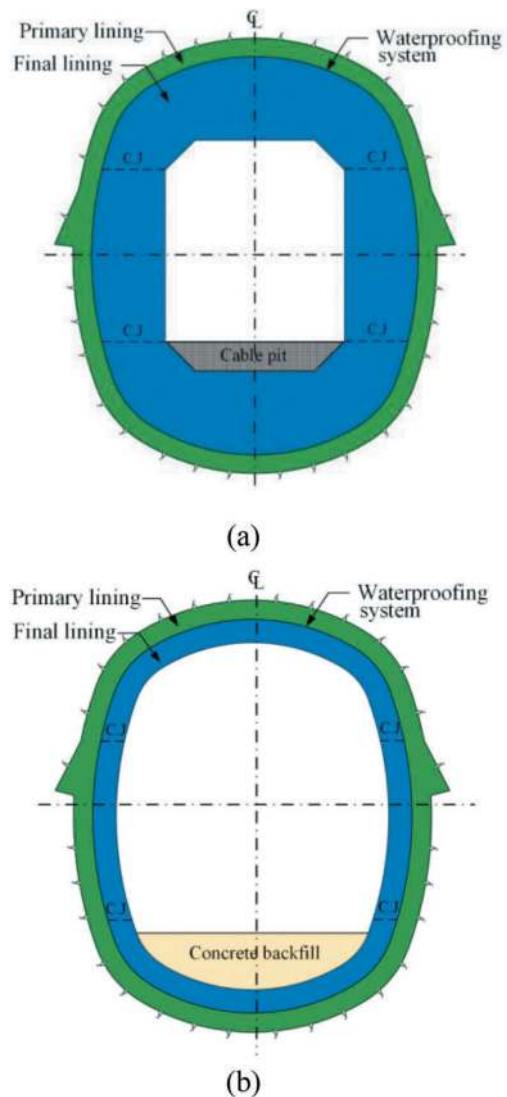

Figure 11. Final lining profiles; (a) collar section, (b) tunnel section.

- Commence excavation and support installation of the emergency egress adit tunnel. A sequential excavation is carried out.
- During excavation of mined adit, instrumentation and monitoring is frequently conducted to observe the responses of the running tunnel, existing structures as well as the shotcrete lining.
- When the excavation reaches to the WB tunnel and support installation is completed, steel segments are then removed to allow for opening.
- Excavate and complete the primary lining of ventilation tunnel as well as remove steel segments.
- Prepare reinforcement work for the final lining. The concrete collar is cast at the site. The tunnel section is subsequently constructed to complete final lining. A waterproofing system is provided between two linings and at every construction joint.
- Remove the temporary steel support inside the WB tunnel.

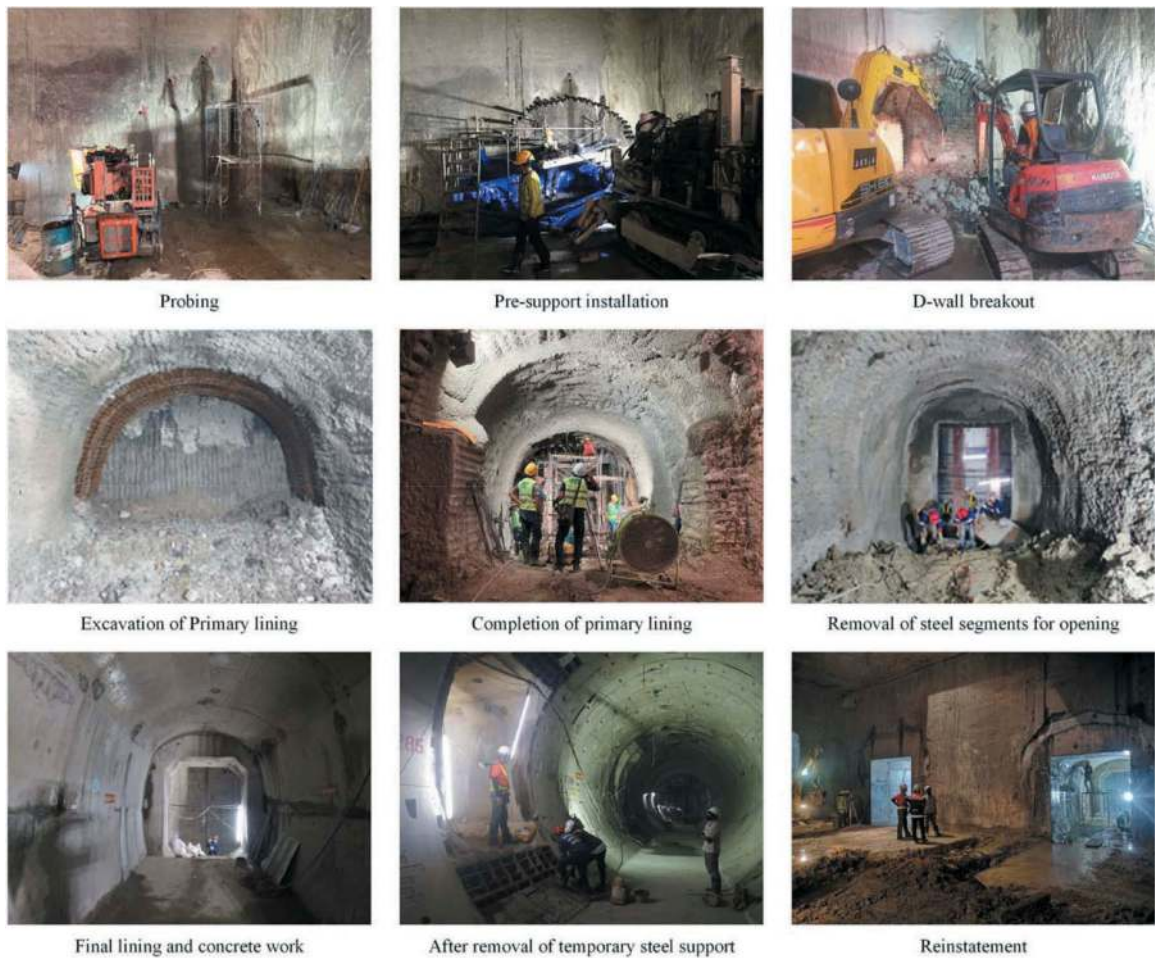

Figure 12. Illustration of cross passage construction.

- Reinstatement the diaphragm wall and complete cross passage work.

5 INSTRUMENTATION AND MONITORING

Instrumentation and monitoring of ground displacements and structural movements play an important role in underground construction, particularly cross passages in urban areas. The results from measurement can be used to verify and alert both the designer and the contractor in order to prevent the potential impacts in terms of structural integrity and serviceability.

In general, geotechnical instruments are proposed to be installed, which consist of ground surface settlement markers and an inclinometer as shown in Figure 13. The purpose of surface settlement points is to determine movements of the ground surface during the excavation of cross passages. An inclinometer is installed to observe a lateral movement of the surrounding soils.

To ensure safety and serviceability of the adjacent existing structures, tilt meters and target prisms are

used to measure inclination and movements in three axes. The control values are typically set based on the allowable movements and distortion that have no adverse impacts on the structures.

In addition, it is important to check the potential effects on the running tunnel during the excavation of NATM tunnels and the stage of tunnel opening. A series of target prisms are implemented in order to monitor the allowable lining deflection.

Convergence monitoring is also conducted to monitor the primary lining deflection of mined adit tunnels. Tunnel displacement results need to be evaluated in every sequence of tunnel excavation.

5.1 Ground surface settlement

Monitoring data of ground surface settlements over the tunnel alignment after the excavation and primary support installation of cross passage is plotted in Figure 14. The maximum ground displacement of 11.28 mm is observed after completion of the emergency egress tunnel. It is obviously evident that a larger ground movement

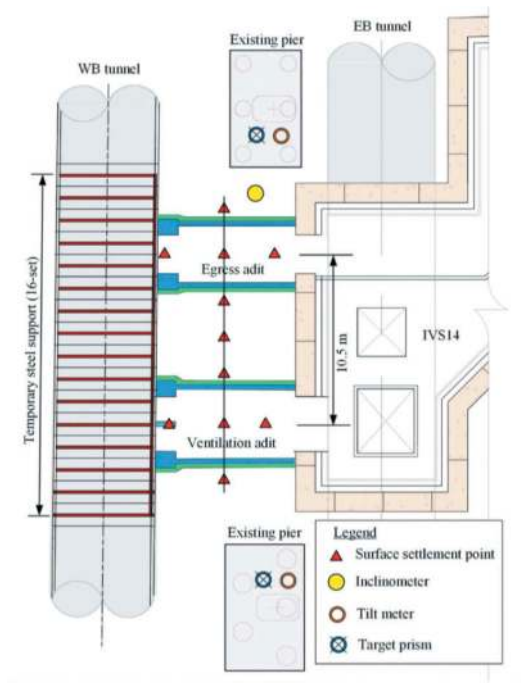

Figure 13. Layout of instrumentation.

Figure 14. Ground surface settlement.

is induced by excavation of the ventilation tunnel in which 35 mm is recorded as the maximum value.

5.2 Lateral movement

Figure 15 shows results of soil displacement in horizontal direction subjected to the advancement of two adit tunnels. As can be seen in the graph, the inward movement of about 5 mm after excavation of the egress tunnel is recorded. This movement continues

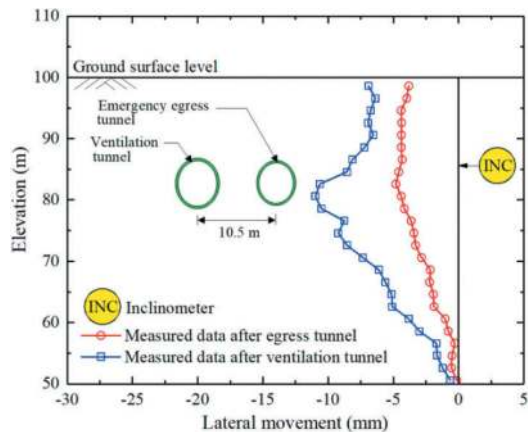

Figure 15. Lateral soil movement.

to significantly increase to 12 mm at the tunnel after the advancement of ventilation tunnel. It is found that large inward displacements commonly appear at the tunnel sprineline and sharply decrease below the level of tunnel position.

6 CONCLUSIONS

Successful cross passage through soft ground in an urban environment can be achieved efficiently and safely using the approach as provided in this article. The success depends on careful consideration of all condition such as ground conditions, geotechnical conditions, groundwater, existing structures, planning, construction work, and ensure that a robust design properly reflects these conditions. A properly design of excavation and support system of the primary lining is the key to mitigating potential risks during excavation and is crucial to ensure minimal ground movements that could damage structures. Careful consideration of site conditions and implementation of a temporary steel support for the running TBM tunnel allow construction of cross passage to proceed with safety. Instrumentation and monitoring system is also a key factor in geotechnical works which can contribute to a successful construction project.

ACKNOWLEDGEMENT

The authors would like to appreciate Mass Rapid Transit Authority of Thailand (MRTA), CKST Joint Venture and Right Tunnelling for their valuable project data.

Construction of underground rail tunnel above deep tunnel sewerage system

Hock Mun Fong, Qiufang Li* & C. Veeresh

Land Transport Authority, Singapore

ABSTRACT: Contract T313 consists of the construction of the underground Xilin Station and Cut and Cover tunnel with a total length of approximately 1,150m. The tunnel configuration is complex with multiple tunnel cells at different levels consisting of Downtown Line and Thomson East Coast Line main lines and reception tracks into the new East Coast Integrated Depot. The west end of Cut and Cover site is bounded by two canals at grade, i.e. 22.5m wide Sungei Ketapang and 45m wide Sungei Bedok, and an existing Deep Tunnel Sewerage System (DTSS) tunnel undercrossing 6m below the tunnel base slab. The excavation is approximately 64m wide and 26m deep, which poses a challenge to DTSS tunnel. The existence of thick soft marine clay with fluvial sand layers adds to the construction risks, as there is concern of blowout and excessive water ingress during the construction. To mitigate any impact to DTSS tunnel, design and construction is planned such that movement on the DTSS are maintained within the allowable limits by closely monitoring the various instruments installed in and around the site. This paper presents the details of various mitigation measures adopted and lessons learned during the excavation works above the DTSS tunnel.

Keywords: Underground construction, DTSS, Fluvial sand, Mitigation measures

1 INTRODUCTION

Contract T313 is part of East Coast stretch of the Thomson-East Coast Line (TEL) for Singapore Mass Rapid Transit (MRT) System. It is a complex contract comprising the construction of Xilin Station and 4.5 km of multiple cell cut and cover tunnels. Long cut and cover construction has been subdivided into various zones of different complexities to facilitate the construction. Cut and Cover tunnel Zone 9A is sandwiched between the existing Sungei Bedok Canal and Sungei Ketapang Canal on the surface and a Deep Tunnel Sewerage System (DTSS) buried underground (Figure 1a and 1b). Sungei Bedok and Sungei Ketapang canals are U shape concrete structures with a depth of 6m, and a width of 45m and 22.5m respectively. DTSS is a deep tunnel located 6m below the proposed Cut and cover tunnel and this tunnel is constructed with a segmental lining and consists of an internal in-situ concrete lining with an internal diameter of 6m. Cut and cover tunnel at Zone 9A is a 60m wide section comprising of 8 distinctive cells to accommodate train tracks for 2 reception tracks each for Down Town Line (DTL) and TEL. Construction of proposed cut and cover tunnel just above the DTSS tunnel and below the intersecting canals poses many challenges for design and construction. This paper

presents the details of design considerations, construction challenges and various mitigation measures implemented during the excavation works.

2 DESIGN DEVELOPMENT

2.1 *Ground conditions*

The site is predominantly underlain by Quaternary deposits of Kallang Formation (KF) overlying Old Alluvium (OA). From soil investigation, the site typically consists of 9m of man-made superficial Fill, which overlies about 27m thick recent sedimentary deposit of Kallang Formation (KF). KF comprises of geological members of Marine Clay (M), Fluvial Sand and Clay (F1 & F2). OA layers below KF are of varying degrees of weathering. Competent OA strata is generally founded at 36m below ground level at this location.

2.2 *Design concept*

Two canals on the surface are temporarily diverted outside the tunnel footprint (Figure 2). The Earth Retaining and Stabilising Structure (ERSS) for cut and cover tunnel utilises diaphragm wall with temporary strutting

*Corresponding author: Li_qiufang@lta.gov.sg

Figure 1a. Site layout plan.

Figure 1b. Zone 9A construction above DTSS.

system. The strutted excavation is designed within perimeter diaphragm walls penetrating to about 70m depth, i.e. to about 40m below FEL. Due to the DTSS tunnel protection requirement, the diaphragm walls have to be terminated at 3m above DTSS tunnel. To facilitate the stage-by-stage construction, a cut-off diaphragm wall with T panels has been constructed parallel to the DTSS tunnel. To minimise heaving or upward movement of DTSS tunnel, mitigation measures such as 3m layer of ground improvement (GI) by Deep Soil Mixing (DSM) below the base slab is designed. This GI will provide resistance against upheaving of base during excavation works. To further minimise the heaving, a sequential compartmentalised excavation and casting sequence is designed (Figure 3).

Figure 2. Canal diversion.

2.3 Design optimisation

While excavation works progressing on adjacent zone to zone 9A, a few incidents of water ingress at diaphragm wall joints were encountered. These incidents have led to the concerns on the 3m of GI's

Figure 3. Zone 9A ERSS and excavation sequence.

effectiveness around the DTSS tunnel, main reason for this concern being the presence of the F1 sands in the area where the DTSS tunnel passes through and blowout of the excavation base may occur due to high water pressures. This would damage the DTSS tunnel and cause lowering of the groundwater pressure in the surrounding area with consequential settlement. Hydrogeological studies have been carried out to review the overall system effectiveness. As a result a progressive groundwater control strategy is formulated as follows:

- Low pressure grouting of F1 sand around the DTSS tunnel to reduce the flow from zones of high permeability through the base of the excavation.
- Provision of passive relief wells in the grouted F1 sand and in the OA in case the treated layers are not effective in reducing the permeability.
- Provision of active abstraction wells in F1 sand in the area inside and outside the excavation. These wells would be activated to reduce groundwater pressure and flow in the event that instrumentation results indicate more than 2m of water head above the excavation level at each stage of excavation.

2.4 Instrumentation and monitoring

Comprehensive instrument and monitoring is implemented inside and outside tunnel excavation to verify the design prediction, groundwater pressure in particular. This consists of the monitoring of the ground

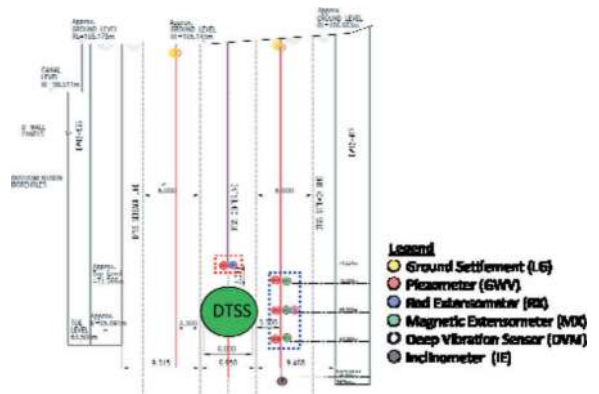

Figure 4. Instrumentation.

and subterranean movement by settlement marker, inclinometer and extensometer, and pore water pressure changes by piezometers. The detailed arrangement of instrumentation is shown in Figure 4.

3 CONSTRUCTION

3.1 Diaphragm wall

3.1.1 Diaphragm wall installation

The cut-off diaphragm wall maintains a 6m lateral clearance from DTSS and embeds more than 40m into competent OA soil. T shape panels are constructed by BC40 trench cutter machine. T shaped panel is prone to trench collapse, especially at connection corner while excavation in weak ground even with the stabilising fluid. To mitigate the risk, ground improvement by DSM is implemented encompassing the perimeter of trench to strengthen the ground before diaphragm wall trenching (Figure 5a, 5b and 5c). With this provision, the verticality of trench also improved.

Figure 5a. Dwall panel layout.

Depending on the actual ground conditions encountered, the diaphragm wall penetration ranges between 70m to 85m below ground. The diaphragm wall panel is heavily reinforced with a maximum rebar cage weight of 120ton. The two section of cage is connected to ensure it function as a monolithic structure. This warrants a tandem lifting by 2 nos. of 180ton crane, during which stitching bars are inserted for the connection.

Figure 5b. T shaped Dwall rebar arrangement.

Figure 5c. Dwall cage tandem lifting.

3.1.2 Water ingress

The Dwall joints have provision of water stop to prevent the water ingress through the joints, further grouting is carried out at the joint where fluid sand layers exist. Despite of the provision, several water ingress incidents occurred. Notably at the most severe case adjacent to Zone 9A, water with fluvial sand gushed in at a rapid rate of approximately $2\text{m}^3/\text{min}$ into excavation (Figure 6). The leak source is immediately covered with sand bags inside excavation while remedial works outside excavation are carried out to grout the flow path. Learning from these incidents, the termination level of water stop for the Dwall joint has been increased to embed into the impermeable soil. The incidents have given a timely warning on the high possibility of groundwater pressure in the F1 sand for excavation above the DTSS tunnel, where there is a gap in the cut-off wall due to existence of tunnel.

Figure 6. Water ingress.

3.2 Struts

Five (5) layers of temporary steel strutting are used to support the excavation. A truss system with hanging king posts is deployed to provide support and restraint to the long span of struts, as it is not possible to install king posts in the proximity to the DTSS (Figure 7).

Figure 7. Strus and truss.

3.3 Low pressure permeation grouting around DTSS

In addition to the GI layer using DSM below the base slab, low pressure permeation grouting (LPPG) is carried out as close as 0.5m away from DTSS (Figure 8) as an additional mitigation measure. LPPG is required to achieve a permeability of no more than 1×10^{-7} m/s to ensure its effectiveness in minimizing the groundwater flow in.

Figure 8. Section of grouting.

3.3.1 Trial LPPG

A field trial grouting prior to the production grouting is carried out to prove the suitability of the method and grouting materials. TAM grouting is employed with a grout diameter of 1.3m and 1m spacing. The grouting pressure is maintained at max of 10 bar and flow rate is 2-20l/min. Grouting material adopts majorly cement grouts with the chemical grouts at the perimeter. The mix ratio of the grouting material is shown in Table 1 and Table 2. Permeability test by falling head method is conducted prior to and after the grouting. It is found k value for post-grouting location achieve 10^{-8} m/s, a reduction in permeability of at least 2 orders of magnitude.

Table 1. Mix ratio for cement grout.

Water (l)	Cement (kg)	Total volume (m ³)
760	760	1

Table 2. Mix ratio for chemical grout.

Solution A (1 m ³)		Solution B (1 m ³)	
Cement	760kg	Sodium silicate	400l
Water	760l	Water	600l

3.3.2 Production LPPG

The close proximity of the drilling works to DTSS requires a tight control of the verticality of drilling operation as well as precise level monitoring. Furthermore, a plastic bit instead of metal bit is used for drilling within 3m clearance of DTSS to eliminate the risk of damage of DTSS tunnel by puncturing the structure (Figure 9). The grouting sequence is planned in a manner that presents the least risk to the DTSS tunnel. Generally, grouting starts from center, i.e. closest to DTSS, and moves towards diaphragm wall. This sequence allows the grout injected in final stage going towards the diaphragm wall rather than the DTSS tunnel, relieving the high forces on existing tunnel.

Figure 9. Plastic drilling bit.

3.3.3 LPPG performance

Falling head permeability tests are carried out at selected grouted column and the result shows the k value is in the range of 10^{-8} m/s. Furthermore, pumping tests are conducted to assess the effectiveness of the improved ground and also to evaluate the extent of water drawdown and details are presented in subsequent sections.

3.4 Groundwater control system

A grouting program resulting in uniform reduction of groundwater flow in the F1 sand will effectively safeguard the DTSS tunnel, while the lack of uniformity of the treatment can result in local channels of groundwater flow that will be difficult to detect prior to excavation. It is for this reason that the pumping wells are installed and ready for activation should actual groundwater flow during excavation indicates concerns about basal instability (Figure 10).

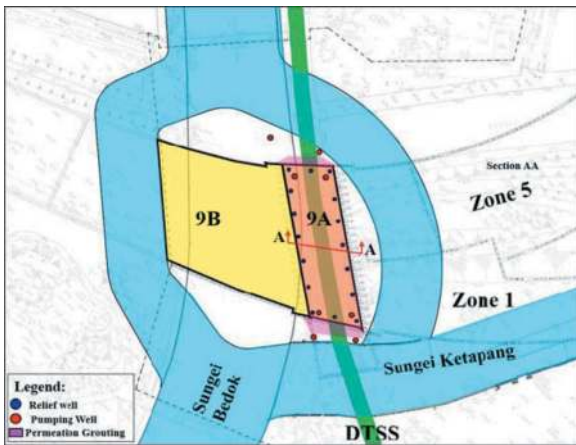

Figure 10. Layout plan of wells.

3.4.1 Passive relief well

A total of 16 nos. of passive relief wells evenly spreading inside the excavation zone are installed. The passive wells are installed with 150mm diameter borehole to a depth equivalent to 2m above the diaphragm wall toe, a 50mm diameter perforated pipe extend from the F1 layer to the base of well provided. These passive wells will relieve any water present in untreated zones below the base and in addition prevent high pressures build up below the base.

3.4.2 Pumping test

Three numbers of pumping tests are conducted to investigate the hydrogeological conditions to assist in the design of the appropriate groundwater control scheme, as well as validation of the efficacy of LPPG. Each test involves a single pumping well and five observation wells installed with piezometers and standpipes. During the test, water is abstracted from the aquifer with measurements of the groundwater response from within the F1 aquifer being taken at the observation wells. An equipment test is carried out before the pumping test to determine the range of abstraction rate for the submersible pump, which is capable to pump up to 0.5l/s to 5l/s (Figure 11). The test is undertaken in accordance with BS

Figure 11. Abstraction pump.

EN22282-4:2012 and comprises three types of test namely Step Discharge Test, Constant Discharge Test and Recovery Test.

In view of the site constraints, first pumping test is carried out outside excavation on the northern side prior to completion of LPPG. The test indicates that the aquifer is connected across a significant distance under the canal. However, the level of drawdown observed is very limited, suggesting that the F1 in this area is well recharged by surrounding aquifers and water bodies. Second pumping test is conducted within excavation after LPPG completed. All the piezo tips inside the observation wells show no response when the groundwater level within the pumping well maintains 10m below original level during equilibrium state, suggesting the grouting in the specific area is effective. Third pumping test is undertaken immediately outside the southern grouted zone outside the excavation. The majority of the surrounding observation wells indicate a clear connection with the pumping well drawdown, suggesting the grouting does not appear to be fully effective and areas of high permeability still exist. As a result, another round of grouting at the outer perimeter is carried out.

3.4.3 Active pumping well installation

In total, 8 nos. of active wells were installed on the northern and southern end, comprising of 2 nos. outside excavation and 2 nos. inside excavation for each case. The active pumping wells are installed with a borehole diameter of 300mm terminating at DTSS invert level, i.e. 66mRL and a 150mm diameter PVC perforated pipe is installed from 80mRL and 67mRL.

3.4.4 Functioning test

Tests are undertaken to check that the active well pumps are functioning correctly, and the auto cut-off /cut-in are working. All eight active wells are tested simultaneously for 4 hours to simulate the actual conditions. The proposed pumping rate is between 1-25l/min inside excavation and 40-150l/min outside excavation. From these tests, water drawdown in the wells is noted in the range of 12m to 20m, indicating the pump and associated system are functioning as per the requirements. However, very limited response is observed in nearby piezometers, partially due to low permeability of grouted zone and short duration of test. These wells are regularly checked for clogging up. All active wells on the south are activated when excavation reached S4 strut level, i.e. 91.5mRL, and the other 4 active wells on the north are activated when excavation reached S5 strut level, i.e.86.5mRL.

3.4.5 Change in excavation sequence

Taking into consideration of the performance of excavation and ground water response from piezometers, the construction sequence from S5 level to formation level is proposed for optimisation. The initial proposal requires a 9-section compartmentalized excavation and slab construction, which takes considerable time and also requires several joints in base slab. As

actual performance is better than anticipated, it is proposed to optimise excavation sequence. Upper 4m is excavated in one stage and remaining 4m depth is in 3 compartments starting from centre towards both ends. Three compartments will expose smaller area when approaching formation level, to check the ground condition and instrumentation readings to gain more assurance prior to full excavation (Figure 12). During excavation, conservative review level of 2m water head above the excavation level is set as limit to stop the works.

Figure 12. Revised construction sequence.

The flow of passive wells records around 36m³/day (from 9 wells) with the bulk volume from one single well on the south (Figure 13). The active wells abstract around 30m³/day mostly from the 2 internal wells on the south. When one of the piezometers reading slightly breaches the suspension level, additional 5nos. of passive relief wells are installed in

Figure 13. Outflow from relief well.

between the wells that see high water flow. At the last stage of excavation, these large wells are converted into active wells by setting up pumps inside to actively drain the water. The measure has shown an immediate effect by bringing down the piezometric pressure. In general, excavation zone is dry and piezometric level dropped in tandem with excavation progress and remained below the target level (Figure 14). Works are carried out 24hrs period and it took around 45 days from the last stage excavation to the successful casting of base slab for entire zone 9A above DTSS tunnel.

Figure 14. Piezo readings in response to excavation.

4 CONCLUSIONS

The strategy of employing ground treatment in F1 together with dewatering system proves its effectiveness in the control of ground movement and groundwater pressure. This strategy, which is implemented prior to excavation, rather than as a contingency to remedy blowout when occurs, reduces the significant excavation risk. Close monitoring and analysis of instrument response that leads to prompt intervention where necessary also plays a major part in the success of the execution of the works.

ACKNOWLEDGMENTS

We greatly appreciate the contributions from LTA project team, design team, contractors, consultants, hydrogeologist, International Panel of Advisors and PUB for their meticulous advice, planning, design, monitoring and implementation of the works in completing zone 9A excavation safely and successfully.

ABSTRACT: Mumbai Metro Rail Corporation Ltd is implementing Colaba-Bandra-SEEPZ (Line 3), a 33.5 Km fully underground metro rail project, in Mumbai, India. With a population of more than 23 million the Mumbai Metropolitan region is the 9th most populated region in the World. Alignment of Line 3 is substantially in old and historic part of the city, with a topography of a narrow land mass and sea/ creek on three sides.

There are 26 underground stations out of which 23 stations are being constructed below arterial/sub-arterial roads. Buildings are at the edge of the footpaths with little or no offsets. These footpaths are also narrow. As a result, extensive amount of temporary decking had to be installed for managing traffic movements and construction logistics.

Two types of temporary decking have been used in the works, concrete decking at 3 stations and steel decking at the remaining 20 stations. Use of these two types of decking has flagged interesting outcome. Steel decking were easy to install and dismantle but costlier on upfront cost of construction. These would have a good scrap value or could be reused. Concrete decking was economical on upfront cost but required more time for construction and had limited salvage value. It also involved breaking and disposal of debris.

The economics of construction of decking is only one aspect as there are environmental and social implications of either of these two types of decking. There are implications for the safety of buildings around the construction site also.

After using both types of decking interesting statistics have been collected which could be of guidance to authorities and contractors for future projects in urban areas requiring decking. This paper would delve into the merits and demerits of these two types of decking using real time data collected during construction of works.

Keywords: Mumbai Metro Line 3, Underground stations, Cut & Cover, NATM, bottom-up, Traffic Management, steel decking, concrete decking, construction cost, construction time, urban environment, merits, demerits

1 INTRODUCTION

Mumbai city, financial capital of India has witnessed very rapid growth in population and employment and invite to mass rapid transit system to reduce the

congestion on roads and existing overcrowded sub-urban railway system. It connects, Bandra-Kurla Complex, both Domestic and International Airport as well as SEEPZ area in Andheri (E). Projects civil work is divided in to 7 packages to facilitate smooth

*Corresponding author: subodh.gupta@mmrcl.com; raviranjana.kumar@mmrcl.com; datta.binnar@mmrcl.com; sunilkumar-vis@tataprojects.com

construction and to ensure timely completion. As Mumbai is densely populated city with very little space available for development, Metro line 3 is planned fully underground and most stations are planned below the roads. After detailed Geotechnical investigation, building foundation study, tunnel alignment was finalized.

2 STATION PLANNING

Station planning for Mumbai Metro Line-3 was preceded by a technical review of the station locations.

1. Adequacy of road width where cut & cover construction is proposed.
2. Availability of land for cut & cover access shafts, where NATM construction is proposed.
3. Availability, adequacy, and suitability of land earmarked for street level facilities such as entrance structures, ventilation shafts and the ancillary building.
4. Availability of worksites at station box ends to allow launching/ retrieving of TBMs and removal of muck from the tunnels.

With the above general considerations, the underground station typology in Mumbai metro line 3 used two different methods: Cut & Cover and Partly Cut & Cover, Partly NATM (New Austrian Tunneling Method) Hybrid method.

3 CONSTRUCTION METHODOLOGY OF THE METRO STATIONS

3.1 Cut & Cover station – bottom-up construction

- (i) Site clearance, temporary, Traffic diversion, utility diversion etc
- (ii) Installation of retaining wall of continuous secant piles
- (iii) Installation of king post, construction/installation of traffic decking, supporting of major utilities below decking.
- (iv) Excavation from top to bottom, installation of steel struts/walers soil anchors at subsequent level, rock anchoring as required.
- (v) Construction of base slab, platform, OTE
- (vi) Construction of station structure, concourse slab, roof slab, Entry /Exit
- (vii) Waterproofing, Backfilling, Dismantling/removal of decking, reinstatement of utility, roads foot-path, street Furniture etc.

3.2 Partly cut & cover, partly NATM/hybrid method

- (i) TBM is driving through the Station area first (use of sacrificial segments, logging of the TBM tunnel face in respect to sub-soil and groundwater conditions).

Figure 1. Typical construction sequence of bottom-up method.

- (ii) Excavation of the station box down to proposed formation level.
- (iii) Ground conditions will be observed and logged during Station box excavation.
- (iv) Stabilizing the portal structure of 6.0m wide cross passage for start-up situation
- (v) Excavation of the cross passages (top heading) from the station box towards the TBM tunnel
- (vi) Dismantling of sacrificial TBM segments, enlargement of TBM tunnel to form top heading portion of platform NATM Tunnel
- (vii) Excavation of the cross passages (invert) from the station box towards the TBM tunnel
- (viii) Dismantling of sacrificial TBM segments, enlargement of TBM tunnel to form complete platform tunnel.

Figure 2. Typical construction sequence of Hybrid station.

4 NECESSITY OF DECKING AND SELECTION OF DECKING

Underground Metro stations are planned below the existing Arterial /sub arterial road and traffic junction. 20 are being constructed below roads out of which 13 are cut and cover methods, and 7 hybrid method partly cut and cover and partly NATM stations with bottom-up construction methodology. As roads traffic in Mumbai city cannot be closed or blocked, Decking is very essential and mainly used for movement of traffic (one Lane south bound + one Lane North bound) and to facilitate as construction platform for construction logistic, labour restroom etc. Decking is also used to

support major utilities like water supply, sewer line, Gas pipeline, Communication and electric cables etc.

For station construction by Cut & Cover method, Hybrid Method, following scenario emerge for traffic management.

Scenario A: Complete closure of traffic – no decking required – Not possible in Mumbai.

Scenario B: On a bi-directional roads one directional traffic diverted to alternate road.

Scenario C: On bi-directional roads, partial traffic is diverted to alternate routes while one + one lane maintained on available reduced carriage way width.

4.1 Selection of decking

MMRC/Civil contractor of respective packages have opted the decking methodology considering the following factors:

- i) Traffic management as per traffic rules and regulations
- ii) Ease of construction, Fabrication/ construction time schedule, availability of resources
- iii) Site condition, location, Environmental and Social aspects,
- iv) Stability of adjoining existing structures, underground major utilities.
- v) cost of installation/Construction and dismantling after-construction works.
- vi) Recycle, reuse, scarp value, Debris disposal, Considering the above factors, most civil work package contractor had preferred steel decking except partly concrete decking in package 3 and package 4.

Details of decking used in Metro Line-3 are summarized in Table 1.

4.2 Design of decking

4.2.1 Steel decking

Steel decking is designed for 70R loading as per IRC-6 specifications and IS-800 2007.

Station size is 26m x 250m.(approx.). Traffic decking is supported on secant pile capping beam and on king post pile. The grids for the decking were designed as per available steel sections.

Design consists of:

1. Steel members spanning between capping beam and king post.
2. The king post column is built up 4-legged circular hollow section. At places RCC piles also constructed to form the king post.
3. King post are planned in a way as to not interfere with station columns, logistic and material, equipment movement and generally at a spacing of 10-12m.

Table 1. Types of decking used in Mumbai metro line-3.

Contract & Contractor-JV	Station Names		Type of decking

	2. SEEPZ		

4. Longitudinal main beams are placed over the king post, which support the transverse beams supported on RC capping beam and longitudinal main beam.
5. Longitudinal beam section as built-up UB/UC and IS beams.
6. Over the main beam secondary beam were placed to form a diagrid system, these secondary beams are UB /UC and IS sections.
7. Secondary beams support the prefabricated decking panels of size varying from 1200 x 1200 to 2000 x 2000,
8. The decking panel is fabricated by forming a frame of IS beams with channel and angle with Chequered plate of 8mm to 10 mm.
9. Decking panel is fitted with neoprene rubber bearing pads to minimise vibrations and noise.
10. Joints are filled with rubber packing.
11. Speed breakers were installed to limit traffic speed to 20 km/hr.
12. Crash barriers were conservatively designed to prevent any mishaps as decking was planned over station deep excavation.

Figure 3. Typical steel decking arrangement.

4.2.2 Concrete decking

Like the steel decking at certain stations RCC deck slab were installed. Due to the congested area of the station location and issues of movement of crane required installation of steel sections it was prudent to provide RCC decking. The loading conformed to IRC loading. To facilitate TBM activity, de-mucking activity, retrieval of TBM cutouts were provided to ensure smooth Station construction and smooth traffic movement. The framing plan for the decking comprises of the following.

1. On one side of the decking RCC capping was taken advantage of for forming the main beam.
2. RCC plunge columns were cast as bored cast in situ piles at a spacing of 10-12 m and over the king post columns RCC main beam was cast.
3. The transverse main beam and secondary beam at suitable spacing along with the deck slab was cast in place for a the RCC decking system.
4. Major utility supporting with steel brackets like 1450mm twin water lines, gas pipelines, dry utilities like MTNL, BEST, many OFC cables, etc.

Figure 4. Typical concrete decking arrangement.

5 CONSTRUCTION METHODOLOGY AND CONSTRUCTION TIME OF DECKING

5.1 Steel decking

Steel decking is constructed in panels of grid of approximately 11m x13m panel, sequence of Steel decking construction is broadly involves following steps.

1. Site clearance, utility shifting, Fabrication of girder, U beam ISMB as per required size, specification in casting yard-10 days
2. Temporary Diversion of Traffic, installation of Main Beam, Secondary Beam, Girder Installation of – ISMB, fixing of chequered plate, Bearing Pad, rambblers, speed breakers etc.- 3 days
3. Supporting Major Utilities Beneath the decking

Figure 5. Steel decking installation in progress.

Overall speed of construction of steel decking was observed to be about 150 m² /day.

Figure 6. Construction of RCC decking.

Table 2. Construction cost of RCC decking and steel decking/m².

Items (Unit)	Concrete Decking			Structural Steel Decking		
	Quantity	Rate (INR)	Cost (INR)	Quantity	Rate (INR)	Cost (INR)
Concrete (Cum)	0.56	10000	5600	0.1	9000	900
Steel TMT (MT)	0.07	50000	3500	0.012	50000	600
Structural Steel including fabrication. (MT)				0.5	80000	40000
Total construction cost.			9100			41500
Dismantling (Cum)	0.56	4000/m ²	4000		1000/m ²	1000
Scrap value (MT)	Nil			0.1 (@20%) Of used material.	-30000	-3000
Reuse of material				0.4 (@ 80 % of used material))	60000	-24000
Disposal cost	7000/10 m ³ -40 km lead		700			Nil
Net cost/m²			14920			15500

5.2 Concrete decking

RCC decking is constructed in following step: (10 m Length)

1. Site clearance, below ground utility shifting-7 days
2. Construction of Caping beam over the secant pile wall-4 days.
3. Excavation till beam and PCC level -4 days
4. Shuttering and Rebar work for the beams (@ 4 m c/c)Concreting of beams – 4 days
5. Shuttering, Rebar work and concreting of deck slab-4 days.
6. Curing of deck slab, Beam -7days

Total construction time of 10m concrete decking was @ 30 days and overall speed was about 20-25m²/day.

The construction cost of steel decking is around 4 times higher than Concrete decking. Initial investment is high cashflow is blocked for construction period of around 6 years. However, its it can be reused at another site after dismantling. It has good scrap value after dismantling. As concrete decking requires high cost and more time dismantling. So net cost of concrete and steel is almost equal at the completion stage.

6 SUITABILITY OF DECKING FOR URBAN ENVIRONMENT

6.1 Traffic management and logistic management

Mumbai City development spanning from South to North both sides surrounded by Arabian Sea. City road network is loaded with heavy traffic and road width are very narrow. Most of the arterial road and sub-arterial roads are catering heavy traffic during

peak hours. Closure or blocking of roads is a very tedious job leads to further traffic congestion and inconvenience to locals and travellers. So, it is very necessary to keep the traffic movement smoothly while development of any infrastructure projects like, bridges, metro, roads, etc. Most of the metro stations of Line 3 are planned on the major arterial roads. While preparing traffic management plan it was planned that 1 north + 1 south bound traffic will be kept open for traffic and balance area of the right of ways will be used for construction of metro as partial or complete closure of road is not possible for long time, expeditious method of decking is need of the city. Steel decking is speedy activity and can be completed within short time span. However, concrete decking is time consuming activity including curing of concrete time.

Keeping this into consideration 16 stations was constructed using temporary steel decking and where area was densely populated, partial or complete closure of the road was possible with the diversion of traffic on the alternate roads, concrete decking was adopted.

6.2 Ambient air quality monitoring & noise level

The Noise Pollution (Regulation and control) Rules, 2000 provides for ambient air quality standards in respect of noise for various categories of urban area for daytime and nighttime in terms of dB(A) Leq. It is observed by the base line monitoring conducted by MMRC before the construction activities of MML-3 the noise values are already exceeding the prescribe standards as per Noise Rules, 2000. Base line levels observed at Cuffe pared are 69.0-73.5 dB(A) in daytime and 59.8-62.3 dB(A) in nighttime. The noise values observed at Churchgate are 70.5-76.0 dB(A) in daytime and 60.8-63.7 dB(A) in

Figure 7. Traffic management at dadar station.

nighttime. The values near Mahim (St. Xavier’s College) are 64.3-69.4 dB(A) in daytime and 54.5-60.0 dB(A) during nighttime. The base line noise levels are already exceeding the permissible standards of noise pollution control rules, for residential zone. This clearly shows the contribution of noise values from other sectors like transport, commercial activities and construction activities other than metro rail construction activities.

While designing the steel decking, bearing pads was introduced below decking panel to absorb vibrations, reduce impact noise generation. Traffic movement speed was restricted to 20 km/hr with suitable arrangement of speed breakers /rumble strips at certain interval as a traffic calming measures. Damaged bearing pads were replaced on time to time, corroded, broken welded joints, of chequered plate, structural member

were repaired from time-to-time periodic maintenance to avoid noise generation during traffic movement.

Ambient noise level monitoring at Steel decking site and concrete decking of similar nature of traffic and surroundings site are as presented following table.

Steel decking panels are very noisy during movement of construction machinery /heavy vehicles. More noise was observed on sites of steel decking during traffic movement. Many complaints were received in Mahalaxmi, Giragaon, Kalbadevi, Cuffe Parade residential areas.

Whereas no complaints of noise was logged at Sitaladevi, Dadar, Worli, where RCC decking was used.

6.3 Logistic management

As most of the stations are planned on roads with densely populated urban area, there is little space available as work area to facilitate logistic management. RCC Decking constructed at Dadar and Sitaladevi has facilitated space for logistic to support station construction like storage of material, Heavy machinery movement, parking etc., without causing much noise and vibration.

6.4 Stability of adjoining buildings/structures, supported utilities

UGC-04 package chosen RCC decking for traffic movement, logistic management and to support two 1450mm water line. To avoid any jerk to it as traffic speed was restricted 20 Km/hr. not much vibration was observed. For ensuring safety of buildings/struc-

Figure 8. Supporting of 1450 mm water pipeline below rcc decking at sitaladevi station.

Table 3. Ambient Noise level (December 2019).

Station	Steel decking		Station	Concrete decking	
	Day time 6.00am-10.00 pm (db.)	Night- time 10.00 pm -6.00 am (db)		Day time 6.00am-10.00 pm (db.)	Night- time 10.00 pm -6.00 am (db.)
Mumbai Central	55-110.1	48.00- 89.2	Dadar	51.6-110.7	46.00-82.7

tures in influence zone, instrumentation and monitoring system was installed on buildings, water pipelines. The precise level markers, bi-reflex 3D optical targets, crack meters, tilt plates, ground settlement marker, vibrometer were used. The real time monitoring system were also installed on the old, dilapidated buildings and has been monitored at regular intervals during tunnelling, piling, NATM excavations, etc.

Major Utilities are also protected with suitable rubber pads and suitable protective measures as approved by concerned utility owner.

Both watermain was successfully supported without any damage during entire project duration while traffic and logistic movement on deck.

7 REMOVAL/DISMANTLING OF DECKING

7.1 Steel decking

- (i) Utility supported on decking is reinstated on compacted soil or permanent pedestal constructed from roof slab.
- (ii) Removal of decking panels
- (iii) Removal of secondary beam with Crane
- (iv) Uninstallation /Removal of main beam with crane

Figure 9. Steel decking dismantling.

7.2 Concrete decking

After completion of work, backfilling of soil, concrete decking dismantling is very tedious task involves stagewise and time-consuming process.

1. Utility supported on decking is reinstated on compacted soil or permanent pedestal constructed from roof slab.
2. cutting/breaking of decking slab in panels using pavement cutter
3. RCC beams breaking using diamond wire rope cutter.
4. Concrete deck cutting average speed of is only 45-50 sqm/ day.
5. This involves debris generation and creates noise and dust. Noise and dust generation is mitigated with the help of water jet.
6. Debris are taken to casting yard /open space, debris are broken in small pieces, after recovery of TMT rebar scrap, debris are disposed in designated dumping site /backfilling area.

Figure 10. Breaking of RCC decking.

8 MERITS AND DEMERITS OF RCC DECKING V/S STEEL DECKING

After due deliberation of Decking used in Mumbai Metro Line 3 station construction in urban environment, merits and demerits of RCC decking and Steel decking are summarized in table given below.

Table 4. Comparison of steel & RCC decking.

Sr. No.	Construction Parameter	RCC Decking	Steel Decking
1	Construction Time	Required 30 days to complete one panel Including curing time, average speed of construction is 20–25 sqm/day.	Requires skilled manpower, Fabrication, Secant piles, capping beams is a independent & parallel activity, speedy installation, @ 150/m ² (approx.)/day.
2	Construction/ installation Cost	INR 10,000 to 12,000/m ²	INR 40,000-45,000/m ² , Net cost INR 14000-15000/m ² Considering 80 % reuse and 20% scrap.
3	Dismantling Time and cost	45-50 m ² / day and activity is a tedious, cumbersome & time consuming. Dismantling is additional cost approx. Rs.5000/m ²	Speedy activity 450-500 m ² /day; dismantling cost is negligible i.e., Rs. 1500/m ²
4	Suitability for Urban Environment Noise, Vibration	Slow progress, Require closure of roads & alternate routes during construction, inconvenience to traffic due to prolonged construction and curing time. Routine and Smooth Traffic Movement. Negligible noise Minimal environment issue due to noise and dust.	Speedy construction, Noise issues can be suitably mitigated. High Noise, Vibration due to Traffic impact on steel plate joints
5 (a)	Reuse, Recycle, Scrap Value	Reuse is nil, retrieve the Re-bar for scrap is also a costly and time-consuming activity, Requires machinery time and space, thus the effective recovery and scrap value is negligible.	80% of the material can be reused with very negligible waste. 20 % scrap has good resale value @30-35% of market price.
5(b)	Debris Generation	Very High volume of debris generation requires space of breaking, High noise and dust during breaking. Debris disposal around 40-50 km from city involves high transportation cost as well as environment issues. Rs. 7000/10 m ³ per truck.	No debris generation, environment friendly.
6	Water Leakage/ Dewatering Cost, construction ease.	Watertight structure, no effect on work during monsoon: de-mucking and logistic lowering activity needs to plan as per the fixed openings.	Water Leakage through joints, affects work progress during monsoon. Flexibility of opening during excavation, speedy de-mucking and construction as per requirement.

9 CONCLUSION

Based on the above study it can be concluded that Steel decking is techno-economical feasible than the RCC decking for the Urban environment. Steel decking affects traffic movement for shorter time as well as road and utility reinstatement is a faster as it requires lesser time for removal/dismantling. As there is no debris or dust generation and it can be reused and recycled, it is environment friendly option.

However, initial investment in steel decking is high and net cost at completion stage is at-par with RCC decking. It is also observed that steel decking causes noise during traffic movement, logistic handling, specially during nighttime which is inconvenience to surrounding urban environment. Noise generation can be mitigated to some extent with bituminous coating over steel decking and installing noise barrier in urban area. RCC decking is feasible in Environment sensitive zones of urban area and cater specific need of project, utility support and working area for logistic

management. It requires more construction time, dismantling time which prolongs overall construction time and affect traffic management, road and utility reinstatement. Initial cost is low as compared to steel decking, however, RCC deck breaking is costly, time-consuming activity, generates debris. Handling and disposal of debris in urban environment is challenging task.

ABSTRACT: In the blasting excavation method for conventional tunnel projects, the stability of the tunnel, excavation cycle time, and construction cost are significantly affected by the fact that if the blasting pattern implemented is suitable for the geological conditions, there is little deviation between the tunnel excavation shape after blasting and the planned excavation line, and overbreak are minimal. One of the parameters that significantly affects the geological conditions is the rock mass strength of the tunnel face; therefore, it is important to design blasting patterns that vary the drilling position, number of holes, and amount of explosive charge according to the strength. The developed automatic blasting design and construction system evaluates the rock mass strength of the tunnel face based on the drilling energy collected when drilling the previous cycle's charging holes using the fully automated tunneling jumbo. Based on the results, the system automatically de-signs blasting patterns by varying drilling positions, the number of holes, and amount of explosive charge. Furthermore, by simulating the drilling sequence in advance using drilling software, the designed blasting pattern can be automatically loaded into the jumbo from the system, and the charging holes can be drilled automatically in the shortest possible time without interference between the individual booms. The results of application tests of this system in highway tunneling project in Japan showed a 41.4% reduction in overbreak of tunnel during excavation and a 7% reduction in the basic unit of explosives consumption compared to before applying the system, and the system contributed to the formation of a smooth tunnel cross-section.

1 INTRODUCTION

In conventional tunneling projects, blasting excavation result in overbreak, where more rock is excavated than required for the designed cross-section, and as well as underbreak, where insufficient rock is excavated (Figure 1). Large quantities of these increase labor and material expenses for tasks such as mucking, scaling, and shotcreting, which result in longer excavation cycles and higher construction costs. Furthermore, especially significant overbreak can cause extensive damage to the rock mass surroundings, enlarging the loosened zone and ultimately reducing the durability and quality of the tunnel. Hence, it is critical to improve the accuracy of blasting excavation and reduce such occurrences.

To improve the accuracy of blasting excavation, it is crucial to have a thorough comprehension of the

geological conditions. Subsequently, a suitable blasting pattern should be designed by choosing the right number and locations of holes, as well as an appropriate charge that matches these specific conditions.

The design of blasting patterns in Japan has traditionally depended on the expertise and intuition of skilled operators. However, this approach lacks a quantitative basis in numerical data, and as such, cannot be reproduced, making it difficult to apply to future automation and mechanization developments.

Therefore, the new system has been developed to automatically design of optimal blasting patterns utilizing quantitative geotechnical data. The system uses drilling energy data, which is correlated with rock strength, a critical factor that significantly impacts geological conditions. Furthermore, by linking the system with a fully automated tunneling jumbo equipped with a machine control system, we have developed an

Automatic Blasting Design and Construction System for Optimized Blasting that automates everything from blasting pattern design to charge hole drilling, although the system is operated under limited conditions. This paper shows an overview of the system and the achievements and challenges encountered during its implementation in highway tunneling project in Japan.

Figure 1. Tunnel forms of overbreak and underbreak after blasting excavation.

2 AUTOMATIC BLASTING DESIGN AND CONSTRUCTION SYSTEM FOR OPTIMIZED BLASTING

2.1 System workflow

The System workflow shows Figure 2. Phases ① to ③ are the design phase of the blasting pattern, and phases ④ to ⑦ are construction phase.

Firstly, during the design phase, the drilling energy is acquired from the previous excavation. This energy

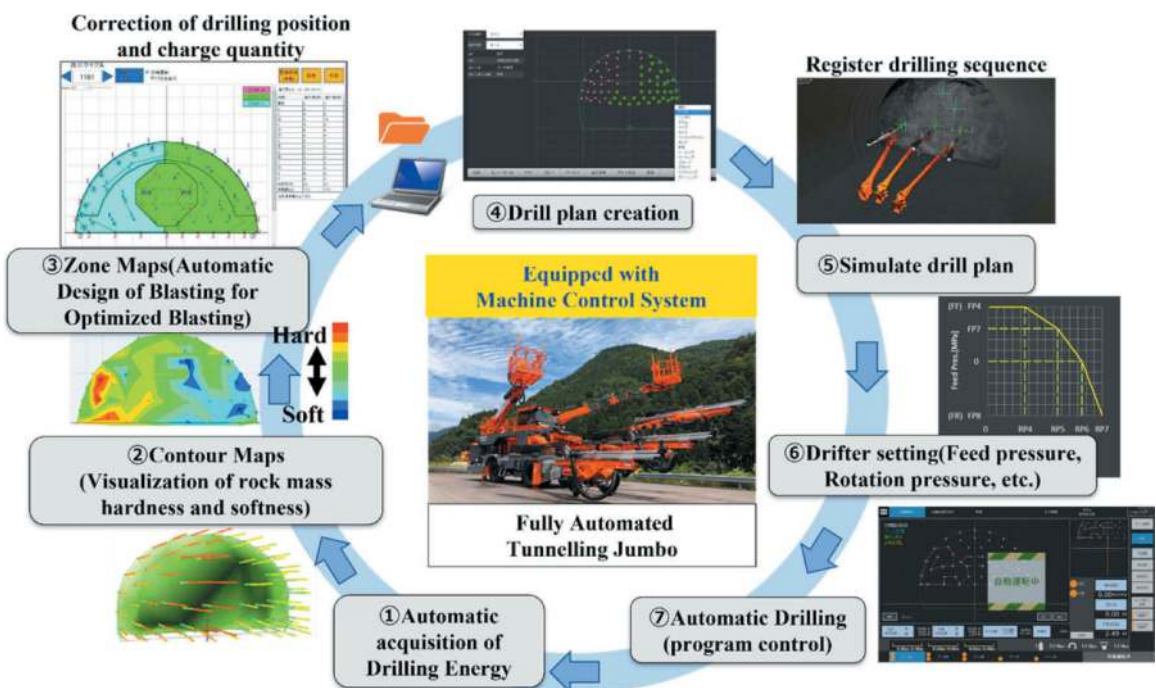

Figure 2. Workflow of automatic blasting design and construction system for optimized blasting.

Figure 3. Contour maps.

represents the calculated energy required by the tunneling jumbo to drill through the face surface, determined using hydraulic pressure data acquired from the jumbo. This parameter correlates with the strength of the rock mass. The system analyses this parameter to determine the distribution of hard and soft areas on the tunnel face, creating a contour map (Figure 3). The drilling energy is also utilized to design a blasting pattern, which are produced as zone maps.

Meanwhile, during the construction phase, a new drill plan is formulated based on the designed blasting pattern. Following this, a simulation is conducted to examine interference between the booms. Drifter settings are adjusted accordingly and the jumbo drills automatically. The drilling energy generated during automatic drilling is then utilized to design the blasting pattern for the next drilling.

2.2 Automatic design of optimal blasting patterns

Within the system, blasting patterns are designed by dividing the tunnel face into five sections to account for its heterogeneity of the face. The first section is situated in the center of the face, playing a crucial role in maintaining blasting quality and forming the free face. The second and third sections, positioned on the right and left shoulders of the face, significantly impact overbreak and underbreak during drilling and blasting. The lower right and left areas constitute the final two sections. The optimal blasting pattern is then selected for each of the divided sections, and the blasting pattern for the entire face is designed by combining the selected patterns. The optimal pattern for each area is determined based on the hardness and softness

of the rock mass as determined by the average drilling energy value within the section. Based on prior experience, a “poor rock pattern” (light blue) is identified as 150 J/cm^3 or less, a “fair rock pattern” (yellowish green) is classified as 150 J/cm^3 to 300 J/cm^3 , a “strong rock pattern” (pink) is defined as 300 J/cm^3 or more, and the blasting pattern appropriate is automatically selected from the three levels of blasting patterns (Figure 4). Different blasting patterns are established for the standard rock mass classification in Japan (CI, CII, and DI), the system selects the most appropriate blasting pattern for the next construction from a pool of 243 patterns (5 sections to the power of 3) based on the rock classifications (Figure 5). Each blasting pattern is assigned a specific file name and is stored in a shared folder within the system.

Figure 4. Criteria blasting pattern (examples when the rock class classification is DI).

Rock Mass Classification (Standard round length(m))	Drilling Energy		
	High	Moderate	Low
CI (1.5m)	0	1	2
CII (1.2m)	0	1	2
DI (1.0m)	0	1	2

243 patterns = 5 sections to the power of 3

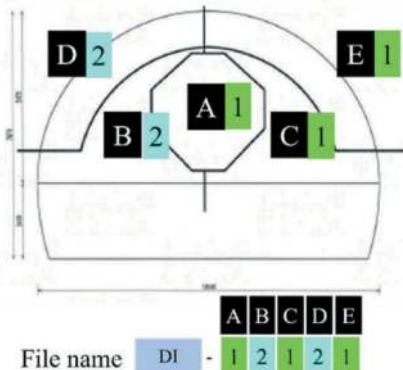

Figure 5. Method of designing blasting patterns.

2.3 Automatic construction

Once a blasting pattern has been designed, the tunneling jumbo with the system automatically reads the shared folders in the system when the machine starts and creates a drill plan corresponding to the designed blasting pattern from the stored file names. After the blasting pattern design is completed, the tunneling jumbo with the system automatically reads the shared folders in the system when the machine is started and creates a drill plan corresponding to the designed blasting pattern from the saved file names.

At this time, if the drill plan’s drilling sequence is simulated before, then the jumbo can drill automatically without any human intervention. Currently, manual input simulates drilling, but the implementation of automatic input is underway to enable future automation.

2.4 Improve the efficiency of explosives management and loading operations

The designed blasting patterns are presented as zone maps (Figure 6). After the system analysis is finished, the zone maps are automatically distributed to the personnel’s tablets and PCs for sharing. Additionally, contour maps demonstrating the rock mass hardness and

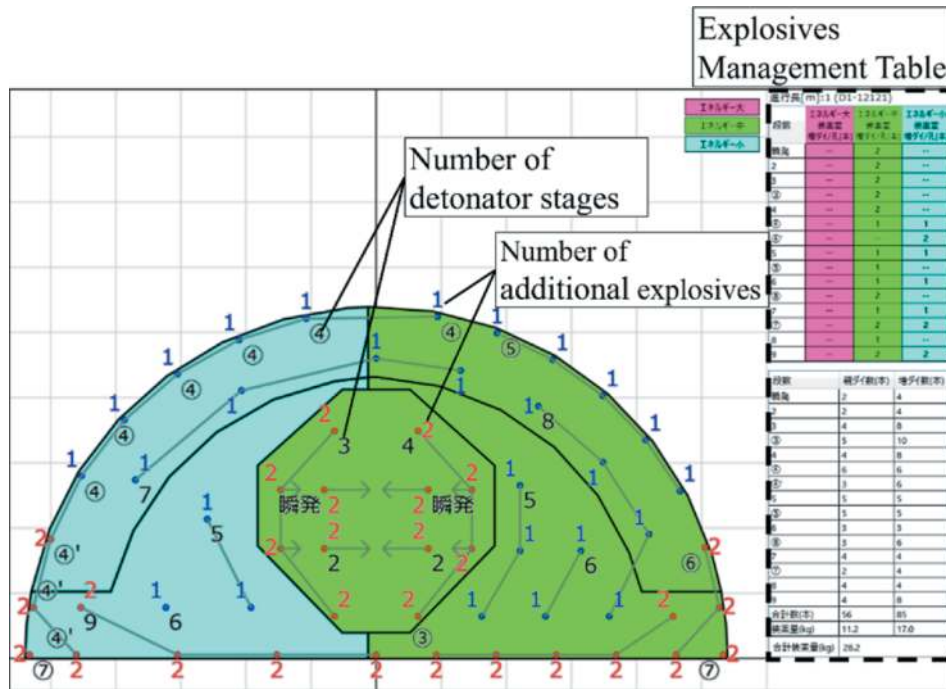

Figure 6. Zone Map(Automatically designed optimal blasting pattern).

softness are sent at this juncture. By comparing the zone and contour maps with the evaluation of the rock mass determined by tunnel face mapping, the responsible individual can review the drilling energy thresholds (Figures 7 and 8). This assessment can aid in the design of optimal blasting patterns that accurately capture changes in the geological condition. The zone maps display the quantity of charge utilized in the blasting pattern, together with the amount of detonating explosives, detonator steps, and additional explosives to be charged in individual holes. This information can improve the effectiveness of explosives preparation for handling operators, optimize the loading operations for tunnel workers, and facilitate the automation of explosives management. these data are instrumental in improving overall efficiency in blasting work.

Figure 8. Confirmation of pattern by the zone map.

Figure 7. Conformation of the rock mass condition using the contour map.

3 IMPLEMENTATION AT A TUNNELING PROJECT

3.1 The project overview

The Maki Tunnel Project is a two-way highway tunneling project currently under construction in Toyama Prefecture, Japan. It spans 1,578 meters in length and was the site of a system demonstration test. The geological formations predominantly comprise rhyolite and rhyolitic pyroclastic rock and feature intermittent andesite intrusions. Based on the laboratory rock tests conducted during the design phase, it was found that the unweathered rock has a uniaxial compressive strength of 132 N/mm², while the weathered rock has a uniaxial compressive strength of 18.4 N/mm². The examined section

showed the widespread distribution of greenish grey to blackish-grey rhyolite, and in some areas weathered and altered rock mass to a brownish-brown color (Figures 9 and 10). Discontinuities in the bedrock were partially developed and intercalated with clay. The rock mass classification for this section was D I. Based on tunnel face mappings, the range of rating varied from 36.75 to 38.0 points, with nearly identical geological conditions.

Figure 9. Tunnel face of the section where the test was conducted.

Figure 10. Completion status of loading.

3.2 Evaluation method

The Digital Finished Shape Surveying method (Sasajima et al., 2020), utilizing 3D-Lazer Scanstation P40 cyclone tunnel, was employed to measure the extent of overbreak and underbreak before and after the system's application. The method's measured accuracy is ± 5 mm. Within one excavation length (DI:1.00 m), the point clouds within an area of every 10 degrees of arc and every 10 cm of depth of the tunnel excavation wall face were averaged, and the underbreak were defined as those inside the design section and the overbreak as those outside the design section. The efficacy of the Automatic Blasting Design and Construction System for Optimized Blasting was assessed through this method.

3.3 Effects of system implementation

3.3.1 Improve blasting excavation accuracy

Before implementation of the system, the average underbreak measured 3.87 cm, with the average

overbreak of 16.87 cm. Following implementation of the system, the average underbreak measured 1.19 cm and the average overbreak measured 9.89 cm. These results indicate a reduction of 69.3% in overbreak and a reduction of 41.4% in underbreak. Consequently, the excavation surface achieved a smoother finish (Figure 11). The explosives consumption intensity decreased by 7% after the implementation of the system, as the post-application value was 0.40 kg/m^3 while the pre-application average was 0.43 kg/m^3 .

- : Less than 20 cm outside of the design
- : Less than 30 cm outside of the design
- : Less than 50 cm outside of the design
- : More than 50 cm outside of the design

Figure 11. The result of finished shape survey on the tunnel excavation surface.

3.3.2 Effect of cycle time reduction

The application of the system has also proven effective in reducing the excavation cycle. The new automated design has eradicated the requirement for time-consuming blasting pattern Drill plan creations. Additionally, automated drilling has improved drilling speed and efficiency, resulting in a reduction of drilling time by 16% (from 37 minutes, standard time (East Nippon Expressway Company Limited, et al., 2022), to 31 minutes) compared to the standard method. The time needed to load explosives was reduced by 23% (standard time: 30 minutes \rightarrow 23 minutes) by optimizing the process of explosive loaded, compared to the standard method.

3.4 Improvements for better system operation.

The system accounts for the rock mass variability and devises blasting patterns by dividing the tunnel face into five sections. This enables accurate design based on actual geological characteristics. However, it cannot take into consideration instances of localized hard rocks like hard rock veins or large boulders. Improvements to the system that allow blasting patterns to be designed for more localized hard and soft parts of the rock mass, such as additional charging holes when the drilling energy is locally high, should be considered.

Additionally, rock fallout resulting from key-blocks may occur on the tunnel face. As the face where the fallout occurred is not flat, the excavation length of charge holes need adjustment according to the excavation results. Improvements of system are necessary to measure excavation conditions utilizing a 3D scanner and lidar, and to adjust the designed blasting pattern based on the obtained data.

4 SUMMARY

A new, Automatic Blasting Design and Construction System for Optimized Blasting has been developed, which automates the blasting pattern design and drilling of charge holes to improve accuracy in conventional tunneling. The following findings were obtained as a result.

- (1) The system analyses drilling energy as a quantitative indicator, assesses the rock mass's hardness and softness in each of the five sections where the tunnel face is divided, and automatically designs blasting patterns based on the evaluation results. The introduction of this system has resulted in a reduction in the overbreak and the underbreak when compared to the pre-system introduction period. Moreover, the amount of explosives used has decreased, and excessive damage to the rock mass has been eliminated.
- (2) The implementation of the system has optimized the drilling and charging processes, resulting in a notable decrease in cycle time in contrast to standard methods.
- (3) To achieve more precise blasting that aligns with the actual geological conditions, the system

needs improvement to create blasting patterns that can adapt to local rock mass variations. It is also imperative to enhance the system to adjust the blasting pattern in accordance with the tunneling excavation progress of the previous cycle.

ABSTRACT: The necessity for underground space development has recently emerged due to overcrowding and the lack of space in downtown areas. Meanwhile, many civil complaints occur due to noise and vibration during rock excavation to create underground spaces in downtown areas. Rock excavation using abrasive waterjet is characterized by low noise and low vibration and has the advantage of resolving these civil complaints. In addition, it does not generate heat during rock excavation, so it does not form a heat-affected zone. It does not transmit mechanical stress to the surrounding ground, so it has the advantage that an excavation damaged zone does not occur. To achieve effective rock excavation, a significant excavation depth is required, necessitating the provision of an appropriate excavation width. The excavation width is related to the dispersion of the jet, and various parameters of the abrasive waterjet system affect jet dispersion. In this study, we experimentally observed the variation in rock drilling width by controlling the focusing tube geometry and abrasive flow rate in an abrasive waterjet system, and based on these observations, we analyzed the dispersion of the jet. The findings of this study contribute to the field of rock excavation techniques by providing a systematic method for estimating excavation width with an abrasive waterjet. Accurately predicting and controlling excavation width enables operators to optimize operations and make informed decisions regarding equipment setup, resulting in more successful excavation outcomes.

1 INTRODUCTION

Waterjet technology is a technology that uses high-pressure water to remove target materials. Waterjet technology is a low-noise, low-vibration method that can solve civil complaints from nearby residents (e.g., construction delays and interruptions) caused by noise and vibration during rock excavation construction in urban areas. Meanwhile, various previous studies on rock drilling and cutting using waterjet technology have been conducted to date (Summers, 1992; Summers, 1995). In the case of high-strength rock, excavation using only water is inefficient, and to solve this problem, abrasive

waterjet technology, which sprays a mixture of water and abrasives, has begun to be used (Hashish, 1989; Momber and Kovacevic, 1998; Karakurt et al. al., 2012). The basic abrasive waterjet mechanism is as follows (Figure 1). High-pressure water generated through a hydraulic pump passes through a tiny diameter orifice and is converted into high-speed water. This high-velocity water mixes with the abrasive in the mixing chamber and transfers momentum to the abrasive. In this process, the abrasive is accelerated and gains kinetic energy (Momber, 1998; Roth et al., 2005; Cha et al., 2019). The water and abrasive mixture passes through a focusing tube, gains a straight direction, and is sprayed into the air.

*Corresponding author: hyunjoong@kaist.ac.kr

The distance between the end of the focusing tube and the target material is called the standoff distance, and while passing through it, the jet partially disperses and removes the target material.

Meanwhile, when rock drilling using abrasive waterjet technology, a wide drilling width must first be constructed for deep drilling. When drilling is performed by fixing the waterjet nozzle at the initial position, there is a limit to forming a deep drilling depth. Therefore, when rock drilling is performed by inserting a waterjet nozzle into the hole using a wide drilling width, it is possible to form an effective drilling depth. Drilling width is affected by various parameters such as standoff distance, abrasive flow rate, water pump pressure, and focusing tube geometry (Oh and Cho, 2014). In this study, experiments were conducted on focusing tube geometry (i.e., diameter and length), water flow rate, and abrasive flow rate among various parameters that affect drilling width. Rock drilling width was observed according to focusing tube diameter, focusing tube length, water flow rate, and abrasive flow rate, and the influence of each parameter was analyzed.

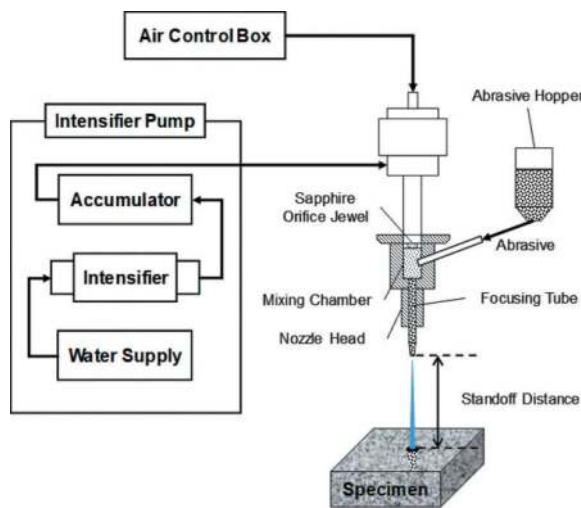

Figure 1. Schematic diagram of abrasive waterjet (Hwang et al., 2019).

2 EXPERIMENTAL PROGRAM

A drilling experiment using an abrasive waterjet was conducted using granite, which is commonly found at construction sites in the Republic of Korea, as the target material. The physical properties of granite are summarized in Table 1. The abrasive used was garnet, which is commonly used in industry. Garnet is a material with a high hardness of 7.5–8.5 Mohs scale, and in this experiment, the experiment was performed with particles with a size of approximately 0.18 μm . Additionally, the abrasive waterjet system used an intensifier-type pump; details are summarized in Table 2.

This drilling experiment sought to observe the influence of four parameters (i.e., focusing tube diameter,

focusing tube length, water flow rate, and abrasive flow rate) on the drilling width of granite. To observe the influence of focusing tube diameter (D_f), two focusing tube diameters of 0.76 and 1.02 mm were applied. To observe the effect of focusing tube length (L_f), an experiment was performed using three focusing tube lengths of 76.2, 101.6, and 152.4 mm. Additionally, to analyze the effect of water flow rate (WFR), two orifice diameters (D_o) of 0.254 and 0.33 mm were used under the same water pump pressure condition of 320 MPa. At this time, an experiment was performed using the water flow rates of 28.3 and 50.0 ml/s as variables. Lastly, to observe the effect of abrasive flow rate (AFR) on drilling width, a granite drilling test was performed at four abrasive flow rates of 5.6, 7.5, 11.1, and 15.0 g/s. In all experimental conditions, the standoff distance, defined as the distance between the abrasive waterjet system and the target material, was applied equally at 100 mm. Additionally, the water pump pressure of 320 MPa was applied equally to all experiments. Details of the parameters applied in the experiment are summarized in Table 3.

3 RESULTS AND DISCUSSION

The results of a granite drilling experiment using an abrasive waterjet system analyzed in detail how parameters such as focusing tube geometry (i.e., diameter and length), water flow rate, and abrasive flow rate affect drilling width. In order to observe the influence of each parameter clearly, all parameters except the corresponding parameter were strictly controlled.

3.1 Effect of focusing tube diameter

Figure 2 clearly shows the effect of focusing tube diameter on drilling width. In all abrasive flow rate conditions, the larger the focusing tube diameter, the larger the drilling width was. Physical reasons can explain these results. This is because the larger the diameter of the focusing tube, the wider the jet spreads when sprayed into the air. Specifically, the larger the focusing tube diameter, the wider the cross-sectional area of the end exposed to the air, so the jet is dispersed more widely. Also, a larger focusing tube diameter means the space inside the focusing tube is wider. This relatively reduces the number of collisions of abrasive particles with the inner wall of the focusing tube due to the large internal space and reduces interference between abrasive particles. Therefore, the larger the focusing tube diameter, the more energy the abrasive has, and when sprayed with air, it is widely dispersed to form a large drilling width. In addition, it was observed that a similar drilling width was formed despite the focusing tube diameter being different under a specific abrasive flow rate condition (i.e., $AFR = 7.5$ g/s). This shows an optimal condition between focusing tube diameter and abrasive flow rate.

Figure 2. Effect of focusing tube diameter on the drilling width.

3.2 Effect of focusing tube length

Figure 3 shows the effect of focusing tube length on drilling width. The drilling width decreased in all abrasive flow rate conditions as the focusing tube length became longer. This is related to the time the abrasive particles stay inside the focusing tube. The longer the focusing tube length, the longer the abrasive particles stay and move inside the focusing tube. Staying inside the focusing tube for a long time relatively increases the

number of collisions of abrasive particles with the inner wall and increases interference between abrasive particles. In this process, the abrasive particles lose some of their energy and form a straight line with the water, aligning the flow. In other words, the longer the focusing tube length, the longer the abrasive particles stay inside the focusing tube, losing some energy due to collision and interference, and are aligned with water in a straight flow, reducing the drilling width. Conversely, if the focusing tube length is too short, the jet does not travel in a straight line, so it can be sprayed widely when sprayed into the air. Therefore, when rock drilling using an abrasive water jet, it is important to determine an appropriate focusing tube depending on the purpose.

Figure 3. Effect of focusing tube length on the drilling width.

3.3 Effect of water flow rate

The effect of water flow rate on granite drilling width was observed in Figure 4. Overall, under abrasive flow rate conditions, the larger the water flow rate, the larger the drilling width was. This is related to the momentum of water, which is the initial energy of the abrasive waterjet system. Water gains energy and gains momentum through a hydraulic pump and orifice. Additionally, water transfers momentum in the process of mixing with the abrasive, and as a result, the abrasive gains momentum and accelerates. All of these processes are the basic mechanisms of an abrasive waterjet system.

Meanwhile, in the same abrasive waterjet system, as the water flow rate increases, the relative momentum of the water also increases. Therefore, if the initial energy of the water is high, relatively more momentum can be transferred to the abrasive particles, forming a wider drilling width. However, under certain abrasive flow rate conditions (i.e., $AFR = 5.6$ g/s), a wider drilling width was observed despite the low water flow rate. This suggests that an optimal condition exists between water flow rate and abrasive flow rate, and an in-depth understanding of the optimization of parameters is necessary.

3.4 Effect of abrasive flow rate

Figure 4 clearly shows the effect of abrasive flow rate on drilling width. In all focusing tube length conditions, as the abrasive flow rate increased, the drilling width tended to increase and then decrease. This

Figure 4. Effect of water flow rate on the drilling width.

means that there is an optimal condition for abrasive flow rate for drilling width. When the focusing tube length was 76.2, 101.6, and 152.4 mm, the optimal abrasive flow rate representing the maximum drilling width was analyzed to be 11.1, 7.5, and 11.1 g/s, respectively. Through this, it can be predicted that the optimal abrasive flow rate for granite drilling width under the same standoff distance condition exists within the range of approximately 8.0–11.0 g/s. In an abrasive waterjet system, the optimal abrasive flow rate is an important factor in field application as abrasive accounts for a significant portion of the total operating cost. When a certain amount of abrasive material is added, the abrasive accelerates, and during movement, frequent collisions and interference between abrasive particles occur, resulting in relatively large energy loss. Therefore, in order to create an effective drilling width, it is efficient to use an abrasive flow rate of 8.0–11.0 g/s.

Figure 5. Effect of abrasive flow rate on the drilling width.

4 CONCLUSIONS

In this study, a granite drilling experiment was performed using abrasive waterjet technology. Drilling width according to focusing tube diameter, focusing tube length, water flow rate, and abrasive flow rate was observed and analyzed. The drilling experiment results are summarized as follows:

- The larger the focusing tube diameter, the larger the rock drilling width was. This is because the cross-sectional area at the end of the focusing

tube is larger, so the jet is absolutely wide when sprayed into the air.

- Drilling width decreased as the focusing tube length became longer. This is because the longer the focusing tube length, the longer the abrasive particles stay inside, resulting in some energy loss due to collision and interference.
- Water flow rate is the initial energy of the abrasive waterjet system, and the larger the water flow rate, the wider the drilling width was observed. This is because the abrasive is accelerated and sprayed by receiving momentum from water with relatively high energy.
- As the abrasive flow rate increased, the drilling width increased and then decreased. Optimal abrasive flow rate ranges from approximately 8.0–11.0 g/s.

ABSTRACT: A lot of manual operations are still inevitable at the tunnel face where's always in danger for rock collapse, and manpower saving and keeping safety there is most important issues. Therefore, advanced automatic operation technology has been studied to replace manual operations. The next-generation construction system with automated machinery called A⁴CSEL (Automated, Autonomous, Advanced, Accelerated Construction system for Safety, Efficiency and Liability) is promoted for 6 main steps of tunnel excavation. In this paper, two steps of them, blasting and shotcrete, are picked up. Blasting conventionally have been implicitly modelled only by tunnel workers with enough experience. Therefore, the theoretical evaluation formula for optimum blasting needs to be constructed with several factors that affect blasting result. Then, the optimum blast planning system is developed based on that formula and can be used by even inexperienced planner. According to the site trials, this system clarified to reduce the amount of overbreak and operation time. Shotcrete is quite difficult for its automation because sufficient skills for nozzle manipulation is required. In order to shift it to advanced operation, the automated shotcrete machine has been developed, and its nozzle manipulation system based on the optimum plan is also integrated. Based on the tests in mock-up tunnel, this system can spray the concrete with high accuracy of thickness, and also reduce the amount of rebound. These two steps of them are sure to reach in certain level for current tunnel site. It is sure that this automated construction system can improve the productivity, safety and manpower saving. In the near future, the A⁴CSEL for Tunnel will be introduced to the many sites in Japan.

1 INTRODUCTION

For construction industry in Japan, the skilled labour shortage, a lot of accidents, and low productivity have been significant issues for a long time. Therefore, epoch-making construction system is extremely required to achieve the goals such as the manpower saving, safety and high productivity. Authors are promoting the A⁴CSEL (quad-accel:Automated/Autonomous/Advanced/Accelerated Construction system for Safety, Efficiency and Liability), a next-generation construction system with automated construction machinery. The key issues to make this system work well is not only introducing automated machines but

also the structuring effective scheme in which the machine's operation data is analysed and operating procedure is improved. This new construction system has been applied at dam site for the first time and is also applied for tunnel construction (A⁴CSEL for Tunnel). In this paper, productive blasting (drilling and charging) and shotcreting are picked up among other steps in tunnel construction cycle.

2 CONCEPT FOR AUTOMATED TUNNEL CONSTRUCTION

As shown in Figure1, mountain tunnel construction mainly consists of 6 steps and repeats them by each

Figure 1. The concept of A⁴CSEL for Tunnel.

1 to 1.5m advance. In Japan, tunnel construction is currently taken place by 5 skilled workers per party, and 24hours operation by 2 parties for day and night shift. They are quite versatile, and excavation advance rate depends on their skill and experience. Recently, they are getting aged and there are still few newcomers due to the negative image of risky

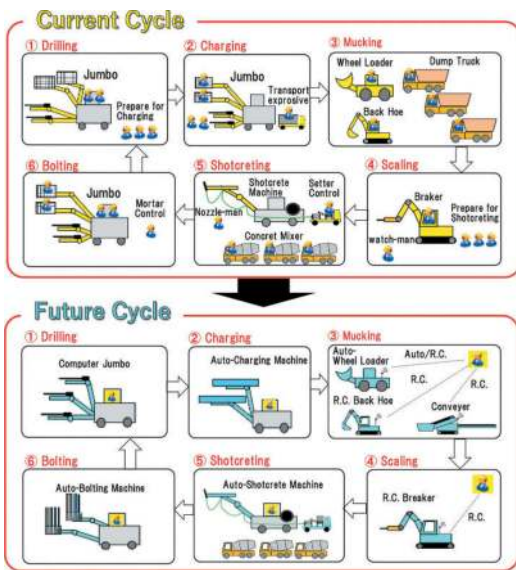

Figure 2. Image of current and future tunnel excavation cycle.

Picture 1. Mock-up tunnel.

Picture 2. Kamioka real-size test tunnel.

and hard work. Now that, time of drastic change is around the corner.

Authors are applying the A⁴CSEL, a next-generation construction system, to the tunnel construction field. The concept of A⁴CSEL for tunnel is shown in Figure 1. As for 6-step cycle from drilling to bolting, once automated machines are fully prepared, A⁴CSEL for tunnel makes it possible to realize the productive construction with one-man operation either on the machine or in the remote-control room (Figure 2). So far, the process of A⁴CSEL for tunnel is advancing with step by step from mock-up tunnel site (Picture 1) to the real-size test tunnel site (Picture 2).

3 THE OPTIMUM BLAST PLANNING

3.1 Overview of optimum blast planning

Blasting consists of drilling and charging. Conventionally, its plan had been implicitly made based on veteran worker's experience. In order to accomplish the optimum blasting using automated machine and digital data, cycling the positive loop shown in Figure 3 is essential, these are:

- Implementing blasting (drilling and charging) according to the optimum plan and digitalizing the data for next blast.
- Visualizing the blast data and analysing it to adjust next blast plan.
- According to the analysis, improving the blast plan via automated planning system.

The key points to make this loop work well are as follows:

- Need to establish the blast evaluation formula in order not to rely on the veteran worker's experience and to be able to judge the blast results by anyone who hasn't been engaged in blasting at all.
- Need to establish the blast planning system that integrates the blast evaluation formula for being able to automatically analyse the blast result and improve its plan.

Figure 3. The positive loop for optimum blasting.

3.1.1 Blast evaluation formula

In order to judge the blast design and its result effectively and evenly, authors have organized the blast evaluation formula based on theoretical solution. In general, there seems to be 3 factors that mostly influence the blast result, these are, rock property (rock strength, fractures, etc.), drilling property (drill diameter, length, etc.), charging property (types of explosives, explosives charge per hole, etc.) Based on these 3 factors mentioned above, blast evaluation formula can calculate the effective blast damaged zone for the rock around the specific blast hole (Figure 4. Figure 5). Validity of this formula had been confirmed at mine tunnel. Through the drilling test in the real-size test tunnel, this formula has been adjusted to be able to normalize the rock strength parameters that don't depend on the Jumbo manufacturer, drifter, and drill setting parameters such as percussion pressure and thrust pressure.

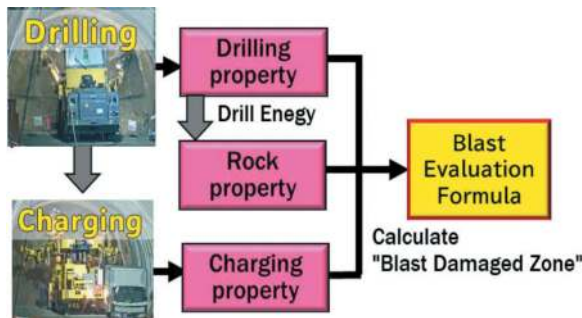

Figure 4. Calculation Flow to Blast damaged zone.

3.1.2 Blast visualized system

Because blasting has been conducted against natural rock, the blast result always contains some sort of dispersion. In order to grab the blast result tendency and evaluate the validity of blast plan from it, the concept of statistics has to be considered. Therefore, authors created the blast visualized system in which both blasting properties and their result in last 20 to 30 blasts are shown in one chart and its tendency is quite easy to grasp for users. As shown in Figure 6, visualized chart is separated into top and bottom in this system. The blast properties are plotted in top and the blast results are in bottom. Blast properties in top

Figure 5. The concept for blast damaged zone.

Figure 6. Blast visualization system chart.

Figure 7. Excavated zone in tunnel perimeter.

of the chart are such as specific drill energy (rock strength), blast damaged range (optimum hole space), hole space at perimeter, charge at perimeter hole. Blast results in bottom of the chart are excavation zone either above (orange) or below (blue) the drilling line. As shown in Figure 7, these separated excavation zones (orange and blue zone) are respectively calculated based on the drilling line data and scanned tunnel profile data after blasting. By showing excavation zone separately like this, the essential reason of having the redundant overbreak can be clarified and the adjustment for next blast plan becomes effective.

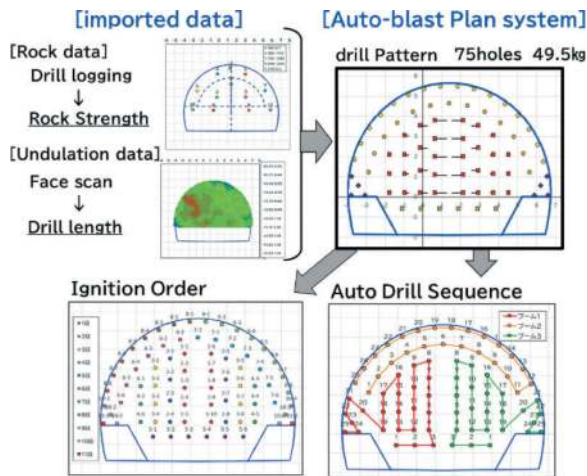

Figure 8. Automated blast planning system.

3.1.3 Automated blast planning system

The automated blast planning system in which blast evaluation formula has been integrated can produce the optimum drilling pattern and its charging plan. In the system, as an input data, previously obtained rock data and tunnel face undulation data are imported. At first, tunnel face is separated into several zones and then, based on the undulation data, the appropriate drilling length and amount of charge per hole are calculated respectively in each zone. After that, with imported rock data, the optimum hole spacing for each zone is calculated via blast evaluation formula. Once previous blast data are obtained, the whole procedure mentioned above can be automatically conducted.

After the automatic drilling pattern is produced, the manual pattern adjustment is possible if necessary. In the system, the hole ignition order and drilling sequence for automatic drilling via computer jumbo can be designed. This system also supports input/output data for different jumbo manufacturers.

3.2 Application to tunnel site

The Optimum blast planning system (blast visualized system and automated blast planning system) is applied to on-going tunnel construction site. As shown in Figure 6, at first the blast plans are conventionally designed by veteran worker even though the computer jumbo and scanner are ready for use, then from No.8 blasting in the Figure 6, the optimum blast planning system has applied. Especially, in the blast optimizing process, hole space at perimeter (black dot line in top chart in Figure 6) is adjusted to minimize the difference between the black dot line and red dot line (blast damaged range; optimum hole space). Since the optimum blast planning system has applied, the productivity of blasting work was found to be significantly improved, such as reduction of drilling time by 25%, charging time by 15%. Totally, the combined time of them reduced by 20%, and the average overbreak also reduced by 60% compared to the blasting designed by experienced workers. Blasting is the first step of the

Figure 9. Comparison for blast productivity.

tunnel construction cycle and tends to contribute the productivity for subsequent steps such as mucking and shotcrete. Therefore, controlling the blasting performance by this system is quite meaningful.

4 THE AUTOMATED SHOTCRETE

4.1 Overview of automated shotcrete

The automated shotcrete system is thought to be quite difficult because it requires not only automated machines but also sufficient nozzle operation that must work in accordance with surface condition. In order to make the system be more productive which means shorter operation time and lower spray rebound, it must integrate the optimum shotcrete planning that are flexibly designed according to the surface roughness and necessary spray thickness for each spray zone. The key issues for developing the automated shotcrete system are as follows (Figure 10):

- Machine motion control
- Shotcrete thickness measurement
- Shotcrete operation planning

4.2 Machine motion control

Conventionally, shotcrete machines are operated by manual operators called nozzle-man via remote controller while they are keeping visual check of the sprayed shape.

Machine motion control is that conventional machine is fully reconstructed by being attached several sensors in order to make it possible to work according to automatic shotcrete planning (Figure 11). These sensors such as telescopic motion and rotary angle are attached with all booms, arms, and nozzles as shown in Figure 12 to be able to digitally communicate with proportional control valves and main control unit. Especially, the swing angle and swing speed sensors are required high precision and resolution because their abilities such as response lag might directly affect the concrete sprayed shape.

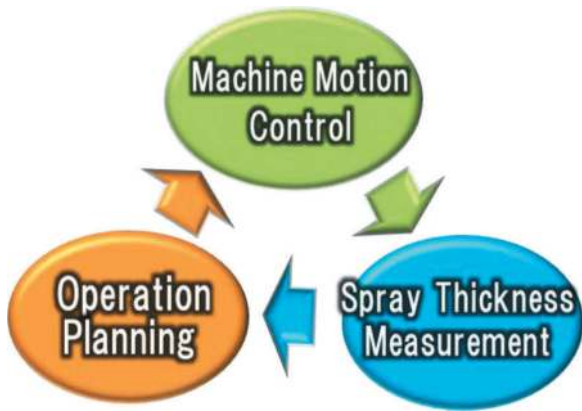

Figure 10. Key elements for automated shotcrete system.

4.3 Shotcrete thickness measurement

3D scanner is mounted in front of the automated shotcrete machine shown in Figure 13 and is applied to grasp the surface shape and roughness on face and wall before or between shotcrete spraying. Before the shotcrete spraying starts, the scanning results enable users to calculate the necessary amount of concrete and to give the appropriate order to the concrete plant. Between spraying the concrete such as the time of altering the concrete mixer truck, the scanning results make it possible to confirm the surface shape as the original plan and to adjust its plan if necessary. The 3D scanning system takes only within one minute from starting scanning to showing the result and has automatic shut cover to protect from heavy dust while spraying shotcrete.

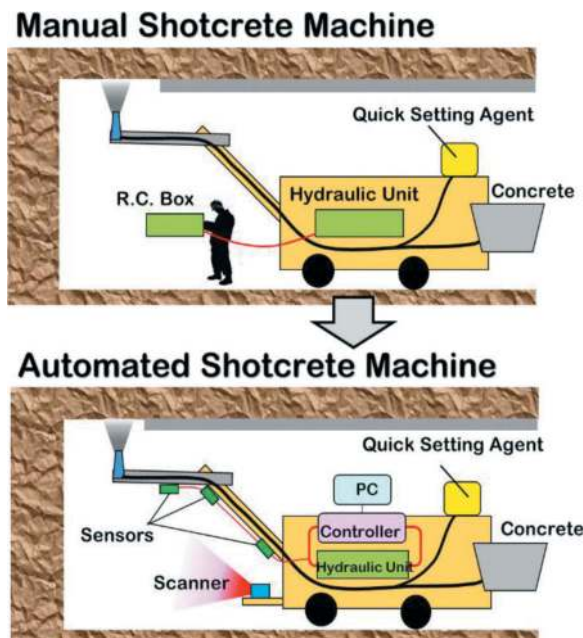

Figure 11. Manual and automated shotcrete machines.

Figure 12. Movable part in shotcrete machine.

4.4 Shotcrete operation planning

Shotcrete operation planning is to make nozzle-work sequence and give it to automated shotcrete machine. The nozzle-work sequence is automatically calculated based on surface shape and the fundamental nozzle-work movements that has previously organized through the studies in mock-up tunnel. Therefore, the shotcrete operation planning does not follow the veteran's nozzle-work as a teaching data but is able to give the optimum combination of fundamental nozzle-work movements which enables shortest operation time and lowest spray rebound with maximum concrete pumping rate. The shotcrete operation planning is divided into three modes such as face spray, wall spray, and steel support spray as shown in Figure 14.

Figure 13. 3D scanner mounted on the shotcrete machine.

4.4.1 Fundamental nozzle-work stereotype at mock-up tunnel

The mock-up tunnel is temporally constructed to implement the fundamental parametric study for shotcrete in which how several parameters affect the spray performance is examined. Through these studies, fundamental nozzle-work movements are established in which final sprayed width and thickness can be numerically estimated from several combinations

Figure 14. Three nozzle-work modes in automated shotcrete.

Figure 17. Face spraying by automated shotcrete.

Figure 15. Parameters that affects the spray performance.

Figure 18. Shotcrete thickness accuracy in wall spray model.

Figure 16. Relation between sprayed width and swing angle.

of parameters. As shown in Figure 15, these parameters are such as the spray distance to the object, swing angle, swing velocity, nozzle motion velocity, concrete pumping rate. The parametric studies clarify the relation between each pair of parameters, such as sprayed width and swing angle shown in Figure 16.

4.4.2 Automated shotcrete trial at real-size test tunnel

Kamioka test tunnel is also constructed as a real-size test site to confirm the automated shotcrete

performance in the realistic situation such as rough surface made by blasting.

For in-situ surface roughness, the shotcrete operation planning is implemented in which the surface is divided into several zones according to the necessary spray thickness, and then nozzle-work sequence for each zone is determined based on the combination of fundamental nozzle-work movements. Figure 17 is the face spray mode by automated shotcrete machine. Figure 18 shows the thickness accuracy of shotcrete in wall spray mode in which the final surface is

within few cm accuracies to target final line.

5 CONCLUSIONS

In order to overcome several urgent problems for current tunnel excavation in Japan, new construction system called A⁴CSEL is under development. In this paper, two steps of tunnel excavation cycle, epoch-making blasting and shotcreting are introduced. The key points for them to be truly productive and

optimum is not only producing automated machines but also structuring effective scheme and planning for these machines. Now other steps of tunnel cycle are also under development in Kamioka test tunnel and in the near future the A⁴CSEL for tunnel will be introduced to the many sites in Japan.

Helle Nilsen

LNS, Risøyhamn, Norway

Alf Kristian Lund

The Norwegian Geotechnical Institute (NGI), Norway

ABSTRACT: The Bergåsen road tunnel located in the northern Norway was pre-investigated and planned to be a 2 km hard rock tunnel through marble and granites. After approximately 600 m tunnelling with conventional drill and blast, the tunnel entered a mixed face soil zone of 70 m length. The mixed face soil consist of an over consolidated clay moraine and a inhomogeneous weathered rock material. The clay moraine has shear strength from 250 – 1200 kPa dependent on the triaxial load conditions, while the weathered rock material's shear strength is from 50 kPa and up to the megapascal range. As the tunnelling entered the unforeseen soil zone, the tunnelling was stopped for almost 4 months in order to carry out additional pre-investigations and revisions of the tunnel design. The basics of the tunnel design are use of reinforced sprayed concrete arches with pipe umbrella bolts for the temporary support. The main aim of this paper is to present results and experiences from the pre-investigations and design, as well as tunnelling speed with unit times and lessons learned from the actual construction of the pipe-umbrella reinforcement, double reinforced sprayed concrete arches, excavation with scaling hammer and road header excavator. The paper also presents details about the temporary support system which is double reinforced sprayed concrete arches (RRSII). The selection of of RRSII over more commonly used lattice girders is mainly due to the additional design and production time of lattice girders compared to RRSII.

Keywords: Tunnelling, soft ground, sprayed concrete ribs, support

1 INTRODUCTION

December 2022 the tunnelling contractor Leonhard Nilsen & sønner (LNS) entered in a partly soil tunnel face during the excavation of the Bergåsen road tunnel close to Mosjøen in Norway. From the pre-investigations of the Bergåsen tunnel it was foreseen a weakness zone in this area of 5 to 10 m length at the tunnel level. In reality the zone consisted of an approximately 70 m long zone of clay moraine material and weathered and disintegrated rock. From mid-january 2023 a pre-investigation scheme started, in parallel with a design study for excavation and temporary tunnel support.

The selected method comprises:

- relative short excavation rounds of 1.5 – 2.0 m under the support of spiling and pipe umbrella bolts.

- drainage holes in the tunnel face to avoid pore pressure, and to control potential erosion
- grouted face bolts with plates
- 10 cm reinforced sprayed concrete, mainly to show potential cracking and to support workers close to the face for potential smaller instabilities
- Monitoring of displacements with inclinometers above the tunnel roof
- Use of reinforced sprayed concrete ribs in a semi-circular tunnel cross-section.

Norwegian tunnelling is main experience derives from hard rock tunnelling (NFF 2022). However, the soil conditions experienced in Bergåsen has similarities to the Joberg tunnel excavated in 2015-2016 (Aagaard et al. 2017). Some of the experiences from the Joberg tunnel was utilised in the design of the Bergåsen tunnel.

Figure 1. Map of Norway, red pin show approximate location of the tunnel. (from www.norgeskart.no).

Figure 2. Geotechnical model of the soil stratas along the soil zone in Bergåsen tunnel. Red legend shows massive rock of marble and granites, cyan colour is clay moraine and brown colour is silt weathered and disintegrated rock.

2 INVESTIGATIONS CARRIED OUT PRIOR TO THE SOIL TUNNELLING

From mid-January to mid-February 5 core-drilling holes was drilled from the tunnel face through the soil zone. 2 of the core holes were drilled with conventional rock core drilling equipment, with low core recovery percentage. Conventional rock core drilling equipment is more easy available in Norway, and was selected to get a certain measure of the soil zone length. The remaining 3 core holes from the tunnel face was drilled with a triple tube with drilling fluids and a core-catcher setup. From the surface it was drilled 3 core holes vertically to establish

knowledge of the various soil stratas above the tunnel. These holes has also been utilized for pore-pressure measurements and monitoring during the tunnelling. Data from pre-investigation drillings, as well as laboratory testing of cores resulted in the following geotechnical model of the soil zone.

The laboratory testing comprised:

- Water content
- Sieve curves
- Mineralogy
- Swelling pressure and free-swelling
- Triaxial tests for determining cohesion and friction angle

The laboratory testing indicated the following average values for the soil materials.

Figure 3. Moment-Axial load plot for various tunnel changes compared to the capacity envelope of reinforced sprayed concrete ribs used for temporary support. The points outside the envelope originates from a sharp edge between the wall and semi-circular tunnel floor in the numerical model.

Table 1. Interpreted average values for clay moraine and weathered rock. The low frictional angle from weathered rock is due to challenges in obtaining reliable cores for laboratory testing.

Material	γ kN/m ³	m	Eoed			
			Ref MPa	c' kPa	ϕ' degrees	Ψ Degrees
Clay moraine	23.8	0.85	100	26	33	1.5
Weathered rock	20.8	0.77	49	42	23	0.4

From the tender stage of the tunnel, it was 7 total sounding drillings from the surface close to the soil zone. The data obtained from the total sounding drillings were interpreted as poor weathered rock mass. All the total sounding drillings ended above the

tunnel level, with the wrong conclusion of showing rock mass above the tunnel profile.

The geotechnical model and laboratory test results (Table 1) was utilized in a Plaxis numerical model for analyses of face-stability during excavation, settlements over time as well as loads on the support, for the temporary construction including support and excavation. During the excavation of the tunnel, Hoek-Brown failure criteria was used to describe the properties of the weathered rock material (Marinos and Hoek 2000), and the interpreted values in Table 1 for weathered rock was abandoned.

3 DESIGN AND EXPERIENCES FROM EXCAVATION AND TEMPORARY TUNNEL SUPPORT

3.1 Design

Figure 5 Shows the basic design of the tunnel with pipe umbrellas. The cross-section area at the start of each pipe bolt is 87.9 m² increasing to 112 m² at the end of one screen. The length of the heading arch is between 22.4 and 26.6 m length.

The design of temporary tunnel support and excavation of the tunnel were based on cyclic rounds comprising the

following activities:

1. Removal of sprayed concrete from the face/parts of the face
2. Excavation with a scaling hammer or rotating drum, and surveying
3. Application of 8-10 cm sprayed concrete with fibres classified as E1000 according to SVV N500 (NPRA 2022) in both face, roof, walls and surveying
4. Installation of grouted radial bolts for support and construction of the reinforced sprayed concrete ribs
5. Construction of reinforcement in the sprayed concrete ribs and surveying
6. Spraying of RRS2 and surveying
7. New excavation round.

3.2 Observations and risk mitigation during excavation

A daily meeting was arranged by the designer NGI with representatives from the contractor and the tunnel owner. The daily meeting assessed the following aspects:

- Water leakages and potential erosion of the tunnel face
- Instabilities at the face during excavation
- Instabilities between the spiling bolts/pipe-umbrella bolts
- Instabilities under the spiling bolts/pipe
- Deformation/displacements in the RRS2
- Visual observation of cracks in the sprayed concrete

- Visual observations of the tunnel floor with special focus on transition from wall to floor
- Instabilities behind the tunnel face.

Based on these aspects together with pore pressure measurements, displacements in the soil every day was graded with “caution level” 0, 1 or 2. Based on these assessment a total of 13 defined counter measures were available at site, where red coloured bullet points was not utilized during construction:

1. Reduce the excavation area
2. Reduce the excavation length
3. Grout leakage in/ahead of the tunnel face

Figure 4. Example of Plaxis 3d interpretation of face stability of fullface excavation.

Figure 5. Basic design of tunnel cross-section with pipe umbrellas. The sprayed concrete ribs are around the tunnel cross-section including the floor.

4. Drill drainage holes in the tunnel face and around the tunnel face
5. Increase bolt lengths
6. Change bolt spacing
7. Apply spiling bolts in lower parts of the tunnel walls
8. Utilize bolts between the reinforced sprayed concrete ribs
9. Drain water away from the tunnel face floor
10. Utilize sprayed concrete in the tunnel floor

11. Utilize coarse rock material to keep the tunnel floor
12. Pre-investigations (probe drilling with measurement while drilling (MWD) or core drilling)
13. Install RRS2 between the already installed RRS2.

For point 1 and 2 the tendency during construction was to increase the excavation length from 1.5 to 2.0 m, and in some cases even up to 2.5 m. For the total of 45 rounds of excavations only 4 rounds utilized divided cross-section. The first round utilized 4 divisions, the second and third round 2 divisions and the 22nd round was divided due to instabilities at the tunnel face.

3.3 Spiling bolts and pipe umbrella

For the initial 12 m of the soil zone spiling bolts with 32 mm diameter was utilized ahead of the tunnel face. The reasons for utilizing these spiling bolts are that delivery time of the more rugged pipe umbrella bolts are long, as well as the tunnel cross-section was too small to install the pipe umbrella bolts from the start of the unforeseen soil zone. After the excavation of the initial zone with spiling bolts, Ø114 mm top hammer pipe umbrella bolts with thickness 8 mm was utilized as shown in Figure 4. A total of 5 pipe umbrella screens of 15 m was used, each containing 34 pipe bolts. Each screen had a 3-4 m overlap. The precision of screen 2 to 5 was very good, and within cm deviation for the whole 12 m screen, while the first screen had deviations in the dm scale. The initial pipe umbrella screen's deviation demanded cutting and removal of 5 of the 34 pipe bolts during excavation. Pipe umbrella #1 was carried out in 115 hours, while pipe umbrella #2 to #5 had an average time consumption of 60 hours, which shows the contractor improvement on capacity and learning.

3.4 Excavation

The excavation was carried out with a scaling hammer mounted on excavator. Some of the rounds were excavated by a rotating drum head. In the softest material the drum head was efficient and secured an even excavation, while in parts containing lower degree of weathering and blocks the drum head was too weak.

The first 10 rounds was based on the excavator operator's skill and pure observations during the excavation. In some cases, this approach exceeded the planned excavation length of 1.5 m, and also caused some minor overbreak and underbreak in areas without spiling bolts. In order to comply with this deviation, a scanner was mounted on a pick up continuously scanning and showing real-time estimations to the excavator operator where to excavate. Experiences with the scaling hammer are:

- Efficient (4-6 hours of scaling for one full face of 1.5 m which is equal to 150-180 solid m³)

- Sufficient power to remove the sprayed concrete on the tunnel face prior to the excavation, as well as blocks and rock with less degree of weathering
- Quality of contour and the face was poorer compared to the drum head.

Experiences with the drum head are:

- Smooth contour in the tunnel walls and roof towards the pipe umbrella system
- Less efficient than the scaling hammer, and in some cases up to 10 hours excavation in cases with blocks and less degree of weathering in the tunnel face.

Figure 6. Excavation with drum head. The left part of the tunnel face is supported by sprayed concrete, and the right part shows the weathered rock (brown material) and clay moraine (grey material on top).

3.5 Sprayed concrete

Immediately after each excavation round, sprayed concrete has been applied to the exposed geo surfaces. The base-case thickness of sprayed concrete has been 8 cm. The concrete fulfilled the Norwegian public road administration R761 criteria for "E1000 sprayed concrete" with fibre. (NPRA 2018). The strength development of the sprayed concrete has been in accordance with (Norsk Betongforening, 2021), for a sprayed concrete "J2+", meaning that 0.6 MPa strength should be fulfilled after 60 minutes after spraying. In order to achieve this development of strength the concrete was heated from the concrete fabric (approximately 60 minutes drive from the construction site).

For the spraying of RRS2 there has not been set any regulations on strength development for the concrete, but site-tests to achieve a good sprayability was carried out.

3.6 Reinforced sprayed concrete Ribs (RRS2)

To support the pipe umbrella and to enable a load bearing element around the tunnel profile, double reinforced sprayed concrete arches (RRSII) was constructed during tunnelling. The c/c distance between each RRSII was 1.5 m for the first 50 m of the soil zone. For the last 25 m the c/c distance was increased to 2.0 m due to knowledge about displacement, experience on excavation and confidence in the design and contractor quality performance.

Figure 7. Design of RRS2 for temporary rock support The ribs are constructed around the whole tunnel cross-section including the floor.

Figure 8. Rebars of RRSII prior to application of sprayed concrete.

For the long term monitoring of loads and displacement in RRS2 it has been installed fibre optic cables in 3 ribs. The fibre optics follows the circumference is attached to the reinforcement bars inside the sprayed concrete rib, enabling micro-strain measurements along the the tunnel walls, roof and floor. The monitoring will be a part of the complete tunnel's ITS system, and can be used for future measurements of possible deformations.

3.6 Displacements during and after excavation

Prior to the excavation, a sub-horizontal extensometer was installed over tunnel roof. Continuous measurements on displacement were recorded and used as a verification of the tunnel stability, with special attention to the unsupported area from the last RRSII and the tunnel face. The inclinometer measurements show that displacement starts approx. 10 m (one tunnel diameter), similar to experiences in deep hard rock tunnels (Vlachopoulos 2009), in front of the tunnel face, with approximately 5-6 mm vertical displacement in the tunnel roof prior to excavation. Additional 10-15 mm displacement occurs during the excavation of the face prior to the construction and hardening of the initial layer of sprayed concrete and RRSII.

Installation of prisms for measuring displacement and convergence on every 2nd RRSII were installed

during the excavation. The maximum displacement on RRSII are 14 mm in one single point. The average displacement measured on RRSII are in the range of 5-7 mm. The total vertical deformation is 25-30 mm.

In order to measure potential long term displacement due to soil consolidation over time, it has been installed fibre optic cables in 3 of the RRSII. This enable to measure micro-strains over time, in order to detect potential deformations in the temporary support.

Figure 9. Scan of excavation profile reinforcement prior to sprayed concrete and fibre optic cable entrance (red line).

Figure 10. Example plot of measured micro-strain in one RRSII.

4 COST AND TIME CONSUMPTION

A rough distribution of the additional cost for tunnelling through the soil zone is presented in Figure 11. The additional cost includes chronologically redesign work, pre-investigations, additional temporary support (e.g. concrete, reinforcement for RRS2, pipe umbrella bolts, grout material), waiting time (the contractor production was halted by 3-4 months), cost affiliated with reduced tunnelling capacity, the normal production rate in hard rock of Bergåsen tunnel is 70-80 m/week, while the performance in the soil zone was approximately 1 m per day as an gross average for the 75 m long zone. The total additional cost for the soil zone is in the range of 150 to 200 MNOK.

Table 2 shows the average tunnelling performance between the pipe umbrella installation, and that the average tunnelling performance had a capacity of 16.5 hours per meter.

Figure 11. Rough distribution of cost for various activities related to excavation of the unforeseen soil zone.

Table 2. Average production time between pipe umbrella installations.

Chainage from	Chainage to	Hours/m
6773	6784.5	21
6784.5	6796	26.7
6796	6808	15
6808	6820	13.4
6820	6832	14.8
6832	6846	10.4

The net time consumption per excavation round is presented in Table 3. One excavation round, of 1.5 to 2.0 m, was typically carried out in 20-30 hours including the installation time of pipe umbrellas.

Table 3. Activities and corresponding net average usage of time per excavation round.

Activity	Time (hours)	Remarks
Excavation	7	Varied from 3 – 15 hours dependent on excavability.
Initial spraying of concrete	3	Varied from 2-4 hours
Bolting	5	Varied from 2 – 10 hours dependent on bolt-hole stability
Installation of rebars in RRS2	3	Varied from 2.5 – 10 hours
Spraying of RRS2	3	Varied from 2-4 hours
Installation of face bolts	5	Only installed every 8 to 12 m of the tunnel. Approximately 0.5-1.0 hours per round
Adjustment of face bolts	0.5	Cutting and installation of new bolt plate after each exc. round
Drilling of drainage holes	0.5	
Unforeseen issues		Cutting of pipe bolts,

5 CONCLUSIVE REMARKS

The unforeseen soil zone at Bergåsen tunnel was successfully excavated by July 2023. The pre-investigations at the tunnel face halted the tunnelling for approximately one month, while the design and approval from the client and third party control took nearly three months. The actual excavation and temporary support of the zone was carried out in 100 days without any major incidents. Two tunnel workers was reported with minor injuries not causing long absence injuries. The quality of e.g. pipe umbrella and sprayed concrete application improved day by day improving both the quality and capacity of the tunnelling method throughout the work.

ACKNOWLEDGMENTS

The Authors would like to show their gratitude to the tunnel owner, Statens vegvesen for the cooperation during the excavation and allowing to publish the experiences in this paper, as well as Bent Aagaard for sharing insights from the Joberget tunnel in quite similar ground conditions.

ABSTRACT: The removable time of tunnel lining formworks was evaluated using surface wave techniques. Our findings are as follows: (1) *Stiffness evaluation:* The change in the stiffness of early-age lining concrete can be assessed by measuring the propagation of surface wave, and the Rayleigh wave (R-wave) velocity is estimated using the Spectral Analysis of Surface Waves method. (2) *Unconfined Compressive Strength (UCS) Evaluation:* UCS can be determined based on the R-wave velocity. To achieve this, the R-wave velocity is converted to the primary wave (P-wave) velocity using a dynamic Poisson's ratio, and the results from test specimen result (i.e., the relationship between P-wave velocity and UCS) are utilized. It is crucial to measure a time-dependent dynamic Poisson's ratio to ensure accuracy. (3) *Measurement system requirements:* We have provided the necessary requirements for the measurement system based on the test results.

Keywords: Removable time, lining formworks, Surface waves, Concrete Surface wave techniques

1 INTRODUCTION

Assessing the removable time of tunnel lining formworks holds significant importance in the management of concrete quality during tunnel construction. Removable time primarily hinges on the unconfined compressive strength (UCS) of the lining concrete, as specified in JSCE 2016 guidelines (JSCE 2016). It is crucial to directly measure the properties of the lining concrete because the strength development of early-age concrete is influenced by the curing environment.

The main objective of this study is to determine the removable time of tunnel lining formworks through the application of surface wave techniques. Initially, an overview of the Spectral Analysis of Surface Waves (SASW) method and the conversion process from Rayleigh wave (R-wave) velocity to primary wave (P-wave) velocity is provided. Subsequently, the proposed evaluation procedure is outlined. The experimental techniques and findings from the full-scale experiment are elaborated upon and discussed in detail. Finally, we furnish the necessary system requirements to ensure the accurate implementation of these measurements.

2 BACKGROUNDS

It is assumed that stresses exerted on the lining concrete by surrounding rocks and mountains are adequately relieved during the concrete casting process, following method like NATM (New Austrian Tunnelling Method). In this context, the self-weight of a lining is the primary factor considered when determining the removable time of the lining formworks. Under these conditions, the typically required UCS falls within the range of 2 to 4 MPa, and this strength is typically achieved within approximately 24 hours of concrete placement, as specified in JSCE 2016 guidelines (JSCE 2016).

The commonly employed method for assessing the UCS of lining concrete is to use test specimen data prepared with the same concrete material and mix as the lining concrete. This approach is favored because it allows for easy UCS determination, although there is no guarantee that the UCS of the lining concrete is identical to that of the test specimens. To address this limitation, several methods have been proposed, including the concrete thermal behavior-based method (e.g., Harrison 1995) and the ultrasonic wave amplitude-based method (*Tobichima Corp*). These

*Corresponding author: kengo.kato@satokogyo.co.jp

methods predict the UCS based on material-specific relationships established through test specimens and lining concrete but may require additional equipment.

The utilization of elastic waves represents a widely accepted method for monitoring the evolution of concrete specimen properties. Numerous studies have demonstrated that dynamic Poisson's ratio and dynamic Young's modulus are sensitive to concrete age and generally register higher values compared to static ratios (e.g., FHWA 2006). Although a few studies have proposed prediction models for time-dependent Poisson's ratio (e.g., FHWA HIPERPAV software), the practical application of such models requires validation through in situ measurements.

In the late 1950s and early 1960s, Jones (1958) pioneered the use of surface waves to determine the thickness and elastic stiffness of pavement slabs and the underlying layers. In the early 1980s, researchers developed a surface wave technique involving an impactor and established a relationship between wavelength and velocity, giving birth to the "Spectral Analysis of Surface Waves" (SASW) method. Given the wide recognition and acceptance of the SASW method, it has been adopted in concrete engineering applications. For instance, Cho (2006) employed the SASW method to assess the compressive strength of single-layer high-strength concrete slabs. Kim et al. (2014) used the SASW method to evaluate primary wave velocities (P-wave) and found the impact echo method effective in determining concrete thickness and defect locations.

To the best of our knowledge, the SASW method has primarily been employed for measuring the properties of hardened concrete in concrete engineering fields. Its application to early-age concrete is currently limited, possibly due to challenges such as (1) difficulty in measuring surface wave propagation through formworks and (2) considerations of heat of hydration, thermal behavior, and drying shrinkage during the hardening process, which are critical for long-term durability.

Our research endeavors revolve around two key objectives: (1) assessing the stiffness evolution of early-age lining concrete beneath the lining formworks by employing impact techniques and (2) evaluating the unconfined compressive strength (UCS), a critical parameter for the removal of tunnel lining formworks, based on R-wave velocities. To accomplish this, we utilize data from test specimens to establish the relationship between P-wave velocity and UCS. Additionally, we employ wave propagation theory to convert R-wave velocity into P-wave velocity.

3 THEORETICAL BASIS

3.1 Spectral Analysis of Surface Waves (SASW)

Nazarian and Stokoe (1985) and Nazarian and Stokoe (1986) provide the practical and theoretical

basis for the SASW (Spectral Analysis of Surface Waves) method. In the SASW method, a transient stress pulse is generated through impact, and the resulting R-wave propagates exclusively within the top layer of the layered system. Richart et al. (1970) established the theory of surface wave propagation, demonstrating that the depth to which the wave travels depend on the depth-to-wavelength ratio. Wavelength is governed by the ratio of phase velocity to frequency, which means that the investigation depth can be controlled by selecting frequency ranges induced by impact.

Phase velocities are computed by measuring the time it takes for a component frequency to travel between two accelerometers. The speed of a component frequency, $V_{R(f)}$, can be determined given that the distance, L , between the two accelerometers is known: The relationship can be expressed as:

$$V_{R(f)} = \frac{L}{\Delta t_f} \quad (1)$$

where $V_{R(f)}$ is the R-wave velocity for a given frequency, L is the distance between two accelerometers, and f is the frequency. The travel time between accelerometers for each frequency can be calculated using the following equation:

$$\Delta t(f) = \frac{\phi(f)}{360 \cdot f} \quad (2)$$

where $\phi(f)$ is the phase difference in degrees for a given frequency. The wavelength, λ_f , corresponding to a component frequency can be determined using the following equation.

$$\lambda(f) = \frac{V_{R(f)}}{f} \quad (3)$$

The cross-power spectrum is a complex function that can be represented with real and imaginary components. In practice, the phase of the cross-power spectrum is used to determine the travel time (Nazarian and Stokoe 1986). The cross-power spectrum is calculated using the following equation.

$$G_{xy} = S_y(f) \cdot S_x^*(f) \quad (4)$$

Where G_{xy} is the cross-power spectrum, S_y is the linear spectrum of the output, and S_x^* is the complex conjugate of the linear spectrum of input motion. These equations describe the fundamental principles and calculations involved in determining phase velocities and other parameters using the SASW method.

3.2 Conversion of R-wave velocities to P-wave velocities

Richart et al. (1970) established the relationship between the P-wave velocity and R-wave velocity and introduced a conversion equation that connects to the R-wave velocity to the P-wave velocity, incorporating the dynamic Poisson's ratio. The conversion equation is detailed as follows:

$$\frac{V_R}{V_P} = \alpha \cdot K_R \quad (5)$$

where V_P is the P-wave velocity and α and K_R are functions of the dynamic Poisson's ratio, can be calculated using the following equations:

$$\alpha = \sqrt{\frac{1 - 2\nu}{2 - 2\nu}} \quad (6)$$

$$K_{R_s}^6 - 8K_{R_s}^4 + (24 - 16\alpha^2)K_{R_s}^2 + 16(\alpha^2 - 1) = 0 \quad (7)$$

Furthermore, *HIPERPAV* offers a time-dependent dynamic Poisson's ratio curve as expressed below.

$$\nu_{dynamic} = -a \cdot \ln(t + 1.1) + 0.425 \quad (8)$$

where t is the concrete age in hours and a is a fitting parameter with *HIPERPAV* using $a = 0.05$. It's essential to note that Eq. 7 is empirical and developed based on a specific concrete type and curing environment. Consequently, its application to all concrete types is open to discussion, a point that will be addressed later in the discussion. These equations collectively describe the relationship between P-wave and R-wave velocities, considering the dynamic Poisson's ratio, and the time-dependent behavior of the dynamic Poisson's ratio as provided by *HIPERPAV*.

4 EVALUATION FLOW

Figure 1 outlines the proposed evaluation process for determining the removable time of tunnel lining formworks.

1. Test Specimen Preparation: Test specimens made from the same material and concrete mix as the lining concrete are prepared. Measurements are taken for the Unconfined Compressive Strength (UCS), P-wave velocity, and S-wave velocity of test specimens.
2. UCS-P-Wave Velocity Relationship: A relationship between UCS and P-wave velocity is developed based on the data obtained from the test specimens.

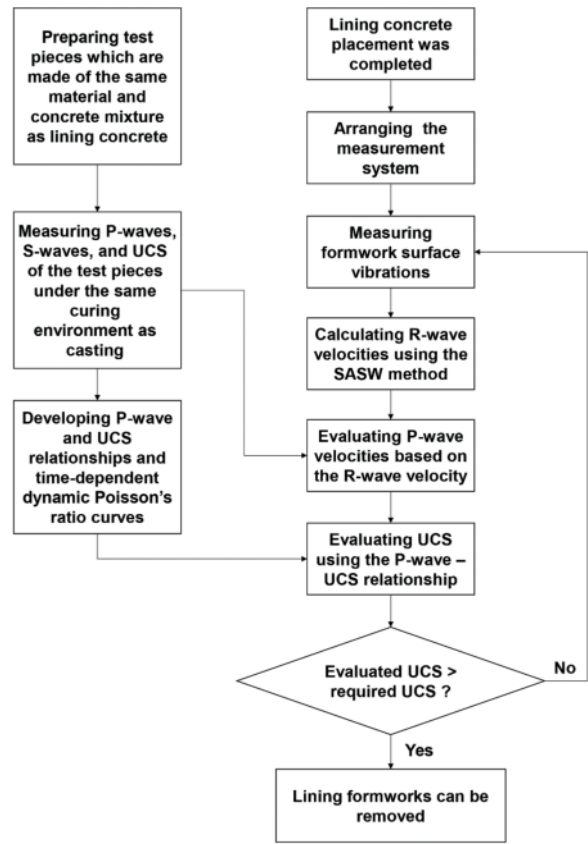

Figure 1. The proposed evaluation process for determining the removable time of tunnel lining formworks.

Figure 2. The measurement system configuration.

3. Dynamic Poisson's Ratio Calculation: Using the P-wave and S-wave velocities, a dynamic Poisson's ratio is calculated, and a time-dependent dynamic Poisson's ratio curve is established. These relationships are essential for the evaluation of UCS and P-wave velocity of the lining concrete.
4. Impact on Lining Formwork: The surface of the lining formwork is impacted using an impulse hammer, either during or after the concrete placement process. Vibrations resulting from this impact are recorded using two accelerometers mounted on the formwork surface.
5. R-Wave Velocity Calculation: Early-age lining concrete's R-wave velocities are calculated using the SASW (Spectral Analysis of Surface Waves) method.

6. Conversion to P-Wave Velocities: The R-wave velocities are then converted to P-wave velocities using the equation described in Eq. 7.
7. UCS Evaluation: Finally, the UCS of the early-age lining concrete is evaluated based on the data collected from the test specimens.

To implement this evaluation methodology, several assumptions are made:

1. Homogeneous Properties: It is assumed that the properties of early-age lining concrete are homogeneous, meaning they are consistent throughout the material.
2. Equivalence to Test Specimens: The physical properties of early-age concrete, including strength and stiffness, are assumed to be equivalent to those of the test specimens.
3. Stability of Lining Formwork: The lining formwork is assumed to remain stable and stationary during and after the impact, implying that it is sufficiently heavy and won't shift due to the impact.

These assumptions provide the basis for the proposed methodology, and the accuracy of the results will depend on how well these assumptions hold in practice.

5 TEST METHODS

Figure 2 illustrates the configuration of the measurement system used in this study, providing an overview of the equipment.

- **Accelerometers**: Two triaxial accelerometers (Model: 356B21, *PCB Piezotronics, Inc*) were employed. These accelerometers had a measurement range of 4.9 g and different frequency ranges depending on the direction: 10,000 Hz in the y and z directions and 7,000 Hz in the x direction. They were mounted on the formwork surface to monitor vibrations.
- **Data Logger**: The NI-9234 data logger from National Instruments Corp was used for data recording. It featured a sampling rate of 50 kHz/s/ch (50,000 samples per second per channel) and a measurement range of -5 V to +5 V.
- **Impulse Hammer**: An impulse hammer with a hammer mass of 0.16 kg (Model 086C04, *PCB Piezotronics, Inc.*) was utilized to generate elastic waves. These waves propagated through the formwork and the placed concrete to be measured by the accelerometers.
- **Distances and Thicknesses**: The setup included specific distances: the distance (L) between the accelerometers was set to 500 mm, and the distance (D) between the impact location and the accelerometer was set to 500, 1,000, and 1,500 mm.

Figure 3. The acceleration responses recorded at the concrete age of 6.5 and 21.1 hours.

Figure 4. The responding time lag, Δt .

The accelerometers were mounted in proximity to the injection hole, and the impact commenced 6.5 hours after the initiation of concrete casting. During the initial 3.0 hours, impacts occurred every 15 minutes. Subsequently, the frequency of impacts was adjusted to every 30 minutes for the 3.0 to 6.0-hour period, every 1 hour for the 6.0 to 15.0-hour period, and every 2 hours for the 15.0 to 21.0-hour period. For each measurement, the formwork surface was impacted five times, and the results were averaged.

6 RESULTS

The methodology was applied during a full-scale tunnel lining experiment conducted in July 2022, involving the use of self-compacting concrete (SCC) cast through an injection hole. The concrete placement took approximately 3 hours. The thickness of the lining concrete was 400 mm, while the thickness of the formwork plate was 6.0 mm.

Figure 3 shows the examples of acceleration responses in the z-direction (i.e., perpendicular to

formwork surface) shown in Figure 2 recorded at 6.5 hours and 21.1 hours from the beginning of casting. The response time lag, Δt , was observed to decrease as time progressed, with a value of 0.528 msec at 6.5 hours and 0.280 msec at 21.1 hours. Figure 4 shows the response time lag, Δt , over the concrete age. The data indicated a consistent reduction in response time lag with increasing concrete age, regardless of the distance between accelerometers. It suggests that the wave propagation speed increased as the concrete aged. The lining concrete surface was directly impacted one year

Figure 5. The actual phase angle and magnitude of cross power spectrum.

Figure 6. $\lambda_{(f)} - V_{R(f)}$ relationship at the concrete age of 6.5 and 21.1 hours.

Figure 7. The comparisons of the V_R , V_P , and F'_c .

later, and surface vibrations were recorded. The response time lag, Δt , at this point was 0.215 msec, indicating that the wave propagation was faster than those recorded within 24 hours after placement.

The R-wave velocity was calculated using the SASW method. Figure 5 shows the examples of the magnitude and actual phase angle, ϕ_p , of the cross-power spectrum at concrete ages of 6.5 and 21.1 hours. The dominant frequency was 3,670 to 5,950 Hz at the concrete age of 6.5 hours and 6,970 to 9,010 Hz at the concrete age of 21.1 hours, showing that the dominant frequency shifted from low to high frequency ranges as concrete aged. Below approximately 1,800 Hz, the actual phase angle, ϕ_p , remained relatively consistent with frequency. However, at a concrete age of 6.5 hours, its value was observed to be larger than that at 21.1 hours, highlighting distinctions related to concrete age. Figure 6 shows the relationship between $\lambda_{(f)}$ and $V_{R(f)}$. The averaged V_{R-aveg} for $\lambda_{(f)}$ was less than 0.35 m was 935 m/s at 6.5 hours and 2,075 m/s at 21.1 hours, highlighting a significant increase in V_{R-aveg} with concrete age. Notably, pronounced differences in $V_{R(f)}$ were observed when $\lambda_{(f)}$ was less than the lining concrete thickness (0.4 m).

Figure 7 shows the R-wave and P-wave velocities of the early-age lining concrete. To mitigate scattering in cases where $\lambda_{(f)}$ exceeded 0.40 m (equivalent to the lining concrete thickness), we calculated the V_{R-aveg} for cases where $\lambda_{(f)}$ was less than 0.35 m (approximately $0.85 \times$ lining concrete thickness). The average V_{R-aveg} was 935 m/s at 6.5 hours, 1,482 m/s at 9.4 hours, and 2,075 m/s at 21.1 hours, indicating a consistent increase in V_{R-aveg} with the age of the concrete. Furthermore, the V_{P-aveg} was 1,947 m/s at 6.5 hours, 2,988 m/s at 9.4 hours and 3,922 m/s at 21.1 hours, indicating an increasing trend in V_{P-aveg} as the concrete aged. The data revealed that the V_{P-aveg} of the early-age lining concrete was overestimated by 5 - 10 % compared to that of the test specimens.

The V_P of the test specimen was measured using the A1410 Pulsar (ACS, Acoustic control systems),

a device that records the velocity of ultrasonic waves traveling on the material's surface. The V_P was 2,987 m/s at 10 hours and 3,776 m/s at 24 hours. These results indicate a consistent increase in V_P with the concrete age. Furthermore, the V_P of the lining concrete was also measured one year later, registering at 4,150 m/s. This suggests that the V_P reached 91 % of its maximum value within the initial 24 hours. Additionally, The UCS was determined in accordance with JIS A 1108. The USC measured 3.69 MPa at 10.0 hours and increased to 16.3 MPa at 24 hours. This demonstrates a progressive increase in USC with concrete age. In addition, we also conducted measurements of the 28-day UCS for cored samples, which yielded an average value of approximately 60 MPa (Kato et al. 2022). Consequently, the UCS reached around 27 % of the maximum within the initial 24 hours.

Figure 8 illustrates the relationship between the V_P and UCS for the test specimen. Assuming a required UCS is 4.0 MPa, the removal of the lining formwork can be considered when the V_{P-avg} of the lining early-age concrete surpasses approximately 3,000 m/s.

7 DISCUSSIONS

The dynamic Poisson's ratio of the lining concrete was back-calculated based on the P-wave velocity of the test specimens. Figure 9 compares these values with those from Eq. 7. The back-calculated dynamic Poisson's ratio ranged 0.287 to 0.214 and exhibited a decreasing trend with the concrete age, with values smaller than those in Eq. 7. These discrepancies resulted in an overestimation of the V_{P-avg} for early-age lining concrete, as depicted in Figure 7. Regression analysis indicates that a fitting parameter of $a = 0.066$ provides the most accurate estimate in this context. The field test was conducted in the summer season, and our data indicated that the SCC began to harden rapidly. This led to the emergence of a distinct time-dependent Poisson's curve. As a result, we strongly recommend the development of a time-dependent dynamic Poisson's ratio curve under the same curing environment as the construction site.

Figure 9. The back-calculated poisson's ratio.

8 MEASUREMENT SYSTEM REQUIREMENTS

1) Accelerometers

The SASW method relies on vibrations recorded in the vertical direction, making one-dimensional accelerometers suitable for measurements. Furthermore, as depicted in Figure 5, the dominant frequency of formwork surface vibrations resulting from the impact falls below 10,000 Hz. However, it's important to note that the frequency range that accelerometers can effectively measure depends on their mounting methods. When accelerometers are mounted using magnets and adhesives, their actual measurement range is reduced, typically by approximately 70% of the maximum capacity, according to information from the seller (personal communication). Consequently, to meet the required frequency range, accelerometers should be capable of measuring frequencies exceeding 15,000 Hz.

2) Data loggers

In general, to ensure measurement accuracy, sampling rates should exceed 10 times the target measurement ranges. As illustrated in Figure 7, the V_{R-avg} of the hardened concrete is approximately 2,300 m/s. With a distance of $L = 500$ mm, the propagation duration of R-waves is approximately 0.2 msec, resulting in a corresponding sampling frequency of 50 kHz. However, it's important to consider the space, L , when determining the sampling rate. As indicated in Eq. 9, space L is calculated as a function of wavelength. Based on the measurements, the wavelength should be smaller than 0.85 times the lining thickness. For instance, in the experimental case, the space L should exceed 100 mm, necessitating a corresponding sampling frequency of 250 kHz. Therefore, it is advisable to determine the sampling frequency of data loggers while taking space L into account.

3) Hammers

In Japan, the standard lining concrete thickness is typically 300 mm (JASCE 2022). As indicated in Figure 7, the V_{R-avg} of early-age lining concrete within 24 hours falls within the range of approximately 900 – 2,100 m/s. In line with Eq. 2, it is essential that impacts produce waves encompassing frequencies of 3,600 – 8,400 Hz to ensure accurate evaluations. As demonstrated in Figure 5, the impulse hammer utilized in this study meets this requirement.

4) Spaces between accelerometers

According to Heisey et al. (1981), for accurate measurements in geotechnical engineering fields, it is advisable to maintain a space, L , between accelerometers that is both less than two wavelengths and greater than one-third of a wavelength.

$$\frac{1}{3}\lambda_R \leq L \leq 2\lambda_R \quad (9)$$

The results indicate that the wavelength should ideally be less than 0.85 times the lining thickness. Therefore, for a lining thickness of 300 mm, the recommended range for space, L , falls between 85 - 510 mm.

5) Spaces between impacts and accelerometers

Sanchez-Salinero demonstrated that an optimal space between impacts and accelerometers can be represented as $D/L = 1.0$ (Sanchez-Salinero 1987). However, as depicted in Figure 4, the response time lag was not significantly affected by the D/L ratio ranging from 1.0 to 3.0. Therefore, we recommend that the space, D , should adhere to the following criterion.

$$1.0 \leq \frac{D}{L} \leq 3.0 \quad (10)$$

9 CONCLUSIONS

We have developed an impact method to determine the removable time of tunnel lining formworks. This method is straightforward and easily applicable in practice. Our key findings are summarized below:

- 1) The evolution of the R-wave velocity in early-age lining concrete can be assessed using the SASW method. P-wave velocities can also be determined by converting the R-wave velocity with a dynamic Poisson's ratio.
- 2) The Unconfined Compressive Strength (UCS) can be estimated based on R-wave velocities. To ensure precision, it is essential to measure a time-dependent dynamic Poisson's ratio.
- 3) Detailed measurement system requirements are provided based on our test results.

Construction of desilting chambers and connecting tunnels for Vishnugad Pipalkoti He Project (444MW) in adverse geological conditions and very remote location - A case study

Rakesh Kumar Khali*

Vice President Operations-Tunnel & UG Works, G R Infraprojects Limited, Delhi, India

ABSTRACT: Vishnugad Pipalkoti HE Project is one of the major ongoing Project in the state of Uttarakhand, Chamoli District. This has been designed to generate 444MW by harnessing hydro power potential of mighty Alaknanda River. Three Desilting Chambers each with a size of 390 m (L) x 16 m (W) x 21.5m (H) designed to eliminate suspended sediments from the water conductor- system and minimize the entry of sediments to powerhouse and to ensure the safety and longevity of the turbines and other under- water parts. Construction of these closely spaced chambers and connecting tunnels posed numerous challenges due to Difficult rock condition, difficult terrain, and complex layout arrangements.

Author wants to highlight the planning process, construction methodology, innovations adopted, construction of access roads and connecting tunnels, non-availability of space for infrastructure, mitigation measures, execution challenges faced, and on the spot, solution adopted at this remote site. Also wants to share the successful experience of construction of this prestigious project with the field engineers.

Keywords: Conventional Tunnelling

1 INTRODUCTION

Vishnugad Pipalkoti HEP with the installed capacity of 444 MW is one of the major ongoing Hydro Electric Projects envisaged to harness the huge potentials of river Alaknanda. The Project shall utilize about 240 m of water head of the Alaknanda River, available in a stretch from Helong in Upstream to Birahi in Downstream. It is a Run-of-the River (ROR) scheme using a diurnal storage. The annual energy generation from the project is estimated to be about 1813 MU.

The Main components of the project are as below:

- Concrete Gravity Dam of 65 m height with four under- sluices for passing 8004 cumecs of flood discharge.
- Three Power Intakes followed by 03 Desilting chambers each with a size of 390 m (L) x 16 m (W) x 21.5 m (H).
- One Head- Race- Tunnel of 8.8 m finished dia and
- 13.5 Km length, to be bored with the TBM and DBM methods.
- An underground Machine Hall sizing 146 m (L) x 20.3 m (W) x 50 m (H).
- An underground Transformer Hall measuring 142 m (L) x 16 m (W) x 24.5 m (H).

- An underground Surge tank measuring 120 m (L) x 16 m (W) x 35 m (H)
- One Tail Race Tunnel of 8.8 m finished dia and
- 3.07 Km length.

3D view of the Desilting chambers of the Project is shown below and its location is shown as Figure 1:

2 DESILTING CHAMBERS

Main feature of Vishnugad Pipalkoti Project are its Desilting Chambers and associated tunnels. Construction of the Desilting Chamber Complex and its associated tunnels for the Vishnugad Pipalkoti HE Project, was carried out from 2014 to 2023, involved excavation of three major Chambers, each of a size like that of a typical cavern of an underground power station, (Figure 1). The Chamber layouts and associated tunnel works, which were principally sized and dimensioned for silt control purposes, were designed by the approved designer for Tehri Hydro Development Corporation Limited (THDCIL), a PSU of the Government of India. As such the layouts of the tunnels and chambers were optimized principally from a hydraulic- viewpoint, with rock- mechanics aspects, considered of

*Corresponding author: rakesh.khali@grinfra.com

secondary importance only. However, in the steep Himalayan topography of the site, steeply dipping geology (phyllites, gneisses and schists) dominated rock conditions, making excavating and reinforcing the Chambers and Intake structures as a challenging task. From the contractor's perspective the main Chamber constructability issues were wall and crown control, pillar reinforcement and excavation sequencing, whereas for the Chamber Intakes, rock-slide stability was of highest concern. Figure 1 shows the Desilting Scheme and location map.

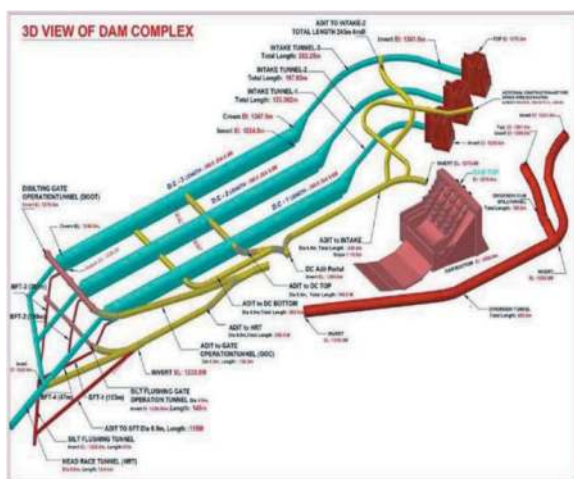

Figure 1. Project desilting scheme and location map.

2.1 Desilting arrangements

The desilting of water is proposed to be done in three underground desilting chambers of 390m length and 16m width x 21.5m high. The design discharge through each chamber is $76.29\text{m}^3/\text{sec} + 20\%$ for silt flushing, that is equal to total discharge of $91.53\text{m}^3/\text{sec}$. The velocity through the chamber has been kept about $0.35\text{m}/\text{sec}$ and smooth flow without turbulence is considered to obtain 90% efficiency for removal of silt particles of size 0.2mm and above.

The shape of the desilting chamber was provided in such a manner that the sediment could easily pass into the flushing ducts at the bottom by sliding over hopper bottom. Sufficient number of holes were provided in the slab at the bottom of hopper portion to pass the flushing water- deposited silt into the ducts.

For maintenance of the sediment chambers periodically, two platforms were provided on either side, just above the hopper. The platforms are of 1.5m width and duly provided with holes to pass the silt deposited on them. Access to the chamber is provided at the top of the chambers themselves on the sides through adits and shafts. From the top up to the platform ladders have been provided to descend.

Water flowing out of all the three sediment chambers is collected into one tunnel at the end, and it becomes head race tunnel to feed water into the power house. A gate is provided at the end of each sediment chamber, so that individual chambers can

be emptied after closing of the gates on either side for maintenance purposes. The gates are operated from a common gate chamber tunnel provided at EL. 1270m . The flushing gates are also operated from the same gate chamber. The intake gates are capable of partial opening so that discharge into the sediment chamber can be controlled and regulated. The silt chamber gates shall remain fully opened or fully closed and used only for maintenance of silt-chambers.

The flushing ducts in each sediment chamber is provided with a gate to regulate the flushing discharge during monsoon and non-monsoon season. During monsoon season continuous discharge is allowed through flushing ducts. During non-monsoon, silt is less in water and hence intermittent flushing is done and thus maximum quantity of water available is utilized for power generation. Therefore, flushing gates shall be capable of partial opening also.

The silt laden water from each flushing duct is collected in one D shaped silt flushing tunnel of size $3.6\text{m} \times 4\text{m}$ to flush the discharge $45.8\text{m}^3/\text{sec}$. The length of silt flushing tunnel is 680m . The design velocity through the silt flushing tunnel is $3.18\text{m}/\text{sec}$.

3 GEOLOGY OF THE PROJECT AREA

The project area forming a part of Alaknanda valley exposes rocks belonging to Garhwal Group and Central Himalayan Crystalline and are composed mainly of calc arenaceous rocks with basic intrusive and migmatite bodies, whereas around Helong low to medium grade metamorphic rocks are exposed. The rocks of 'Carbonate Suite of Chamoli' of 'Garhwal Group' occur between Chinka and Helong and also contain the major magnesite bodies of this region. Generally, the magnesite deposits are restricted to the non- siliceous horizons of dolostones and show a distinct structural control. Pipalkoti Anticline (double plunging anticline) is a regional fold between Birahi and Helong, representing the western continuation of anticlinorium of Tejam.

All the project components are in between Birahi and Helong. The rocks occurring at the dam and Desilting Chamber site are quartzites and along most of the length of the tunnel alignment are, quartzite with biotite schist, interbedded and interbanded with grey slates and dolomites/limestone. Grey thinly bedded slates with minor interbeds of limestone, dolomitic limestone with subordinate grey slates, grey pyritous shale/slates, thinly bedded dolomitic limestones, grey slate/phyllite, white siliceous dolomite with magnesite and talc schist are a common presence. Light grey dolomite with stromatolitic structures, interbedded quartzite phyllite and dolomite, all belong to Garhwal Group. However at the powerhouse site rocks occurring are the calcareous shale and dolomitic limestone/dolomite, while along TRT dolomitic limestone, meta basics, augen

gneisses and schist. The rocks overall are very complexly folded and faulted. The rocks of the area can be categorized into four formations viz. Pipalkoti Formation, Chinka Formation, Gulabkoti Formation and Helong Formation.

3.1 Intakes and desilting chambers

Three numbers intake structure rectangular shape have been proposed on the right bank of the river Alaknanda upstream of the diversion structure. Three numbers of intake tunnels designed as 6m modified horse shoe are proposed on the right bank of the river Alaknanda.

So far as the hot water springs are concerned the same will not create any problem for accommodating Desilting chambers in the right bank as confirmed from the geological investigation. From the available space it is observed that putting the desilting basins downstream of the dam axis in the right bank of the river is the right choice based on the geological investigation carried out. Three numbers of desilting chambers of size 320m (L) x 16m (W) & 21.5m (H) are proposed on the right bank to ran over sediment particles of size 0.2 mm and above.

This hole is located at the 20 m U/S of dam axis in the desilting chamber area. The vertical hole has proved Overburden up to 9 m depth (EL. 1318.93 m) below which bed rock consisting of mainly fine grained grayish white- quartzite with a biotite chlorite schist band between 12.45-14.0 m has been met up to drilled depth of 110.3 m (EL. 1208.73 m). The overburden consists of boulders and pebble of quartzite in a sandy matrix. Thin shear zone has been recorded from 49.50-49.70 m, 57.47-57.65 m, 78.50-78.70 and 91.70-92.40. The percentage core recovery ranges from 80 to 100 percent while the RQD varies from 10 to 100 percent.

4 METHODOLOGY

The excavation and concreting of De-Silting Chambers was done in following steps for all three De-Silting Chambers. The step of Top ramp and Bottom ramp removal and plugging of Adits has to follow completion of activities in DC-3, DC-2 and DC-1 scheduled from Top and Bottom Adit.

After extension of Adits into De-Silting Chamber, junction treatment was done as per good for construction drawings, only then the activities of De-Silting Chamber started.

4.1 Excavation of Adit to De-Silting Chamber Top & Bottom

Excavation was done by drill blast method, using Two Boom Hydraulic Drill Jumbo for drilling,

excavator PC-200 or equivalent and 10T/ 18T dumper for mucking, Two Boom Hydraulic Drill Jumbo for rock bolting and Shotcreting equipment with robo arm (Cifa/ Normat or equivalent) for shotcreting. Generated muck was disposed to the nearest dumping yard from Adit to DC top.

Figure 2. Cross section of Adit to Desilting Chamber top.

4.2 Excavation of Pilot tunnel and side slashing inside De-Silting Chamber

Excavation of pilot tunnel 8m x 8m, D-shape was carried out in both Up-Stream and Down-Stream directions after extension of Top adit into DC by drill & blast method. Drilling & charging activity was carried out with the help of Two Boom Hydraulic Drill Jumbo.

Scaling was done after blasting and de-fuming to avoid any incident by removing any visible fallout rock mass. Scaling was done with excavator PC-200 or equivalent or manually with the help of crowbar.

As soon as scaling is completed, geological mapping of the face and crown was done and 3-D log to be maintained from time to time.

Initial layer of sealing SFRS to be applied if required to support the rock mass after blasting. Shotcreting was done with the help of shotcrete machine with robo arm and 4Cum/ 6Cum Transit mixers available at site.

Mucking activity was carried out with the help of Side dump loader CLG 856 or equivalent and 10T/ 18T dumpers. Generated muck was disposed to the nearest dumping yard from Adit to DC top.

Permanent cement grouted rock bolts of 25 dia and 6m/ 8m with c/c spacing as per rock class was done after mucking is completed.

Permanent SFRS shotcreting as per rock class was carried out after rock bolting activity. Shotcreting was done with the help of shotcrete machine with robo arm.

After excavation of 390m long pilot tunnel, slashing works to be carried out in the same sequence as explained above for pilot tunnel.

Figure 3. Cross section of desilting chamber showing pilot and arch slashing.

4.3 Drilling & blasting of 1st bench of 2.5m

Activity comprises of only drilling & blasting of 1st bench to provide platform for concreting works of 1st beam and wall portion. Drilling was carried out with the help of ROC-203. Ramp was prepared in a gradient of 1:10.

Drilling & blasting then carried out in both directions from Adit to DC Top. Drilling was done with the help of ROC-203. after leaving 6m from either sides of Adit to DC top for turning and smooth movement of traffic.

Figure 4. Cross section shows the excavation of 1st bench.

4.4 Muck removal after drilling & blasting of 1st Bench

Mucking activity was carried out with the help of Side dump loader CLG 856 or equivalent and 10T/ 18T dumpers. Generated muck was disposed to the nearest dumping yard from Adit to DC top.

Permanent cement grouted rock bolts of 32dia and 6m/ 8m with c/c spacing as per rock class was done after mucking is completed.

Permanent SFRS shotcreting as per rock class then carried out after rock bolting activity. Shotcreting was done with the help of shotcrete machine with robo arm.

Muck removal was done from Adit to De-Silting Chamber Top.

Figure 5. Show the arrangement of mucking for 1st bench.

4.5 Drilling & blasting of 2nd bench of 2.5m

Activity comprises of only drilling & blasting of 2nd bench to provide platform for concreting works of 1st beam and wall portion. Drilling was done with the help of ROC-203. Ramp was prepared in a gradient of 1:10.

Sand bags were used to cover the blasting area to avoid damage in wall concrete due to fly rocks.

Muck removal and permanent rock supports was done as explained in Section 7.2.5 after concreting of 2nd lift of side walls.

Muck removal was done from Adit to De-Silting Chamber Top.

Figure 6. Cross section shows the excavation of 2nd bench.

4.6 Drilling & blasting of 3rd and 4th bench up to hopper top

Activity comprises of only drilling & blasting of 3rd bench to provide platform for concreting works of wall portion. Drilling was done with the help of ROC-203. Ramp to be prepared in a gradient of 1:10.

Muck removal and permanent rock supports was done as explained in Section 4.5 after concreting of 3rd lift of 2.5m explained in Section 4.9.

Muck removal was done from Adit to De-Silting Chamber Top.

Figure 7. Cross section shows the excavation up to 3rd bench.

4.7 Concreting of the desilting chamber up to the 4th bench of 10m

Reinforcement fixing for the beam and wall portion up to a height of 10 m was accomplished in a single operation using 5m shutters. The reinforcement fixing for the 10 m height was carried out manually using staging and scaffolding. To prevent sagging of the reinforcement, anchor bolts were inserted according to the design specifications before concreting.

The concreting of the beam and wall was executed with the assistance of standard shuttering plates with a height of 10 m and length of 5m. The concrete was compacted using mechanical vibrators. The grade of concrete used was as per the design, with a specification of M25, and the maximum size of the aggregate used was 40mm. Contact grout holes, as specified in the design, were provided by inserting PVC pipes during concreting.

Concreting was done by a concrete pump and 6Cum Transit mixers. The concrete was supplied through Adit to DC Top from the nearest batching plant located at the dam site. Sandbags were placed under the wall portion to prevent slurry leakage, and reinforcement bars were curtailed inside for further tying down.

Proper treatment was applied at construction joints before resuming the work. The junction between the crown shotcrete and wall concrete was filled with SFRS to rest on the concrete wall.

Figure 8. Shows the wall concreting of desilting chamber.

4.8 Excavation of 5th bench of 2.75m

Sequence of execution is same as explained earlier was followed. Muck removal was done from Adit to De-Silting Chamber Bottom.

Figure 9. Shows the excavation of 5th bench.

4.9 Excavation of construction adit to flushing trench up to DC, excavation of 2nd Ramp and Trench

Construction adit (Adit to Flushing Trench) interconnecting all three DC's was done to facilitate for excavation and concreting works of part wall and trench portion which shall be plugged after completion of DC works instead of enlarging all BFT's for excavation and concreting purpose which resulted excess cost. Sequencing of works is explained below considering this construction adit in place.

Excavation of Adit to Flushing Trench up to DC was completed to provide passage for further activities inside DC.

Excavation of Adit was done from Silt Flushing Tunnel (SFT) towards DC. Adit was excavated in a minimum dimension of 4m D-shaped for effective and smooth working and was plugged with concrete after completion of works in DC.

The junctions with trenches were flared for getting required turning radius for equipments to move inside DC; same was backfilled with concrete and will become a part of plug structure.

Excavation sequence is same as for any tunnel by Drill Blast Method (DBM)

a) Drilling b) Charging & Blasting c) De-fuming d) Scaling & Mapping e) Initial sealing Shotcrete or SFRS (if required) f) Final Rock support

Excavation of 2nd Ramp was carried out by drill & blast method. Drilling was done with the help of ROC-203.

Completion of Excavation of Adit to Flushing Trench from SFT was ensured before excavation of ramp and below ramp portion for mucking purpose.

Drilling & blasting of Trench area then carried out. Drilling was done with ROC-203. Ramp was prepared in a gradient of 1:10.

Muck removal and permanent rock supports was done as per the requirement.

Figure 10. Shows the completed excavation.

4.10 Concreting of hopper portion and Trench

Concreting of hopper portion was done only after excavation of DC up to trench level.

Concreting method is same as done for walls except for the shutter used with gantry traveller. Concrete was supplied from Adit to Flushing Trench. Shutter length considered is 6m.

Concreting of trench was done after concreting of hopper portion and gantry removal with the help of traditional shuttering.

Concrete then supplied through Adit to Flushing Trench from nearest Batching plant located at dam site.

Figure 11. Shows the concreting of hopper and trench.

5 EQUIPMENT USED

Most modern equipment's were used for excavation and concreting of various stages oDC-1.2 &3 as explained below:

5.1 Pilot excavation and arch slashing

Two Boom Hydraulic Drill Jumbo: 1no
 Side Dump Loader CLG 856 or equivalent: 1no
 Excavator PC-200 or equivalent: 1no
 Shotcrete machine 30m³/hr: 1no
 Dumpers 18T: 5nos
 Transit Mixers 4Cum: 6nos

5.2 Benching

ROC 203 or equivalent: 2
 Excavator PC-300/200:2nos

Shotcrete machine 30m³/hr: 1no
 Dumpers 18T: 5nos
 Transit Mixers 4Cum: 6nos

5.3 Concreting

Transit Mixers 6Cum: 6nos
 Batching Plant 60m³/hr: 1no

6 SAFETY PRECAUTIONS: RISK HAZARD ASSESSMENT

All safety measures to be followed as per the standard Safety Management Plan.

Operator & supporting labour staff shall put on necessary PPE's during the work at heights as proposed.

During excavation, the excavated profile shall be cut in specified shape and dimensions with designed rock support methods to ensure safe working area.

Scaffolds of proper type shall be provided for all work that cannot be done from the ground or from part of a permanent structure or from ladder or other available means of support and safe means of access shall be provided to every place at which workers are required to work.

All working platforms, gangways and runs from which workers are liable to fall more than 2 meters shall be

- Of adequate width depending upon the type of work done and closely boarded, planked or plated. For platforms, the width shall not be less than 60cms. For gangways or runs are used for passage or materials the width shall not be less than 60 cms.
- Provided with suitable guardrails of adequate strength to height of 1 meter above the working surface and toe-boards of at least 20cms in height to prevent fall of persons, materials or tools.
- In addition to the above listed precautionary and safety measure. Certain IS codes for safety norms enlisted below should also be strictly followed:

Table 1. Shows the safety codes referred during execution.

Sr. No.	IS Code Description	IS Code
1	Safety Code for Excavation Works	IS : 3764
2	Safety code for blasting & related drilling operations	IS : 4081
3	Safety code for working with construction machinery	IS : 7293
4	Code of practice for safety colors and safety signs	IS : 9457

7 DIFFICULTIES IN CONSTRUCTION

During execution lot of problems faced by the working team. Some of the major problems are highlight here below:

7.1 *Managerial difficulties in streamlining the VPHEP:*

While talking so much of poor geology as a major challenge to the underground work, we often tend to overlook many other extraneous factors which cause serious delay in execution of the project. Coupled with it stand up the hostile local populace and remote location of site.

The VPHEP was planned to commission by 2025 but been inordinately delayed. Local people have posed lot of problems to the project authorities and contractors: viz, non- transfer of land required for the project even after drawing 75% of the payment as compensation and raising issues related to employment and petty construction-contracts. Authorities have assured employment to local people and given them a chance to work in the project on the basis of their qualifications. After getting the job they more than often formed a union in connivance with local leaders and collected hostile- rabble-rousers and disrupted the smooth functioning of the company authorities and district administration. Instead of silently working on the posts allotted to the local workers, they engage in protest marches and sometimes in pilfering construction material too. The company has lodged several FIR's in this matter and has also removed some hostile staff from the project. Project activities are seriously hampered due to local disturbances and continuous strikes, for more than a month at a stretch. As a result, in 7 year only 14% work of the project was completed.

Finally, the work started at this site but still the project is moving ahead with the re scheduled dates. It looks from the speed picked up now work will be completed soon with support of authorities.

Dam site at Helong is stands at a remote location near Joshimath where the Project components like diversion tunnel, desilting chambers, silt flushing tunnels, part HRT and intake structures which are the starting points of the project, could not be made functional because authorities faced lot of problem due to non- cooperative attitude of local people. Alternative ways were explored by the management and, in some cases, paid an extra amount to carry on the works. Several cases of manhandling with engineers and staff working at site. Such cases were given legal cognizance reported thereof.

Finally we restored the work sequence by doing efforts and educating people with help of district administration.

The blockade of National Highway especially during the monsoon, made the situation worst: supply chain management was severely affected. As a result, construction material like cement, steel, structural steel could not reach the site on time. Storage facilities were limited for want of flat land available in the region. Lack of diesel storage also created hurdles and further delayed the execution of the project. Internal road links passing through the

acquired land of the locals were also laid seizure upon by the so-called owners who continue demanding undue compensation. It also delayed the project schedule.

Construction of Char Dham project, a govt project, was started to widen the roads and to give good accessibility to pilgrims. The project also created interruptions during its implementation which was further complicated by the huge rush of vehicles during the yatra season.

Covid -19 also gave a big setback to the project. All movements were stopped by govt Nakas at different places even for human movement documents were demanded, at every nakka, for vehicles carrying construction materials. This severely delayed the project.

Transportation of big equipment was hit the most. Equipment's were transferred in various consignments to the site after strengthening the weak bridges and dismantling big equipment's in pieces and then reassembling at the site. This was a major exercise which directly caused enormous delay in mobilization of equipment's to the site. Lot of innovative thinking was given to identify safe routes for the equipment's to reach the site. Finally, with the help and cooperation of local authorities we could mobilize the site but huge wastage of time did take place.

7.2 *Problem in vertical wall concreting in desilting chamber and innovative solution adopted.*

Vertical wall concreting was critical activity and very time consuming, to overcome this 10m shutter was introduced and 5m length of vertical wall was done at a time on each wall by providing 2 shutters in each chamber. This proved to be a successful innovation and concreting was done in a faster way.

Figure 12. Shows the shutters used on both sides of Desilting chamber and view of dumping yard.

7.3 *Non availability of Dumping Yard*

Dumping space at dam site was limited and after continuous dumping the space got occupied fully. By providing gabion walls to some extent the space was increased but that also was not sufficient. Then with

the consent of THDCIL some local land was taken on lease for dumping at a distance within 7-8km and this arrangement worked well and work was done in a faster way.

8 CONCLUSIONS

The scheme, the considerably big in India at 444 MW, will generate power after completion with the Desilting Complex Chamber excavations and ancillary tunnels providing their designed role.

Despite so many problems requiring significant engineering input, the Desilting Complex, comprising three Chambers 390m long, 16m wide, approximately 21.5m high has been completed to the original hydraulically designed shapes. Execution of the final works has not been without challenges however, and the final arrangements have only been accomplished through the cooperation and integration of important ideas put forward by many parties, and then engineered to detailed design level only as part of the construction works. The overall final arrangements now comprise several support elements not foreseen in the original tender design drawings and by introducing in-house innovation at

project level, this was the key of success to complete these important structures.

ACKNOWLEDGMENTS

Author is thankful to THDCIL for giving this opportunity to execute the job and all kind of support extended during execution of this prestigious project.

Construction of Tunnel T-49A on Dharam – Qazigund section of Udhampur-Srinagar-Baramulla New BG railway line project in highly adverse geological conditions- A case study

Rakesh Kumar Khali*

Vice President Operations-Tunnel & UG Works, G R Infracore Limited, Delhi, India

Sharanappa Yalal*

Cluster Head, J&K, Hindustan Construction Company Limited, Mumbai, India

ABSTRACT: A number of challenging tunnelling projects are under construction across the length and breadth of the country to connecting significant but remote places to rest of the country. With a serious intent to ease the day –to-day life of the people of Jammu and Kashmir and to connect them through railway network to the world outside the valley, it has become necessary to create a passage through the mountains therein. The Indian Railways decided to connect the people of this beatific valley all through the weathers. Hence the most economic rail linking project officially known as Udhampur Srinagar Baramulla Rail Link Project (USBRL). The whole track passes through an insurmountably adverse Himalayan Geology, keeping in view the fact that 70% of the track is covered by series of tunnels between Udhampur and Qazigund. The length of tunnels between Udhampur to Qazigund ranges between few hundred meters to 12.78 kms. The first longest length of the Tunnel is 11.20km. The Pir Panjal Tunnel (T-80) has already been commissioned in 2013 and is fully operational on date. Another longest railway tunnel in the series of this project is T-49, having a length of 12.78km surpassing the length of the previously built longest tunnel, i.e., T-80 Tunnel. Considering the construction difficulties, approach and time bound project, Tunnel T-49 has been split into two projects- T-49A measuring 5100m and T-49B covering a distance of 7700m. Hereunder we will discuss the T-49A project.

The project - which is in the advance stage of construction, has been christened as Tunnel Package T-49A, forms an important part of Prestigious Udhampur Srinagar Baramulla New BG Rail Line Project in the Union Territory of Jammu and Kashmir.

The Twin tunnels, i.e., “the Main” and the “Escape tunnels” of 5.1 Km length each, horse shoe shaped, with 7.12m and 4.5m finished dia respectively, are to be bored through NATM through a fragile geology where surprises confront our engineers day in and day out .

The authors wants to highlight the details of the planning process, execution challenges, innovations done, introduction of additional adits, simultaneous working of various activities and extremely poor road conditions faced where supply- chain- management was the key to success. Being the project of national importance this stretch was tunnelled within the time schedule. This successful experience will be helpful for all the field engineers who are working day and night in different part of the country and abroad.

1 OUTLINES OF THE PROJECT

Tunnel T-49 is the longest Railway tunnel in USBRL Project having a length of 12.78 Kms, divided into 2 parts viz T-49A and T-49B.

Here, we will discuss T49A Project which consists of two major rail bridges 2 and 3, summer station-yards, combining the 5100m main tunnel & 5205ms long Escape Tunnel. Both tunnels are intersect each other by cross passages at every 375m. The T-49 tunnel will connect the two-railway

stations, namely Sumer in the south and Arpinchala on the North. The Main Tunnel starts from chainage 111500 and ends at 116600.

The project is located around 200Km from Jammu, in the Ramban district of State of Jammu and Kashmir. It can be approached through NH44 up to Ramban, and from Ramban to Harog, 30kms, through the State highway. From Harog to the site, it is connected through a very difficult 20km long hilly road. All access roads are slide- prone and frequently blocked due to rain fall. Figure 1&2 shows the site location maps.

Figure 1. Location map.

2 GEOLOGY

Regional Geology within the current project area consisting of three major geological formations (FRM) can be distinguished in general: the Ramban FRM, the Salkhala FRM and the Ramsu FRM. The Dumgali FRM can be mapped too, but its appearance is rather scarce. The main tectonic feature within the project area is the Main Central Thrust (MCT), which crosses the alignment close to the Sumber Nala.

2.1 Geology along the alignment

The individual rock types of the above described geological formations are characterized below,

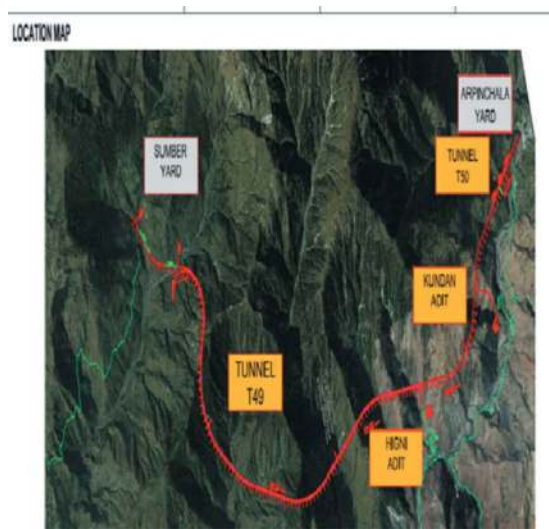

Figure 2. Site location map.

based on the current knowledge and the current state of geological investigations within the project area.

2.1.1 Phyllites

Phyllites are widespread and common project area. They occur in almost every formation. Their texture is manifold: near the portal T49-P1, the Phyllites are mapped as massive rock - body (Figure 3). But in general, the schistosity planes are thinly laminated and the jointing is closely spaced. Hence the rock mass is strongly fractured (Figure 2). Generally its colour varies between light brown to grey, but at times, also with a darker brown; in combination with other

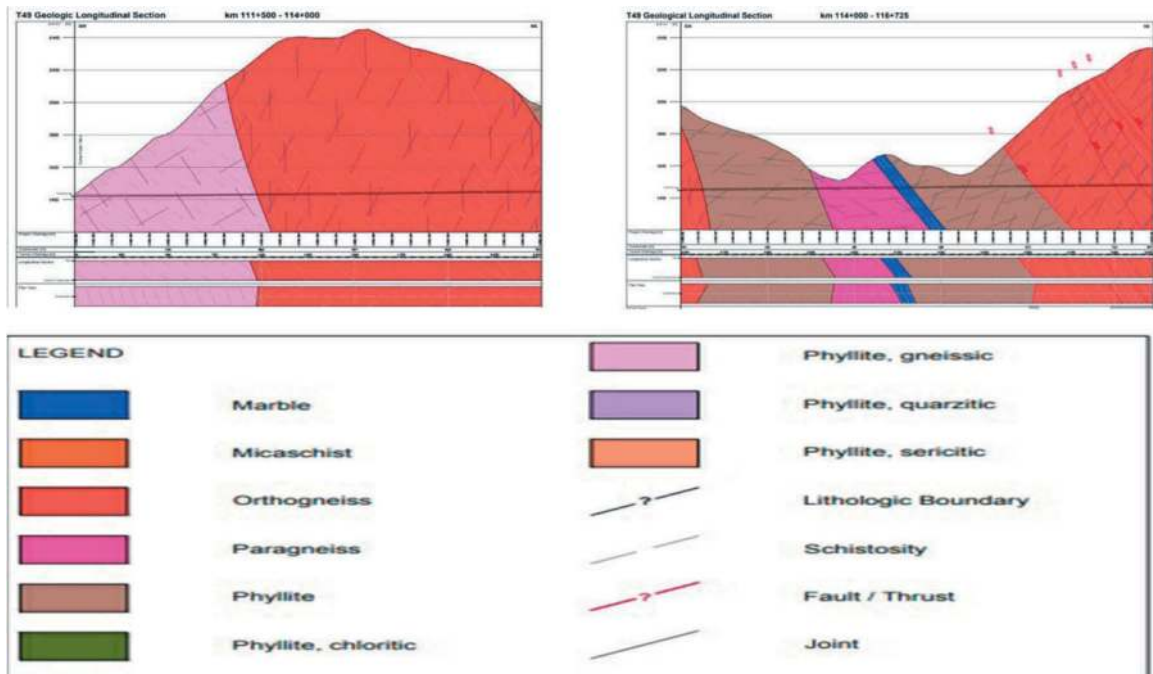

Figure 3. Geological L Section of T49.

minerals also greenish and greyish. The Phyllites sometimes show open joints up to 10 cm wide, but as a whole below 0.5 cms. The schistosity- planes display in general a high persistency; hence they are mechanically active. The schistosity planes are predominately dipping into 355° - 50° with a dipping angle of about 40°. The joint orientation shows generally a NW to W striking, but with a few exceptions.

2.1.2 Orthogneiss

Orthogneiss within the current project area is located mainly along the ridges which build the topographic boundaries of the Urnihal catchment. This Orthogneiss is generally massive, the foliations and joints display a wide spacing of up to 200 cm.

2.1.3 Paragneiss

Paragneiss, apart from Phyllite, is the most dominant rock type in the project area and occurs within the entire Salkhala FRM. The Paragneiss is interbedded within the Phyllites, because of their common sedimentary origin. The dip direction of the Paragneiss is almost entirely NE, with dips between 40 and 70°

2.1.4 Micaschists

Micaschists are much less common in the current project as the Phyllites and Paragneisses are. They have been mapped around the Urnihal Nala at its orographic right-hand flank. The schistosity displays a thin thickness of approx. 6-20 cms.

2.2 Regional- scale tectonic features

2.2.1 Main Central Thrust (MCT)

The MCT runs through the project area. Although its direct morphological impact is marginal, its influence on the structural inventory and, therefore, on the geotechnical behaviour of the rock mass in the project area is of paramount significance. The MCT follows a northward -incline from the confluence of the Sumber Nala and the Anchah Nala, along the northern slopes of the Sumber Nala over a flat top at Sinkhli (Figure 10); and, thereafter, continues through a small valley lying in north of the settlement called Duda in the Bishelari River valley. Somewhere near Digidol, the MCT enters the mountains on the other side of the Bishelari River. Within the current project area, the MCT crosses the alignment only once at bridge BR-3. In the literature concerned, a strict NW-SE orientation is annotated to the MCT, but it appears, that the MCT regionally follows a more differentiated pattern.

2.2.2 Pir Panjal Thrust (PPT)

The PPT thrust is inter-bedded between the MCT in the north and the Main Boundary Thrust (MBT) in the south. The PPT is easily detectable by using

aerial photographs, as it defines the northern boundary between a brighter rock- type in the south and a darker one in the north, the latter in most of the cases, is a Phyllite. The rock, south of the PPT, is mainly a volcanic basalt and other sediments of the so-called Panjal traps. For the current project, the fault is not relevant because it crosses the alignment south of the project area.

2.2.3 Main Boundary Thrust (MBT)

The MBT is the best detectable in the topography. It follows the Chenab River from Peerah to the area around Dharamkund. At Dharamkund, it leaves the Chenab valley and continues along the Chinji Nala. From thereon, the MBT continues all along this valley unto the settlement of Damni in the Ans River valley, farther in the West. This thrust separates the upper Dharamsala (Murree) formations in the foot-wall from the Panjal traps **in the hangings**. This thrust describes a horizontal overthrust of approx. 100 kms. Its morphologic significance is very prominent.

2.2.4 Seismicity

The proximity of young thrust planes like the Main Central Thrust (MCT), indicates that the project area is located within a tectonically high active area in the past and also probably so in the future. The largest recorded earthquakes in the region show Richter magnitudes of up to 6 which means, that the intensity may also rise to 7, even if no record of such an event exists. The project is defined to be located within the Seismic Zone V, as per the IS: 1893-7

3 CONSTRUCTION SEQUENCE

The Tunnel -construction moves in a sequential manner which involves

1. Excavation
2. Primary Support
3. Geotechnical Monitoring
4. Water Proofing of tunnel,
5. Final Lining
6. Second Stage concreting and conduit fixing

As per the current worldwide practice, sequence from 3 to 6 are mostly common, but as far as the sequence A & B are concerned, methods of excavation and primary support vary largely depending upon the site conditions.

Ground Behavior Type	Classification Method	Ground type	Relevant Parameters											
			Orientation of mechanically relevant foliations		t/s	Moisture water inflow		stress tolerance		Size of jointed rock body		Abrasivity		
			horizontal	vertical	100 to 200m	100 to 1000 m	10 to 100	100 to 1000	low	high	100 to 200 cm	200 to 1000 cm	low	high
SOFT 01	MBM	SOTh 02, 03, 04	X		<5	<2	<3	X	X	X	X	X	X	X
SOFT 02		SOTh 01, 06, 07	X	X	<5	>5	>3	X	X	X	X	X	X	X
SOFT 03		SOTh 04, 05, 08	X	X	>5	>3	>3	X	X	X	X	X	X	X

Figure 5. Ground behavior type and support classes.

3.1 Excavation

Excavation of tunnel is based on the ground types, ground behavior type and finally selection of support type. Before excavation of tunnel face ground types, ground behavior type is characterized by detailed geo-mechanical study at tunnel face and at the project site and geotechnical design is established for selection of support type (Figures 5 & 6)

3.1.1 Support classes

Following support classes are encountered at the project-

Normal drill-and-blast method was adopted to excavate in support class SC2, SC3 and SC4. Wedge-cut blasting pattern was adopted here to fragment the rock mass into the desired size. For supporting class SC5 and SC6, special techniques were adopted to excavate the rock mass without disturbing the equilibrium of the surrounding rock mass, a process hereafter discussed in Para 8.

3.1.2 Primary support

Based on the support-classes, the supports have been designed to stabilize the excavated tunnel.

Typical support measures have been shown in the following Figures 6,7, 8, 9, and 10

SUPPORT CLASS 2 (SC2) - MAIN TUNNEL
S 1:100

Figure 6. Support measures SC2.

SUPPORT CLASS 3 (SC3) - MAIN TUNNEL

SC5SQ	0.00
SC6SQ	0.00

3.1.3 Adverse geological conditions

Tunnelling through Himalayan region is always a challenge and our team faced many of them during the execution of T49A. Excavation through support classes SC1, SC2, SC3 and SC4 were almost easier to cross through but in support classes SC5 and SC6 were very challenging. A number of thick- to- very thick, very weak and unstable shear zones were confronted (Table 01) where the mining team struggled day and night, and finally crossed effectively through the challenging zones without wasting a single day- no minor or major injury sustained, no mining equipment damaged .

As mentioned in para 7.1.1 **SC5 and SC 6 encountered were 3.93% i.e. 200.43m**

Very loose and unstable strata were encountered as shown in the table no 2:

SUPPORT CLASS 4 (SC4) - MAIN TUNNEL
S 1:100

Figure 8. Support Measures SC4.

SUPPORT CLASS 5 (SC5) - MAIN TUNNEL

5	4003	4029	m	26
6	4092	4098	m	6
7	Total		m	152

As shown in Figure 11, sequential excavation of top heading, benching and invert excavation was adopted to tackle the adverse geological conditions:

Figure 11. Excavation in adverse geological conditions.

3.1.4 Top heading excavation

2. Excavation of the left Crown and installation of lattice girder followed by wire-mesh fixing and shotcrete.
3. Excavation of the right Crown and installation of the lattice Girder, followed by wiremesh fixing and shotcrete
4. Installation of 12m long (27nos)76mm dia fully grouted pipe roof
5. Repeating the sequence no 1 and 2 till excavation of 8m length **with leaving Support core body** (Figure 12)
6. Removal of Partial Support- Core body and installation of rock bolts.
7. Repeating the sequence no 01 to 06 for further advancements.

3.1.5 Benching excavation

1. left wall and installation of lattice Girder followed by wiremesh fixing and shotcrete
2. Excavation right wall and installation of lattice Girder followed by wiremesh fixing and shotcrete
3. Installation of fully grouted rock bolts
4. Repeating sequence no 01 to 03 for further advancements.

3.1.6 Invert excavation

After stabilization of tunnel and after monitoring its geotechnical instrumentation data, when no deformation located, invert excavation of 2m length was carried out with full primary support and the

excavation cycle repeated till crossing the loose and unstable ground.

4 CHARGING & BLASTING

The charging pattern followed for excavation was in accordance with the norms of wedge- cut and the drilling and blasting patterns. The only modification made in charging was: two numbers of primers were used in cut holes. Owing to the presence of phyllite and quartzitic phyllite rock, powder factor was also moderately used.

It varied from 1.0 to 1.5 kg/m³, depending upon the rock strata encountered. Power gel 80% explosives with non-electrical delay detonators were used with cortex.

5 CYCLE- TIME AND SEQUENCE

Sequence of boring cycle time in different rock class is as under –

As explained earlier, drilling was done with Atlas Copco- make Boomer at the Main Tunnel and With Tam Rock Make- boomer at the Escape Tunnel.

6 LINING OF TUNNEL

The entire portion of the tunnel was concrete –lined, and the weak portion was covered with RCC lining. The concrete lining was done by using shuttering gantries of 12m lengths with CIFA hydraulics and shutter vibrators mounted on gantry shutters. The

gantry was movable on rails. Concrete placing was done by using BP 1800 concrete pumps.

After completion of the primary support and after stabilization of the area, a final support with concrete lining, both with reinforcement and without reinforcement depending upon the rock classes, was done successfully. It included the following steps-

- (a) Erection of gantry
- (b) Preparation of the bed and PCC (M15) concrete for Kerb beam.
- (c) Placing of a perforated 250mm dia. Pvc pipe.
- (d) No fine concrete over the Pvc pipe.
- (e) Erection of **form work**.
- (f) Fixing of geotextile.
- (g) Fixing of water proofing membrane

7 DIFFICULTIES IN CONSTRUCTION

7.1 *Poor ventilation, fault zones encountered and innovation done by introduction of a new Adit*

Since the Tunnel had to be bored from one face for a length of 5.1Km, after crossing 2.5 km, it had become impossible to maintain proper ventilation inside the tunnel, even after lot of efforts. Somehow, we could reach up to 3.2Km in the Main Tunnel and Escape tunnel. Also the fault zones were encountered while advancing creating operational problems. Disadvantage at this 5.1Km long face was a result of the poor geology throughout the advancement of the initial length, as water seepage from the crown was travelling along the tunnel- alignment. The Fault zone was encountered at several places where heavy seepage occurred. As a result, the work of the whole face came to a standstill at one point of time. Heading- benching method was adopted with the NATM, followed by a 76dia pipe roofing and grouting. One set of pipe roofing of 10m advance contains 27nos of pipes with self-drilling bits. To consolidate the area, various SD anchors were provided to stabilise the roof and the side, followed by lattice girder and shotcreting. Also, it was felt to introduce a new ADIT to mitigate a 5.1km length of single- face to provide an additional 2 faces. This decision brought about a turn around and we could complete the excavation on time. The author wants to highlight this innovation for the information of fellow engineers as explicated below:

This Tunnel (T-49A) was awarded in 2013 December for execution of a 5.1 Kms twin -tunnelling with a single face. As per the standard tunnelling methods, we could take up the mining only with one face covering about 2.5 KM. Doing 5.1 Km long mining

Figure 15. Concrete lining arrangements.

with one face is difficult and maintaining safety and environmental parameters were very much difficult. Maintaining good ventilation inside the tunnel for boring such a long tunnel, is not possible by adopting any random methodology as per the tunnelling guidelines. In addition to the ventilation, maintaining supply -chain for tunnelling activities and for hauling excavated muck from the face to the dumping yard is also one of the major challenges in such conditions.

It is pertinent to mention that the contract was awarded without provisions of any intermittent Adit to divide the tunnelling into two zones. In order to overcome the challenge, the Project team successfully coordinated with the client consultant and convinced him for reviewing the provision of an additional Adit. As a result, the client agreed upon and approved our proposal for taking up an additional Adit at the tunnel chainage, 3650m, from the South Portal.

The location of the Adit was decided considering the favourable geology and the minimum length to be excavated for the Adit. For this, the detailed investigation was conducted to finalize the location and, after deliberations, the length of Adit was finalised as 310 m. The working team completed the entire Adit length within 4 months, including portal development from the starting point. The excavation diameter of the Adit was kept the same as that of the tunnel, i.e., 7.15 m finished diameter.

With the introduction of the new Adit, we successfully completed about 1.8 Kms tunnelling through the new Adit. The detailed diagram showing the mining done by the Adit is shown below:

Figure 16. Pictorial view of T-49A Tunnels and new Adit.

With this new innovation, the following favourable advantages were achieved as detailed below:

- Maintained good air quality inside the tunnel to keep hazard free atmosphere in the tunnel which is the prime requirement of excavation.
- Ensured reduction in the cycle time and maintained speedy progress.
- Reduction in construction cost by reducing the lead for hauling the muck and other construction materials.
- Ensured an accident-free construction site by reducing the existing lead inside the tunnel by diverting vehicle through the newly constructed Adit.
- Diverted heavy seepage of water through the newly constructed Adit and ensured a dry tunnel for (3650 m) construction of the second stage construction works.
- Imparting an overall support to the construction activities inside the tunnel to executing the works parallelly and reducing the construction period.

The innovative idea of introducing an additional Adit not only facilitated the smooth and quality construction but also saved the overall construction period of the Project to about minimum 20 months.

7.2 Project roads

The project is linked through 150 km long Jammu-Srinagar National highway up to Ramban, and thereafter through a 50 km long Ramban Gool State Highway. From the State highway, the Sumber and Kohli sites are connected through a very rough and earthen 25 km long hilly road. The Dharam site is further connected through a 15 km long rough, undulating hilly, and earthen project-approach road. The National Highway traffic is badly affected during the winters and the rains. Mostly, one way traffic is permitted over more than four months in a year. As a result, the transportation of construction materials, diesel, and other essential material supplies is heavily affected, further escalating the cost. Moreover, the project approach roads are very slide prone as the road remains blocked due to mass movement of hill slope debris most of the time.

As the approach road to the site is in hilly region, the maintenance is very difficult. Initially, we mobilised our equipments to this site via Reasi, as only

Figure 17. Photo: Condition of project approach road at different locations during rainfall.

one bally bridge was available to cross the Chenab River at Dharamkund and the same was not capable to take more than 15 tons of load. Later on, a steel girder bridge was constructed for 70R loading. Still,

we were able to mobilise the heavy equipment's to our site as per and requirement. This resulted in a loss of more than six-month work time. During the monsoon, the road would be washed away at several

places and also get blocked because of the landslides. The reason was the sinking tendency of various stretches which stand already detached from the mountain slope. Not only a considerable time was lost due to poor roads, but a few accidents also occurred during construction. We suffered a setback due to the break in the supply chain stopping the work for many months altogether. The same was restored by putting manifold all efforts, equipments, and manpower. Apart from the blockage, the gradient is very steep and the bends are very sharp. As a result, only six-wheel vehicles with a limited load can travel through.

During the rainy season, the life becomes very miserable and even survival becomes a challenge. It becomes clear from the above photographs that the workforce engaged at the project site is fighting with nature for survival.

7.3 Muck management

The major activity taken up during construction of the tunnel is disposal of excavated material or spoils. This material, if disposed off into nearby water bodies, insidiously increases water turbidity, thereby causing adverse effect on aquatic flora and fauna. For the success of any underground project, muck dumping yards are the key facility. Therefore, at every location, a separate dumping yard was required to accommodate the huge quantity of excavated tunnel muck. As this area is undulating and there is steep slope, a limited land for muck disposal is available. There are no approach roads either. Due to unavailability of the dumping area and the approach road at all location, adverse effect on the progress was recorded. Over the time, a land for the dumping yard was acquired near the Portal identified and the negotiations were initiated.

To acquire this land from the local inhabitants on lease, the clients and district administration were lia-soned. Stability was ensured at steeper locations by properly protecting the same in benches, providing base drainage and surface protection against erosion. The excavated material was also tested at reputed labs for reutilization as coarse and fine aggregates. The left-out material was used for developing the job facilities, playgrounds, and other project infrastructures.

7.4 Non-availability of power

Construction power was not available for execution of the job. DG sets of 5.5MW capacity were deployed at all three locations for power production. Possibility was explored for grid power in close coordination with the power department; and, as

a result, we got grid power at all locations. This way mitigated to get rid of the costliest captive DG power.

7.5 Nonavailability of area for Infrastructure

No space was available for infrastructure at the site. Benches were made on the hill with the help of dozer and the slopes were protected with the help of gabions and shotcrete. The foundations were made at different work fronts for installing batching plant, compressors, transformers, etc. Extra efforts were required for initial mobilization.

8 CONCLUSION

1. Most of the problems in the Himalayan tunneling can be attributed to the lack of knowledge of the geology ahead of the face. These problems have resulted in loss of time and costs overrun, which eventually deprives the country of the project benefits. It is essential that detailed exploration of the work must be carried out before the start. The exploration ahead of face should be undertaken on a continuous basis.
2. Selection of proper equipment's is significant for the speedy and successful completion of a Project.
3. NATM Technology is the best and safe in soft ground conditions and is recommended to be implemented widely at different Himalayan location for infrastructure projects.
4. Proper construction planning of each activity of this railway Tunnel paved way for faster construction.
5. Timely decision of introducing new Adit paved the way for faster construction and ensured better ventilation of the 5.1 km long twin tunnels.
6. Teamwork, proper co-ordination/co-operation, and dedication of our engineers have been the formulae to bring the project into proper shape and achieving this success.

ACKNOWLEDGEMENTS

The authors are thankful to Northern Railways and IRCON International for their support and cooperation during the execution of the works.

Construction of a new tunnel in proximity to an in-service tunnel by implementing measures to control blasting vibration and ground displacement

Yasunori Kobayashi*, Takaaki Ishii & Tadahiro Koma
West Nippon Expressway Co., Ltd, Osaka, Japan

Kiyoto Nakano
Nippon Expressway Research Institute Co., Ltd, Tokyo, Japan

Yusuke Kinomura
Obayashi Corporation, Tokyo, Japan

ABSTRACT: The Myojinsan Tunnel Phase II line of the Matsuyama Expressway is a two-lane road tunnel construction project with a length of 2,545 m and an excavated cross-sectional area of 75 m². By establishing a new parallel line to the expressway in service, it is expected to alleviate traffic congestion and serve as an alternative road in the event of a disaster. The service line is an important route for local life and economic activities, and it was essential to secure local lifelines, so it was necessary to minimize road closures and road restrictions associated with the construction. This tunnel has a varied and complex geology influenced by the Median Tectonic Line. The end portal side was a blasting excavation section mainly made up of hard andesite, while the start portal side was a mechanical excavation section mainly made up of unstable landslide deposits. Because of the proximity to the in-service tunnel, a major challenge was to control the impact of blasting vibration and ground displacement. In blasting vibration countermeasures, we established a blasting vibration monitoring system, and mitigated the impact on the in-service tunnel by adopting split blasting based on blasting vibration predictions. As countermeasures against the displacement of the unstable ground, we controlled the ground displacement and mitigated the impact on the in-service tunnel by installing landslide restraint piles from outside the tunnel, steel pipe forepiling and long face bolts from inside the tunnel, as well as by adopting top heading temporary invert with shotcrete. By implementing these various measures and taking safety into consideration, we have successfully completed the construction work.

Keywords: proximity construction, Phase II tunnel, in-service tunnel, blasting vibration predictions, Median Tectonic Line, landslide ground

1 INTRODUCTION

Construction work is conducted on an approx. 6.3km section between Iyo and Uchiko Ikazaki interchanges to expand the Matsuyama Expressway to a four-lane highway as illustrated in Figure 1. The excavation work of the Myojinsan tunnel began in May 2019.

The Myojinsan tunnel was 2,545m long, and the excavation area of the tunnel reached 75 m². The construction site is parallel to the Matsuyama Express way currently in service, thus passing through Myojinsan mountain with an altitude of 634m. The construction was difficult due to the

complicated geological structure with variations influenced by the Median Tectonic Line as well as the neighboring construction parallel to the in-service line. Under such a condition, excavation could have both dynamic and static impacts on the in-service line, so it was crucial to understand the behaviour during construction. On the other hand, the in-service line had to minimize road closures and road restrictions due to construction to ensure human flow and logistics. Hence, the inspection and monitoring of in-service line during construction of Phase II line was also limited in time and duration. This paper reports on the measures taken to reduce the

impact on the in-service line, management methods and the results of these measures, which were issues in the construction of Myojinsan tunnel as previously reported by Ishii et al. (2022, 2023).

2 CONSTRUCTION OVERVIEW

A summary of the construction work is given in Table 1.

Table 1. Construction Overview.

Construction Name	Matsuyama Expressway Myojinsan tunnel construction
Contractee	West Nippon Expressway Company Ltd. (Shikoku Branch)
Construction Period	Apr 6th 2018 - Jan 29th 2023 (1,760 days)
Overview	Construction extension: 4,073m Tunnel extension: 2,545m
	Major material: concrete: 22,300m ³
	Reinforcing steel: 134 t
	Rock bolt: 21,300 pieces Steel support: 1,470 units

3 OVERVIEW OF TOPOGRAPHY AND GEOLOGY

Figure 2 Is the geological longitudinal section. The geological structure of the tunnel can be divided into two major sections, that is, the blasting excavation section mainly made up of hard andesite and the mechanical excavation section mainly made up of unstable landslide deposits. The paper is going to cover the details in both sections.

3.1 Blasting excavation section

80% of the tunnel is made up of andesite thus extremely hard with an unconfined compressive strength of 100 MPa and a high elastic wave velocity of up to 5 km/s despite the existence of columnar joints as shown in Figure 3.

Figure 3. Face conditions of andesite.

The support patterns at the time of design were mainly the B or the C type with some D type. Blasting excavation was adopted as an efficient excavation method. Figure 4 shows the representative support pattern in the blasting excavation section.

Figure 2. Geological longitudinal section.

Figure 4. Support pattern in blasting excavation section.

3.2 Mechanical excavation section

As shown on the left side of Figure 2, the 250m section at the start portal side was affected by the Median Tectonic Line and consisted of landslide deposits as shown in Figure 5. The geological structure is Izumi Group shale dominant alternation with a low elastic wave velocity of 1.5 km/s, and the most unstable areas were soft enough to allow breaker excavation and were interbedded with a thin layer of clay. Mechanical excavation was adopted to minimize the impact on the landslides.

Figure 5. Face conditions of landslide deposits.

4 CONTROL OF BLASTING VIBRATION IMPACTS

4.1 Blasting vibration issues in hard rock ground

The distance between the Phase II line tunnel and the in-service line was as close as about 3D at the tunnel center distance relative to the tunnel excavation outer diameter D. The construction was carried out in an indirect influence area where loads, displacement, and deformation could affect the existing tunnel. Furthermore, the in-service line, which has been in service for about two decades since

construction, had cracks in some sections of the tunnel lining according to the prior management inspection records. There were sections that were in the preventive maintenance stage, a condition in which no functional problems had occurred, but it is desirable to take measures from the viewpoint of preventive maintenance. Therefore, it was necessary to study the impacts of blasting vibration on the lining of the in-service line.

Vibration velocity meters were installed before the excavation at two points, TD (Tunneling Distance) 350m and 650m, during the night closure of the in-service line, which was executed twice a year. The impacts on the in-service tunnel were then monitored on a steady basis. The allowable vibration velocity was set at 2-4 cm/sec for each soundness classification of the existing tunnel (East, Central and West Nippon Express Company Limited, 2020). To minimize the impact on the in-service line from the viewpoint of the unevenness of the ground and the safety of the in-service line, the control standard value was set to the $V=2.0\text{cm/sec}$, which is applied in the AA judgment, the most severe of all, "immediate repair is required".

4.2 Blasting vibration control

4.2.1 Monitor system for the in-service line

In general, the explosive amount increases in proportion to the unconfined compressive strength of the site, so blasting vibration also tends to increase accordingly. Especially in hard rock ground, the maximum amount of explosives per stage (hereafter referred to as "simultaneous explosive amount") was thought to be around 10 kg at which could result enormous blasting vibrations. Moreover, although the explosive amount for each blast is reviewed based on the actual result of the previous blast, an excessive amount might still be used for the improvement of the excavation cycle. Test blasting thus became necessary in the pursuit of the optimal explosive amount to minimize the blasting vibration.

The test blasting provided useful data for the calculation of the maximum simultaneous explosive amount that does not exceed the control standard value of blasting vibration and the minimum amount required for excavation. The tunnel consists of highly variable geology, which also plays a major role in the propagation of blasting vibrations. Hence, test blasting was carried out whenever the support pattern was changed or the degree of the weathering of the ground and fracture spacing were changed.

Since the purpose is to reduce the vibration at the in-service line, the blasting vibration V' was measured at the measuring point of surveillance walkway on the in-service line side, the same location as the blasting point, as shown in Figure 6. The value V'

was then converted to blasting vibration V_c at the control point. The above conversion from the measurement points to control points was based on equation (1). Measuring instruments were permanently installed on the in-service line side even during non-test blasting, and the vibrations were daily monitored.

$$V_c = V' \sqrt{(D_L/D_L')} \quad (1)$$

D_L : Distance between the blasting point and the measuring point (=36.0m)

D_L' : Distance between the blasting point and the control point (=27.0m)

Figure 6. Arrangement of vibration measuring point.

4.2.2 Reduction of simultaneous explosive amount

The results of the test blasting in the hard rock ground proved that the simultaneous explosive amount must be suppressed to meet the control standard value. A common countermeasure is the usage of detonators to provide a time delay between blastings, such as MSDS detonator, nonelectric delay detonator with fuse, and electronic detonator (Oshima et al., 2014), but split blasting using a sequential blasting machine is also an applicable option. Considering the construction conditions, the split blasting was adopted as the least expensive method that can suppress the vibration caused by blasting on the in-service line. As illustrated in Figure 7, the split blasting is a method of reducing the simultaneous explosive amount by dividing the tunnel face blasting into blocks.

Figure 7. Split blasting using sequential blasting machine.

4.3 Result of countermeasures

The K value was calculated from the blasting vibration obtained by the test blasting, and the maximum simultaneous explosive amount W_{max} at which the control standard value of $V = 2.0\text{cm/s}$ occurs was calculated using equation (2).

$$W_{max} = \sqrt[1/0.75]{V \times D_L^2 / K} \quad (2)$$

K: The value obtained in the test blasting

The assumption is that the blasting vibration can be suppressed to less than 2.0cm/sec if the simultaneous explosive amount is below W_{max} . Figure 8 shows the relationship among W_{max} (the maximum simultaneous explosive amount based on equation (2)), W (the actual simultaneous explosive amount when using split blasting), and W_c (the estimated simultaneous explosive amount based on equation (3) when conventional blasting is used).

$$W = W_c / n \therefore W_c = W \times n \quad (3)$$

n: number of divisions

No countermeasures were required at TD=100m and TD=1500m as the simultaneous explosive amount used at the site was small compared to W_{max} . In the other sections, the simultaneous explosive amount was reduced by using split blasting, which allowed blasting without the simultaneous explosive amount exceeding W_{max} . Figure 9 shows a comparison of the vibration velocity when using split blasting and conventional blasting. Although the allowable vibration velocity exceeded in most cases with the conventional blasting, the use of split blasting allowed excavation below the allowable vibration velocity. Figure 10 is an example of the results from the measuring instrument installed permanently in the lining of in-service line at TD = 650m. It clearly indicates that the blasting vibration did not exceed the set allowable vibration velocity of 2.0cm/sec. Thus, by calculating the K value from the test blasting and controlling the simultaneous explosive amount by split blasting, the blasting vibration could be suppressed to the allowable vibration velocity of 2.0cm/sec.

Figure 8. Comparison of simultaneous explosive amount.

Figure 9. Comparison of vibration velocity.

Figure 10. Vibration velocity on the in-service line.

5 DISPLACEMENT CONTROL OF LANDSLIDE DEPOSITS

5.1 Challenges in Phase II line construction

In the mechanical excavation section, there was a landslide ground affected by the Median Tectonic Line. The landslide is characterized by seven landslide blocks divided into A to E, which are in a folded position, blocks E and F are the largest landslides with 120 m long and 100m wide in the main line direction. Figure 11 shows an overview of the landslide ground. Therefore, landslide countermeasures were studied during the construction of the in-service line, and countermeasure works were carried out from the inside of the tunnel as well as from the surface directly above the tunnel. From the surface, construction was carried out using vertical pre-reinforcements and restraint piles.

The landslide control works are shown in Figure 12, where landslide control work shown in red was conducted during the Phase II line, and other colours were conducted during the in-service line. Countermeasures were also carried out from inside the tunnel by different kinds of auxiliary methods such as pipe forepiling. On the other hand, it was recorded that during the construction of the in-service line landslide sliding was observed on the surface area, and a maximum of 250mm of both

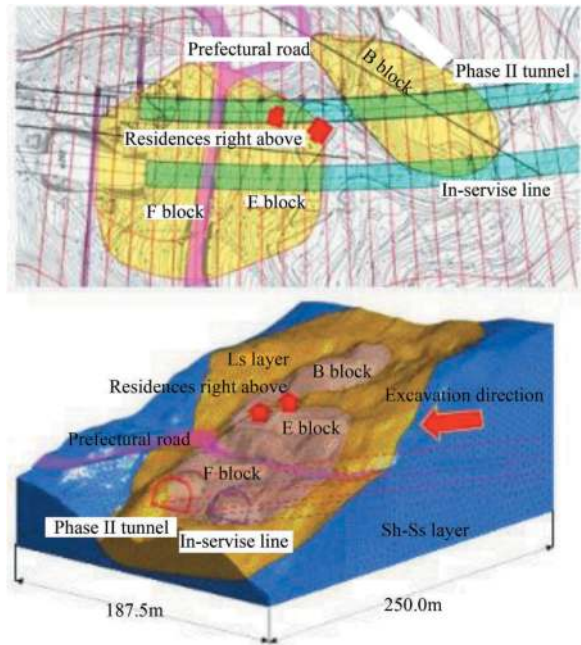

Figure 11. Overview of landslide ground.

crowns settlement and convergence occurred during excavation of the in-service tunnel, and both crown settlement and convergence generally remained above 100mm in other sections. Furthermore, since the excavation of the in-service tunnel had some impact on the ground surface, we have continued to monitor the landslide even after the construction of the in-service line was completed and the landslide was confirmed to be under control. In the construction of the Phase II line, it was necessary to prevent the landslide from sliding and to control the impact on the ground surface and the in-service line because there were two residences and a prefectural road in the affected area.

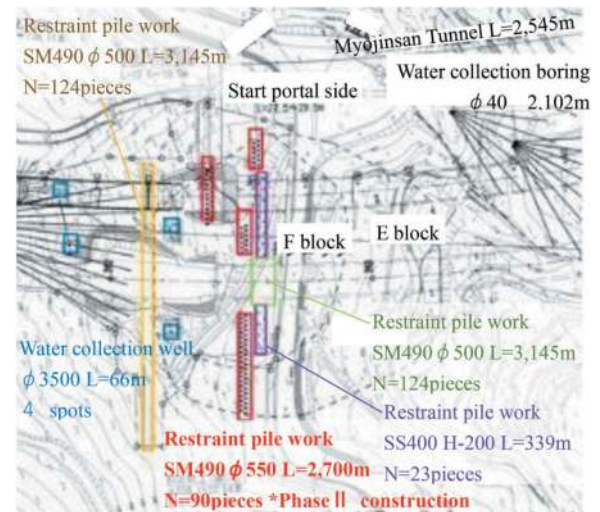

Figure 12. Overview of landslide control works.

5.2 Landslide prevention work and measurement work

Prior to the construction of the Phase II line, a landslide study committee organised by academics and others was held to discuss the countermeasure works. As a result, a plan was recommended to complete the landslide restraint piles before the tunnel face reached blocks E and F, where there was concern about the impact of tunnel excavation.

It was therefore decided to take measures to drive a total of 90 steel pipe piles with a length of 30m and a diameter of 550mm for the restraint piles around the start portal side of the Phase II line as shown in Figure 12. To monitor the surface displacement due to landslide sliding and tunnel excavation, several measurement items have been set up as shown in Table 2, including TS (total station) automatic 3D measurement. A large monitor was installed in the site office for real-time monitoring of various measurement results and early detection of abnormalities. An environment that facilitates the prompt identification of signs of abnormality has been created by using a system, which clearly indicates measurement graphs and always updates them automatically. In the system, numerical data were displayed in different colours and visualized so that abnormal values could be recognised immediately.

Table 2. Measurement Items.

	Measurement Item	No. of measured cross-sections /points
In-service tunnel measurement	Lining concrete stress	9
	Convergence/Crown settlement	9
	Temperature in the tunnel	9
	Vibration velocity	2
	Crack displacement	4
	Radial displacement of surrounding ground	3
Measurement B	Shotcrete stress	3
	Steel supports stress	3
	Prior crown settlement ahead of face	27
	3D ground surface settlement	111
Other measurements	Residence inclination	10

5.3 Displacement control measures in tunnel

Early closure of this section was planned by the full-face method with auxiliary bench cut in mechanical excavation. The early closure is highly effective in reducing displacement as the section is closed in the immediate vicinity of the face and has a good track record (Sato et al., 2015, Awaji et al., 2016, Toyama

et al., 2018). However, the in-service line construction records showed that face collapse and sudden water inflow had occurred during the excavation, and it was considered that the in-service line and landslides might be affected due to the tunnel excavation. Therefore, it was considered difficult to cope with rapid changes in the face conditions in the case of large division of heading, where the bench is excavated just below the top heading face.

As a result, long bench cut method excavation was brought into the plan since it can respond flexibly to various ground conditions based on the behaviour of the ground during the top heading excavation. However, as the long bench cut method has a longer closure distance and a smaller displacement control effect compared to early closure, temporary closure with top heading temporary invert in the immediate vicinity of the face was also adopted in combination. Hence, a temporary closure immediately after the top heading excavation, as in the excavation procedure shown in Figure 13, was considered to both cope with sudden changes in ground conditions and to control displacement.

Auxiliary methods were also studied as countermeasures to stabilise the face and to control surface settlement. Six patterns of auxiliary methods, including the initial design, were studied as well as the economics of these method. As a result, it was decided to adopt the L=12.5m, 180° steel pipe forepiling and long face bolt shown in Figure 14 as the most rational auxiliary method, taking into account the impact on the in-service line.

Figure 13. Excavation procedure.

5.4 Revising the management standard values

A pre-measurement period of approximately 20 months without the influence of Phase II line excavation was used to study the influence of temperature and other factors on the measurement of the in-service line. The measurement results are shown in Figure 15. The stress increment in the lining showed a correlation with temperature, with seasonal fluctuations increasing and exceeding the control standard

Figure 14. Support pattern in mechanical excavation.

value even during the periods when there was no effect of excavation. In particular, the lining stress varied widely from a minimum of -1.5 to a maximum of 1.1N/mm^2 depending on the season. In addition, two-dimensional FEM analysis during design assumed that the stresses at the inner edge of the in-service line lining were on the tensile side, but the measurement results during the actual construction indicated a compressive tendency and different deformation modes. The control standard values for the displacement measurement of the Phase II line at the planning stage were determined from the stability of the ground around the Phase II line, that is, the critical strain of the ground, and were managed independently of the in-service line, as there was no relationship with the in-service line. Therefore, based on the actual measurement results, the following procedure was adopted to eliminate external factors such as seasonal fluctuations and to revise the control values for the lining stress increment of the in-service line and the displacement measurement of the Phase II line, which have a mutual relationship.

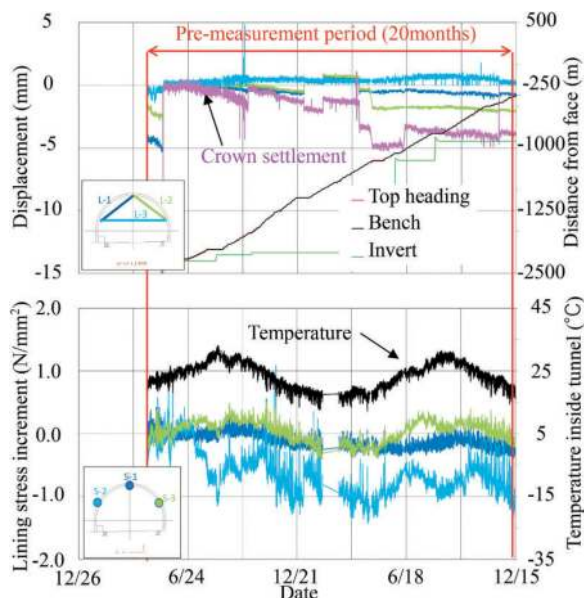

Figure 15. Measurements during pre-measurement period.

From the pre-measurement results, seasonal fluctuations were eliminated as far as possible and the amount of change due to the effect of excavation was extracted. In other words, the position where the excavation of the Phase II line starts to affect the in-service line was set at 30m (about twice the tunnel diameter) before the measurement position, the lining stress at this time was set as the initial value, and the control standard value for the lining stress increment on the in-service line was re-established. To find a relationship between the in-service line and the Phase II line, a control standard values were set with the feedback from the measurement results. First, to understand the relationship between the displacement measurement results of the Phase II line and the lining stress increment of the in-service line, we focused on the changes in both as the face progresses, as shown in Figure 16. Figure 17 shows a scatter diagram with the convergence, crown settlement and foot settlement on the horizontal axis and the lining stress increment at the in-service line on the vertical axis. A linear correlation with some variations can be observed. The displacement at which the lining stress increment at the in-service line reaches the control standard value (compressive stress, -5.40N/mm^2 as specified by East, Central and West Nippon Express Company Limited (2020)), was then determined from the linear approximation and re-established as the control standard value for the displacement measurement.

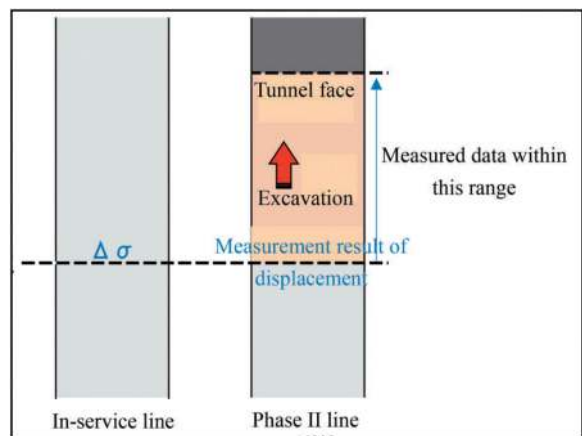

Figure 16. Lining stress increment and displacement.

5.5 Results of countermeasure works

Figure 18 indicates the results of displacement measurements of the Phase II line. Overall, the crown settlement tended to be greater than the convergence. Particularly, the final settlement of 67mm was relatively large at the right shoulder of the tunnel. However, the displacements tend to converge around 20 days after the bench excavation and invert shotcrete. The displacement converges after about 2D (twice the tunnel diameter), which is similar to the trend of

Figure 17. Phase II displacement and lining stress.

convergence in the in-service line shown in Figure 19. It means if the displacement on the Phase II line side can be suppressed and converged earlier, the impact on the in-service line side will also be reduced.

At TD = 2,370m, the final settlement reached 129mm, the largest amount for the entire tunnel line, which exceeded the control standard value Level III. In this section, as the ground conditions gradually deteriorated, the convergence was small, but there was a tendency towards increased foot settlement and a higher displacement rate during the top heading excavation. Considering that a large displacement of 250 mm had occurred in this section during the construction of the in-service line, additional horizontal rock bolts were urgently installed to control the settlement. On the other hand, as shown in Figure 19, the measured values of the in-service line indicated only small changes with respect to the control standard value confirming that the impact was small. No new deformations were found in the crack displacement gauges of the lining installed in the same section, and the same was true in the visual inspections.

Figure 18. Displacement of Phase II line.

Figure 19. Convergence of in-service line.

6 CONCLUSIONS

In the blasting excavation section, the impact on the in-service line was significantly reduced by determining the K value through test blasting, setting the maximum simultaneous explosive amount, and adopting the split blasting with a sequential blasting machine. Generally, the calculation of K value is often based on the results of one or a few times of test blasting. However, as this tunnel is a case of blasting in close proximity to the in-service line, it was considered important to capture the impacts of blasting vibrations for each change in ground conditions, and the maximum simultaneous explosive amount was determined with a high degree of accuracy.

Also, preliminary studies have been conducted in the mechanical excavation section right from the beginning, considering the geological risks in the landslide ground. Although the construction was in close proximity to the in-service tunnel, there was a wealth of geotechnical information available, such as previous construction records, compared to newly constructed tunnels. This information could be used comprehensively and reflected in the safety of the Phase II line construction. The results of the various measurements could be fed back to the construction quickly and appropriately. In recent years, with technological innovations in auxiliary methods, early closure, which can reduce the closure time as much as possible, has become mainstream where displacement control and the influence on surrounding ground are concerned. However, in the case of landslide weak ground, it is crucial to be able to respond quickly to the risk of face collapse as the ground changes, and the excavation method adopted in this project has demonstrated its superiority.

Besides, although it is commonly recognized that the top heading temporary closures is effective in controlling displacement, there have been many reported cases of sudden displacement occurring when the temporary closure is removed in landslide ground similar to this tunnel, and this concern was also raised at the study stage. For this reason, the frequency and point of displacement measurements were increased, and second opinions from geological experts were used to determine the class of ground.

On the other hand, although the maximum displacements that occurred during the removal of temporary closure were 50 mm of settlement and 30mm of convergence, the displacements converged after the primary invert was completed.

The tunnel was constructed safely and reasonably by using a management method based on the initial values set and the actual measurement result. As similar issues in close proximity construction are expected to increase in the future, it would be great if the newly studied methods in this paper could be taken as a reference. Still, depending on the condition of the ground and the lining of the in-service line, further measuring instruments could be added, but if the number of items to be managed increases, it may instead become more difficult to assess the condition of the ground and the lining. A comprehensive study of the reliability and reasonability of the measurements needs to be carried out.

ABSTRACT: lots of soft & hard ground tunnels, including metro tunnels, railways tunnels and road tunnels, have been constructed in many cities in an India. Nearly all tunnels have cross passages between two tubes. In soft ground area, cross passages could be built in many kinds of methods, such as, cut-and-cover, mining methods and combined method and in hard rock will be excavated with traditional mining techniques including use of excavators, rock hammers and splitters, drilling & blasting, drilling & chiseling and stitch coring with rock splitter, shot creating and rock bolting. Cross passage tunnel in Metro Line-3 of Mumbai is a sequentially excavated (SEM) by core cutting with help of rock splitter, more than 10m long tunnel in volcanic breccia rock with 15m² excavation area which accommodates 6.35m O.D of pre cast segment lining. Twin tube TBM tunnels. Continue excavation process with using advanced methodology and equipment rather than the normal excavation methodology by pneumatic hand breaker. The methodology has be followed for construction of cross passages in MML-03 UGC07.

1 INTRODUCTION

Mumbai Metro Line – 3 (Aqua Line), also known as Colaba–Bandra–SEEPZ line, is a part of the metro system presently under construction in Mumbai, India. Mumbai is the financial capital of India and Mumbai Metropolitan Region Limited (MMRL) is one of the fastest growing metropolitan regions in India. The major challenge in the region today is to provide connectivity and drive growth by providing adequate inputs in infrastructure that will improve the quality of life of the residents. The Metro model has been recognized as an efficient, economically viable and environment-friendly mass transport system to improve the overall traffic and transportation scenario in Mumbai. Currently Mumbai Metro Line 3 (CBS 33.5 km: Colaba - Bandra - SEEPZ) is being implemented by MMRC (Mumbai Metro Rail

Corporation). When completed, the 33.5-km fully underground corridor will be the first underground metro line in Mumbai and will cater to 1.75 million passengers daily with a frequency of 3-4 minutes, ferrying more than 2500 passengers at a time. Line-3 is expected to reduce road congestion and have a significant sustainable environmental impact on CO² emissions and fuel consumption as well as. Underground Stations at Marol Naka, MIDC, SEEPZ and associated tunnels on CBS (Contract No. UGC 07 awarded to L&T & STEC JV) by MMRC. L&T & STEC JV has appointed AMBERG-STUP JV as Consultants for the design of the project.

Main tunnels consist of twin tube configuration of 5.8 meters internal diameter each, excavated using an Earth Pressure Balance (EPB) Machine of 6.66 meters boring diameter. A total of 42 Tunnel Boring

Machine (TBM) breakthroughs by 17 TBM machine in entire length.

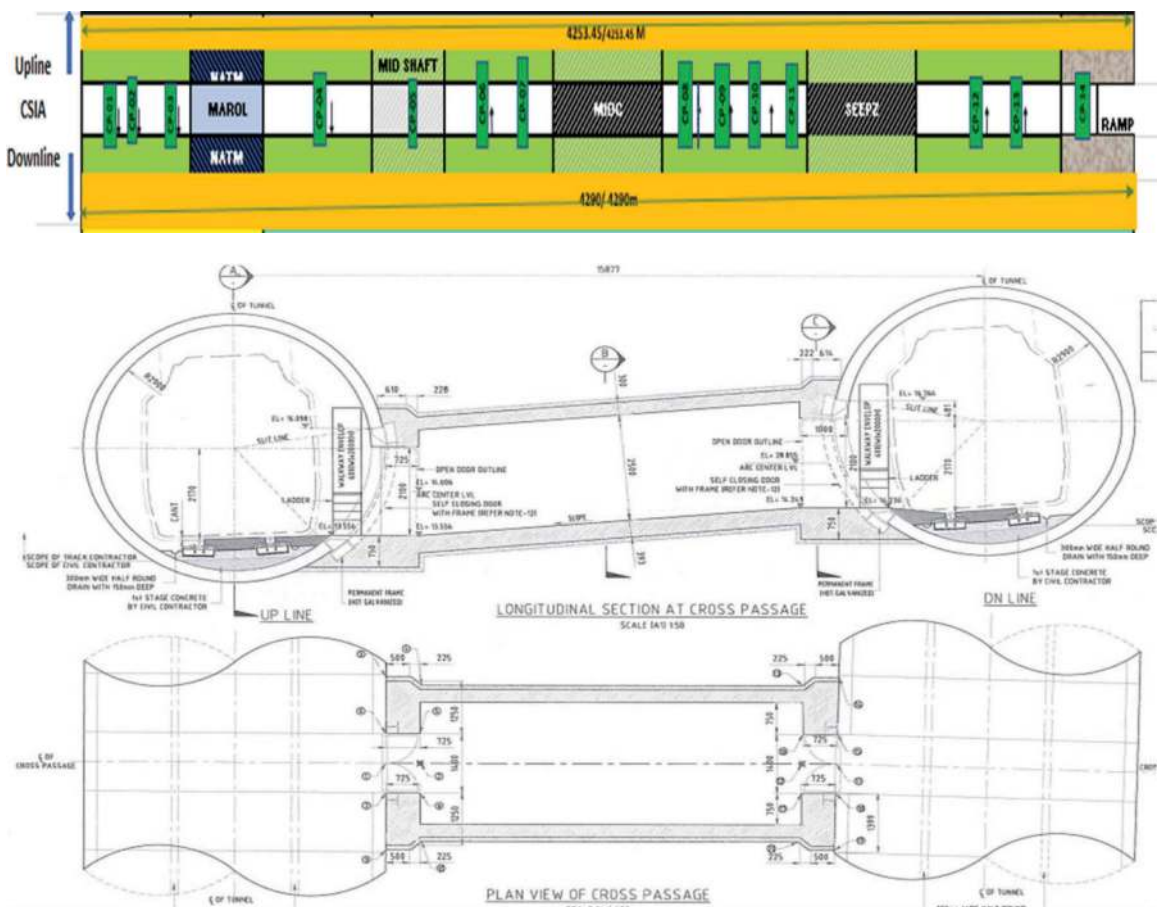

2 PURPOSE

Cross passage are designed to allow final evacuation from train cab to track bed. The exit from the tunnel is through the track bed between the two rails of the track, from where passengers must enter a protected cross-passage (complying with the provisions of NFPA 130:2010) which shall be located one at each point station the end of the platform where the emergency exit staircase is located or 244 m (maximum distance) from the portal access point. Access is available from the tunnel to street level and to the exit station through a tunnel portal. In long tunnel sections (tunnels between two consecutive stations) where there is a mid-ventilation shaft, to ensure the presence of only one train in the ventilation section, an emergency stairway leading to road level is to be provided within the shaft and located within 2 hours of a protected cross way. The cross-passages of the tunnel will be protected with jet fans to prevent the entry of smoke when the doors are opened.

3 ALIGNMENT AND LAYOUT PLAN OF TBM AND CROSS PASSAGE TUNNEL

Cross passage in between TBM tunnel from CSIA to RAMP at UGC07 under Mumbai Metro Line – 3 (Aqua Line).

Layout plan of cross passage

4 COSTRUCTION METHODS OF CROSS PASSAGE IN METRO TUNNEL

The construction of cross passage is most important to participate in metro construction. If any process encounters improper operation, the overall construction safety of the cross passage will be affected, resulting in the tunnel body being the main risk.

4.1 Temporary bracing support system to carry out the work of cross passages

Bracing systems generally consist of ring girders (and cross beams /tie beams which are connected by means of bolted and welded connections. To reduce the deformation of the lining due to cross passage openings, a third ring beam is included with the cross beam. The design assumed that the steel ring beam was placed in close contact with the tunnel segmental lining. Therefore, it is important that the gap between the lining and the steel support is filled Suitable material to avoid excessive deformation. The analysis is performed using the structural analysis program STAAD Pro V8i. The structure is modeled as a 3D space structure frame. Steel rings are installed in the springs depending on the modulus of elasticity of the soil

4.2 Ground behavior

The ground behavior is evaluated for the full cross sectional area without considering any modifications including the excavation method or sequence and support or other auxiliary measures.

Influencing factors are considered for the evaluation of the Ground Behavior:

3D schematic View of Temporary Bracing

Door opening

Bending Moment Envelope - ULS

Shear Force Envelope - ULS

- o Ground Type (GT)
- o Virgin stress conditions
- o Shape and size of the underground structure (final shape and size)
- o Position of underground structure in relation to surface or existing structures
- o Boundaries between different ground types
- o Ground water, seepage force, hydraulic head

The support design need to cater to take care of the predicted ground behavior. To initiate the design, an empirical approach is used to understand support requirement to stabilize the cavity. Support derived from empirical method is used as input for numerical modelling.

The maximum unsupported span of 2.5m for rock class III is on higher side as compared to the size of cross passage, so maximum unsupported span is limited to 1.5m for rock class III. The minimum length, L of rock bolts has been estimated from the excavation width B and the Excavation Support Ratio ESR as per Barton et al (1980):

$$L = 2 + (0.15 \times B) / \text{ESR}$$

From the above formula, minimum length, L of rock bolts has been determined to be 2.5 m for cross passages. The above length of rock bolts may be optimized based on numerical modelling and radius of plastic zone at around the tunnel. Shotcrete with steel fibers is also recommended to prevent spalling. Initial layer of shotcrete is to be provided on a necessary manner before spalling is occurred. Based on Grimstad and Barton (1993)'s chart provided in figure below, primary support system can be derived on an initial basis as given below.

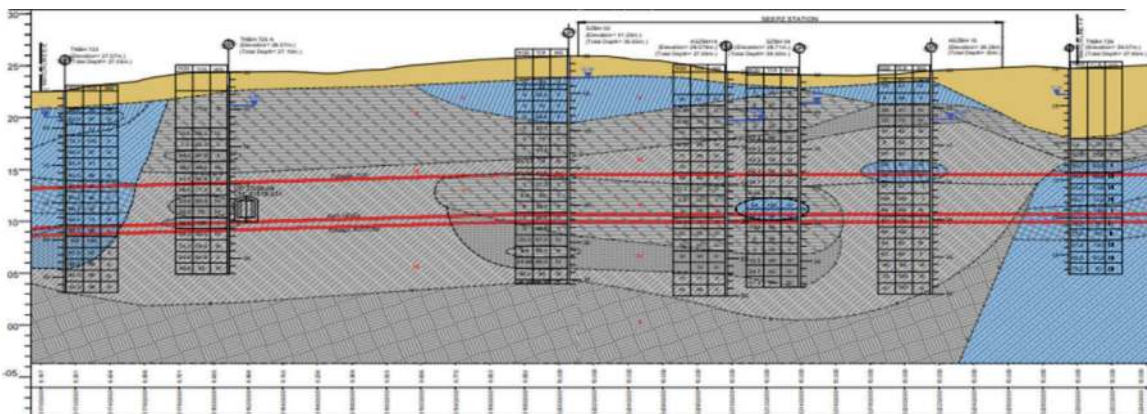

Excavation of Cross Passage, application of internal pressure and application of disturbed rock mass around excavation periphery.

5 EXCAVATION METHODS OF CROSS PASSAGE IN METRO TUNNEL

Excavation of cross passage will start from the completed tunnel. The concept of excavation in rock or soft ground will be based on partial excavation, which is divided into two stages, heading and bench/inverted excavation. excavation by heading and benching method will be safer and better in terms of performance.

5.1 Above spring level Excavation by Core cutting machine (5 Kw) and Hydraulic Rock splitters (4 Kw)

Excavation will be done in two parts as heading & benching and it shall be followed only higher grade of rock which RMR value has 75 to 100 Mpa. Above the spring level (SPL) it means semicircular portion is known as heading and remaining lower portion is benching below the SPL. Heading portion will be limited to arch portion only, cannot be extended below to arch portion in any case. This

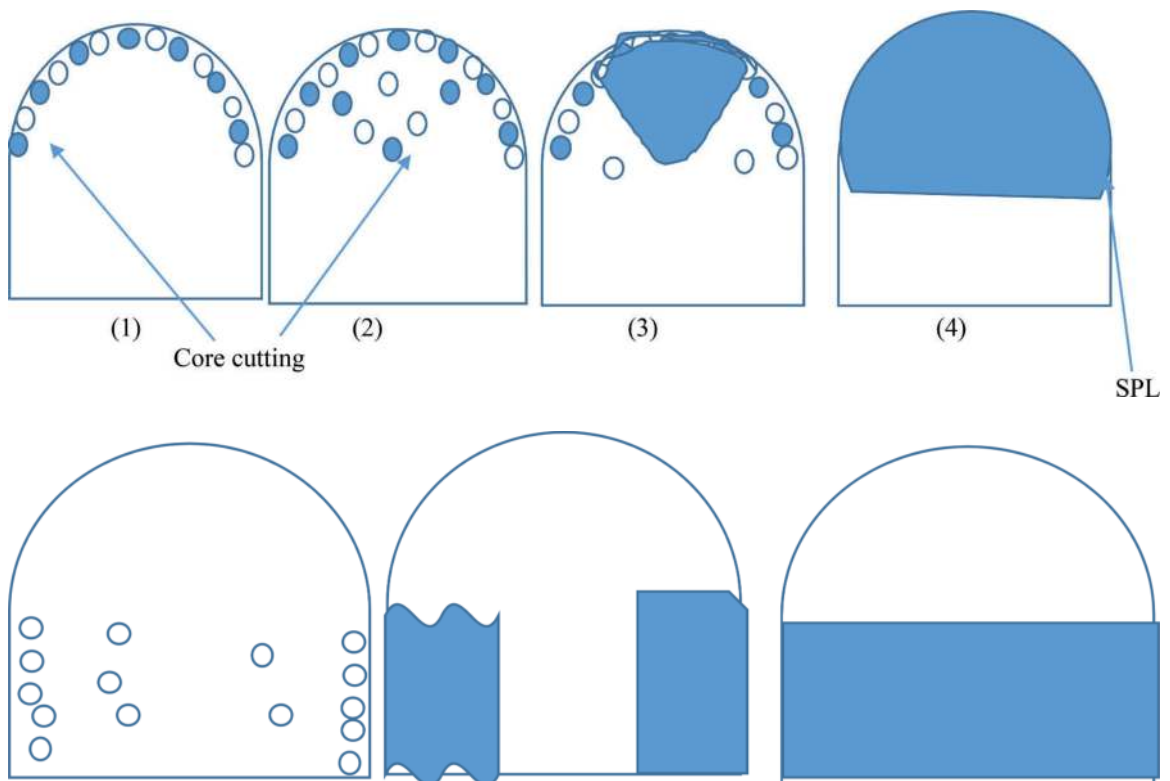

heading portion shall be excavated by peripheral coring, rock splitting, handheld breakers and excavator mounted breakers only. Length of each cycle of excavation along the axis of the cross passage shall be limited to less than 1.0 meter. Once the excavation completed for full 1.0m length final dressing & trimming to the required profile shall be done manually.

Then arch stabilization shall be done by fixing wire mesh and applying dry shotcrete i.e., primary lining as per approved designs, drawings and geological report of RESS (Required excavation supporting system).

After drilling 100 mm-200 mm diameter, 800 to 1000 mm long core holes as shown in figure (2) and (3) above, rock splitters are placed inside such holes to split or break the rock. Will go Once the rock splitting/breaking is done, the rock pieces will be further broken by excavator breaker or pneumatic hand breaker, To ensure that pieces of dirt can be picked up manually.

After achieving two rounds of heading excavation, benching excavation will be done either by excavator installed rock breaker or core cutting machine depending on the quality of the rock. Before going for further benching works, ensure that all necessary rock supports are provided as per the drawing and recommendation of the geologist. To produce less impact throughout the rock profile, the benching would be divided into sections by drilling some holes vertically. The complete sequence is detailed as shown below.

6 CONCLUSIONS

The construction activities of cross passage should be taken up to start construction of permanent structural works in TBM shaft at the earliest. TBM separated from shaft. Therefore, a circular vertical shaft was established between the two main tunnels from the ground surface level and then horizontal cross passages were made under the shafts to connect both the tunnels so that Cross passage are designed to allow final evacuation from train cab to track bed.

Professional work of all parties involved and cooperation based on trust and mutual appreciation are key factors in the success of the project.

Test and research on load spectrum of tunnel drill jumbo

Xin Liu*

China Railway Construction Heavy Industry Corporation Limited, Changsha, China

ABSTRACT: The drill jumbo is an excavation equipment widely used in tunnel drilling and blasting works. To better ensure the reliability of the whole life cycle of the equipment, establishing a scientific and reasonable fatigue strength theory and safety assessment system is the key to the stable operation of the equipment. Combined with the construction experience of drilling and blasting method, this paper collects the load spectrum of reliability test for a certain type of drill jumbo, studies the load collection method and load spectrum compiling method, develops the load spectrum database, introduces the load spectrum acquisition method integrating various parameters such as stress, torque and rotation speed, and forms a complete process of load spectrum data pre-processing, editing and compiling by using measured data, so as to provide accurate and simplified data for the study of load spectrum of drill jumbo. It also provides important technical support for the fatigue damage analysis and life prediction of equipment components under pavement random load spectrum based on fatigue damage theory, as well as the fatigue durability research of drive system.

Keywords: drill jumbo, drive system, load spectrum, fatigue life analysis

1 INTRODUCTION

During construction, the drill jumbo will bear random loads caused by road roughness. Such random loads usually cause cumulative fatigue damage to components of the drive system of the drill jumbo. To ensure that the trolley drive system components do not suffer fatigue damage during their service life, it is necessary to carry out fatigue strength analysis on the trolley drive system components. Many scholars have studied the load spectrum of equipment in different fields, but there is relatively little research on the load spectrum of drive system under complex working conditions of drill jumbo. The main research focuses on the theoretical strength analysis and fatigue life of work boom. Song Yingpeng^[1] simulated the fatigue life of the boom of drill jumbo under extreme working conditions, and calculated the fatigue life to provide a reference for the boom design of similar equipment.;^[2] Wu Nan carried out modal and fatigue analysis on the feed beam of drill jumbo based on SolidWorks Simulation Module, obtained relevant natural frequency and service life data, and proposed improvement measures.;^[3] Wang Yansheng studied the relationship between average stress and fatigue limit of telescopic boom material of drill

jumbo during tension-tension or tension-compression fatigue test, and estimated the stress fatigue life formula of telescopic boom material under different conditions of frequency according to equivalent theoretical fatigue limit and stress fatigue life.

2 STRUCTURE ANALYSIS OF DRIVE SYSTEM

The drive system structure of a drill jumbo is shown in Figure 1. In the actual operation of the drill jumbo drive system, the drive shaft inputs power to the front rigid drive axle and the rear steering drive axle to drive the wheels to realize the traveling of the drill jumbo. The axle not only bears the weight of the whole vehicle, but also needs to withstand the impact caused by uneven road surface during driving. It is functionally both a bearing part and a force drive part. It is the most critical and complex drive component in the drive system. Its frequent cumulative fatigue damage caused by alternating loads will cause fatigue failure of the axle housing. Therefore, the drive system is the most ideal test object for road load spectrum collection and also the key to fatigue reliability research of the drive system.

Figure 1. Structure diagram of drive system of a certain type of drill jumbo.

3 AXLE SIMULATION ANALYSIS

3.1 Load simulation analysis

The finite element analysis software Abaqus should be used to simulate and analyze the drive axle housing. According to the running characteristics of this type of trolley and the axle load, the stress condition of the axle housing can be simplified into the following three load conditions: tangential force F_x when the trolley runs and brakes, lateral force F_y when the trolley travels on the side slope, and vertical force F_z of vehicle weight when the trolley travels. The axle housing is loaded and analyzed under the one-way load condition in Table 1. For example, as shown in Figure 2, the tangential force F_x loading is the same, but the lateral force F_y is limited by the test of axle housing structure form. It is considered to decompose it equivalently into lateral tensile pressure along the axle housing axis and bending moment along the upper and lower surfaces of the axle housing for load analysis. The load response sensitivity analysis is shown in Figure 3. According to the stress results of measuring points in Table 2, the selected area has obvious stress and strain responses, the change gradient is less than 10%, and the stress does not exceed the yield limit, which is an ideal test area. Accordingly, the positions of measuring points for real vehicle load test will be determined. At the same time, according to the load magnitude, it can be seen that the maximum contribution load is vertical force F_z . Based on the basic factor of vertical force F_z , the composite load contribution analysis of lateral force F_y and vertical force F_z under the working conditions in Table 3 is carried out. According to the stress results of measuring points in Table 3, the composite load of tangential force F_x and vertical force F_z has a great impact on the axle housing, with a load contribution rate of 31.7%; the lateral bending moment F_{my} decomposed by the lateral force F_y has a great impact on the axle housing, and the load contribution rate is 74.9%; the contribution rate of lateral tension F_{yl} decomposed by lateral force F_y to the axle housing is 3.7%, which has little influence and can therefore be ignored. It can be seen from the

comprehensive analysis that when the trolley is running on a side slope, the lateral bending moment F_{my} and vertical force F_z decomposed by the lateral force F_y are both acting on the upper and lower surfaces of the axle housing. The load test is carried out on the real vehicle against the vertical force F_z , and the tangential force F_x and lateral force F_y are characterized compoundly by the tested vertical force F_z .

Figure 2. Schematic diagram for application of vertical load (F_z).

Table 1. One-way load condition of axle housing.

	Load condition	Applied load/N
Condition 1	Tangential force F_x	12.8×10^4
Condition 2	Lateral force F_y	12.1×10^4
Condition 3	Vertical force F_z	40.2×10^4

4 AXLE ROAD LOAD SPECTRUM DATA ACQUISITION

4.1 Setting of load test conditions

The working conditions of the trolley in actual operation will be random, which are mainly reflected in the construction site, road conditions and driver's driving habits. It is necessary to determine a certain representative industrial test site. After investigation and analysis of typical operation conditions on the construction site, a mountainous tunnel construction site will be selected. Combined with jumbo operation conditions and on-site road conditions, the test conditions will be determined as shown in Figure 5 below, and the reference mileage and driving speed of the test section are shown in Table 5.

4.2 Acquisition of load spectrum

The expression form of load spectrum involves many parameters, mainly including force, moment, acceleration, displacement, torque, strain, velocity, etc. According to the load spectrum test requirements of the drill jumbo, strain gauges are used to collect the strain of key parts of the axle housing, torque strain gauges are used to collect the strain of the drive shaft, and wireless speed sensors are used to collect the rotation speed of the drive shaft.

Sensor pasting is shown in Figure 6. The above various sensor signals are connected to a multi-channel data acquisition instrument, and all channels should be synchronized by the acquisition software

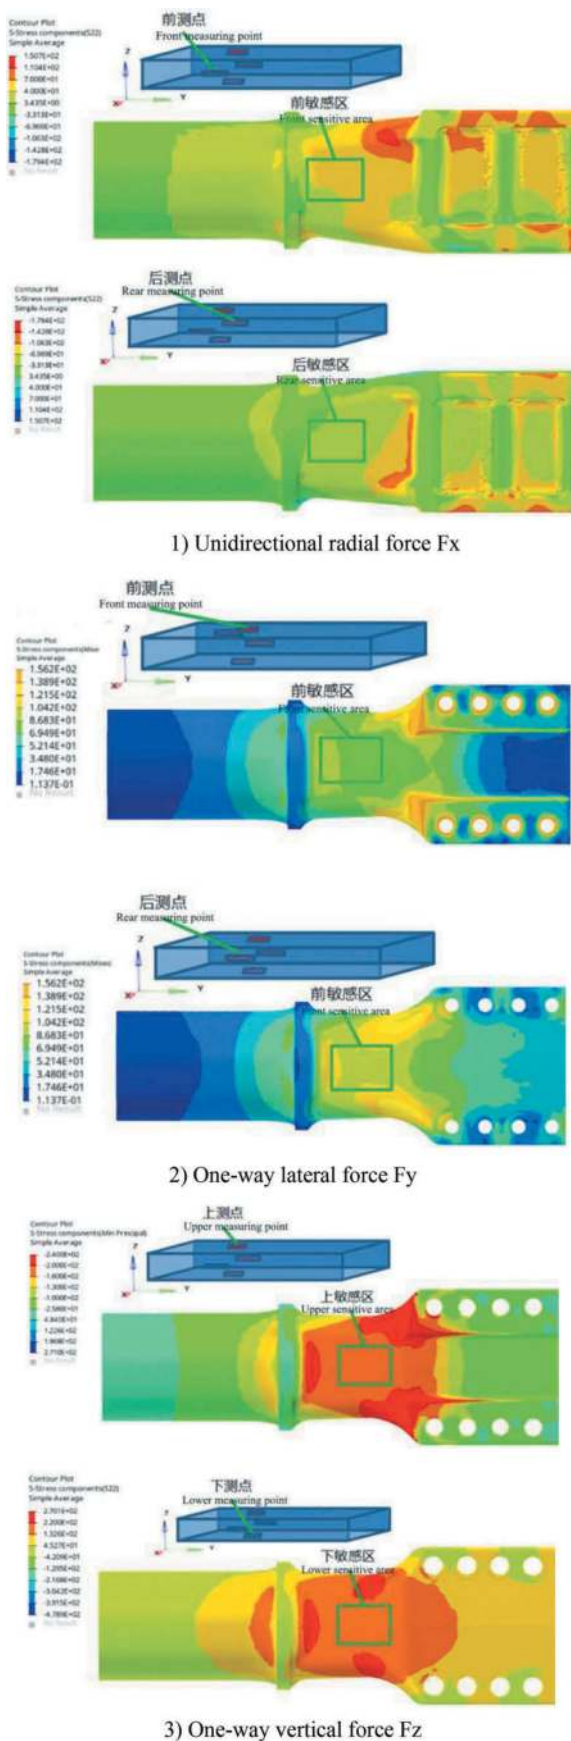

Figure 3. Simulation nephogram of axle housing load sensitive area.

according to time domain to collect various data at the same time. The acquisition scheme and device and equipment are shown in Figure 7.

4.3 Load calibration

The axle housing load calibration is to paste strain gauges on the tested parts, assemble bridges, output voltage signals, use a calibration loading table as shown in Figure 8 to load the axle housing, apply vertical force F_z from small to large to the axle housing, measure the corresponding output strain value of the strain gauges, and obtain the values of test strain and external load. The static torsion test bench is used to obtain the values of torque and strain for the drive shaft. The load test scheme and equipment are shown in Figure 7. The acquisition device is a dynamic signal testing, analysis and acquisition instrument. The axle housing can send the half-bridge circuit output signals of single direct strain gauge set, and the drive shaft can send the full-bridge circuit output signals of torque gauge set. The calibration results are shown in Table 6. It can be seen from the data results that the calibration test has good linearity, and the correlation coefficients after calibration data fitting are all above 0.95, indicating high calibration fit accuracy. The results are accurate and reliable, meeting the requirements.

5 PREPROCESSING OF LOAD SPECTRUM DATA

The original load-time history of jumbo test has certain randomness, which is difficult to be directly applied in engineering. It is usually necessary to remove singular values, trend terms, filter and denoise the original data, then compile the required load spectrum according to the actual conditions, and at the same time, it can also carry out frequency spectrum analysis on the data to study the regularity of the load spectrum.

5.1 Zero drift processing

Usually, due to device heating, strain gauge pasting deviation, structural residual stress and other reasons, the initial output signal of the dynamic acquisition instrument has a "drift phenomenon" that is not zero. The piecewise linear zero drift hypothesis can be used for signal processing. The measured signal is processed in M sections to obtain the mean value of each section of signal $S_1 \sim S_5$, and the zero drift in each section is $A \sim E$. The average solution point values are $A(0,0)B(M, (S_1+S_2)/2)$, $C(2M, (S_2+S_3)/2)$, $D(3M, (S_3+S_4)/2)$, $E(4M, (S_4+S_5)/2)$ and $F(5M, S_6+(S_6-S_5)/2)$. The zero drift value of each segment is subtracted point by point from the measured signal amplitude to obtain the load signal after eliminating

Table 2. Simulation analysis results of one-way load sensitive area of axle housing.

	Measuring point	Micro strain	Stress/MPa	Maximum stress	Stress difference
Condition 1	Front measuring point	324.2	68.1MPa	179.4MPa	12.9MPa

5.2 Removal of trend items

Trend items often cause the test signal to deviate from the baseline. When there is an obvious trend item in the signal that has not been eliminated, distortion will occur during correlation analysis and power spectral density analysis. The trend item is fitted by least square method, and then the trend item will be removed by subtracting the trend item from the original data.

Figure 9. Segmented zero drift processing method.

The load data obtained from the test is $\{x_k\} (k = 1, 2, 3 \dots, n)$, and the test data fitting is carried out by an m -order polynomial, then:

$$\hat{x}_k = a_0 + a_1k + a_2k^2 + \dots + a_mk^m = \sum_{j=0}^m a_jk^j \quad (1)$$

$$k = 1, 2, 3, \dots, n$$

Based on the principle of least squares, the coefficients to be determined for each order of the function are confirmed so that the sum of squares of errors between the function and discrete data is minimized, namely: $\hat{x}_k k = 1, 2, 3, \dots, n \hat{x}_k x_k$

$$E(a) = \sum_{k=1}^n (\hat{x}_k - x_k)^2 = \sum_{k=1}^n \left[\sum_{j=0}^m a_jk^j - x_k \right]^2 \quad (2)$$

$E(a)$ The conditions for the existence of extreme values are:

$$\frac{\partial E}{\partial a_1} = 2 \sum_{k=1}^n k^i \left(\sum_{j=0}^m a_jk^j - x_k \right), k = 1, 2, 3, \dots, n \quad (3)$$

For each partial derivative, an $m+1$ -member linear system of equations is produced: a_i

$$\sum_{k=1}^n \sum_{j=0}^m a_jk^{j+i} - \sum_{j=0}^m x_kk^i = 0 \quad (4)$$

$$k = 1, 2, 3, \dots, m$$

The $m+1$ linear equations are solved to obtain $m+1$ undetermined coefficients. $a_j (j = 1, 2, 3, \dots, m)$
In the above equations, m is the order of the set polynomial, and its value range is $0 \leq j \leq m$.

1) When $m=0$, the trend term is a constant, including:

$$\sum_{k=1}^n a_0k^0 - \sum_{k=1}^n x_kk^0 = 0 \quad (5)$$

It is solved as follows:

$$\hat{x}_k = a_0 = \frac{1}{n} \sum_{k=1}^n x_k \quad (6)$$

It can be easily obtained from Formula (6) that when $m=0$, the trend term in the signal is an arithmetic mean value of the signal data and a constant. At this time, the calculation formula for eliminating the constant trend term is:

$$y_k = x_k - \hat{x}_k = x_k - a_0, k = 1, 2, 3 \cdots, n \quad (7)$$

2) When $m=1$, the trend term is linear, including:

$$\begin{cases} \sum_{k=1}^n a_0 k^0 + \sum_{k=1}^n a_1 k - \sum_{k=1}^n x_k k^0 = 0 \\ \sum_{k=1}^n a_0 k + \sum_{k=1}^n a_1 k^2 - \sum_{k=1}^n x_k k = 0 \end{cases} \quad (8)$$

It is solved as follows:

$$\begin{cases} a_0 = \frac{2(2n+1) \sum_{k=1}^n x_k - 6 \sum_{k=1}^n x_k k}{(n-1)} \\ a_1 = \frac{12 \sum_{k=1}^n x_k k - 6(n-1) \sum_{k=1}^n x_k}{n(n-1)(n+1)} \end{cases} \quad (9)$$

$$y_k = x_k - \hat{x}_k = x_k - (a_0 + a_1 k)$$

$\hat{x}_k = a_0 + a_1 k$, the calculation formula for eliminating trend terms is:

$$y_k = x_k - \hat{x}_k = x_k - (a_0 + a_1 k) \quad (10)$$

$$k = 1, 2, 3 \cdots, n$$

The analysis of the collected data shows that most of the data trend terms are linear, mostly primary and a few quadratic. Therefore, $m=2$ is selected to carry out polynomial elimination processing on the test signal. On the basis of the principle of least squares method, the trend term of axle housing strain signals with significant trend terms is eliminated. The trend term elimination results are shown in Figure 10.

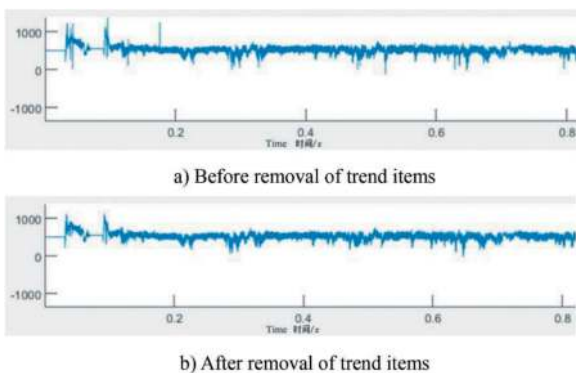

Figure 10. Elimination results of torque trend terms for front drive shaft.

5.3 Filtering and noise reduction

Noise, as an interference item to be avoided in the load spectrum signal, should be eliminated. The locality of non-stationary signals within a single cycle in time domain is an important characteristic of vehicle load spectrum signals. According to the principle of Fourier transforming, the corresponding program is compiled in MATLAB. Through the spectrum analysis of the signal before filtering of the front drive shaft, it can be known that the working frequency of the trolley is mainly concentrated within 5 Hz, so low-pass filtering can be used to remove high-frequency interference signals. Figure 11 is a comparison diagram of signals before and after drive shaft filtering under curved slope working condition. It can be seen from the figure that selecting Babbitt low-pass filter can achieve the effect of removing interference signals without obvious changes in signals before and after the filtering.

Figure 11. Signal diagram of front drive shaft before and after torque filtering.

5.4 Inspection and elimination of singular values

In the acquisition of load signals, the load-time history measured by sensors will usually lead to abrupt changes in test data due to computer test systems or human errors, so there will be some anomalies in the acquired signals. These abnormal peak points are also called singular values. The existence of singular values will affect the accuracy of data processing and cause relatively big errors in fatigue life, so they must be identified and eliminated during pre-processing of load signals. The common methods include amplitude threshold method, gradient threshold method, standard deviation method and "6" gradient method. According to the characteristics of the test data, the "6" gradient method is used to remove abnormal peak points. σ

In the "6" gradient method, it is believed that the gradient obtained by differentiating the original data at equal time intervals approximately obeys the normal distribution $N(\cdot)$. According to the "6" principle, most of the positive values are located in (\cdot) , and the probability of value taking within this range can reach 99.74%. It is generally believed that the situation of not taking values within this range will hardly occur in a test. Therefore, for a group of data, $= 1, 2, 3 \cdots, n$, calculate the mean and standard deviation as: $\sigma \mu, \sigma^2 \mu - 3\sigma, \mu + 3\sigma \{X_i\} \quad i \mu \sigma$

$$\mu = \frac{1}{n} \sum_{i=1}^n \mu_i \quad (11)$$

$$\sigma = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (\mu_i - \mu)^2} \quad (12)$$

By setting a gradient threshold and comparing it with the difference between the gradient mean value and the variance of the gradient, if the difference is greater than the gradient threshold of the variance, it will be recognized as a singular peak. The signal curve of the front axle before and after abnormal points elimination is shown in Figure 12.

Figure 12. Signal comparison of rear drive shaft before and after singular value removal.

5.5 “Principle of valley-peak extraction

In the process of trolley acquisition and test, to ensure the authenticity and integrity of the acquired data, the sampling frequency is usually set very high. The initial acquisition frequency of this trolley is set to 50 Hz, which will lead to a particularly large amount of collected data. Only by signal compression, editing and counting can truly useful random signals be obtained.

The inflection point of the time-domain signal is a key point constituting the load cycle, but the non-inflection point in the time-domain signal does not affect the fatigue damage result. The waveform of the signal after valley-peak extraction is basically the same as that of the original signal, and the sequence of the original signals is not changed. See Figure 13 below for the comparative analysis of arbitrarily selected front axle loads.

Figure 13. Signal diagram before and after load Valley-peak Extraction of Front Axle.

6 PREPARATION OF LOAD SPECTRUM DATA

The jumbo test is characterized by harsh road conditions, strong comprehensiveness of operating conditions and strong randomness of loads. However, for

each road condition, its load characteristics still have a certain regular trend. The load-time history of each working condition after removal of zero drift, trend term, filtering and noise reduction, singular value inspection and elimination is shown in the following Figure 14.

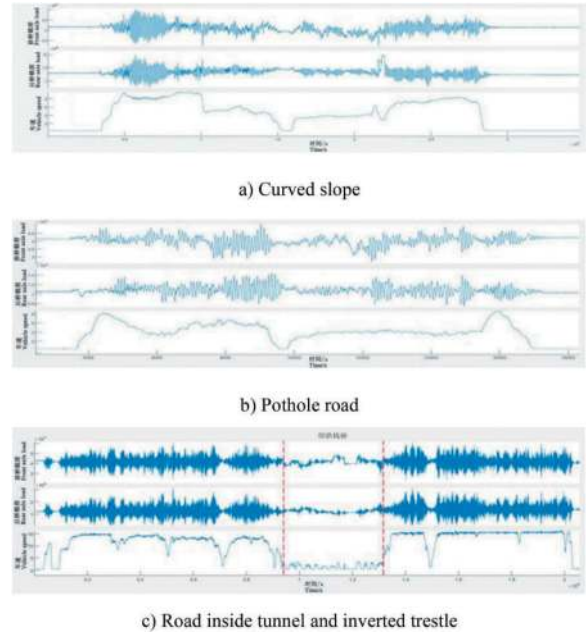

Figure 14. Load-time history diagram under various working conditions.

7 CONCLUSIONS

This paper puts forward a load test scheme of the drive system combined with the load characteristics of the drive system, drilling operation conditions and actual use by users. The load tests under different road conditions during actual operation should be carried out to reproduce the loads of the jumbo in actual use.

By removing zero drift, trend item, filtering and noise reduction, singular value inspection and elimination and other data processing links of load test data, the load time history diagram under various working conditions will be compiled.

Through the test load time history diagram, it provides important load data for subsequent fatigue damage analysis and life prediction of equipment components under pavement random load spectrum based on the fatigue damage theory.

Experimental study of step method construction in soft and broken surrounding rock section of super-long and large section tunnels

Yuanming Liu*, Yiqian Wang, Ting Zhu, Miaoliang Tian & Qingzhi Cheng
College of Civil Engineering, Guizhou University, Guiyang, China

ABSTRACT: The construction method of long and big section soft and broken surrounding rock tunnels has a significant impact on the construction period. The double-sided methods, CRD methods and CD methods are slow in construction speed and not conducive to mechanized construction. The step method has the characteristics of simple process, fast construction, timely support, and high mechanization. To meet the requirements for the construction period of ultra long tunnels, the step method should be selected for construction under safe conditions. At present, there are the following shortcomings in the research on the construction of weak and fractured tunnels using the step method: 1) The variation law of tunnel arch settlement with step height is not yet clear; 2) The optimal step height method has not been established yet. A tunnel bench method construction model test was conducted based on the Tongzi Tunnel to analyze the influence of bench height on tunnel arch settlement, surrounding rock pressure, and internal force of tunnel support. Research has shown that as the excavation height of the upper step increases, the settlement of the tunnel arch increases, and the maximum settlement of the arch is reached when the height of the upper step is 0.5H (H is the tunnel height). The excavation height of the middle step should not exceed 0.4H. The optimized construction industrial parameters are as follows: 0.45H for the upper step, 0.35H for the middle step, and 0.2H for the lower step; The length of bench should be 4-6 meters. On site construction monitoring shows that when the tunnel adopts the three-step method in the V-level surrounding rock, the settlement displacement of the tunnel vault and the convergence displacement of the arch waist are both within the control range, and the construction efficiency is high and safe.

1 INTRODUCTION

In recent years, along with the rapid development of Chinese expressway, the tunnels in China are getting longer and longer, with larger spans and more complex geological conditions for crossing. Chinese tunnel construction level is getting higher and higher, and the construction machinery and equipment are getting more and more advanced. But the tunnels whose length are more than 10,000 meters, still faces the problem of tight schedule. Especially, the tunnel construction method has a significant impact on the construction period of large-span tunnels with weak and fractured surrounding rocks. CD method, CRD method and double sides heading method inevitably lead to slow construction schedule and low economic efficiency (Cui 2010, Gu and Huang, 2014, Li et al, 2018, Wang et al, 2018, Wei et al, 2011, Zhang et al, 2013). However, the step method has the characteristics of simple process, fast construction, timely support, and high mechanization.

In China, many tunnels with soft and weak surrounding rocks have been successfully constructed by

the step method. Xin Guo simulated the three-step method which was used Ping'an Tunnel, and the results showed that the step method was beneficial to the stability of the surrounding rock (Xian, 2016). The three-step method was used instead of double sides heading method in V-class surrounding rock section of the Dawangding Tunnel, which was completed 10 months earlier than the original schedule and saved construction costs (Liu and Xie, 2010). The step method instead of the double sides heading method, also improved the construction progress of V-class surrounding rock section of Qihaoling Tunnel (Chen 2008). Lu Dewen conducted a test on the construction of Liangjiashan Tunnel's V-class surrounding rock section using the three-step method, which showed that the tunnel deformation and lining structure stresses were in a safe condition (Lu et al, 2018). Lin Minxing proposed that the construction of highway tunnels with class V surrounding rock can be completed faster by using the step method than the CD method, which shortens the construction period and saves the construction cost (Lin 2018).

*Corresponding author: liuym_2021@163.com

In order to further promote the efficient construction technology of soft and broken surrounding rock tunnel, the step method construction should be optimized. Several scholars have carried out research on optimization of construction parameters for the step method. Song Shuguang and others studied the mechanical effect law of the construction process of the step method in liangshui tunnel of the Lanzhou-Yuzhou Railway with soft and crushed perimeter rock, and concluded that the height of the step was optimal at the maximum width of the program (Song et al, 2011). Zou Chenglu found that the settlement of the vault increased as the height of the step method increased from 0.55H to 0.75H. It was considered that the optimum height of the step was 0.65H (Zou et al, 2013a, Zou et al, 2013b). Deng Tao studied the Zhongtiaoshan Tunnel of the Menghua Railway and optimized the length and height of the steps. When Step length was controlled in 4.8m~6.4m, the structural stress was the most favorable. Increasing the height of the upper step can reduce the deformation of the tunnel, but it was not the higher the better. It was more appropriate that the height of the upper step was controlled in 0.5H~0.7H (H refers to the height of the tunnel, the same below) (Deng et al, 2017). Liu Zhaowei found the arch settlement decreased when the step height of Duanjiaping Tunnel of Menghua Railway was from 0.2H to 0.5H, but the value of arch settlement was very close. The step height which was 0.3H~0.5H was good for controlling tunnel deformation (Liu and Li, 2017).

To sum up, there are still deficiencies in the optimization of step height, mainly in: 1) there are contradictions in tunnel vault settlement change law and step height; 2) a number of optimal step heights were proposed, but they are very different; 3) the research was mostly based on numerical simulation, and very few studies on modeling tests or field test validation (Wangle 2004, Xu et al, 2018).

Tongzi Tunnel which was the key project of Chongzun Expansion Project (in Guizhou), is the first longest tunnel under construction in karst area and the first longest tunnel under construction in Guizhou Province. It is separated two-way six-vehicle oversized sectional tunnel, traversing through karsts, faults, coal seams and other adverse geological conditions, with a maximum depth of 639m and length of 10,500m. About 19.0% of its length is in class III surrounding rock, and about 70.5% is in class IV surrounding rock, and about 10.5% is in class V surrounding rock. In order to meet the schedule requirements, there is an urgent need to optimize the construction method of the weak and broken perimeter rock section.

This paper carries out the construction model test of the step method in the soft and broken surrounding rock section of Tongzi Tunnel, analyzes the influence of the step height on the settlement of the tunnel vault, the pressure of the surrounding rock and the internal force of the tunnel support, and researches the optimal step height of the step method for the construction of tunnels through the weak and broken zone.

2 TUNNEL CONSTRUCTION MODEL TEST PLAN

2.1 Model test benches

The section ZK44+665~ZK44+645 of Tongzi Tunnel was taken as a typical section. The section of the enclosing rock level V, medium weathering tuff sandwiched between mudstone, rock quality is softer, the overall enclosing rock is more broken. As shown in Figure 1, the tunnel lining of Tongzi Tunnel is a composite tunnel lining with V-class surrounding rock. The tunnel lining is a composite lining with the span of 17.4m and the height of 11.85m.

Figure 1. Composite lining drawing.

As shown in Figure 2, the tunnel model test rack is designed according to a 1:50 similarity ratio. The front of the test rack consists of square steel tubes and tempered glass and acrylic panels. The sides are composed of steel plates and square steel. The internal dimensions of the tunnel model test stand are 2m wide, 0.8m deep and 1.2m high. The modeled tunnel is 0.237m in height and 0.348m in width.

Figure 2. Tunnel model test bench diagram.

2.2 Tunnel surrounding rock materials

Similar material ratios were used with the mass ratio barite powder: quartz sand: petroleum jelly = 600:420:80. The test specimens for mechanical properties of similar materials are shown in Figure 3.

Figure 3. Sample.

Determination of cohesion and angle of internal friction of materials using fully automated triaxial instrument. The physical-physical-mechanical properties of the surrounding rock of the prototype tunnel and the similar materials of the model tests are shown in Table 1.

Table 1. Physical and mechanical properties.

Surrounding rock level	Severek N/m ²	Deformation modulus / GPa	Poisson's ratio/ μ	Internal friction horn / φ°	Cohesion/ MPa
prototype	21.0	<1.3	0.40	26	0.05
model	21.0	0.026		24	0.04

2.3 Tunnel surrounding rock pressure test method

As shown in Figure 4, a pressure box was pre-built within the simulated tunnel envelope to test the pressure variations in the tunnel envelope. Tunnel perimeter rock pressure was measured using a DH3181-2 static strain tester.

Figure 4. Arrangement of surrounding rock pressure measuring points.

2.4 Supporting materials

In modeling tests, gypsum simulation and thin metal shell simulation are usually used for the simulation

materials of initial support. In this test, 0.5mm post thin steel plate was used to simulate the initial tunnel support.

As shown in Figure 5, applying strain gauges to the simulated support surface can test the support deformation and then calculate the internal force of the tunnel support. Support deformation was measured using a DH3181-2 static strain tester.

Figure 5. Measurement point arrangement.

Due to the small internal space of the model test tunnel and the small value of the vault settlement, the measurement of the tunnel vault settlement is difficult and no suitable measurement method has been reported.

This test cleverly uses the percentage meter to measure the settlement of the arch of the model test tunnel, which is a good solution to this problem. A schematic diagram of the percentage meter arrangement is shown in Figure 6(a). The percentile meter used for the model test is shown in Figure 6(b). The accuracy of the meter is 0.01 mm. The model test is set up to measure the section: 0+20 cm.

(a)

(b)

Figure 6. Schematic diagram of the layout of the dial indicator.

After simulating the surrounding rock is filled, the model test first stood for 24 hours, then excavated work.

3 ANALYSIS OF THE BENCH METHOD CONSTRUCTION

3.1 Bench excavation program

The height of the step method construction steps should meet the space requirements for mechanical

excavation. The construction plan for the step method is shown in Table 2, with the height of the upper step increased from 0.4H to 0.6H.

Table 2. Step height.

Programs	Model test tunnels			Prototype tunnels/m		
	Up	Middle	Down	Up	Middle	Down
Program One	0.4H	0.4H	0.2H	4.74	4.74	2.37
Program Two	0.45H	0.35H	0.2H	5.33	4.15	2.37
Program Three	0.50H	0.4H	0.1H	5.93	4.74	1.19
Program Four	0.55H	0.35H	0.1H	6.52	4.15	1.19
Program Five	0.60H	0.3H	0.1H	7.11	3.56	1.19

Tunnel step method excavation process is shown in Figure 7. According to the step overrun 10cm (i.e., the upper step overrun the middle step 10cm, the middle step overrun the lower step 10cm), each step of the excavation footing 10cm. The length of the model test tunnel is 80cm, according to each cycle of footage is 10cm, a total of 8 cycles, need 24 steps to complete the tunnel excavation.

Taking excavation program 2 as an example, the morphology of the various stages of construction, such as upper step excavation, upper step excavation, lower step excavation, upper penetration, and lower penetration, is shown in Figure 8.

Figure 7. Schematic diagram of excavation.

3.2 Analysis of arch settlement

The tunnel vault settlement curves for the five scenarios are shown in Figure 9, and the tunnel vault settlement for each key process is shown in Table 3. The relationship between the final vault settlement values and step heights for the five scenarios is shown in Figure 10.

As shown in Table 3, after the excavation of the upper step of scheme 1 (step 4), the top of the arch sinks 0.075mm, after the excavation of the middle step (step 8), the top of the arch sinks 0.655mm, after the excavation of the lower step (step 12), the top of the arch sinks 0.935mm, after the upper part

Figure 8. Construction process and form of bench method. (a) Upper bench excavation (b) Middle bench excavation (c) Lower bench excavation (d) Upper penetration (e) Lower penetration

of the test section passes through (step 19), the top of the arch sinks 1.405mm, and after the lower part of the test section passes through (step 24), the bottom part of the arch sinks 1.405mm. The other schemes are so similar. The other scenarios were similar.

Figure 9. Settlement displacement diagram of arch crown.

Table 3. Settlement displacement of arch crown unit: mm.

Name of program	Upper bench excavation	Middle bench excavation	Lower bench excavation	Upper penetration	Lower penetration
	Step 4	Step 8	Step 12	Step 19	Step 24
Program One	0.075	0.655	0.935	1.405	1.405
Program Two	0.032	0.404	0.918	1.333	1.417
Program Three	0.440	1.141	1.581	2.166	2.495
Program Four	0.132	0.786	1.707	2.191	2.402
Program Five	0.157	0.223	0.612	1.691	2.147

Figure 10. Settlement displacement of arch crown in key construction steps.

From Figures 9, 10 and Table 3:

- (1) From 0.4H to 0.50H, the vault settlement increases with the step height. From 0.50H to 0.60H, the settlement of the vault decreases with the increase of the step height. When the height of the upper step is 0.5H, the maximum settlement of the vault is 2.495mm.
- (2) When the upper step height of 0.4H→0.45H, the vault settlement increased by 6.4%; when the upper step height increased to 0.5H, the vault settlement increased by 87% compared to 0.4H.
- (3) From the viewpoint of arch settlement, the average arch settlement of tunnel arch of Option 1 and Option 2 is lower than that of Option 3, Option 4 and Option 5, which is a better excavation plan.

It can be seen that when the three-step method is used in the construction of the tunnel in the weak and broken surrounding rock section, the height of the upper step should not be more than half of the total

height of the tunnel excavation, while the middle step of the excavation height is smaller for the stability of the tunnel, the more favorable. Of course, the height of the middle step excavation should also meet the minimum space requirement for construction machinery. The lower step excavation has basically no effect on the settlement of the tunnel vault.

3.3 Surrounding rock pressure

The perimeter rock pressures after excavation for Scenarios I to V are shown in Table 4, Table 5, Figures 11 and 12.

Table 4. 0+20cm section perimeter rock pressure/kPa.

Position	Program One	Program Two	Program Three	Program Four	Program Five
Left arch foot	37	38	45	46	47
Left arch shoulder	28	29	41	41	38
Vaulting	2	2	3	2	2
Right arch shoulder	22	24	45	42	36
Right arch foot	41	39	48	47	45

Figure 11. 0+20cm section perimeter rock pressure.

The following conclusions can be drawn from Figure 11.

- (1) the pressure of the surrounding rock at the vault is the smallest, which is about 2 kPa or so. It shows that the closer to the critical surface, the smaller the surrounding rock stress in the radial direction of the tunnel. meanwhile, the radial surrounding rock pressure is maximum at the foot of the arch.

- (2) The pressure on the surrounding rock caused by different excavation schemes is also different. Option 3 has the highest surrounding rock pressure, indicating that the tunnel is most unfavorably stressed when Option 3 is adopted. Option 1 has the least stress in the surrounding rock of the tunnel.
- (3) As the excavation height of the upper step increases, the stress value of the tunnel surrounding rock increases, but when the excavation height of the upper step exceeds 0.5H, the stress value of the surrounding rock decreases instead. If the height of the upper step of Option 3 is 0.6H, the maximum value of perimeter rock pressure occurs at the foot of the arch as 48kPa, and the maximum value of surrounding rock stress of Option 1 occurs at the foot of the arch as 41kPa, which is reduced by 7kPa in comparison.

Table 5. 0+40cm section perimeter rock pressure/kPa.

Position	Program One	Program Two	Program Three	Program Four	Program Five
Left arch foot	27	27	35	35	34
Left arched shoulder	35	36	46	50	45
Vaulting	17	19	29	27	20
Right Arch Shoulder	35	36	46	51	40
Right arch foot	26	26	33	33	35

Figure 12. 0+40cm section perimeter rock pressure.

The following conclusions can be seen in Figure 12:

- (1) The pressure of surrounding rock at each position shows that the pressure of surrounding rock at the

arch shoulder is the largest, the pressure of surrounding rock at the foot of the arch is the second largest, and the pressure of surrounding rock at the top of the arch is the smallest. Taking Scheme 1 as an example, the peripheral rock pressure of the left and right arch shoulders is 35kPa and 35kPa, the peripheral rock pressure of the left and right arch footings is 27kPa and 26kPa, and the peripheral rock pressure of the arch top is 17kPa.

- (2) As the step height increases from 0.4H to 0.55H, the pressure of the surrounding rock at each location tends to increase. Taking the left arch foot perimeter rock pressure as an example, the perimeter rock pressure is 27kPa, 27kPa, 35kPa, 35kPa at step heights of 0.4H, 0.45H, 0.50H, and 0.55H, respectively; When increasing from 0.5H to 0.6H, the peripheral rock at each position except the right arch foot shows a decreasing trend. Take the right arch shoulder surrounding rock pressure as an example, when the step height is 0.55H and 0.60H, the surrounding rock pressure is 51kPa and 40kPa respectively.

Comparing Figures 11 and 12, as the tunnel is excavated, the pressure of the perimeter rock at the top of the arch and the arch shoulder increases, and the pressure of the perimeter rock at the foot of the arch decreases. It indicates that the pressure of the surrounding rock is shifted to the deeper part except the foot of the arch. From the first layer position, the pressure of surrounding rock at the top of the arch is the smallest, the pressure of surrounding rock at the shoulder of the arch is larger, and the pressure of surrounding rock at the foot of the arch is the largest. Pay attention to the foot of the arch support measures during construction.

3.4 Internal force of lining

The axial force of the support for each scheme option is shown in Figure 14 and Table 6, and the bending moment values are shown in Figure 13 and Table 7.

From Figures 12 and 13, and Tables 6 and 7, the following conclusions can be seen.

- (1) The lining axial forces of the scenarios are relatively close to each other, indicating that the step excavation height has a small effect on the lining axial forces. As the height of the upper step increases, the value of lining bending moment increases, with the maximum bending moment in Scenarios III and IV. The point of minimum value of bending moment occurs at the bottom of the arch and maximum value occurs at the arch waist.
- (2) The left and right arch girdle axial forces are larger, and the arch top and bottom axial forces are smaller. Step height 0.4H increases to 0.5H, axial force in each part increases. Step height 0.5H increases to 0.6H, and the axial force in

each part decreases. Take the left arch waist axial force as an example, when the step height is 0.4H, 0.45H, 0.5H, the axial force is 3.3kN, 3.65kN, 3.81kN respectively; when the step height is 0.5H, 0.55H, 0.6H, the axial force is 3.81kN, 3.50kN, 2.4kN respectively.

- (3) The left and right arch waist bending moments are larger, and the arch top and bottom bending moments are smaller. Step height 0.4H increases to 0.55H, bending moment increases in all parts. Step height 0.55H increases to 0.6H, and the bending moment decreases in each part. Still take the left arch waist bending moment as an example, when the step height is 0.4H, 0.45H, 0.5H, 0.55H, the bending moment is 5.2 N·m, 15.8 N·m, 31.1 N·m, 32.0 N·m respectively; when the step height is 0.55H, 0.6H, the bending moment is 32.0 N·m, 22.3 N·m respectively.

Figure 13. Axial force.

Table 6. Axial force unit: kN.

Position	Program One	Program Two	Program Three	Program Four	Program Five
Left arch foot	1.80	2.00	2.45	2.50	2.05
Vaulting	3.30	3.65	3.81	3.50	2.40
Right arch foot	3.45	3.70	3.85	3.80	2.15
Arch base	1.85	2.10	2.35	2.60	1.65

3.5 Optimization of construction parameters of bench method

When the height and length of the steps was chosen, the force and deformation are not the only limiting conditions. when analyzed from the aspects of construction interference, operational efficiency and equipment arrangement, but the efficiency of

Figure 14. Bending moment.

Table 7. Bending moment unit: N·m.

Position	Program One	Program Two	Program Three	Program Four	Program Five
Left arch foot	4.9	10.4	22.8	30.0	21.5
Vaulting	5.2	15.8	31.1	32.0	22.3
Right arch foot	5.4	16.0	30.2	32.5	25.6
Arch base	3.9	7.75	21.0	22.5	17.7

construction and convenience issues are also the key factors in controlling the dimensions of the steps.

From the point of view of deformation and mechanics, the length and height of the steps are adapted to a wider range, so when determining the parameters of the steps, more consideration can be given to the construction machinery as well as the convenience of manual operation and construction efficiency.

- (1) The length of the upper step can be controlled within 6 m to better control the deformation of the tunnel, and the mechanical operation is convenient, but should not be less than 4 m; the length of the middle step is mainly to consider the drilling operation space requirements.
- (2) taking into account the construction workspace, blasting machinery pick ballast efficiency and other factors, the length of the upper step is appropriate for 4 to 6 m, the length of the middle step is appropriate for 3 to 5 m. The length of the middle step is appropriate for 3 to 5 m.
- (3) The upper step mainly considers the excavator picks the ballast and the wet spraying manipulator operation efficiency, the step height is determined as 3.5~5.5m, uses the simple pedestal construction; The middle and lower steps (with up-arches) are assisted by climbing ladders, and the height of the steps should not be too high in consideration of the convenience of manual drilling and arch stand operation.

To summarize, when the tunnel class V perimeter rock section is excavated by the three-step method, the following conclusions can be drawn from the analysis of three aspects: vault settlement, perimeter rock stress and lining force:

- 1) As the excavation height of the upper step increases, the settlement of the tunnel vault increases and reaches the maximum value of the vault settlement when the height of the upper step is 0.5H.
- 2) The height of the center step excavation also has an effect on the internal force of the tunnel. The excavation height of the center step should not exceed 0.4H.
- 3) The lower step excavation has basically no effect on the tunnel surrounding rock.

If Tongzi Tunnel V perimeter rock section using three-step method of excavation, it is recommended that the construction industry parameters are as follows:

Step height: upper step 0.45H, middle step 0.35H, lower step 0.2H.

4 SUMMARY

Tunnel similarity modeling work was carried out for the soft and broken surrounding rock section of Tongzi Tunnel, and its main contents and related conclusions are as follows:

1. Compared with the double sidewall guide pit method and CD method, the construction efficiency can be improved by using the three-step method. Under certain conditions, the use of three-step method in the soft and broken section of Tongzi Tunnel can accelerate the construction progress under the premise of ensuring safety.
2. Tongzi Tunnel V perimeter rock section using three-step method of excavation, the optimized step height used in practice, the specific construction parameters are as follows: the upper step 0.45H, the middle step 0.35H, the lower step 0.2H, effectively controlling the deformation of the surrounding rock.
3. Comprehensive consideration of construction workspace, blasting machinery pick ballast efficiency and other factors, and ultimately determine the three-step method of the steps suitable for rubbing and length, the length of the upper step is appropriate for 4 ~ 6m, the length of the middle step is appropriate for 3 ~ 5m.

ABSTRACT: In order to implement the national high-quality development goal and further improve the level of railway tunnel construction technology, during the construction of Zhengzhou-Wanzhou high-speed railway, we have carried out experimental research on tunnel drilling and blasting mechanization construction technology, forming fundamental innovative achievements in intelligent construction technologies such as mechanized full-section construction method, high-performance active support technology, and intelligent equipment cluster. On this basis, by integrating the new generation of intelligent information perception technology, neural network algorithms, machine self-identification and self-learning technology, research on intelligent construction technology for the main construction processes of tunnel drilling and blasting method is carried out, trying to illustrate innovative achievements such as intelligent advanced geological prediction, intelligent identification and classification system for surrounding rock, intelligent optimization system for support parameters, intelligent construction system for excavation and support, and intelligent control and detection system for tunnel quality; furthermore, taking the change design as an example, this paper elaborates on the application of intelligent construction technology in the construction process of Zhengzhou-Wanzhou high-speed railway tunnel, and preliminarily establishes an intelligent tunnel drilling and blasting method construction system with certain intelligent characteristics.

Keywords: Mountain tunnel, Intelligence, Active support, Deformation pressure, MWD, Change design

1 INTRODUCTION

With the rapid development of technology and information technology, significant progress has been made in the research and application of new generation cutting-edge information and communication technologies such as industrial internet, Internet of Things, artificial intelligence, big data, cloud computing, image/video recognition, and 5G, which greatly improves industrial production efficiency and rapidly penetrates into the field of engineering construction, promoting industry transformation and development.

The scale of transportation engineering construction in the western region of China is gradually

expanding, and mountain tunnels are developing towards the “four super” directions of “super long, super deep, super large, and super complex”. At the same time, they are gradually entering extremely harsh environmental areas such as extremely frigid, high-altitude, high-intensity earthquake zones, etc. The longest railway tunnel currently under construction in China has exceeded 40km^[1]. Existing engineering practices^[2] have once again proven that the drilling and blasting method is still the most reliable, mature, adaptable, and widely used tunnel excavation method. However, due to the prominent extreme adverse geological problems such as high rock temperature, high heat, extremely high stress, deep

active faults, and ultra-high water pressure, the use of drilling and blasting method in tunnel construction faces unprecedented challenges. The only way is to replace people with machines, reduce man or even become unmanned. However, tunnel engineering faces a series of problems such as the complexity of the construction process, the randomness and fuzziness of rock mass changes, the adaptability of support materials and support systems, the safety and economy of engineering construction, etc., which drive the development of intelligent construction technology integrating mechanization and digitization /informationization to achieve construction goals.

Currently, some scholars have conducted research on intelligent tunnel construction technology. Guo Weishe^[3] elaborated the main problems and development prospects faced by TBM intelligent construction method; Wang Tongjun^[4] studied the intelligent construction technology system of railway tunnels from a management perspective; Ma Weibin^[5] conducted research on intelligent construction technology for prefabricated and assembled tunnels using drilling and blasting methods; Wang Zhijian^[6-8] conducted research on the use of mechanized, information-based, and intelligent construction technologies for railway tunnels; Liu Feixiang^[9] and others have developed a series of complete sets of equipment with intelligent features for extremely complex environments on high plateaus. The intelligent construction of tunnels is currently in the exploration and development stage. Due to the complex process of drilling and blasting method, there are still few research results on the use of drilling and blasting method for multi process construction of mountain tunnels. There are few discussions on intelligent construction methods with high reliability and high implementation based on the multi-process construction characteristics of drilling and blasting method for tunnel. The full-process mechanization and intelligent construction technology of drilling and blasting method is still under active exploration and research.

In recent years, in the construction process of complex mountainous railway projects such as Sichuan-Qinghai, and Zhengzhou-Wanzhou, we have actively explored and studied the large-scale mechanized construction technology in drilling and blasting method, achieved rich results and practical experience, and gradually promoted it to the construction of the Sichuan-Tibet Railway. Especially

represented by Zhengzhou-Wanzhou High Speed Railway, from 2018 to present, under the approval of China State Railway Group Co., Ltd, research has been carried out on the mechanized and intelligent construction technology of high-speed railway mountain tunnels using drilling and blasting methods. Some of the achievements have been preliminarily applied. Based on the research and practice of intelligent design and construction technology for the Zhengzhou-Wanzhou high-speed railway tunnel, this article elaborates on the foundation and key technologies of intelligent tunnel construction during the design and construction stages of the drilling and blasting method.

2 URGENCY OF RESEARCH ON INTELLIGENT CONSTRUCTION USING DRILLING AND BLASTING METHOD

Looking at the current situation of railway engineering construction in China, the level of intelligent construction in bridges, tracks, and other areas is relatively high. However, the level of large-scale mechanization in tunnel construction, especially in mountain tunnels, is still very low. The level of intelligence is even lower, and it has become a shortcoming that restricts the development of railways. The drilling and blasting method for mountain tunnels involves multiple construction processes, complex work processes, and uncontrollable factors. In addition, the construction environment is poor and the construction risks are high. Against the backdrop of the younger generation's increasing unwillingness to choose tunnel construction as a high-risk work, the demand for mechanized and intelligent tunnel construction is increasing. Taking the project department of a section of the Zhengzhou-Wanzhou high-speed railway as an example, there were approximately 1935 participants. The distribution of each age group is shown in Table 1. Among them, the proportion of workers aged 40-60 who are truly engaged in frontline operations is as high as 62%! The aging of the workers conducting construction of tunnels using drilling and blasting methods is obvious, and the proportion is continuing to expand. Therefore, the current research on intelligent construction technology for the entire process of tunnel drilling and blasting is extremely urgent.

Table 1. Age statistics of personnel in a project department of Zhengzhou-Wanzhou high-speed railway.

age	Below 20	20~30	30~40	40~50	50~60	Above 60	Total
Number	6	160	494	645	561	69	1935
Proportion (%)	0.3	8.3	25.5	33.3	29.0	3.6	100.0

3 BASIC TECHNOLOGY OF INTELLIGENT CONSTRUCTION OF MOUNTAIN TUNNEL DRILLING AND BLASTING METHOD

The intelligent construction of mountain tunnels is based on mechanized construction technology, which includes intelligent construction equipment covering various processes, simplified mechanized construction methods suitable for large-scale equipment operations, and high-performance active support technology for tunnels that provide construction safety and structural support for mechanized methods. All three are indispensable.

3.1 Intelligent construction equipment

Intelligent equipment is an important foundation for the construction of drilling and blasting methods. Cutting-edge technologies are comprehensively utilized such as intelligent sensing, image recognition, artificial intelligence, and the Internet of Things to overcome core technologies of intelligent equipment such as high-precision measurement and positioning, machine automatic control, and data standardization interaction in tunnels. Matching software and hardware are also developed and intelligent upgrading of 9 sets of equipment for the main construction process are conducted, covering the main equipment for four major work areas, i.e., advance support, drilling and blasting excavation, initial support and secondary lining. Details are shown in Table 2.

3.2 Mechanized full-section construction method^[10]

The mechanized full-section method is a construction technique that utilizes large machinery to excavate and shape the designed section in one go (see Figure 1 and Figure 2). It includes variations such as the full-section method (without invert), full-section method (with invert), and micro step method.

Figure 1. Construction process of full-section mechanized method.

Table 2. Intelligent construction equipment for drilling and blasting method.

Work area	Name of equipment	Main function	Sketch map
Advance support	Intelligent grouting jumbo	Automatic measurement, slurry production, mixing, grouting, and cleaning; remote pumping; automatically generating grouting logs; data exchange	
Drilling and blasting excavation	Intelligent rock drill-jumbo	Intelligent positioning; automatic drilling; remote control; intelligent surrounding rock classification; automatically generating drilling logs; data sharing	
	Intelligent rock bolting jumbo	Intelligent positioning; integrated intelligent construction of anchor rod including drilling, injection, and anchoring; generating anchor rod construction logs; data sharing	
Initial support	Intelligent lagging jack installation jumbo	Remote control; 3D reconstruction of contours; intelligent precise positioning; assembly trajectory planning; Automatically generating assembly logs	
	Intelligent wet shotcreting jumbo	Intelligent positioning; automatic shotcreting; automatically calculating the shotcreting volume; remote control; Automatically generating shotcreting logs; data exchange	
	Intelligent waterproof board laying jumbo	Automatic installation of waterproof boards; automatically calculating the amount of waterproof board and evaluating its looseness; automatically generating laying logs	
Secondary lining.	Intelligent lining jumbo	Pressurized pouring, and automatic vibration; real time liquid level display, temperature monitoring, pressure monitoring; automatically generating lining logs; data exchange	
	Intelligent maintenance jumbo	Constant temperature and humidity maintenance, real-time monitoring of constant humidity; automatically generating maintenance logs	

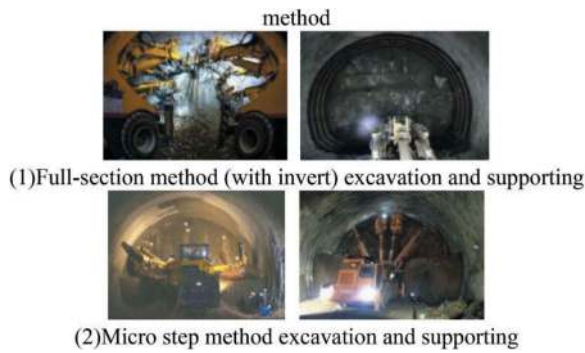

Figure 2. Full-section mechanized construction.

The mechanized full-section method is characterized by full ring excavation and overall support. One variation, the micro step method, involves excavating the section with a stepped face, typically with a step length of 3-5m. The upper step is excavated to a height of 1/2 to 2/3 of the section height, while simultaneous excavation and support are carried out for both upper and lower steps, including the invert. For more details about the scope of application of the mechanized full-section method, please refer to Tables 3.

Efforts are made to ensure the stability and safety during excavation. In hard rock areas, a specific slope rate can be applied to enhance the stability of the tunnel face. This helps prevent potential instability issues. In soft rock areas, an alternative approach involves designing the excavation face as a spherical curved surface. This design mitigates stress concentration and improves the stress flow distribution around the face. The spherical tunnel face offers advantages over an upright face, particularly in areas where the stress exerted on the face exceeds the strength of the rock. By adopting a spherical tunnel face, the longitudinal extrusion displacement of the tunnel face can be effectively controlled.

3.3 High-performance active support technology^[10]

3.3.1 Active forepoling technology for tunnel face

The mechanized full-section method requires a much larger excavation area compared to the multi-step method. This increased scale has negative implications for the overall stability of the tunnel face

under similar geological conditions. In order to address this challenge, an active forepoling system is designed to actively control the pre-deformation of the rock ahead of the tunnel face. This support system includes various components such as shotcrete, grouting small ducts, grouting pipe sheds, anchor rods, and pre-grouting. The objective of the active forepoling system is to reduce the pressure exerted by the rock on the potential sliding area of the tunnel face or enhance the mechanical properties of the rock. The applicability of this support system depends on the specific categories of tunnel face stability, as indicated in Table 4.

3.3.2 Active support of tunnel body

To address the issue of rapid and excessive early deformation in mechanized full-section construction tunnels, a new active support system has been

Table 4. Application of forepoling technology for tunnel face.

Construction method	Full-section method	Micro step method
Tunnel face stability		
Stability (LS)	①Local shotcrete on the tunnel face	—
Temporary stabilization (TS)	①Local shotcrete on the tunnel face ②Advance pipe shed (small duct) or tunnel face anchor rod	①Local shotcrete on the tunnel face ②Advance pipe shed (small duct) or tunnel face anchor rod
Unstability (US)	—	①Local or full shotcrete on the tunnel face ②Advance pipe shed or tunnel face anchor rod or tunnel face pre grouting ③Combination of advanced pipe shed and anchor rod on the tunnel face, and pre grouting on the palm surface ④Other measures

Table 3. Application of mechanized full-section construction.

Rock Category Construction method			IV	Other sections	General sections	V
	II	III	General sections			Other sections
Full-section method(without inverted arch)	○	○	○	△	—	—
Full-section method (with inverted arch)	△	△	△	○	△	—
Micro step method	—	—	—	△	○	○

implemented. This system incorporates anchor rods, high-performance shotcrete, and high-strength full-ring steel frames, as shown in Figure 3 and Figure 4. It takes advantage of the properties of the support component materials and structures while leveraging the efficiency of large-scale equipment. It intervenes and improves the bearing conditions of the rock before excavation or provides rapid support inside or outside the rock after excavation. By implementing primary support and early closure, a collaborative “rock-support” bearing system is established. This system actively enhances the mechanical parameters of the rock by providing timely and effective support force, protecting the surrounding rock, and utilizing the inherent stability of the rock. At the same time, it restricts rock deformation and constrains the deformation load on the rock, thereby reducing the burden on the support structure. This comprehensive approach ensures the safety of tunnel construction and structure while achieving reliable and cost-effective tunnel support.

Figure 3. High-performance active bearing system.

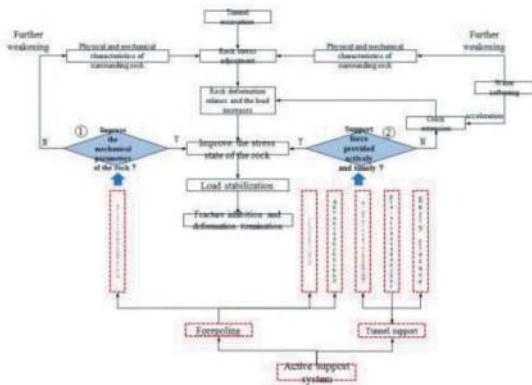

Figure 4. Principle and roadmap of high-performance active bearing system.

4 KEY TECHNOLOGIES FOR INTELLIGENT CONSTRUCTION OF MOUNTAIN TUNNEL DRILLING AND BLASTING

Intelligent construction methods for tunnel drilling and blasting are built upon full-process mechanized

construction and incorporate cutting-edge technologies such as intelligent perception, artificial intelligence algorithms, and machine self-recognition and self-learning capabilities. These technologies enable information perception, interconnection, processing, and decision-making regarding various aspects of tunnel construction, including rock conditions, support systems, equipment, personnel, and materials. The aim is to achieve safe, reliable, green, and efficient tunnel construction across survey and design, construction, quality control, and construction management stages. In general, the intelligent construction technology of tunnel drilling and blasting includes intelligent geological prediction, intelligent rock identification, intelligent design of support parameters, intelligent construction of excavation and support, intelligent construction quality control, etc.

4.1 Intelligent geological prediction

Intelligent geological prediction technology combines traditional drilling methods with Measurement While Drilling (MWD)^[11] (Figure 5) and artificial intelligence. During drilling, integrated sensors in drilling rigs and anchor rod rigs collect real-time data on drilling direction, formation characteristics, and drilling parameters. This data is then analyzed to create a visual geological cloud map where hardness and completeness of different rocks are shown in different colours, displaying rock strength and crack development, and predicting the geological structure ahead of the tunnel face. The technology enables real-time, visual, accurate, automatic and well-informed geological prediction, improving the accuracy of predictions and providing a basis for intelligent support parameter design. Parameters such as propulsion speed, impact pressure, propulsion pressure, rotary pressure, water pressure, and water flow rate are measured during advance long drilling, borehole deepening, bolt drilling and other drilling process. The geological cloud map can be visualized

Figure 7. MWD technology forecasting DK451+150 karst cave at Gaojiaping Tunnel.

separately based on drilling parameters or through assigning weights to each indicator. Please refer to Table 5 and Figure 6 for more details.

In the Gaojiaping Tunnel on the Zhengzhou-Chongqing High-speed Railway (Figure 7), the geological cloud map at DK451+147 (tunnel portal) indicates uniform rock strength at the tunnel face, which is consistent with the excavated rock. However, in the lower cycle at DK451+148-+150, the geological cloud map of the boreholes shows a sudden change to red near the right wall in front of the tunnel face, indicating a predicted sharp decrease in rock strength. This is attributed to the extensive development of karst in the tunnel. Additional advanced drilling techniques were employed, and after excavation, a karst cave extending 5m along the tunnel's axial direction was discovered in this area.

4.2 Intelligent identification of surrounding rock

When applying drilling and blasting construction method, surrounding rock can be quantitatively classified, wholly or partial, by a variety of indicators, and there are many classification methods. The commonly used methods in the world are RMR method [12], Q method [13], GSI method [14], RMI method [15], BQ method [16] and hydropower system HC method [17]. Generally, BQ method is applicable for traffic tunnels, and local optimization is carried out according to the characteristics of tunnels. As proposed by the Standard for Classification of Engineering Rock Mass (GB/T50218), classification of surrounding rock should be determined by comprehensive comparison of various classification methods, but there are many problems in practical application: 1) different methods differ in adaptability, resulting in inconsistent classification results, or even differ greatly, so there is a large deviation

between the classification results and the actual situation; 2) some evaluation indexes and values of most classification methods depend on the subjective judgment of geological professionals, which are uncontrollable and rely on their work experience and identification skills, so the classification results may be unreliable; 3) when a key indicator is difficult to obtain due to objective conditions, the method cannot be implemented. In general, the reason for the above problems is that most of the core indicators of surrounding rock classification methods pay too much attention to the physical parameters of surrounding rock, but in fact it is difficult to truly realize the rapid, interference-free and reliable value of core parameters.

4.2.1 Intelligent classification of surrounding rock

Use intelligent drilling jumbo to collect thousands of samples of drilling parameters of tunnel faces with different lithology and different rock grades. Through analysis, it was found that there was a certain correlation between the drilling parameters and the rock grade: there was a monotonic correlation between the rock grade and six drilling parameters, which provided the possibility and feasibility of using the drilling parameters to classify the surrounding rock. The scatter diagram of some drilling parameters and rock grade is shown in Figure 8.

Figure 8. Scatter diagram of relationship between drilling parameters and rock grade.

There are two kinds of intelligent classification methods of surrounding rock based on drilling parameters: ① direct classification, that is, collecting enough drilling parameters of tunnel face by drilling jumbo and forming a one-to-one sample library based on the classification results of surrounding rock based on the current standard, based on which

the machine model of “drilling parameters - surrounding rock grade” is established, and the accuracy is gradually improved through autonomous learning of machine and the continuously improved sample library, so as to realize the intelligent classification of surrounding rock; ② Indirect classification means that enough drilling parameters and rock classification indexes (including rock hardness, rock integrity and groundwater development) are collected by the drilling jumbo to form a one-to-one sample library, based on which the machine model of “drilling parameters - classification indexes” is established, and then the accuracy is gradually improved through autonomous learning and the continuously improved sample library, so as to indirectly realize the intelligent classification of surrounding rock. The main difference between the two methods is the intelligent acquisition of classification index, such as the technologies of real-time acquisition of rock strength and the intelligent acquisition of rock integrity.

There are many factors affecting the grade of surrounding rock, which belongs to a typical highly nonlinear problem. It is difficult to determine the relationship between drilling parameters and the grade of surrounding rock with traditional statistical analysis methods. However, with the support of big data samples and machine learning, a strong nonlinear fitting ability can be formed, with the characteristics of continuous learning and optimization, which can solve the problem of highly nonlinear fitting. Based on machine learning theory, five kinds of intelligent classification models for surrounding rock tunnel face (i.e., ① support vector machine (SVM) model, ② particle swarm optimization support vector machine (PSO-SVM) model, ③ error back propagation (BP) model, ④ genetic algorithm neural network (GA-BP) model, ⑤ forward neural network (RBF) model) are established. By comparison, the accuracy of SVM and BP models is higher, and the overall accuracy is 86.8% and 86.9% respectively. Its model structure is shown in Figure 9.

Figure 9. SVM model structure.

The intelligent classification model of surrounding rock tunnel face is adopted to realize the intelligent classification of grid area of tunnel face, which

is realized in four steps, as shown in Figure 10- Figure 12.

① Tunnel face zoning: the tunnel face is divided into grids based on the distribution characteristics of boreholes. Each zone must contain at least one borehole. The grid size of the zone is 2m. Taking the tunnel face with a line spacing of 5m at a speed of 350km/h as an example, it can be divided into 6 rows and 6 columns, a total of 34 zones.

② Surrounding rock classification while drilling: call the intelligent classification model of surrounding rock when drilling with the trolley, and classify the surrounding rock at the borehole in real time and dynamically according to the drilling parameters.

③ Regional classification of surrounding rock of tunnel face: according to the classification results of surrounding rock while drilling, the classification of surrounding rock of boreholes in each zone is mathematically averaged to determine the rock grade of each zone and realize the regional classification of surrounding rock of tunnel face.

④ Comprehensive classification of surrounding rock of tunnel face: the grid weight value of each zone of tunnel face is proposed (see Table 6), and the classification results of each zone are weighted average, and finally the overall rock grade of tunnel face is obtained. The overall weight parameters are determined according to the principle of arch crown>side wall>inverted arch> the middle part.

Figure 10. Grid zoning of tunnel face.

Figure 11. Classification of surrounding rock of blast hole in tunnel face.

Figure 12. Classification of surrounding rock in tunnel face grid zone.

Table 6. Weight value of tunnel face zoning.

Zone	Zone number	Single zone weight value	Total weight value
Arch crown	Zones of 1, 2, 3, 4, 5, 6, 7, 8, 9, 10	0.049	0.49
Sidewall	Zones of 11, 12, 15, 16, 17, 18, 21, 22, 23, 24, 27, 28	0.03	0.36
Invert arch	Zones of 13, 14, 19, 20, 25, 26	0.015	0.09
Middle part	Zones of 29, 30, 31, 32, 33, 34	0.01	0.06

4.2.2 Intelligent prediction of surrounding rock classification

Based on the characteristics of lateral zoning and vertical stratification of the surrounding rock of the tunnel face, and the revealed intelligent classification of the surrounding rock of multiple tunnel faces, the spatial mapping relationship of the surrounding rock grade of the tunnel face along the longitudinal direction is established, so that the surrounding rock grade in a certain range in front of the tunnel face can be automatically and dynamically predicted, and then the surrounding rock in front of the tunnel face can be comprehensively predicted in real time by combining the prediction information of advance drilling, geophysical prospecting and the surrounding rock prediction information at the survey stage, see Figure 13.

Figure 13. Intelligent prediction of tunnel surrounding rock.

4.3 Intelligent optimization of support parameters

4.3.1 Intelligent design of support parameters

The intelligent design of support parameters is an important part of the intelligent construction of tunnel. It is followed by intelligent construction process of excavation and support based on the intelligent identification of surrounding rock, including the support parameter database, intelligent matching and recommendation of support parameters, intelligent verification and optimization of support parameters, etc.

- (1) Support parameter database: collect general reference drawings of tunnels with different designers, different speeds, single and double lines, and deep and shallow buried tunnels, and use Oracle11g to establish a database with characteristic information, including seven functional objects: tables, queries, forms, reports, pages, macros, and modules. The database contains 255 sets of design parameters, including advance support, reinforcement of tunnel face, primary support, and secondary lining parameters.
- (2) Intelligent matching and recommendation of support parameters: it is carried out by using intelligent searching of database to match feature information of database feature parameters and parameters such as line design speed, surrounding rock grade, single and double line, buried depth, etc.

- (3) Intelligent verification and optimization of support parameters: in order to facilitate the quantitative verification and optimization of the advance support parameters of tunnel face and support parameters of tunnel body, the advance support design method based on the limit equilibrium theory and the high performance active support design method based on the deformation pressure theory are used to optimize the preliminary support parameters of the system.

Figure 14. Quantitative design model of advance support of tunnel face.

According to the model figure ^[10] in Figure 14, with reference to the safety factor of slope stability, the calculation stability factor K of the tunnel face is introduced, and the calculation formula that can quantify the stability of the tunnel face is derived by using the limit equilibrium method:

$$K = \frac{P_1 + P_2 + \beta_1 \alpha_2 F_c}{\beta_2 (F_w + \alpha_1 F_q)} + \beta_3 \quad (\text{Formula 1})$$

$$\beta_1 = \frac{1}{\sin \theta_0 \tan \varphi + \cos \theta_0} \quad (\text{Formula 2})$$

$$\beta_2 = \frac{\sin \theta_0}{\sin \theta_0 \tan \varphi + \cos \theta_0} \quad (\text{Formula 3})$$

$$\beta_3 = \frac{\cos \theta_0 \tan \varphi}{\sin \theta_0} \quad (\text{Formula 4})$$

Where P_1 is the shotcrete support force of the tunnel face, P_2 is the bolt support force of the tunnel face, α_1 is the rock pressure reduction coefficient of the tunnel face advance pipe shed, α_2 is the cohesion increasing coefficient of grouting in the tunnel face. The stability coefficient K of the tunnel face is calculated through the trial calculation of the support parameters continuously and automatically adjusted by the system until $K \geq [k]$. The stability coefficient $[K]$ of tunnel face design is taken as $[K]=1.15$ according to *Technical Code for Rock Bolt and Shotcrete Support Engineering* (GB 50068). The optimization design process is shown in Figure 15 below.

As shown in Figure 16, the parameters of primary support and secondary lining are optimized according to the calculation formula of surrounding rock deformation pressure derived from large-scale test. The optimized calculation of vertical and horizontal deformation pressures of surrounding rock shall consider the grade of surrounding rock and the BQ value of the basic quality index of surrounding rock.

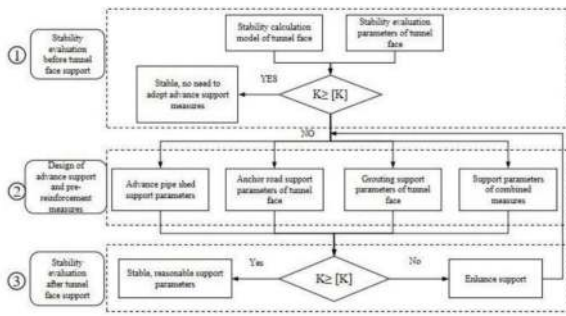

Figure 15. Design process of quantitative advanced support parameters for tunnel face.

Figure 16. Schematic diagram of deformation pressure calculation of deep buried tunnel.

Here is the expression^[10] for vertical value q and horizontal value e of deformation pressure derived from factors such as unit weight of surrounding rock γ , surrounding rock grade s and tunnel span B :

$$q = 0.33\gamma \cdot w \cdot e^{0.6s} \quad (\text{Formula 5})$$

$$e = \lambda q \quad (\text{Formula 6})$$

Where, s is the grade of surrounding rock, $h = 0.33w \cdot e^{0.6s}$ is the calculated height of equivalent deformation pressure, and $w = 0.2 + 0.1B$ is the correction factor of tunnel span, λ is the lateral pressure coefficient. The value of grade III surrounding rock is not greater than 0.25, the value of grade IV is among 0.25~0.5, and the value of grade V is among 0.5~1.0.

Here is the expressions of vertical value q and horizontal value e of deformation pressure derived from factors of the unit weight of surrounding rock γ , the basic quality index BQ of rock mass, the tunnel span B and other factors:

$$q = 0.33\gamma(0.2 + 0.1B)e^{-0.006BQ+4.2} \quad (\text{Formula 7})$$

$$e = 2.7e^{-0.0066BQ}q \quad (\text{Formula 8})$$

Where, BQ is the basic quality index of rock mass, which is calculated and determined according to *Standard for Engineering Classification of Rock Mass* (GB/T 50218).

Considering the structural safety and cost, the maximum value of the safety factor of the optimized support system shall be twice the minimum value, and shall be controlled according to Table 7.

Table 7. Safety factor control table of intelligent optimization design.

Category of supporting structure	Section tension/compression control type	Maximum value	Minimum value
Advance support of tunnel face	/	2.3	1.15
Primary support with profile steel	Pull Press	3.6 3.06	1.8 1.53
Primary support without profile steel	Pull Press	5.4 3.6	2.7 1.8
Reinforced concrete lining	Pull Press	4.8 4.0	2.4 2.0
Plain concrete lining	Pull Press	7.2 4.8	3.6 2.4

4.3.2 Visual expression of support parameters

To make support system visible, and reflect the progress of the support system in the construction process, the lightweight BIM Technology based on parametric and procedural modeling with the advantages of visualization, coordination, simulation and graphing, is adopted to solve the problems of difficult to modeling and integration, high cost, large volume and high requirements for equipment and operators, which commonly exists in the traditional BIM Technology, and realize the dynamic simulation of the construction process of the support system, see Figure 17.

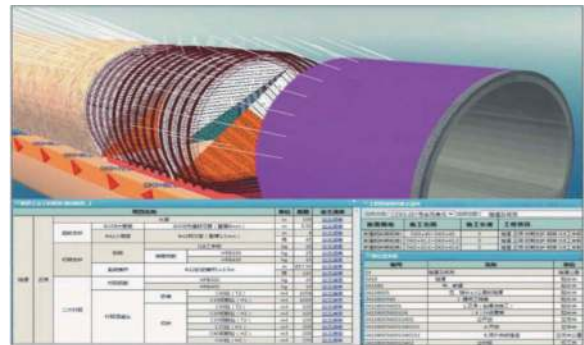

Figure 17. Visual expression of design and construction.

4.4 Intelligent construction of excavation and support

Intelligent excavation and support is the core part of intelligent construction of tunnel drilling and blasting. Its essence is that it can only be equipped with the process of execution of construction orders, real-time data acquisition and real-time feedback. According to the operation requirements of the main processes, the high-efficiency and high-quality construction operations are realized by giving the main construction equipment highly intelligent functions.

4.4.1 Environmental perception of intelligent equipment

The intelligent perception of construction equipment on the construction process and environment is the basic and core element of the whole intelligent construction system, the source and basis of all data, and is equivalent to the “eyes” and “ears” of the whole system. A series of intelligent equipment such as rock drilling jumbo, concrete wet spraying jumbo and concrete lining jumbo, is used to real-time collect and precept ambient temperature, pressure, speed, acceleration, angle, displacement, voltage and structure length, width, thickness and flatness. Various airborne sensors automatically collect process information during the construction of intelligent equipment to form construction logs, and realize the real-time dynamic perception of different sources and types of information through analysis, such as information of drilling parameter, tunnel contour (excavation contour, support contour, lining contour, etc.), support construction, lining pouring and equipment real-time status, provides basic data support for intelligent identification and classification of surrounding rock, intelligent optimization of support parameters and intelligent control of construction quality, as shown in Figure 18.

Figure 18. Dynamic environment perception by intelligent equipment.

4.4.2 Mutual recognition of intelligent equipment cluster

Because the tunnel construction process is relatively complex, there are many types of equipment with different functions, the construction data acquisition communication protocols of different processes are different, and the types, formats and storage forms of intelligent sensing data are also different. Therefore, it is necessary to integrate and establish the interactive method of unified multi-source and heterogeneous data, clarify the unified interactive system between tunnel geological data, support data, construction data, quality data and equipment perception data, establish a IOT system on construction site with high reliability and low delay, build information data interaction and conversion interfaces for intelligent equipment cluster, and realize the interconnection and mutual recognition of data, making each equipment cluster an important part of the intelligent construction system chain to identify each other, rather than an independent individual, as shown in Figure 20.

4.4.3 Remote cooperative control of intelligent equipment cluster

The tunnel construction environment for drilling and blasting is poor, and there may be adverse geological risks. Remote control center can be developed through remote control technology to realize the safe and efficient construction of the main process of the tunnel with fewer or no people. By real-time collecting image information and equipment status information of tunnel excavation and support, based on 4G, 5G and WiFi networks and other communication means and information interaction units, with the help of online high-definition video, and through in-depth analysis of the control center, machine instructions are formed to manipulate the equipment to automatically carry out drilling, charging, spraying, moving, positioning, scanning, pouring and other operations, greatly reducing the number of operators in harsh construction environment, and realizing back-end operation by equipment and remote measurement and video monitoring, to reduce the construction risk in practical, as shown in Figure 19. According to the requirements of construction process, function levels and positioning of equipment, movable remote control or indoor fixed remote cooperative control center (Figure 20) can be used to realize centralized monitoring and remote command of various equipment for tunnel construction.

Figure 19. Schematic diagram of remote cooperative control of intelligent equipment cluster.

Figure 20. Type of remote cooperative control center.

4.5 Intelligent control of construction quality

According to the construction quality evaluation index of the main process of drilling and blasting method, evaluate whether the construction is implemented to the extent to meet the design parameters, such as control of overbreak and underbreak, support thickness, support flatness, reinforcement cover thickness, reinforcement spacing, lining thickness, etc. Its core is to preliminarily realize the process control of construction quality through the accurate operation of

intelligent equipment, and obtain the quality parameters of engineering entities through the intelligent sensing elements after the completion of construction, to form the quality parameter detection database, compare the key parameters with the evaluation standards specified in relevant specifications, obtain the construction quality evaluation results, and put forward engineering countermeasures to realize the final control of construction quality. The quality inspection mainly relies on high-precision laser scanning technology, which has the following functions: ①High-precision and fast scanning of excavation contour, accurately detect overbreak and underbreak, evaluate the excavation quality by comparing with the design contour, and estimating the quantities of supporting structures; ②Before and after the completion of shotcrete, the 3D contour is reconstructed quickly with high precision, so as to evaluate whether the thickness and flatness of shotcrete meet the requirements, and the material loss and shotcrete construction quality; ③Before and after the construction of secondary lining, the deformation of surrounding rock and primary support, as well as the construction quality of the main structure of lining, are evaluated by high-precision reconstruction of 3D contour, the spacing of lining reinforcement and the thickness of protective layer, as shown in Figure 21.

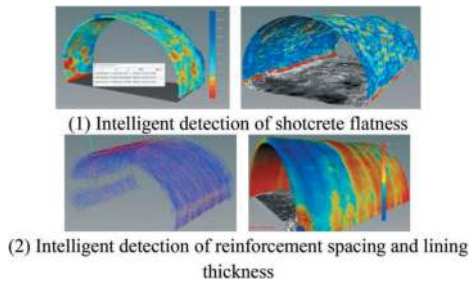

Figure 21. Schematic diagram of intelligent control of construction quality.

5 CASE STUDY OF INTELLIGENT CONSTRUCTION OF MOUNTAIN TUNNEL BY DRILLING AND BLASTING METHOD

Tunnels in Hubei section of Zhengzhou-Wanzhou HSR took the above technology as core intelligent development program, established the intelligent construction collaborative management platform to coordinate the implementation of the whole process of intelligent construction technology, and solve a series of challenges in the implementation of intelligent construction technology, and guided the design, construction and construction management of works in practice. Taking the design change as an example, since it involves the rights and responsibilities of all parties involved in the construction, it is of strict logical relevance; In traditional way, design change needs to be completed jointly by all parties involved in the construction on site, featured complex, many data, long cycle, and heavy workload. So

the traditional way cannot meet the requirements of high standards and high requirements for railway construction management. Therefore, a intelligent process of design change was developed to automatically compare the rock grade of the tunnel face obtained from the intelligent classification and identification of surrounding rock, digital imaging of the tunnel face, advanced drilling and other multi-source geological information with the original design. The design change process would be started if the above two were inconsistent, and the parties involved in the construction would put forward their opinions online and form minutes, and the intelligent optimization of support parameters would be synchronously started, and relatively optimal design parameters would be recommended and finally confirmed by the person in charge of the design unit. The changed design parameters were distributed to each equipment cluster to complete the construction in the form of data that could be identified by the construction equipment. In this way, the efficiency of design change based on clear rights and responsibilities was improved by implementing the design change process with fewer people and no one on site, as shown in Figure 22 below.

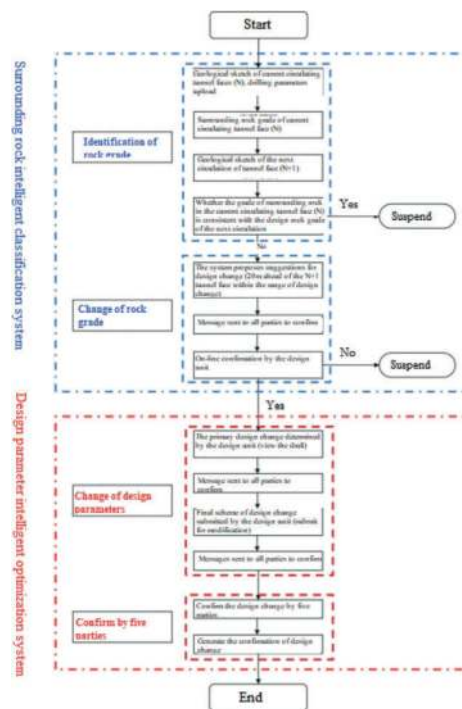

Figure 22. Overall flow chart of intelligent design change.

6 CONCLUSIONS AND OUTLOOK

6.1 Conclusions

- (1) Driven by the development direction of cutting-edge technologies in the world and major national development strategies, it is an urgent

need to integrate new technologies such as artificial intelligence, big data, cloud computing and robots into the construction process of tunnels.

- (2) As the demand of the drilling and blasting method for the number and quality of construction personnel is gradually increasing, the intelligent level and degree of construction equipment need to be gradually improved, the range and accuracy of intelligent perception of equipment for the environment and surrounding rock still need to be improved, and the function integration of intelligent equipment and the collaborative ability between equipment clusters still need to be strengthened.
- (3) Although the traditional surrounding rock classification reflects the actual physical characteristics of the surrounding rock itself based on the physical and mechanical parameters such as rock strength, rock integrity and groundwater state, it is relatively difficult to obtain parameters quickly, so is difficult to adapt to the intelligent demand. While the technical path, which indirectly reflects and evaluates the surrounding rock quality based on real-time dynamic feedback, and combines with artificial intelligence, big data and machine learning, will gradually become the research focus of intelligent drilling and blasting method.
- (4) With the extensive application of intelligent construction technology, the essential theory and design method of tunnels using large-scale equipment will be gradually improved to adapt to new construction technology, such as surrounding rock deformation pressure theory, accurate and quantitative design method of three-dimensional advanced support of tunnel face, design method of high-performance active support system, etc.

6.2 Outlook

Chatgpt^[18], the natural language processing tool driven by generative AI technology, has profoundly changed people's cognition of the application of AI technology. AI technology has been developed to the extent to cause social change. However, the research and application of intelligent construction technology of tunnel drilling and blasting in the field of infrastructure still remain in the initial stage, and various technical paths and implementation methods are quite different, so it is necessary to continue to invest in and intensify on research and development efforts. In the future, with the improvement of perception and accuracy of equipment, the iteration and evolution of artificial intelligence algorithms, the improvement of machine recognition and learning ability, and the improvement of the essential theory of tunnel engineering, the highly-intelligent design and construction of the whole unmanned process of drilling and blasting based on complex and multi-process operation will become a reality in the foreseeable future.

The Brenner Base Tunnel: An overview of the excavation types used in the project

David Marini* & Giuseppe Venditti
BBT SE, Bolzano, Italy

David Unteregger & Romed Insam
BBT SE, Innsbruck, Austria

Roberta Marazzo
BBT SE, Bolzano, Italy

ABSTRACT: To date, the Brenner Base Tunnel project has completed more than 160 km of tunnels, including 60 km of the main tunnels. The latter include large stretches excavated using machines, but D&B as well, with low and high overburdens. Double and single shield TBMs are the favoured choice for the excavation of the main tunnels, as they allow the laying of prefabricated segments. For the excavation through important fault zones, but also in particular geological, geotechnical and hydrogeological conditions, more conventional excavation methods were selected, including drill and blast, hammers and excavators, preventive consolidation by jet-grouting, cut and cover, and artificial tunnels as well as ground freezing. And it was precisely the freezing method that proved to be a winning choice when it came to excavating under the Isarco river, also with a view to respecting the environment.

Keywords: Brenner Base Tunnel, ground freezing, TBM

1 BRENNER BASE TUNNEL PROJECT

1.1 Introduction

The Brenner Base Tunnel is a flat railway tunnel that connects two States and is the central part of the new Munich-Verona railway corridor, along the extended Scandinavian-Mediterranean corridor within the European TEN-T transport network. It stretches between Innsbruck (Austria) and Fortezza (Italy) for a total length of 64 km including the Innsbruck bypass) and will be the longest underground railway link in the world.

The main benefits of the project include the shift of freight and passenger traffic to rail, eliminating traffic congestion, to the benefit of people and the environment, greater safety from natural hazards and a significant reduction in journey times. Today, travelling by train from Fortezza to Innsbruck takes 80 minutes for passenger traffic and 105 for freight traffic, while in the future, when the tunnel is completed, it will take 25 and 35 minutes respectively.

1.2 Progress of the works

In September 2023, the Brenner Base Tunnel (BBT) reached approximately 70 per cent of excavation progress corresponding to 160 km of a tunnel system that altogether includes almost 230 km distributed among main tubes, exploratory tunnel and other service and/or logistics tunnels (see Figure 1).

Along the entire corridor covered by the BBT project, there are four main lots in progress. Work on the following construction lots is in progress (see Figure 2):

- H21 “Sill Gorge”
- H41 “Sill gorge – Pfons”
- H53 “Pfons – Brenner”
- H61 “Mules 2-3”
- H71 “Isarco river underpass”

In lot H41, the TBM “Lilia” started excavating the main east tube from Ahrental towards South on 2 May 2023. The TBM, with its diameter of 10.4 m, will complete the approximately 8.1-kilometre-long

*Corresponding author: david.marini@bbt-se.com

Figure 1. 3D plan of the Brenner Base Tunnel with construction progress.

tunnel section to reach the town of Navis where it will meet up with the tunnel excavated as part of lot H53. The assembly of the TBM “Ida”, which will similarly excavate the west main tube, is currently in progress. On 4 April 2023, the last construction lot of the BBT as well as one of the longest of the entire base tunnel was awarded, namely the H53 Pfnos-Brenner contract. Construction work on this lot started in May 2023. In Italy, construction is ongoing on the construction lots H61 Mules 2-3.

The excavation and lining activities of the Isarco river underpass lot were completed in August 2023 in accordance with the scheduled contractual deadlines and costs; the landscaping and renaturation of the external areas continue. TBM “Virginia” in the Mules 2-3 lot excavated a total of 14.2 km of the east main tunnel and completed its journey to the Brenner Pass on 30 March 2023. The lot has reached an overall progress of 91 per cent and work is in progress on the

final lining in the emergency stop (see Figure 3), the access tunnel to the emergency stop and the cross passages, as well as the last kilometres of TBM excavation in the west main tunnel.

The excavation of the emergency stop in Trens, in lot H61 ‘Mules 2-3’ was completed in April 2022, with the exception of the opening of the diaphragms in the ventilation tunnels to the east main tunnels, which was postponed for logistical reasons.

2 CONSTRUCTION LOTS

The civil engineering works of the Brenner Base Tunnel are divided into several construction lots, of which seven main lots have been completed (considering the main railway tunnels, the exploratory tunnel as well as the access tunnels), two has been completed in 2023 and four are under construction (see Figure 2).

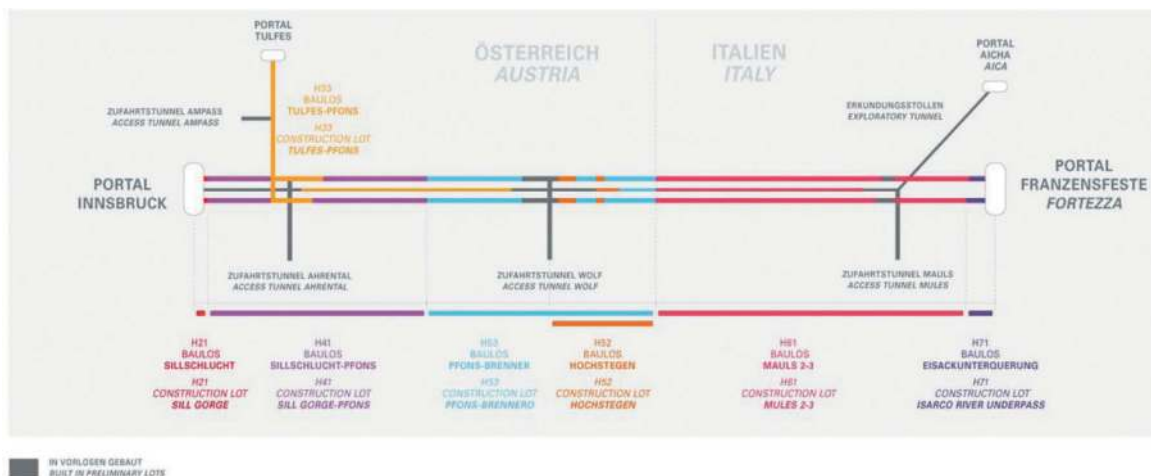

Figure 2. Overview of main construction lots underground works.

Figure 3. Photo central tunnel Emergency stop and cross passages.

3 EXCAVATION METHODS

3.1 Introduction

Depending on the geological, geotechnical and hydro-geological conditions of the rock mass, the geometric constraints and the scheduling of the activities, roughly 50% of the excavation work will be excavated with TBMs, 50% using drilling and blasting as well as mechanical digger. The choice was made to use shielded TBMs, as they allow the precast tubbing ring lining to be placed immediately behind the TBM, thus guaranteeing a high degree of safety during execution, and at the same time the creation of a ring that under normal conditions serves as the final lining.

3.2 Mechanised excavation

Depending on the performance requirements and the main purposes identified, mechanised excavation involves the use of double shield, single shield and open TBMs.

In Italy, a 24.5 km section of the exploratory tunnel was excavated with a double shield TBM, whereas the Austrian section involved the excavation of 16.5 km of the exploratory tunnel with the use of an open TBM.

The TBM excavation of the main tunnels involves the use of prefabricated segments with high performance characteristics in both Italy and Austria. This required the use of double and/or single shield TBMs.

In Italy, more than 25 km of main tunnels were excavated with double shield TBMs, with an excavation diameter of 10.7m, a length of approx. 205m and a weight of approx. 2,400t (see Figure 4).

When fully operational, each individual TBM requires a nominal capacity of 4,200 kW (12x350 kW) and a main cylinder thrust force of 95,000 kN, corresponding to 9,500 t. The forces at play are impressive and require not only a high quality of the materials used, but above all highly complex and properly designed systems.

The peculiarity of the main tunnels is the application of a lining made of tubbing rings, despite the great excavation depth. This tubbing ring lining, for

Figure 4. TBM cutter head, construction lot Mules 2-3.

excavations in Italy, is 45 cm thick and is made up of 6 +1 elements plus a base arch in reinforced concrete with an average length of 1.75 m. It uses a double sealing system. The ring laid down in the project is a universal size, and by rotating it around its axis it is possible to stagger the longitudinal joints between the segments and to follow the altitude/plane profile and the deviations of the route. The tunnel complex uses a system drained externally from the tubbing ring by 20-25 cm pea-gravel and internally by a groundwater collection system, consisting of openings at the base of the ring and two micro-fissured collectors placed next to the base element. The water flows into the collectors and is then conveyed to the cross passages identified for vertical discharge to the exploratory tunnel along which it flows to its respective outlets at Aica on the south side and at the Sill Gorge on the north side. The peak of the main tunnels is located at the state border.

In May 2021, TBM 1072 achieved record excavation production by exceeding a monthly production of 860m, corresponding to an average daily production for that month of 30.71m/day.

In the H41 construction lot Sill Gorge-Pfons, two single shield machines with an effective drilling diameter of 10.4 m have been used to drive the main tunnel tubes from Ahrental southward, starting in May and June 2023, respectively and excavating stretches of approx. 8.1 km and 8.4 km. The two TBM with backup structure are each approx. 160 m long and weigh approx. 2,420 tons. The total engine power of each TBM is 4,550 kW (13x350 kW). In total, the TBMs used have 18 double presses and thus a total of 36 thrust cylinders. The installed nominal thrust is 128,000 kN each at an operating pressure of 300 bar and the maximum jacking force is approx. 183,000 kN at 500 bar.

The tubbing ring system to be used is a single-sealed and bolted universal ring system with a tubbing ring thickness of 40 cm and a ring concavity of 40 mm. The ring pitch is 6+0 in accordance with the requirements of the tender, and the ring width is 1.95 m (see Figure 5).

The ring pitch in question consists of four rhomboid tubbing rings (tubbing rings B1, B2, C1 and C2) and two trapezoidal tubbing rings (tubbing rings A and K).

Figure 5. Tubbing ring lining in construction lot H41.

The width of the ring gap varies between 28 cm in the crown and 25 cm in the base slab. In order to take into account the drainage effect of the tunnel tube, the ring bedding, where the geological conditions permit, is usually carried out with pea gravel, which is injected and compacted in some areas if necessary, and a mortar bed or pearl gravel - mortar mixture in the base slab.

Ordinary, additional and special measures have been defined for mechanical excavation with TBMs, which include additional mechanical equipment and technical measures in order to be able to react to critical excavation situations and to avoid long-term excavation interruptions.

In planning the mechanical TBM excavations, the findings from driving the exploratory tunnel, which was completed with an open TBM in the period between October 2015 and July 2020 as part of the H33 Tulfes-Pfons construction lot, were considered in their entirety.

3.3 Excavation with conventional methods

3.3.1 Drill and blast excavation

Some sections of the Brenner Base Tunnel are characterised by changes in the geometry of the excavation sections and different lengths, thus requiring a drill & blast excavation with consolidation of the tunnel by means of radial anchors, welded mesh mats and shotcrete and, where necessary, supplemented with ribs, forepoling and consolidation of the excavation front. In Austria the methodological approach is to excavate tunnels usually with a partial section, in Italy full-section excavation is preferred, the partial section is also applied to sections larger than 10m in diameter (e.g. TBM assembly chambers) and under special conditions.

3.3.2 Excavation in fault zones

The fault zone of the Periadriatic Seam (located approximately at km 46+800 to km 47+600) at the point of tectonic contact between the European Plate

and the African Plate was also excavated using mechanical diggers, requiring major geognostic investigation in advance and special consolidation measures. The data clearly show that the rock mass with cathyrites, cataclasites and tonalitic mylonites is significantly less resistant to deformation as compared to “healthy” rock (granite and tonalite), thus causing more deformation with subsequent ample plasticisation around the cavity itself. Furthermore, intensely fractured rock was found in stretches along the route, due to tectonic activity (see Figure 6).

Parametrisation had shown the need to include rock face consolidation measures which in some cases would still not succeed in reducing convergence at the rock face to acceptable levels.

Figure 6. Excavation front in the fault zone of the Periadriatic Seam.

For this reason, a controlled deformation of the cavity to be modulated based on the maximum expected deformation has been applied as starting solution. In the execution phase, the observational method combined with careful monitoring identified strongly asymmetric behaviour with significant deformations along the tunnel axis and somewhat lesser deformations along the radial. These conditions led to the choice of a rigid lining to consolidate the cavity, combined with rock face consolidation that limited the deformations along the tunnel axis to an acceptable level.

During the works, in-depth monitoring was performed with extensometers at the front, convergence measurements, strain gauge and load cells mounted on the ribs, bolts and radial multi-base extensometers.

In the Austrian section, the Hochstegen fault zone, a water-bearing and therefore hydrogeologically very challenging tunnel section, is located at km 29+500 to km 30+200. Geologically, the zone lies in a heterogeneous lithological sequence between the Bündner schists of the Glockner nappe in the north and the central gneiss in the south. Worth mentioning in this respect is the eponymous Hochstegen marble and the Rauhawacke zone lying to the north of it. With overburdens of 600 m to 800 m, transient water

inflows of 150 l/sec/10 m and pressures of up to 80bar were predicted here. The situation was further complicated by the fact that a Natura 2000 site and important groundwater resources for the region lie above the hydrogeologically sensitive section. Therefore, very restrictive construction measures (injections, sealing, etc.) were prescribed by the authorities for this section. The major challenge is that the groundwater level at the surface must not be lowered by more than 30 cm as a result of the tunnelling activities. To ensure this, massive and time-consuming injection campaigns were tendered to ensure a largely sealed excavation that prevents a lowering of the groundwater level (see Figure 7).

Figure 7. 3D model of the injections from the exploratory tunnel.

In particular, the high-water pressures of up to 80 bar meant that the injection campaigns and injection screens had to be very tightly meshed and carried out in several rings in order to seal the tunnel as much as possible.

Currently, the injection and excavation work are being carried out as a preliminary measure in the exploratory tunnel, and it has been possible to avoid any significant water inflows in the excavated areas of the Rauhwaacke zone and the Hochstegen marble (see Figure 8). The findings from the exploratory tunnel will be subsequently incorporated into the excavation of the main tunnel tubes, so that they can be optimized.

Figure 8. Injection work in the Hochstegen fault zone.

3.3.3 Innovative Jet Grouting technology in alluvial soils

For the tunnel stretches excavated in the valley floor area north of the Isarco River, which were not accessible from the surface due to the high overburdens, sub-horizontal advance pre-consolidation with Quick Set Jet Grouting technology was used injections (see Figure 9).

Figure 9. Longitudinal excavation profile with QSJG®.

The QSJG® technology, thanks to the use of special setting accelerators conveyed in the jet-injection phase through independent circuits within the drill rods, which allowed the cement mixture and setting accelerator to mix only downstream of the injection nozzle, created columnar jet-grouting treatments even in the presence of significant hydraulic head (up to 30m from the keystone) without the need for preliminary waterproofing injections.

The use of a specific hydraulic preventer also prevented the column from being emptied by counteracting the high hydrostatic pressures involved, and also allowed the installation of special plugs to seal the consolidated column. By employing appropriate injection parameters, it was possible to carry out columnar treatments with a diameter of up to 1,400 mm, larger than those carried out with traditional methods (see Figure 10).

Figure 10. Excavation with QSJG® method.

The transition between the debris and the rock substrate inevitably involves mixed excavation fronts, i.e. partially occupied by debris and partially by medium fractured and altered rock.

A technical solution was also provided for these transition sections, proposing QSJG® interventions in the debris sector, and interventions called Roto Injection Controlled Parameters (RICP), for the altered and fractured rock sector.

The technique, as compared to the QSJG® technology, consists of injecting a more permeating mixture with reduced energy, partly using the same equipment as the QSJG®.

The aim was to cement the fine debris that fills the fractures and discontinuities in the rock mass which had been intercepted and brought into contact with the cavity, for a sufficient distance to prevent the flow of water in the rock mass around the excavation, interrupting the communication between the various fractures and discontinuities and guaranteeing the impermeability of the rock sector as requested by the design.

A single injection treatment using the RICP technique has an influence radius of approximately 90 cm, comparable to a treatment using traditional valve injection. A further feature of the implemented technical solution was the possibility of carrying out the two consolidation techniques, RICP in the rock section and QSJG® in the debris section, in separate but continuous phases, and above all within the same hole, for all those treatments that were necessary in the transition areas between rock and debris (see Figure 11).

Figure 11. Excavation cross-section with RICP.

For the excavation of the tunnel stretches in the areas of the Isarco River valley floor, which are completely surrounded by groundwater debris and landslide material, large-diameter (2000 mm) vertical bifluid jet grouting treatments were carried out to create a ring of consolidated soil around the tunnel cavity (Figure 12), varying in thickness between 3.00 and 4.50 m depending on the type of excavation section and position (dome or inverted arch).

In order to allow the realisation of compartmentalised excavation “fields”, the construction of baffles of consolidated soil was planned, again by

means of columnar jet-grouting treatments; the individual excavation fields were no longer than 15 m and the length depended on the excavation geometries. A plug of approximately 3.5 m thickness was planned at the cross-section changes: the partition is positioned astride the cross-section change. If the distances between one section change and the next were greater than 15 m, a further internal partition was provided, in this case 2.0 m thick, i.e. a row of interpenetrating Jet Grouting treatments.

The excavation, following this consolidation technique, was carried out full-section without ground-water drainage.

3.3.4 Ground freezing technology

The Isarco river underpass was built by means of four tunnels, driven with full-section excavation from shafts placed laterally to the riverbed, after consolidation works were carried out using artificial soil freezing technology in order to obtain a reduction in the speed of the underground water flows (Figure 12).

Figure 12. Excavation section type and jet grouting consolidation.

The freezing of the ground was carried out by means of the so-called ‘mixed method’:

- Phase one - liquid nitrogen freezing (open or direct circuit) during which the compressed liquid nitrogen, at a temperature of -196°C , is conveyed from 4 storage silos of 50,000 litres/each to the two portals at the entrance to the tunnels inside special insulated pipes. Once the refrigerant fluid reaches the distribution portals - outside the perimeter of the tunnel to be excavated - it is conveyed into coaxial stainless steel pipes, called ‘freezing probes’, subtracting heat from the ground and dispersing it into the atmosphere in the form of gas through suitable venting chimneys located at the top of the shafts. In this phase, an ice wall is formed around the area to be excavated with the geometric characteristics and temperatures in the design;

- Phase two - brine maintenance (closed or indirect circuit), during which this calcium chloride solution is circulated within a closed circuit by means of sending pumps from a refrigeration plant, consisting of 3 chillers of 240 kW each, one of which is a backup, and sent inside the same freezing probes already used in the liquid nitrogen freezing phase at a temperature of between -30 °C and -35 °C. The brine removes heat from the ground by heating up and returns to the refrigeration system where it is cooled again and fed back into the circuit. This allows the ice shell formed in the first freezing phase to be preserved, without significantly increasing its size.

The second phase remained active and after verifying that the design requirements had been met, the excavation phases began (see Figure 13).

Figure 13. Consolidation section of the Isarco underpass.

Thanks to this technique, which is both safe and eco-compatible as no products are injected or dispersed into the ground, it was possible to safely excavate the four tunnel sections under the Isarco River in an environmentally friendly way, managing to avoid temporarily re-routing the river and subsequently returning it to its natural bed.3.2 xxx

3.3.5 Cut-and-cover method

Coming from the Innsbruck railway station, the Sill Gorge construction lot is the connection to the Brenner Base Tunnel. The route leads through the upstream Silltal tunnel, which is approx. 130 m long, before crossing the river Sill to reach the main portal of the Brenner Base Tunnel.

The Sill-valley tunnel passes through the foot of Mount Isel, with primarily blocky flow debris; only in the central area with the highest overburden, was the first appearance of the bedrock from the geological explorations expected.

After extensive variant studies, tunnelling using cut and cover was finally selected, requiring a slope cut of up to 45 m in height. Based on the geological prognosis, the slope cut was secured with bolted shotcrete and 2 anchor beams with tensioned braided anchors. Due to the highly fissured boulders found during the works, it became necessary to reinforce the consolidation of the slope cut by adapting and strengthening the nailing and tie-back anchors (now with 5 anchor beams).

The execution of the cut was successful, the construction of the concrete structure for the Sill-valley tunnel is ongoing (see Figure 14). Finally, the Sill-valley tunnel will be covered, landscaped and renaturalized as a recreational area for the city of Innsbruck.

Figure 14. Cut-and-cover method in construction.

4 CONCLUSIONS

The tunnel system of the Brenner Base Tunnel - due to the diversity of rock masses to be crossed, the different geometries required (main tunnels, access tunnels, passages, chambers, etc.) and a subdivision into construction lots with logistical and time constraints - requires a multiplicity of excavation methods: these methods are described in this article, considering the experience gained in the excavation more than 160 km of tunnels.

ACKNOWLEDGMENTS

We would like to express our sincere thanks to BBT SE CEOs Gilberto Cardola and Martin Gradnitzer, both for their willingness to share the technical experience of the Project and their support of our active participation in international events in our sector.

ABSTRACT: In loess platform the special genesis has shaped the complex groundwater occurrence conditions and special surrounding rock conditions. When a high speed railway tunnel has to cross the loess platform in the form of shallow depth and gentle slope, it faces technical difficulties caused by many factors such as gentle slope with long distance, and poor stability of the surrounding rock. Taking into consideration the engineering geological characteristics in loess platform, this paper studies the relationship between the critical buried depth and space, the change law of water content of the surrounding rock, the overall mechanical behaviors and deformation characteristics of the tunnels with shallow buried depth and gentle slope in loess tableland areas. The classification formula and correction factor for the critical overburden depth are derived in terms of the tunnels with shallow buried depth and gentle slope in loess tableland areas, and the spatio-temporal variation rules and the key change time points of water content of the surrounding rock are determined. The comprehensive subgrade treatment measures, pre-grouting measures to improve the strength of the surrounding rock, and key control measures for roof ripping construction are proposed for the tunnels with shallow buried depth and gentle slope in loess platform.

Keywords: Loess platform, Shallow buried depth and gentle slope, Tunnel construction, Key technology

1 INTRODUCTION

Since the beginning of the new century, the transportation industry has developed rapidly^[1], and a large number of railway trunk lines, branch lines and special lines have been built in the loess area^[2], among

which the Yinxi high-speed railway is an important part of the national “eight vertical and eight horizontal” high-speed railway network^[3].

Domestic and foreign experts and scholars have conducted a large number of field test studies on the shallow burial problem in the construction of loess

Fund Project: Science and Technology Research and Development Program of China Railway Corporation (2017G007-G)

tunnel. Combined with theoretical analysis, systematic studies have been conducted on the boundary of deep and shallow burial, surrounding rock pressure, the interaction mechanism between the initial support and surrounding rock, and reasonable initial support in loess tunnel^{[4]~[7]}.

Li Guoliang, Jin Baocheng, Shao Shengjun, Wang Zaiguang, Mi Weijun et al.^{[8]~[12]}, relying on the construction of Zhengzhou-Xi'an and Baoji-Lanzhou high-speed railway, the applicability of large section loess tunnel construction method is studied experimentally, and the deformation and stress characteristics of the surrounding rock and supporting system of the step method are proved, which provides a basis for solving the key technology of the construction of large section loess tunnel.

Wang Mingnian et al.^{[13], [14]} investigated and studied the relationship between surface cracks and buried depth in 12 tunnels of Zhengzhou-Xi'an high-speed railway, and conducted in-depth research on the deep and shallow buried boundary of super-large cross-section in loess tunnels, and drew the dividing line of deep and shallow buried.

The Loess Tunnel Engineering, edited by Zhao Yong, Li Guoliang, Yu Yu et al.^[15], summarized the history and current situation of loess tunnel construction, and pointed out the existing technical problems and development direction of loess tunnel construction. The calculation method of the boundary between deep and shallow loess tunnel and the design load of loess surrounding rock are determined. The construction technology of basement treatment of collapsible loess tunnel is introduced based on engineering examples.

According to the existing research results, our country has accumulated a lot of tunnel construction experience in the loess region. Especially in recent years, domestic scholars have done a lot of related research work for the new high-speed railway, Such as Zhengzhou-Xi'an high-speed railway, Lanzhou-Xinjiang high-speed railway, Baoji-Lanzhou high-speed railway and Lanzhou-Chongqing high-speed railway.

There are 22 tunnels crossing the loess platform in Gan-ning section of Yinchuan-Xi'an high-speed railway, with a total length of 84.18km, accounting for 57.53% of the total length of the whole line. Due to the regional differences in origin, particle composition and engineering characteristics of loess age, Yinchuan-Xi'an high-speed railway still faces many technical problems in loess tunnels when it is built in Loess platform.

Especially when the tunnel passes through the shallow buried and slow slope section in the loess platform, there are obvious differences in the vertical and horizontal topography, the thickness of the loess layer and the engineering characteristics of the tunnel. The main problems to be solved are as follows: (1)the definition of deep and shallow buried tunnels in the loess Tableland; (2)Changes of water content of surrounding rock and key control time points of construction changes; (3)Deformation

mechanism and control measures of surrounding rock in shallow and slow slope section; (4)Suitable base treatment method.

2 CHARACTERISTICS OF SHALLOW BURIED AND SLOW SLOPE TUNNEL IN LOESS PLATFORM

2.1 Engineering geological characteristics of loess platform

As a part of the Ordos Platform, Ganning Loess Plateau is based on the Mesozoic palaeo-geomorphic basin, and has formed the typical Quaternary Early Pleistocene(Q₁) and Middle Pleistocene(Q₂) deep protogenetic loess in the long deposition of 2 ~ 3 million years. In the Late Pleistocene period (Q₃), affected by the geological tectonic movement, the platform rose intermittently in the region, and was gradually cut up by the tractive erosion of rainwater collection, rivers, floods, etc., forming the geomorphic unit of the loess latform today.

Figure 1. Topography and geomorphology map along Yinxi high-speed Railway.

Between Ning Xian County and Huan Xian County is the typical latform unit of Dongzhi Loess platform. the surface is gentle, open, flat and continuous, covering about 700 square kilometers, it spans the four counties and districts of Qingyang City. It is the largest loess latform with the thickest soil layer and the best preserved Loess latform, and is called "the first Loess latform in the world". The elevation of surface on Dongzhi loess platform is 1237 ~ 1442m, the elevation of the bottom of the Loess latform is 980 ~ 1112m, and the relative elevation difference is 257 ~ 330m.

Figure 2. Geological profile of Dongzhi loess platform.

As shown in Figure 2, the bottom layer is Upper Neogene mudstone or sandstone, on which there is large thickness of Middle Pleistocene loess of Quaternary system (Q_2^{eol}), and the top layer is shallow Upper Pleistocene loess (Q_3^{eol}). In the gully area of the margin of the loess platform, there are 5 ~ 6m thick landslide accumulation loess and alluvial loess on the surface. The loess in Dongzhi platform has typical characteristics of aeolian loess, with no obvious bedding, high clay content and vertical joint development. In addition, affected by local topographic characteristics, it also has engineering characteristics such as high water content and poor self-stability. Geotechnical parameters are shown in Table 1.

Table 1. Geotechnical parameters of surrounding rock in loess platform.

stratum	Upper Pleistocene clay loess of the Quaternary system (Q_3^{eol})	Middle Pleistocene in the fourth system Clay loess (Q_2^{eol})
thickness /m	10.0~25.0	150.0~190.0

Relation to water level	above	above below

2.2 Shallow buried and slow slope characteristics of tunnels in loess platform

The length of DK182+493 ~ DK280+200 section of Yinxi high-speed railway crosses the Dongzhi loess platform is 97.71km, and the DK207+517.55 ~ DK214+300 section of Shangge-cun tunnel has a total length of 6782.45m, which passes through the loess platform. The maximum buried depth of Shangge-cun tunnel is 102m, the exit is located at surface, and the minimum buried depth is about 5.5m. The longitudinal slope of the tunnel is 25‰, and the buried depth of the exit section, DK211+376 ~ DK214+300, is less than 50m, and 2924m is in the shallow buried section, accounting for 43.11% of the total line length. As shown in Figure 3.

Section DK254+200 ~ DK259+006.36 of Yima Tunnel, with a total length of 4806.36m, enter Dongzhi Loess platform in a downward direction. The maximum buried depth of Yima tunnel is about 122m, the entrance is located at surface, and the minimum buried depth is about 3m. The longitudinal slope, DK254+200 ~ DK254+900, at the entrance of the tunnel is 22.5‰ and the longitudinal slope, DK259+900 ~ DK259+006.36, is 25‰. The buried

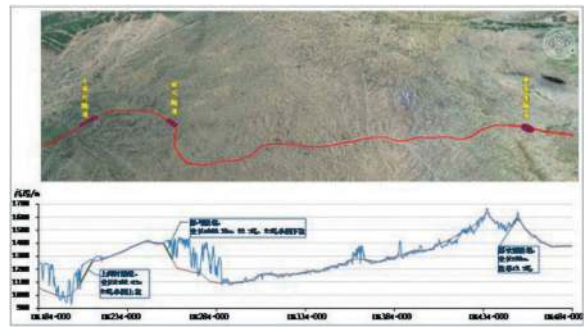

Figure 3. Route diagram of Yinxi high-speed railway crossing Loess platform.

depth, DK254+200 ~ DK255+975, at the entrance is less than 50m, and 1775m is in the shallow buried section. It accounts for 36.93% of the total line length.

3 CRITICAL BURIED DEPTH OF SHALLOW BURIED DEPTH AND GENTLE SLOPE TUNNEL IN LOESS PLATFORM

3.1 Comparison between the calculation of the standard formula of critical depth and the actual buried depth

The Technical Specification for Railway Loess Tunnel (Q/CR 9511-2014) stipulates that the depth of the loess tunnel is 1.4 ~ 2.1 (H+B); New loess (Q_3, Q_4) tunnel deep and shallow buried depth h_c can be upper limit 1.8 ~ 2.1 (H+B); Old loess (Q_1, Q_2) tunnel depth h_c can be lower limit 1.4 ~ 1.7 (H+B).

According to the survey and design data, the excavation height H and width B of the excavated section of Yinxi high-speed railway tunnel are 12.09m and 15.1m respectively. The tunnels in the Loess Tableland are located in the Upper Pleistocene clay loess (Q_3^{eol}) and the Middle Pleistocene clay loess (Q_2^{eol}) of the Quaternary system, among which the DK214+116 ~ DK214+300 tunnels in Shangge-cun are located in the Upper Pleistocene clay loess (Q_3^{eol}). The upper part of DK213+842 ~ DK214+116 is located in Upper Pleistocene clay loess (Q_3^{eol}) of Quaternary system, and the lower part is located in Middle Pleistocene clay loess (Q_2^{eol}) of Quaternary system. Section DK211+000 ~ DK213+842 of Shangge-cun Tunnel and section DK255+440 ~ DK256+281 of Yima Tunnel are located in Q_2^{eol} of Middle Pleistocene system.

According to the Technical Specification for Railway Loess Tunnel (Q/CR 9511-2014), the depth h_c of the deep and shallow buried depth of the tunnel on the Loess Plateau is as follows:

- 1) In the Upper Pleistocene clay loess (Q_3^{eol}) stratum, the depth of DK214+116 ~ DK214+300 section of Shangge-cun Tunnel is $h_c = 48.94 \sim 57.10m$;
- 2) In the Middle Pleistocene clay loess (Q_2^{eol}) stratum of the Fourth system, the deep and shallow buried depth of Shangge-cun Tunnel DK211+000 ~ DK213+842 and Yima Tunnel DK255+440 ~ DK256+281 is $h_c = 38.09 \sim 46.22m$.

The loess platform is flat and open, the stratum soil is uniform and the stratum line is straight. There is no flowing water on the surface, the underground water depth is 50 ~ 70m, and the aquifer thickness is 10 ~ 30m in the exploration depth. The groundwater type is mainly Quaternary unconsolidated layer pore diving, which has both the general characteristics of unconsolidated layer pore diving and the hydraulic properties of fissure water. It is mainly distributed in the top part, and the aquifer is mainly Middle Pleistocene loess.

The pore water recharge of the quaternary loose layer in the tunnel area is mainly vertical infiltration of atmospheric precipitation and lateral and downward infiltration of surface water. According to the actual situation on site, Shangge Village tunnel DK210+884.1 ~ DK210+958.45, tunnel buried depth of 61m, affected by groundwater, tunnel positive hole is located in the soft plastic clay loess layer (Q_2^{col}), as a V-level surrounding rock, normal tunnel excavation still has an impact on the surface deformation. The soil at the top of the tunnel is difficult to form a natural arch, which is still under the influence of construction. The actual buried depth of the tunnel is obviously greater than the critical depth calculated by the standard, as shown in Table 2. Therefore, according to the actual situation, it is necessary to modify the depth h_c of the tunnel in Loess Yuan.

3.2 Correction of the formula of critical depth about tunnel which with shallow buried depth and gentle slope in loess platform

Different from the shallow buried tunnel in loess beam and Loess hill of geomorphic units, the tunnel running through loess platform has certain deviation between the calculated and measured critical depth h_c due to the influence of groundwater and high water content, which needs to be verified and corrected by calculation, simulation and measured values.

1) Derivation of the calculation formula of critical depth h_c for deep and shallow buried tunnels in loess platform

According to the code, the surrounding rock pressure of shallow buried loess tunnel mainly consists of vertical surrounding rock pressure and horizontal surrounding rock pressure, and the vertical surrounding rock pressure directly affects the buried depth of loess tunnel.

Figure 4. Schematic diagram of surrounding rock pressure in shallow buried loess tunnel.

As shown in Figure 4, the calculation formula of vertical surrounding rock pressure is as follows:

$$q = \gamma h - \frac{\lambda \gamma h^2 \tan \theta}{B} \quad (3.1)$$

the formula: γ —Surrounding rock weight, kN/m^3 ;

h —Tunnel depth, m;

λ —Pressure coefficient of tunnel surrounding rock, $\lambda = \frac{\tan \beta - \tan \theta_c}{\tan \beta (1 + \tan \beta (\tan \theta_c - \tan \theta) + \tan \theta_c \tan \theta)}$;

θ —The friction Angle between the two sides of the roof soil column is generally selected according to the experience value of the Design Code for Railway Tunnels, as shown in Table 3;

θ_c —The friction Angle of surrounding rock and the values of each soil layer in Shangge-cun tunnel and Yima tunnel are shown in Table 4;

β —Rupture Angle at maximum thrust,

$$\tan \beta = \tan \theta_c + \sqrt{\frac{(\tan^2 \theta_c + 1) \tan \theta_c}{\tan \theta_c - \tan \theta}}$$

2) Determination of correction factor k of critical depth h_c for deep and shallow buried tunnels in loess platform

By substituting all parameters into equation (3.1), the calculation values of the depth and shallow buried depth h_c of the tunnel in Loess platform when it passes

Table 2. Calculation value and actual buried depth of some tunnel sections in loess platform.

Tunnel name	Paragraph mileage	Surface characteristics	Stratigraphic lithology	The vault is buried deep /m	
				Calculated buried depth	Actual buried depth
Shangge-cun tunnel	DK213+872~DK213+994	Slight fluctuation	Q_3 Clay loess	48.94~57.10	5.6~9.0
	DK213+845~DK213+860	Gentle terrain	Q_3 Clay loess	48.94~57.10	12.8~13.1
	DK210+884~DK210+958	Gentle terrain	Q_3 , Q_2 Clay loess	38.09~46.22	60.9~59.5
	DK210+050~DK210+175	Gentle terrain	Q_3 , Q_2 Clay loess	38.09~46.22	71.1~72.5
Yima tunnel	DK255+440~DK255+450	Gentle terrain	Q_3 , Q_2 Clay loess	38.09~46.22	35.4~35.6
	DK256+260~DK256+281	Large fluctuation	Q_3 , Q_2 Clay loess	38.09~46.22	52.1~58.6

through the Upper Pleistocene clay loess (Q_3^{eol3}) formation, the middle Pleistocene clay loess (Q_3^{eol3}) formation and the Upper Pleistocene sandy loess (Q_3^{eol3}) formation are shown in Table 5.

Table 3. Statistical table of θ values of surrounding rock at all levels.

The level of surrounding rock	I, II, III	IV	V	VI
θ The values	$0.9\theta_c$	$0.7\theta_c \sim 0.9\theta_c$	$0.5\theta_c \sim 0.7\theta_c$	$0.3\theta_c \sim 0.5\theta_c$

Table 4. Statistical table of friction Angle of surrounding rock of shallow buried depth and gentle slope tunnel in loess platform.

Tunnel name	Stratigraphic age	Stratigraphic origin	Soil layer name	Mean friction Angle φ°
Shangge-cun tunnel	Q_3	eol	Clay loess	20.57~23.68
	Q_2	eol	Clay loess	18.60~22.73
Yima tunnel	Q_3	eol	Clay loess	28.64~32.30
	Q_2	eol	Clay loess	18.60~20.21

As can be seen from Figure 4 and formula (3.1), the surrounding rock pressure of the shallow buried loess tunnel is closely related to the depth and width of the tunnel in addition to the weight of the surrounding rock, the coefficient of surrounding rock side pressure, the friction Angle on both sides of the roof and soil column, the friction Angle of surrounding rock, and the fracture Angle of the surrounding rock, etc. In addition, the surrounding rock pressure q is a quadratic function of the tunnel buried depth h . When the surrounding rock pressure reaches a maximum value, the surrounding rock pressure will be reduced to a maximum value. The corresponding buried depth of the tunnel is h_c .

The partial derivative is calculated on the left and right sides of equation (3.1), that is, when $\frac{\partial q}{\partial h} = 0$, the tunnel buried depth obtained is h_c , the depth of deep and shallow buried boundary of loess tunnel.

$$h_c = \frac{B}{2\lambda \tan\theta} \quad (3.2)$$

2) The correction factor k of the critical depth h_c buried in the tunnel in loess platform is determined

By substituting each parameter into equation (3.2), the calculation value of the depth and shallow buried depth h_c of the tunnel in Loess platform can be obtained when it passes through the Upper Pleistocene clay loess (Q_3^{eol3}) formation, the middle Pleistocene clay loess (Q_3^{eol3}) formation and the Upper Pleistocene sandy loess (Q_3^{eol3}) formation.

The critical depth calculated by the empirical formula h_c is obviously less than the actual buried depth when part or all of the tunnel is located in the groundwater table due to the special landform and engineering geological characteristics of the Loess platform. In this case, the critical depth h_c calculated

by equation (3.2) is close to the actual buried depth. When part of the tunnel is located in the water table, the actual buried depth of the tunnel is 49.4 ~ 58.1m, and the calculated critical depth is 56.68 ~ 58.84m. The actual buried depth is 0.87 ~ 0.99 times of the calculated value. When the tunnel is completely below the groundwater level, the actual buried depth of the tunnel is 60.9 ~ 68.0m, the calculated critical depth is 59.53 ~ 60.70m, and the actual buried depth is 1.02 ~ 1.12 times of the calculated value.

Therefore, the determination of critical depth h_c for deep and shallow tunnels in Loess platform can be divided into three cases: above groundwater level, partly in groundwater and below groundwater level.

(1) Determination of the critical depth h_c for deep and shallow burial when the tunnel is located above the groundwater level. According to the empirical formula h_c , the upper limit of the depth h_c of the new loess (Q_3, Q_4) tunnel can be 1.8 ~ 2.1 (H+B). Old loess (Q_1, Q_2) tunnel depth and shallow buried boundary depth h_c recommended lower limit 1.4 ~ 1.7 (H+B);

(2) Determining the critical depth h_c of the deep and shallow buried in the water table of the tunnel part. According to the formula, $h_c = \frac{B}{2\lambda \tan\theta} k$, k is 0.87 ~ 0.99.

(3) To determine the critical depth h_c for the deep and shallow burial of the tunnel below the groundwater level, $h_c = kh_c = \frac{B}{2\lambda \tan\theta} k$, k is derived from the formula, and k is 1.02 ~ 1.12.

Based on the above correction, the critical depth of the tunnel in the Loess platform is 48.9 ~ 58.6m when it is located above the groundwater level, 57.6-60.2 m when part of the tunnel is located in the groundwater, and 61.0 ~ 62.3m when all of the tunnel is located in the groundwater. Therefore, the starting and ending mileage of the shallow buried section of Shangge-cun Tunnel of Yinxi High-Speed Railway is DK210+050 ~ 214+000, and the length is 3950m, which is 58.24% of the total length of the tunnel (the original calculated length is 2924m/43.11%). The starting and ending mileage of the shallow buried section of Yima Tunnel is DK254+320 ~ DK256+737, and the length is 2417m, which is 50.21% of the total length of the tunnel (the original calculated length is 1775m/36.93%), which accords with the original calculation results.

4 VARIATION LAW OF MOISTURE CONTENT IN SURROUNDING ROCK OF SHALLOW BURIED DEPTH AND GENTLE SLOPE TUNNEL IN LOESS PLATFORM

4.1 On-site layout of test components

According to the characteristics of engineering geology and hydrogeology in loess platform and the characteristics of tunnel excavation, representative sections DK256+280, DK255+443 and DK211+493 of Yima Tunnel and Shangge-cun tunnel were selected to study the variation rule of surrounding rock water content.

Figure 5. Layout of full-section test components.

In the whole section, 6 groups of moisture sensors are arranged in the surrounding rock at the position of arch top, left arch waist, right arch waist, left arch foot, right arch foot and arch bottom, as shown in Figure 5.

4.2 Change law of water content of all surrounding rocks in groundwater

Figure 6 shows the variation curve of water content at monitoring points of DK256+280 section of Yima Tunnel. When the tunnel vault is located below the groundwater level, the variation of surrounding rock water content has a certain correlation with the construction process.

Figure 6. Variation curve of water content at monitoring points of DK256+280 section.

Because the tunnel is located in groundwater, the water content is high, among which the water content in the left and right side walls is greater than 32%, the water content in the left and right surrounding rock is 28.1 ~ 29.9%, the water content of the center of the surrounding rock is 25.9%, the water content of the surrounding rock at the lower step is basically less than 30%, and the surrounding rock soil is basically in a soft plastic state. Due to the disturbance of the original soil by excavation, the downward migration of water from the upper arch, the water content at the bottom of the arch and the right arch foot is larger, with an average value of 27.5 ~ 29.1%. Under the influence of groundwater on the tunnel vault, the water content of surrounding rock on the upper step takes longer to reach stability after 28d, while that on the lower step reaches basic stability after 3-9d.

4.3 Change law of moisture content of surrounding rock, when part surrounding rock in groundwater

Figure 7 shows the aging curve of water content of surrounding rock in section DK255+443 of Yima tunnel. In the past 2 months after the excavation of the face of the monitored section, the water content of surrounding rock basically shows a two-stage change law of “gradually increasing first and then leveling off”, namely “increasing period” and “stable period”.

Figure 7. Variation of water content at monitoring points of DK255+443 section.

The water content in the surrounding rocks at the arch roof and the arch waist increased gradually from the initial 16% to 16.6% ~ 19% and then stabilized, with an increase of 1.1% ~ 3.1%. The water content in the surrounding rock at the arch foot and the center of the arch bottom gradually increased from the initial 20% ~ 24% to 26.6% ~ 30.2% and then stabilized, with an increase of 5.6% ~ 7.3%. The growth period is basically within 7 days, and the water content of surrounding rock fluctuates in a small range during the stable period.

4.4 Change law of moisture content of surrounding rock, when the surrounding rock above groundwater

Figure 8 shows the field test results of water content in surrounding rock of DK211+493 section at the Shangge Village Tunnel.

Figure 8. Variation of water content at monitoring points of DK211+493 section.

The water content in surrounding rock represented by this section of tunnel shows certain regularity in time and space. In terms of space, the water content in

surrounding rock varies from 15% to 18.5% at the arch roof and arch waist, and from 22.3% to 24.4% at the invert and arch foot. In terms of time, the initial water content in surrounding rock at the arch foot and the center of the arch bottom increases in a small range, and basically remains unchanged with the initial water content, and only fluctuates in a small range, with the change range generally ranging from 0.3% to 0.8%.

5 KEY CONTROL MEASURES IN THE TUNNEL CONSTRUCTION PROCESS

5.1 *Control measures for comprehensive treatment about foundation of loess tunnel*

Affected by the special landform and geological conditions of loess platform, the exit section of Shangge-cun Tunnel and the entrance section of Yima Tunnel of Yinxi high-speed Railway are both located in collapsible loess layer. According to the foundation treatment principle of shallow buried and gentle slope section of tunnel in loess area, and compared with the foundation treatment method of loess tunnel, replacement filling method and compact-pile method are selected as the foundation treatment methods suitable for the shallow buried section of tunnel of Yinxi high-speed railway in loess platform.

1) Comprehensive treatment measures for foundation replacement in the exit section of shallow buried and gentle slope section of tunnel.

According to the survey data, at the junction of light and dark at the exit of Shangge-cun Tunnel, the loess layer under the foundation does not have collapsibility that between DK214+000 and DK214+150, while the loess layer under the foundation that between DK214+150 and DK214+300 has collapsibility, the thickness is 0.0~2.6m.

In order to ensure the stability of open cave foundation and make the foundation treatment have continuity at the intersection of light and dark, the replacement is used to treat the foundation in DK214+000 ~ DK214+300 sections of all open cave. The thickness of the replacement section is 1.0m, the replacement material is the mixture of lime and soil, and the compaction coefficient is 0.95.

For the excavation section of the shallow buried depth and gentle slope tunnel, when the tunnel base is Q2 clay loess, the foundation bearing capacity is significantly increased by 1.69 ~ 2.37 times after the treatment of the replacement measures with the mixture of lime and soil, and the allowable bearing capacity and the ultimate bearing capacity of the ash filling layer are more than 790kPa and 7.7MPa, respectively. This fully shows that the method of using replacement with the mixture of lime and soil to improve the basement bearing capacity of the shallow buried section of tunnel in Dongzhi loess platform.

2) compaction treatment of foundation at section in entrance of tunnel which is shallow buried depth and gentle slope.

The thickness of the collapsible loess layer under DK254+200 ~ DK254+399 section at the entrance of Yima tunnel is 0.0 ~ 4.9m, and the collapsible loess layer between DK254+399 section and DK254+570 section at the entrance of the dark cave is not collapsible. DK254+200 ~ DK254+375 section used compaction pile with the mixture of lime and soil in the basement treatment.

The compaction pile is arranged in a triangular plane, with a diameter of 0.4m, a pile length of 7.0m, and a pile spacing of 0.8m. The top of the pile is equipped with mat of the mixture with lime and soil, and the material of the compaction pile body is 10% cement improved soil.

In the range of compaction depth, the collapsibility coefficient δ_s of soil that between piles ranges from 0.000 to 0.009, which is less than the limit value of 0.015. The average compaction coefficient η_d of soil between piles ranges from 0.91 to 0.96, which is greater than the limit value of 0.90. Pile compaction coefficient λ_c is 0.97 ~ 0.99, not less than the limit value of 0.97. The unconfined compressive strength q_u of the pile is 1176 ~ 1252kPa, which is greater than the limit value of 1000kPa.

The load test curve of composite foundation is basically a progressive smooth curve. The bearing capacity of composite foundation in the test area of No. I, II and III cement-soil compaction piles is 335kPa, 345kPa and 355kPa, respectively, which are all greater than the design value requirements of 215kPa.

5.2 *The control of compaction with hydraulic high frequency vibration*

Hydraulic high frequency compaction treatment device is mainly composed of base parts, hydraulic exciter, fixture hydraulic cylinder, clip, hole forming device and other components. When hydraulic high frequency vibration compaction is used, the hole formation time of 6m depth is 118 seconds. Construction vibration monitoring shows that the maximum vibration wave velocity occurs within 0 ~ 2m below the base surface, all of which are less than the range of the safe construction control wave velocity of the loess tunnel, and the farther away from the compaction hole, the smaller the vibration wave velocity, and the deeper the working surface from the ground, the greater the attenuation range of vibration wave velocity.

When the diameter of the high frequency vibration compaction pile is $D=300\text{mm}$ and the spacing is 600mm or 750mm, the soil collapsibility between the piles is completely eliminated, the average compaction coefficients η_d are 0.91 and 0.94, respectively, are greater than 0.9, and the minimum compaction coefficients η_{dmin} are 0.89 and 0.93, respectively, are greater than 0.88. Meet the requirements of 《Technical Regulations for Foundation Treatment of Railway Engineering》 (TB 10106-2010, J 1078-2010). When the pile

spacing is 900mm, the minimum densification coefficient η_{dmin} is 0.88, and the average densification coefficient η_d is 0.89, which is less than the standard limit of 0.90. Therefore, when hydraulic high-frequency vibration compaction is used to treat collapsibility loess layer and the hole spacing is $S=2.5D=750\text{mm}$, the compaction effect of foundation soil is the best. In engineering application, the pile spacing can be controlled at 800mm according to the actual field test.

5.3 Control measures for surface grouting to change surrounding rock characteristics

1) Surface grouting design

The average buried depth of DK213+880 ~ DK213+900 in Shangge-cun Tunnel is 6.76m, and the surface has a depression about 3.86m in length. The cracks appear on the surface of the tunnel at DK213+882. In order to ensure the safety of excavation, the treatment of vertical grouting with rigid sleeve valve tube on the surface.

The transverse range of grouting reinforcement is 5m on both sides of the tunnel excavation contour line, the vertical direction is 3m below the vault to 5m above the vault, and the invert bottom to 5m above the vault.

2) Effect analysis of grouting measures

The surrounding rock in the grouting area was experimented with indoor geotechnical tests, and the changes of main physical and mechanical parameters before and after grouting were obtained, as shown in Figure 9.

Figure 9. Comparison of mechanical parameters of surrounding rock in adjacent sections before and after grouting.

As can be seen from Figure 9, the main physical and mechanical parameters of surrounding rock have improved after grouting, the average water content of surrounding rock has decreased from 18% to 16%, and the maximum, minimum and average values of compression modulus, cohesion and other parameters have increased to varying degrees, with their respective average values increasing by about 10% ~ 35%. It shows that the slurry and soil combination formed after surface grouting directly

increases the compactness of surrounding rock itself, improves the strength of surrounding rock as a whole, and significantly improves the stability of surrounding rock.

5.4 Control measures for roof ripping about inclined shaft of soft plastic loess tunnel

1) Technical scheme of key control measures for roof ripping

In the construction of shallow buried tunnels in loess platform, the roof ripping of soft plastic loess tunnels is related to tunnel support and deformation. There is an obvious arch molding area at the intersection, if the strength of structure about intersection support is insufficient, the arch pressure is over-developed, and the surrounding rock will appear settlement, deformation and cracking, and then produce the “closed door” collapse accident in the roof ripping section. Therefore, it is necessary to strengthen the measures of closed-loop support at the inclined shaft lining and intersection, control the excavation process strictly, reserve enough deformation subsidence, strengthen the strict monitoring of the process and improve early warning before the implementation of the roof ripping.

In order to quickly complete the closure of the support system in the cross section of inclined shaft and positive tunnel, based on the experimental study of the key construction technology of the soft plastic loess inclined shaft in the shallow buried section, the beam of steel frame with landing gate type in the positive hole of the intersection section is added, and the technology of the tunnel with advanced support and strengthening support are optimized.

In the monitoring measurement, the main contents are the sinking of arch in inclined shaft, the settling of portal frame, the sinking of vault in the lifting section and the change of headroom. There are 8 observation sections with a longitudinal spacing of 5m, which are arranged in the arch of the strengthening section and the positive hole of the lifting section about the inclined shaft respectively. There are 5 observation points in each section.

2) Effect analysis of key control measures for roof ripping

Figure 10 is the curve with time history about the cumulative settlement of the arch top in inclined shaft No. 1, and Figure 11 is the curve with time history about the cumulative settlement of the arch top at large mileage section in inclined shaft No. 1.

It can be seen from Figure 10 and Figure 11 that: (1) The maximum cumulative Settlement deformation of the arch top at the intersection of inclined shaft and positive hole is 15mm, and the maximum cumulative displacement value of headroom change is 5.4mm. (2) The maximum cumulative settlement value of the gantry at the intersection is 47.3mm, which appears at the section measurement point GD00. (3) The maximum cumulative settlement value of the positive tunnel after the initial support is

Figure 10. The curve with time history about the cumulative settlement of the arch top in inclined shaft.

Figure 11. The curve with time history about the cumulative settlement of the arch top at large mileage section in inclined shaft.

97.6mm, and the maximum cumulative displacement value of intersection headroom change is 49.07mm.

It can be seen from the above analysis that with the excavation of the straight hole at the intersection of inclined shaft, the surrounding rock will produce plastic deformation, and the settlement of the tunnel arch will gradually increase during the excavation of the middle and lower steps. The settlement deformation tends to be stable after the inclined shaft cross gate frame is closed into a ring by compressive composite lining.

6 CONCLUSIONS

- 1) Based on the analysis of engineering geology and hydraulic characteristics of Dongzhi loess platform, combined with the analysis of the buried depth, longitudinal slope and length of Shangge-cun Tunnel and Yima tunnel respectively, the tunnel whose longitudinal slope is greater than 10% and buried depth is less than 50m is defined as a shallow buried depth and gentle slope tunnel in Loess platform.
- 2) Based on the characteristics of groundwater level in loess platform, experiment in lab and field, the load calculation method of large-section tunnel in soft plastic loess stratum is proposed, and the corresponding load distribution model of surrounding rock is determined. For the condition that part or all of the tunnels in the Loess platform are located in groundwater, the correction formula of the critical burial depth is derived as $h_c k$, and the classification range of the coefficient

k value is limited (0.91 ~ 0.98 for part of the tunnels in groundwater, 1.0 ~ 1.09 for all the tunnels in groundwater).

- 3) According to the changes of water content about surrounding rock in different strata of tunnels in Loess Plateau, the variation trends of time and space is "increasing period" and "stabilizing period" of water content with time were obtained, and the increasing period of water content about surrounding rock in different lithologies was determined to be 10 ~ 15 days.
- 4) When treating the basement of the shallow buried depth and gentle slope section in the loess platform, factors such as the layering position and thickness of collapsible loess layer, collapsible grade and extent of loess under the tunnel basement, foundation treatment method and treatment depth should be considered in combination with the engineering geological characteristics of loess. Accordingly, comprehensive treatment measures such as replacement and precompression, impact compaction pile treatment, and high frequency vibration controllable compaction treatment with hydraulic should be adopted. During the construction of the shallow buried depth and gentle slope section of loess tunnel, the physical and mechanical parameters of surrounding rock are significantly improved after the prevention and control measures of changing the characteristics of surrounding rock by advance grouting, with an average increase of 10% ~ 35%, which improves the strength and overall stability of surrounding rock.
- 5) After the special measures of roof ripping in inclined shaft, the maximum cumulative settlement value of arch top is 15mm at the intersection of initial support about strengthening section of inclined shaft, and the maximum cumulative displacement value of headroom change at intersection is 5.4mm; The maximum cumulative settlement value of the cross-port door frame is 47.3mm; The maximum cumulative settlement value of the initial support of the positive tunnel is 97.6mm, and the maximum cumulative displacement value of intersection clearance is 49.07mm. The settlement deformation tends to be stable after the inclined shaft cross gate frame is closed into a ring by compressive composite lining.

Construction procedures of the tunnel for the extension works of Madrid Metro Line 3 from Villaverde Alto to El Casar

Miguel Núñez

Doctor Civil Engineer, General Manager of Collective Transport Infrastructures of Community of Madrid, Spain

Jesús Zurdo

Civil Engineer, General Direction of Collective Transport Infrastructures of Community of Madrid, Spain

ABSTRACT: The extension of Line 3 of the Madrid Metro to El Casar includes the construction work of the infrastructure necessary for operation, including the execution of the double-track underground section that, starting from the current end of the tunnel in Villaverde, will reach El Casar. allowing the connection with the Line 12 station (MetroSur) and the Cercanías Line C3 station, in Getafe. Among these works, the construction of a new station and 2,600 m of tunnel is currently being carried out. Given the compactness of the materials present in this section, with the presence of crystallized gypsum in a considerable proportion, part of said tunnel is being carried out with the Madrid Sequential Excavation Method (MSEM). This construction procedure is based on systems widely used in areas with materials that are more similar to those found in this section. The system uses flexible support through the application of shotcrete on the contour of the excavation and the collaboration of perimeter metal trusses. This type of procedure is favored by the layout of the tunnel, far from buildings and, above all, by the nature of the terrain, which has high compactness and resistance, which allows this method to be used without reducing the level of safety or causing any damage. to nearby structures. The performance achieved after applying this procedure are 3 - 4 passes per day (1m each), carrying out work on the fronts 24 hours a day from Monday to Friday and concreting the invert on the weekend, which represents a monthly advance of about 60-80 m per front.

Keywords: underground, Tunnel, Construction methods

1 INTRODUCTION

The construction works for the extension of the Madrid Metro Line 3 to El Casar are made up of a double track underground section that, starting from the current end of the tunnel in Villaverde, will reach the height of the Suburban C3 line and MetroSur El Casar stations in Getafe, with which it will interconnect. For this, a new station and 2600 m of tunnel are being constructed.

The tunnel is being constructed using three construction procedures depending on various factors, among which can be highlighted depth, geological-geotechnical characteristics of the excavated ground, construction performance, works safety, etc.

These procedures are the:

1. Cut and cover method

Figure 1. Typical cross section cut and cover method.

2. Belgian or Traditional Madrid Method

Figure 2. Section type traditional madrid method.

3. Madrid Sequential excavation Method

Figure 3. Section type madrid sequential excavation method.

2 CUT AND COVER TUNNEL CONSTRUCTION

If the tunnel grade level is at a shallow depth, a cut-and-cover tunnel is constructed between diaphragm walls, as it is not advisable to bore a tunnel with small overburden depth. This is the case of the section that will access the future line 3 station at El Casar, and the end-of-line for shunting after the station. At some 200 m from the start of the works, a complex geological section was detected in which materials of anthropogenic origin are overlaid, which are alluvial material with water flow, altered green clays, other clays and gypsums. To cross these materials with a mined tunnel would require prior treatment of the ground, therefore it was considered safer to cross them using the cut-and-cover method between diaphragm walls with a prior cutting of the ground.

The construction procedure consists of the digging of two side trenches in which are installed diaphragm walls on which a reinforced concrete slab will be constructed that will form the tunnel roof. This slab can either be build on the levelled ground between the crowning of the retaining walls and, after its hardening, the excavation can be started below the slab or open-cut excavation carried out between the walls, floor slabs then constructed, and the excavation covered with a roof and the original ground surface replaced. Both approaches are used

for the tunnel for the extension of Line 3 to El Casar: the first allows the replacement of the surface to be progressed while the tunnel is executed underneath, while the second is necessary at excavation machinery entrances where temporary ramps are form from the outer surface.

The construction sequence in the case of covering before excavating the tunnel consists of the following phases:

Preparation of the work platform.

Figure 4. Phase 1 cut and cover.

Construction of guide stub walls and the retaining walls.

Figure 5. Phase 2 cut and cover.

Excavation and preparation of the ground at the cover slab support level.

Figure 6. Phase 3 cut and cover.

Positioning of rebar and concreting of the cover slab.

Figure 7. Phase 4 cut and cover.
