Figure 15. In-situ plate load test.

5 CONCLUSION

This paper has covered the experience of design development and construction of deep powerhouse cavern of Snowy 2.0 project from the owner's engineer perspective. In structured ground with elevated in-situ stress, the global stability of excavation governed by the layout of the caverns and IPB galleries is the primary consideration. The post failure behaviour of rock mass is playing an important role in the stability assessment. The rock reinforcement is designed as the main support element maintaining the temporary and permanent stability. The failure mechanism is discontinuity-controlled, and the rock

bolt performance is governed by bolt shear and strain-based criteria established. Rock bolt pre-production laboratory tests (Double shear tests and Double embedment elongation tests) are developed to verify the performance of bolt under the proposed acceptance criteria. Risk control by applying observational method to confirm the actual conditions within the range of design predictions. With the back-analysis of numerical modelling based on the encountered rock features and ground response observed, critical areas with special attention/additional support measures or re-bolting can be identified and properly managed.

Minimising impacts on the local habitat in relocation and construction of a large cavern for track crossover at Acharya Atre Chowk Metro Station of the Colaba-Bandra-Seepz (Line 3) in Mumbai, India

Subodh Kumar Gupta*, Rajeshkumar Mittal, Maheshkumar Dange & Rohit Tilak
Mumbai Metro Rail Corporation Limited, Mumbai, India

ABSTRACT: Mumbai Metro Rail Corporation Ltd is implementing Colaba-Bandra-Seepz (Line 3), a 33.5 Km fully underground metro rail project, in Mumbai, India. The landscape of Mumbai has been formed over a period by joining seven islands through multiple land reclamations in the 19th century. The Line 3 is substantially in South Mumbai, which is the old and historic part of the city. It is a narrow land mass and congested, with sea/creek on three sides. Road space is less compared to the population density and traffic congestions are norm rather than exception. As a result, major underground intervention is challenging on technical, social, and logistic grounds. In the approved project, track crossover was part planned at the Science Museum Station. However, at execution stage, local authorities refused permission for excavation of the portion of this area due to its potential impacts on a major civic water tunnel that was passing beneath and reservations to relocation of underground grid cables of 220 KV infringing the site. This resulted in exploration of either an alternative method of construction at the planned location or relocation of the crossover nearby to meet operational needs. The adjoining station of Acharya Atre Chowk was also a difficult site, being constructed in a residential and commercial locality and below a busy major arterial road with a junction of 5 roads on one side. There were massive civic utilities limiting further elongation of the station box to accommodate the crossover. This paper explores alternate options examined to arrive at the most appropriate solution. It delves into how, working closely with local community and technical experts, the finalised option of a large cavern was designed and executed in a sustainable way by minimizing social impacts on the local habitat while meeting the operational requirements expected from the crossover.

Keywords: NATM, Metro3, Crossover, Turnouts, Mumbai

1 INTRODUCTION

Mumbai Metro Rail Corporation Ltd, a Joint Venture company of Government of India and the Government of Maharashtra state, has undertaken Colaba-Bandra-SEEPZ (Line-3) Metro line construction in Mumbai, India. Civil infrastructure construction work of this 33.5 Km long fully underground line is divided in seven contract packages. The subject work is part of Package 03 of these seven packages and being implemented by a joint venture of M/s Doğu İnşaat ve Ticaret A.Ş(Turkey) and M/s Soma Enterprise Limited(India).

A crossover cavern of 106m length, 11m high and 18m wide has been constructed below E. Moses Road between under-construction Science Museum and Acharya Atre Chowk Stations. This road carries heavy city traffic. A crossover is a track structure that permits transfer of trains from one line to another and is an operational necessity. There are

limitations related to curves and slopes/grades in the track alignment that have to be factored in to locate a crossover.

This location of track crossover was not originally envisaged at this location and, in a way, was fait-accompli as no other alternative location could be found within acceptable operational parameters after the authorities refused permissions for construction for this facility at the original location. Also crossover could not be shifted adjacent to Acharya Atre Chowk due to presence of junction of five roads with massive utilities beneath it. Construction of cavern for the crossover at this location faced challenges of shallow ground water table, highly weathered to moderately weathered rock strata (Breccia), presence of civic utilities and high-rise buildings in close vicinity. The site would also have had negative impact on local habitat if proper precautions were not taken during implementation due to its being in the midst of residential and commercial localities, and a crematorium.

*Corresponding author: subodh.gupta@mmrcl.com

2 ORIGINAL PLAN

As per original proposal in the Contract, the crossover structure is planned at the north end of the Science Museum Station, Mumbai, India with Cut and Cover construction method. The crossover structure is planned to be a part of the main station box structure. The length of station box was indicated to be 363m out of which 162m length was allocated to the crossover. The box structure is placed on either side of a T-shaped road junction called Rakhangi Junction and crossover is planned at one end of it. Multiple entry/exit structures are planned on either side of the roads of the T-shaped junction. Extent of civic utilities at this junction is highlighted in the inset.

Figure 1. Location plan for station and crossover.

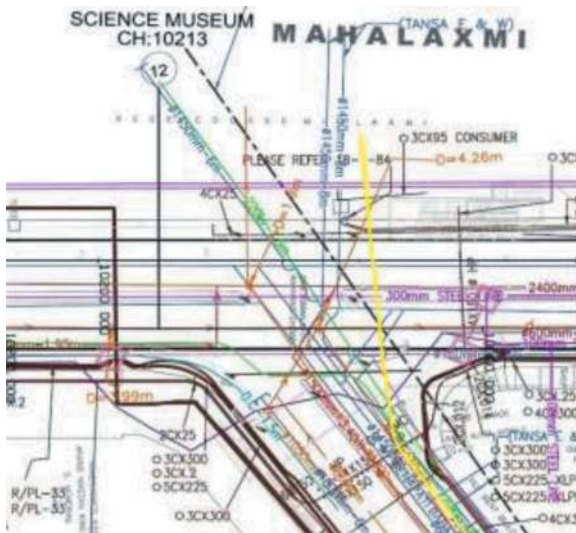

Figure 2. Science Museum Station vis-a-vis Rakhangi Junction. Civic utilities at the junction shown in the inset.

After the contract was awarded and utility management scheme was finalised and submitted to the utility owning agencies, two reservations from authorities were received. There were other impediments also to deal with as below:

- 1) Local Municipal Corporation advised shifting of station box away from their 45 m deep water

main tunnel that was crossing the site due to its potential effect on the structural safety of this water main. [Pressurized water main tunnel of 6m diameter, M 20, 300 mm RCC Concrete lining, water pressure of 12 bar]

- 2) Local power distribution authorities communicated their inability to divert 220 KV power cables passing at shallow depth from this site.
- 3) A 9 m wide double barrel RCC box barrel drain at the junction of Rakhangi chowk cannot be laterally shifted due to other obligatory civic utilities.
- 4) Area had many trees that had to be factored in to avoid felling.
- 5) Underground tanks of a Petrol pump to be relocated.

There is a hospital for old age people, a Christian and Muslim cemetery on one side while a Racecourse on the other.

In view of various conflicting limitations and complexities the Employer (MMRC) and the General Consultants explored various options proposed by the contractors and decided to shift the Science Museum station about 350m away from the Rakhangi junction towards north from the existing location without the crossover component to reduce its longitudinal length. It was also decided to shift the crossover to the adjoining station by making modifications in the existing plans of that station.

This paper will now discuss various alternatives that were explored to arrive at above decisions.

3 SOLUTIONS PROPOSED

Option 1: Rakhangi junction area to be crossed with a NATM structure of 136 m length for crossover while the main station box structure shifted by 350 m towards North.

Figure 3. Conceptual plan for option 1.

Geological conditions at this location – on same location, methodology of construction has been modified from Cut & Cover to NATM with similar geological conditions.

Advantages – Minimum land acquisition, minimum tree felling, minimum impact on traffic, minimum utilities diversion.

Disadvantages –

- 1) Likely higher settlement due larger crossover cavern in weaker ground.
- 2) Longer construction timeline due to related impacts on TBM scheduling for the remaining tunnel length.
- 3) More bureaucratic reservations and complexities in monitoring of the water main tunnel that would now have been below the cavern instead of initial concept of Cut and Cover box.
- 4) Logistic limitations as station portion also to be utilised as the access shaft for the NATM cavern thus having adverse impact on the project timelines.

Option 2: Crossover to be shifted towards South of the Rakhangi junction, junction area to be crossed with two individual NATM tunnels and the Station box shifted towards North.

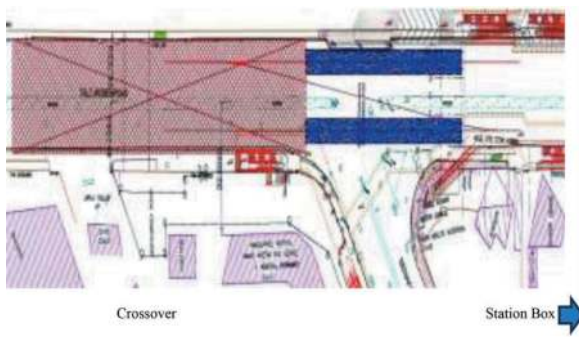

Figure 4. Conceptual plan for option 2.

Advantages – Simultaneous construction of NATM Tunnels from either side, ease of construction and logistic movement.

Disadvantages –

- 1) Longer construction timelines due to sequencing of NATM tunnel and Cut & Cover structure of the crossover.
- 2) A separate TBM shafts for undertaking tunneling between the crossover and up to Mumbai Central Metro Station towards south.
- 3) Water main tunnel safety related concerns still remains for the municipal authorities even though the cavern size has reduced.
- 4) Logistic limitations as station portion also to be utilised as the access shaft for the NATM cavern thus having adverse impact on the project timelines.
- 5) Higher costs due to additional NATM and Cut & Cover construction for crossover and tunnel.
- 6) Sufficient space not available to divert 9 m wide double barrel storm water drain. Traffic diversion sequence to be complex due to space constraints.

Option 3: A staggered scissor crossover by widening a TBM tunnel by NATM (Downline-169.28 m, Upline-114.16 m) on the south end of the adjoining Acharya Atre Chowk Station

Figure 5. Conceptual plan for option 3.

Geological at the location is predominantly Grade III & IV Breccia weathered rock.

Advantages – Location below the road. No tree felling, no impact on traffic, no utilities diversion.

Disadvantages –

- 1) NATM cavern with variable tunnel profile and higher number of construction stages
- 2) for logistic movement, no separate access is available for construction of NATM cavern. Station (Cut & Cover) to be utilised as the access shaft affecting project timelines.

Option 4: Crossover cavern in the mid-section by widening the TBM tunnels by NATM between the Science Museum and Acharya Atre Chowk Station to have a single cavern for both the tracks.

Figure 6. Conceptual plan for option 4.

It is similar to the Option 3 except that the crossover was moved midsection to have benefit of marginally better geological conditions to contain settlement on the surface. Advantages/disadvantages in this Option were same as of the Option 3.

Option 5: Crossover cavern in the mid-section by widening a TBM tunnel by NATM between the Science Museum and Acharya Atre Chowk Station with a logistic shaft on the median area of the road. This is to be a single cavern for both the tracks.

A shaft at the site of NATM cavern would remove logistical and timeline constraint to a large extent as against Option 3, 4 and 5 but still pose problems of traffic management and handling of construction logistics from a small shaft in the middle of the road even if a component of road is taken over for construction purposes.

Figure 7. Conceptual plan for option 5.

Option 6: Crossover cavern near the Acharya Atre Chowk station by widening a TBM tunnel by NATM with a logistic shaft on the footpath of the road.

Figure 8. Conceptual Plan for Option 6.

This option is considered superior to the previous option in terms of handling traffic and construction logistics even though few trees on the kerb side would be affected and were to be fell.

Option 7: Crossover cavern of 106 m length near the Acharya Atre Chowk station by widening a TBM tunnel by NATM with a logistic shaft the adjoining plot owned by the Municipality and agreed to be given on temporary basis. This is to be a single cavern for both the tracks.

Figure 9. Conceptual plan for option 7.

An appropriately sized vacant plot, belonging to the Municipality for a future requirement of the Worli cemetery, was identified. Authorities agreed to spare the plot temporarily for the purpose of the shaft and for managing construction logistics.

By further optimisation in the metro track alignment the UP-Line tracks were brought closer to the Down Line Track. This helped in reducing the cavern size as well as in reducing the length of the crossover, thereby that of the cavern.

Advantages-No utilities, no impact on traffic being away, no interdependencies on construction sequence for shaft, TBM tunnel work or with the adjoining station construction.

Disadvantages- bureaucratic delay for land

Result of examination of various options led to selection of the most suitable size and location for crossover. This resulted into a solution that was beneficial because of no utilities were to be tackled, no traffic diversion to be implemented and the logistic management was easier. Dependency of construction of cavern on the TBM tunnelling and that of the station was also avoided.

Figure 13. Crossover end wall shotcrete.

Figure 17. Final NATM cavern.

Figure 14. Waterproofing & rebar work in progress.

Figure 15. Overt rebar fixing work in progress.

4 CONCLUSION

The fate-accomplish situation resulted from the concerns of the municipal authority could be addressed in the most optimum method by analysing 7 options and selecting the most appropriate one, i.e. **Option 7** by a fairly joint effort by the Employer, the Contractors and the General Consultants. The Crossover cavern construction works has been completed and the experience during construction ratified the assumptions. The entire Metro Line 3 works will be completed by July 2024.

The project could be done with least impacts on the local habitat, civic utilities and other facilities like cemeteries, which were all factored in while taking the decision and thus contributed in sustainable development and preservation of local ecosystems.

Innovation practice of indoor space of rail transit hub

Liwei Ji*, Yanqiao Li & Kaiqi Wei
China Railway Design Corporation, Tianjin, China

Yongzhong Deng & Yongyu Fu
Shenzhen Metro Construction Group Co., Ltd, Shenzhen, China

ABSTRACT: With the development of the city, the development of underground space and the construction of underground buildings are paid more and more attention. In the past, the underground space represented by the subway station is often low, narrow, cold, damp, the space shape is uniform, the demand of urban space development and the limitation of space environment form a distinct contradiction. Rail transit hub is the urban transportation function body most closely connected with the city. It provides travel services for a large number of citizens every day. Its large volume, long construction cycle, large investment and long service life, which has a profound impact on urban development. Its architectural space is in urgent need of further innovation to provide high-quality travel services for citizens. Based on the construction practice of Huangmugang Hub and Gangxiabei hub, this paper summarizes the design experience from the aspects of underground building lighting, building space configuration, and green plant planting, so as to provide reference for the innovation of indoor space of underground buildings.

Keywords: Rail transit, Indoor space, identifiability, Natural environment

1 FOREWORD

At present, the construction of large transportation hub in China is in the stage of rapid development, and the corresponding demand for underground space development and utilization is increasing. The scientific and reasonable utilization of urban underground space can effectively relieve the tension of urban ground space. As a space resource with huge potential in the city, the construction of rail transit hub also makes the underground space more deeply integrated into the urban space system. Facing the vision of sustainable development of urban space, how to establish an efficient, high-quality and three-dimensional underground space and improve people's use experience has become one of the problems that need to be considered recently. Based on the construction examples of Shenzhen Huangmugang hub and Gangxiabei hub, this paper analyzes the interior space design of underground hub station, and provides case reference and innovative experience for the space construction of urban underground rail transit hub.

global intelligent terminal innovation center and Bagualing financial technology center, the original regional transportation was five road cross and four layer overpass, with complex traffic organization, severe urban fragmentation, difficulty for citizens to cross the street, and prominent travel safety issues, which have had a significant impact on the urban landscape and citizens' lives.

Figure 1. Location map of Huangmugang Hub.

2 PROJECT OVERVIEW

Huangmugang transportation hub project is located in Futian District, the central urban area of Shenzhen. It is an important transportation node serving Huaqiang-step

In order to optimize city function of the area, improve the traffic efficiency in the area, build high quality of urban development space, the municipal

*Corresponding author: 18824652@qq.com

government decided to take advantage of the construction of the Huangmugang subway on Line 14 to demolish the Huangmugang overpass, and comprehensively improve the municipal transportation (road and rail transportation), land use, slow system for comprehensive improvement. The emergence of transportation hub plays an extremely important role in the optimal allocation of transportation resources, the construction of urban landscape and the service experience of citizen life. At the same time, important infrastructure projects such as the Shenzhen Sports Center, the Second People's Hospital, and Huafu Village around the area have included expansion and renovation projects in the planning and construction, which will inevitably enhance the future transportation demand of the area. Driven by these dual updates, Shenzhen is coordinating the development of tracks, roads, surrounding plots, and underground spaces, striving to build a new era urban hub that is ecological green, open and coordinated, and integrated with stations and cities.

Figure 2. Situation of the base before construction.

Figure 3. Future hub and urban living room.

3 CURRENT SITUATION AND DESIGN IDEAS

3.1 Analysis of the hub status quo

The surrounding environment of Huangmugang Hub is complex, including schools, hospitals, sports centers, large communities, parks, office buildings, etc. The above-ground traffic is a four-storey overpass, and the underground traffic is Metro Line 7. Due to the existence of the interchange, the urban function and landscape in the whole area, the slow traffic system is poor, the mixed traffic situation of people and cars is serious, and the connection between the

subway and other surrounding facilities is not smooth, which cannot be well supplemented.

Figure 4. Poor slow traffic system.

Figure 5. Severe mixed traffic of people and vehicles.

Figure 6. Urban landscape fragmentation.

In addition, the Sports Center of the city around the hub will be expanded, and the expansion project will be positioned as the high-level competition center in the Pearl River Delta and the leisure and fitness center serving the citizens; the beds of the reconstruction project of the Second People's hospital will be increased from 1500 beds to 2500 beds, and the shantytown reconstruction project of Huafu Village will implement the requirements of expanding industrial space and enriching the industrial supporting facilities of residential area, and the important urban renewal project to promote the integration of industry and city. Therefore, the hub construction should be closely combined with the surrounding urban renewal, to shape a fusion of urban functions.

3.2 Design ideas

In response to a series of current problems, we are considering how to reduce the number of ground structures while ensuring traffic flow during design, and ensure smooth operation of the slow moving system? How to improve the area environment, enhance the vitality of the area, and maximize the urban efficiency through the hub construction? We incorporate the TOD concept into the construction of

the hub, shape the design concept of “Quality Oriented Development”, and sort out the elements of the area from both the above ground and underground parts, breaking them down one by one. We propose corresponding strategies and implementation plans, and ultimately build the hub as a new node in the area, enhancing the charm of urban space and improving the travel experience of citizens, promoting high-quality urban development.

Firstly, in order to achieve Quality Oriented Development, we have implemented a series of development strategies for the over-ground space: (1) Lightweight the ground building. As an urban hub, it is necessary to consider whether the need to strengthen the presence of the hub based on the surrounding environment. The urban buildings around Huangmugang Hub area are dense. In order to fit the whole construction environment, the ground buildings should be minimized as far as possible to ensure the open and smooth vision of the area. (2) Establish a new image. Due to the fact that Huangmugang Hub is located at the intersection of five cross roads, as the gathering point of the roads, the image of the hub can enhance the attractiveness of the area, so as to play a role in driving the social and economic benefits of the area. (3) Build a green ecological network. The spatial form in the southeast and northwest of the area where Huangmugang Hub is located is long and narrow and has a sense of extension. We can introduce green plants in various directions and extend to the surrounding ecological parks to achieve a green axis network, and rely on the green axis to build a slow traffic system in the area, achieving the experience of citizens traveling under green shade.

Secondly, in order to improve the traffic function, avoid the adverse effects of ground structures on the underground space, and create a new form of underground space, we have implemented a series of development strategies for the underground space: (1) Strengthen the traffic nodes, improve the walking environment of the underground core space, and build open three-dimensional traffic nodes. (2) Strengthen the mobility of returning, connect the underground with the above-ground space through the sunken square, improve the walking space environment on the ground, and achieve the return tour through the underground space, thereby promoting the enhancement of urban vitality integration of urban functions. (3) Urban functional integration. Combined with the various urban functions around the hub, the underground space and the sunken square, so as to achieve the complementary effect of space shaping and promote the process of urban renewal around the hub.

Finally, we aim to build a model of urban renewal and create a vibrant city as the means to create an innovative space that blooms the senses of citizens.

4 STRUCTURE SHAPING IN SPACE

Combined with the design concept and the current situation of the hub, we reconstructed the traffic organization of the area. By adopting the three-layer

traffic mode of the upper bridge, the ground traffic and the lower tunnel, we created the slow traffic system space underground, so as to improve the travel environment of the citizens in the area.

Figure 7. Schematic diagram of slow traffic in the base before construction.

Figure 8. Schematic diagrams for improving slow traffic.

From the perspective of shaping the underground space of the hub, due to the closed and introverted characteristics of the underground space, we should pay attention to the open design in the space design, so that each space can penetrate into each other and broaden the space boundary. The internal space of Huangmugang hub is easy to be blocked and lifeless because the vertical and horizontal direction is set up with the underpass tunnel and the upper span bridge. In order to improve this situation, we innovate in the design of ground bridge and sunken tunnel, open the middle area, and set up a skylight in combination with the ground environment, so that sunlight can reach the internal space of the hub through the bridge, ground and tunnel to the hub of the internal space. In addition, in order to achieve the further openness of the space, in the vertical design, each layer is equipped with a continuous atrium, so that the space and space penetrate, expand the openness of the space, and also make the sunlight throughout the underground space through the atrium, so as to reduce the sense of closure of the underground space. In the horizontal direction, the transfer hall of Huangmugang hub is surrounded by sunken squares, the fire glass between indoor and outdoor area, make indoor and outdoor contact on the line of sight, to broaden the boundary of the space. It also makes the citizens through the sunken square to complete the ground underground slow traffic system space back, improve citizens travel experience. A variety of design elements and techniques are combined to create a tall and extended open space, greatly alleviating the sense of depression of the space.

As a transportation hub space, in addition to considering the openness of space, identifiability is also one of the elements of space design. It can be convenient for pedestrians to judge the direction in the open space, so as to improve the efficiency of passengers. The improvement of spatial identification

Figure 9. Design mentality 1.

Figure 10. Design mentality 2.

Figure 11. Real scene of sunken square of Huangmugang Hub.

Figure 12. Real scene of atrium space of Huangmugang Hub.

can be accomplished either by shaping the nodal space or by adopting special construction elements. In the space design of Huangmugang hub, the east-west fish belly shaped sinking tunnel is incorporated into the space according to local conditions, formed a suspended inter-layer running through the

underground layer of the whole junction. And connect it to the fourth layer of rectangular platform form underground, naturally formed the east-west V-pillar support system. The V-pillar runs through the entire transportation space of the first to fourth underground layers, making it one of the most distinctive structural elements of Huangmugang Hub. It not only shapes a charming spatial structure, but also improves the recognition of the hub space, allowing passengers to determine their location and destination direction through the position of the V-pillar on any floor, greatly improving passenger travel efficiency and achieving a balance between open space and directional space required for transportation.

Figure 13. Real view of V-pillar of Huangmugang Hub.

Figure 14. V-pillar formation and atrium formation process.

5 CONSTRUCTION OF THE INDOOR MICRO-ENVIRONMENT

Underground space itself is closed and easily detached from natural elements. Therefore, the design of underground space environment should fully consider human needs, pay attention to the introduction of natural elements, create a pleasant underground space environment, and reduce the sense of difference of indoor and outdoor transition as far as possible.

5.1 Light introduction into the transit hub

Introducing natural light into underground space design is one of the commonly used space design techniques. We have also fully considered the impact

of natural light on the environment in the design of the Huangmugang Hub and Gangxiabei Hub. We have set up skylights as much as possible and set up sunken squares, introducing a large amount of natural light from the entrance and top of the hub, allowing people to feel the changes in the spatial environment brought about by sunlight in the underground space, and experience the atmosphere of the natural environment like standing on the ground.

Figure 15. Location of skylight location of Gangxiabei Hub.

Figure 16. Annual average quantity analysis of the first and four underground layers of Huangmugang Hub.

5.2 Bring in the wind into the transit hub

Underground space compared with the ground environment has thermal stability, but due to the rock and soil characteristics, condensation water is easily generated inside the structure, giving people a feeling of dampness. Moreover, the air flow in underground spaces is generally poor. Therefore, air conditioning systems are often used in modern rail transit underground hub spaces to regulate indoor temperature and humidity, reducing discomfort. In the design process of Huangmugang Hub, we fully considered the differences in air between the above ground and underground spaces. Multiple sunken squares were installed around the large space, and the upper part was equipped with openable skylights to encourage outdoor air to enter the room and form convection, thereby generating wind and alleviating the dull feeling of the space itself.

5.3 Introduce the green into the transit hub

In addition to the introduction of natural light and air, the introduction of green plant landscapes is also an important means to enhance the ground feel of underground spaces. It extends the natural environment outside the building in the form of landscape green plants into the underground space environment,

Figure 17. Schematic diagram of “bringing the wind into the city” of Huangmugang Hub.

blurring the boundary between indoor and outdoor humanities and nature, reducing the sense of isolation between indoor and outdoor spaces, and enhancing people’s sense of scale identification with open spaces. In the design of the Huangmugang Hub, the introduction of green plants is also an important means of establishing a connection with nature. By utilizing the light resources brought by skylights, simulating and analyzing the light angle and intensity, plant varieties and planting environment, more than 30 types of green plants were planted indoors, with a planting area of 1200square meters. A miniature garden landscape was constructed, and combined with the atrium space, the ecological functions of plants were utilized. At the same time, it form a staggered layout of green plant planting, establish a healthy and natural green system in the underground environment, improve the comfort of the space, break the concept of indoor and outdoor, and create a comfortable ecological environment for waiting for cars under the shade of green.

Figure 18. Schematic diagram of green plant planting in Huangmugang Hub.

6 SUMMARY

As an important mode of transportation, rail transit is increasingly infiltrating people’s lives. As a gateway to the area and even the city, rail transit hubs are gradually moving towards a trend of functional diversification and integration, with the goal of meeting the travel needs of users. This has achieved the coordinated layout and efficient operation of various functional spaces in the hub area. The internal

Figure 19. Micro-environment construction of Huangmugang Hub.

Figure 20. Relationship between green plant planting and skylight and atrium in Huangmugang Hub.

environment serves as an important catalyst for people's experience and feedback perception, and space design and innovation are urgent. In the space design of Huangmugang Hub and Gangxiabei Hub, we have combined the inherent conditions of the underground hub to create an open and recognizable transportation space. At the same time, we fully consider the environmental characteristics of underground buildings, and from the perspective of people's psychological needs. We adjust the indoor micro-environment to improve the lack of natural light, lack of air circulation, and monotony of space, attempting to create a space atmosphere that is indistinguishable above and below the ground. At the same time, exploring the development and utilization direction of underground resources also hopes to provide beneficial references for the high-quality development of large transportation hub areas in China.

Hexane section and its section combination honeycomb type underground structure system. Design and implementation of the program study

Qianou Jiao, Lin Guo* & Wenjie Chen

China Railway Shanghai Design Institute Group Corporation Limited Tianjin Branch., Tianjin, China

ABSTRACT: In view of the current domestic and abroad underground project due to the lack of overall planning, design and construction and form a single section, mutual sharing, its system lead to underground space, low utilization rate, zipper excavation, put forward a new hexagon section and by its section combination honeycomb underground engineering structure system design scheme. Comprehensive use of numerical simulation, model test, theory derivation and other means, the hexagonal section and section combination honeycomb underground engineering structure system simulation analysis, and the traditional underground engineering system structure stress, economic and functional analysis, put forward all kinds of honeycomb underground engineering system applicable scope and conditions, design and calculation method and feasible construction scheme, to guide the engineering application of the structure system.

Keywords: hexagon, honeycomb underground structure system, double and multiple compartments, correction coefficient, prefabricated segments

1 INTRODUCTION

With the rapid development of society and economy and the continuous intensification of the urbanization process, the contradiction between urban development and the shortage of land resources is more prominent. The development and utilization of urban underground space resources has become one of the important directions of the social sustainable development, especially in the urban rail transit and municipal pipeline laying. At present, the design sections of underground tunnel and comprehensive pipe gallery in China are mostly rectangular or circular sections, in which the circular section is more reasonable, with small thickness, and the section space is wasted, but the force is poor, especially the corner and cross parts, so thick beams and large reinforcement are needed. The advantages and disadvantages of circular and rectangular conventional sections are relatively obvious, which cannot achieve a better balance in force and space utilization. At the same time, the phased implementation of multi-line interval, especially for the near construction of double circle and multi-round tunnel, it is necessary to take protection measures for their respective projects and reserve enough safe distance, which will cause a lot of waste for underground engineering quantity and space. In order to realize the underground tunnel and comprehensive pipe gallery structure stress and space utilization balance, improve the overall structure performance at the same time reduce cost, realize the intensification of underground space utilization and the optimization

of underground engineering construction process, can the traditional pipeline “plane staggered layout” into “three-dimensional centralized layout”, greatly increase the utilization efficiency of underground space. Mr. Qian Qihu, an academician of the Chinese Academy of Engineering, once wrote that “the underground comprehensive pipe corridor is of great significance to promoting the new urbanization, strengthening the shortcomings of urban infrastructure, and realizing the transformation of urban development mode”^[1].

In nature, honeycomb is hexagonal in nature, and theory proves that this form uses the least material, occupies the largest spatial area, and has the best structural stability^[2]. Therefore, we proposed the honeycomb underground engineering structure system of hexagonal section and its section combination, mainly including single cabin hexagonal structure, upper and lower double cabin combined structure, four cabin combined structure, seven cabin combined structure, etc. This paper will focus on the combined structure of hexagonal single cabin and four cabin.

2 FORCE STUDY OF THE HEXAGONAL STRUCTURE

2.1 Force characteristics of the hexagonal single-cabin structure

The longitudinal length of the tunnel and pipe gallery structure is usually very different from the section size, which can be considered as a plane strain problem in

*Corresponding author: 1933156821@qq.com

the calculation, so this paper makes a numerical analysis through the two-dimensional plane strain model. The calculation section is calculated on the premise of meeting the subway limit of type A vehicle, and the buried depth is 18m. (Figure 1)

Figure 1. Three sectional dimensions.

The soil in the model of this paper is simulated using the modified Cambridge configuration^[3]. In the calculation of the typical silty clay layer parameters in the urban area of Tianjin, a single soil layer is used for calculation and analysis. The specific physical and mechanical parameters of the soil are shown in Table 1.

Table 1. Corrects the calculation parameters of the Cambridge model.

	γ	E_s							
	(kN/m ³)	(kN/m ²)	ν	λ	κ	M	e	k_0	
Powder quality clay	19.4	5.31	0.3	0.0476	0.005	1.139	0.758	0.5	

The tunnel structure is simulated by equivalent stiffness method, assuming that the concrete structure has been in the elastic deformation stage in the construction process, and the elastic modulus reduction method is adopted to reflect the stiffness weakening of the underground structure in the construction process. In the model, the underground structure is simulated by beam unit. The thickness of different forms of tunnel structure is taken as 350mm, and the elastic modulus is taken as 80% of the C50 concrete modulus value ($E_{c50}=34.5\text{GPa}$), that is, $E=0.8\times E_{c50}=27.6\text{GPa}$, and the Poisson ratio is 0.2.

2.1.1 Hexagonal underground structure, the calculation results

(1) The hexagonal single cabin structure is deformed in the horizontal direction of the underground structure, showing a horizontal stretching shape, especially at the inflection point of the left and right sides of the largest displacement value, reaching 3.9mm. Due to the effect of the upper soil pressure, the top of the underground structure has a downward deformation, and the maximum settlement of the roof span is 3.9mm; the bottom has an upward deformation due to

the unloading of the soil, the maximum uplift of the bottom span is 5.2mm, and the underground structure is in a compressed state. Under the action of soil surrounding pressure, the underground structure is horizontal tensile vertical compression deformation, the maximum tension amount is about 7.8mm, and the compression amount is 9.1mm, the value is relatively close. (Figure 2)

Figure 2. Distribution of hexagonal underground structure.

(2) The axial pressure of the underground structure at the left and right corners is the largest, reaching 968 kN, but because the horizontal soil pressure is less than the vertical, the axial pressure of the top and bottom plate of the horizontal distribution structure is the minimum, which is 535 kN. Because the stress concentration is easy to occur at the corner, the maximum shear force occurs at each corner of the structure, with the maximum value of 451 kN. The maximum bending moment of the inner side of the underground structure occurs in the middle position of the top and bottom plate, and the maximum value is 226 kN.m. From the underground structure of the vertical deformation distribution can be found, under the action of upper soil pressure of the upper part of the underground structure downward deformation, and the soil discharge rebound, the lower part of the underground structure of the upward deformation, lead to the underground structure vertical compression, and the compression effect of the extrusion on the corner of the structure, the structure in the lateral moment of the maximum, the maximum value of 398 kN.m. (Figure 3)

Figure 3. Internal force distribution diagram of the hexagonal underground structure.

2.1.2 Comparative analysis of the force deformation of three different forms of underground engineering structures

The vertical displacement values in Table 2 are the maximum absolute value in the structural settlement

or uplift value. Through the numerical comparison in this table, it can be found that the hexagonal underground structure and the circular tunnel both show the relative deformation of vertical compression and horizontal stretching, and the displacement and relative deformation value of the structure are also relatively close. The rectangular pipe corridor is different from the other two in terms of horizontal deformation, and the deformation value is relatively large. It can be seen that under the same net area, the stiffness of the circular tunnel is close to the hexagonal underground structure, while the stiffness of the rectangular tunnel structure is slightly worse.

Table 2. Summary of the calculated results for the three different structural forms.

	circular tunnel	The hexagonal tunnel	Rectangular pipe corridor
horizontal shift /mm	3.6	3.9	1.4
vertical displacement /mm	5	5.2	6.4
Horizontal to relative deformation/mm	7.2	7.8	-2.8
Vertical relative deformation of the region/mm	-8.2	-9.1	-12.2
pull-down /kN	1011	968	846
Inner-side bending moment/kN.m	164	226	333
Outer bending moment/kN.m	149	398	470
shear force /kN	129	451	633

Note: 1. The relative deformation value is positive for stretching and negative for compression.
 2. The vertical displacement is the maximum absolute value in the settlement or uplift value

In terms of internal force comparison, the circular tunnel bears larger axial pressure with smaller bending moment and shear, which can give full play to the compression capacity of concrete structure, and the structural force is reasonable; the rectangular tube tunnel bears the smallest axial pressure and shear, especially at the structural corner; The hexagonal underground structure is in the intermediate state of the three structural forms, and the internal force is larger than the circular tunnel, but less than the rectangular tube tunnel. Both hexagonal underground structure and rectangular pipe corridor have corners, which is easy to produce stress concentration. The internal force in this position is large, so more attention should be paid in the design.^[4]

Comparing the distribution of bending moment of circular tunnel, hexagonal underground structure and rectangular pipe corridor, the larger range of bending moment requires a larger structural section and reinforcement, and the larger range of rectangular

tunnel will be much larger than the hexagonal underground structure. From the above analysis, it can be seen that the hexagonal underground structure is much better than the rectangular pipe corridor than the rectangular tunnel in terms of force and reinforcement, and is more reasonable than the circular tunnel in terms of function use.

2.2 Comparison of the force-bearing deformation characteristics of hexagonal underground structures under different buried depths

Through the comparison of Table 3, it can be found that for the hexagonal underground structure, except for the uplift of the roof, the vertical displacement of the other cases is the subsidence of the roof plate and the uplift of the bottom plate. With the increase of the buried depth, the settlement of the roof gradually increases, while the uplift of the bottom plate does not change much, and the overall vertical relative deformation increases. The maximum horizontal displacement, vertical relative deformation and horizontal relative deformation of the structure all increase linearly with the increase of the buried depth.

In terms of the internal force of the structure, the lateral bending moment is always greater than the medial bending moment, and the lateral bending moment of the structure increases more obviously as the buried depth increases. This is mainly because the lateral bending moment occurs at the corner of the left and right sides of the structure, and the extrusion effect of the surrounding soil is more serious. The maximum axial force, maximum shear force and maximum bending moment of the structure also show a trend of linear increase with increasing burial depth.

2.3 Comparison of hexagon underground structure with circular tunnel and rectangular pipe gallery

In terms of structural deformation, the deformation values of circular tunnel and hexagonal underground structure under different buried depths are relatively close, indicating that the stiffness of these two structural forms is similar. The rectangular tube corridor is larger than the other two in vertical displacement and vertical relative deformation, especially under the condition of deep burial, the difference of the maximum deformation value is more obvious, indicating that the stiffness of the rectangular tunnel structure is relatively poor, especially it is not suitable for the situation of large buried depth. It should be pointed out that the horizontal displacement and horizontal deformation of the rectangular tube corridor are relatively small. According to the above analysis, this is mainly caused by the deformation of the inner structure of the rectangular structure under the horizontal soil pressure, which is opposite to the horizontal deformation characteristics of the other two structures.

Table 3. Summary of structural deformation and stress results under different burial depths.

depth of burial /m	displacement /mm					bending moment /kN.m			
	roof subside	baseboard rise	Vertical phase To the deformation	haunch displacement	Level phase To the deformation	The inner bending moment (Central top and bottom)	The lateral bending moment (Two sides of the corner)	Axis force/ kN	shear force / kN
6	1	5.8	4.8	2.2	4.4	112.9	182.2	380.9	182.2
12	-2	5.3	7.3	3.2	6.4	175.4	298.2	677.9	323.9
18	-3.9	5.2	9.1	3.9	7.8	225.9	397.8	957.9	450.8
24	-5.3	5.3	10.6	4.5	9	266.2	486.3	1250.1	571.3
30	-6.3	5.4	11.7	4.8	9.6	299.5	567.1	1525.5	687

Table 4. Comparison table of the calculation results under different buried depths.

Structure buried depth / m	Structural type	horizontal shift /mm	vertical displacement /mm	Horizontal to relative deformation/ mm
6	circular tunnel	2	5.8	4
	hexagon tunnel	2.2	5.8	4.4
	Rectangular pipe corridor	0.4	6.1	0.8
12	circular tunnel	3	5.2	6
	hexagon tunnel	3.2	5.3	6.4
	Rectangular pipe corridor	0.9	6.1	1.8
18	circular tunnel	3.6	5	7.2
	hexagon tunnel	3.9	5.2	7.8
	Rectangular pipe corridor	1.4	6.4	2.8
24	circular tunnel	4.1	5	8.2
	hexagon tunnel	4.5	5.3	9
	Rectangular pipe corridor	2	7.9	4
30	circular tunnel	4.4	5.4	8.8
	hexagon tunnel	4.8	6.3	9.6
	Rectangular pipe corridor	2.6	9.2	5.2

Structure buried depth/m	Structural type	Vertical relative deformation of the present form/mm	pulldown / kN	bending moment /kN.m	shear force / kN
6	circular tunnel	4.4	405	105	67
	hexagon tunnel	4.8	380	219	182
	Rectangular pipe corridor	5.7	366	258	291
12	circular tunnel	6.6	713	161	103
	hexagon tunnel	7.3	678	358	324
	Rectangular pipe corridor	9.3	612	415	468
18	circular tunnel	8.2	1011	197	129
	hexagon tunnel	9.1	958	477	451
	Rectangular pipe corridor	12.2	846	563	633
24	circular tunnel	9.5	1301	222	148
	hexagon tunnel	10.6	1250	584	571
	Rectangular pipe corridor	14.7	1068	700	786
30	circular tunnel	10.4	1587	239	164
	hexagon tunnel	11.7	1526	681	687
	Rectangular pipe corridor	16.8	1283	828	929

This stress of the three structural forms does not change with the depth. In addition, with the increase of structural buried depth, the internal force difference between circular tunnel and hexagonal underground structure and rectangular pipe corridor is more obvious. Especially in terms of bending moment and shear force, the maximum bending moment ratio of the three structures is 1:2.1:2.5, and the maximum shear ratio is 1:2.7:4.8; when the buried depth increases to 30m, the maximum bending moment ratio has increased to 1:2:8:3.5, and the maximum shear ratio has even increased to 1:4.2:5.7. Therefore, the stress performance of hexagonal tunnel has great advantages than that of rectangular tunnel.

In conclusion, the deformation of the circular tunnel structure is relatively small, and the force is more reasonable, which is suitable for different burial depths. However, when the circular tunnel does not meet the requirements of functionality or other aspects, the hexagonal underground structure is close to the circular tunnel, and the deformation and range of the force is relatively small, especially in the case of deep burial, its advantages are more obvious. But in the structural design, it is necessary to focus on the corner position, especially on the left and right corners.

3 COMPARISON OF THE FOUR-CHAMBER HONEYCOMB UNDERGROUND STRUCTURE WITH THE CALCULATION RESULTS OF DIFFERENT STRUCTURES

The underground structure of the four-cabin is more suitable for the multi-functional combination of pipelines, subways and roads. Referring to the combination form of honeycomb structure, the following two combination forms are preliminarily conceived for the hexagonal four-cabin underground structure. (graph 4)

(a) Four-cabin structure form 1 (b) four-cabin structure form 2

Figure 4. Combined type of the four-cabin structure.

Using the finite element model, through the overall comparison in Table 5, the stiffness of the large area circular tunnel is the worst, so its deformation value is the largest among various structures. And the rectangular tunnel can effectively reduce the deformation of the structure, so the deformation is relatively smallest. The deformation of the hexagon four-cabin structure is in the middle, and the vertical direction is slightly larger than the rectangular pipe corridor, while the difference of the horizontal deformation is relatively large.

Compared with the internal force of the structure, the large area circular single-line tunnel bears the largest axial force, but the bending moment and shear force are relatively small, which can give full play to the compressive ability of concrete, so the force is the most reasonable. The rectangular duct gallery bears the least axial force, but the bending moment and shear force of both forms are relatively large, which is unfavorable to the force of the structure. Compared with the rectangle, the four-module combination of the hexagonal underground structure has a slightly larger axial force, but the bending moment and shear force are relatively small, and the force is more reasonable. Therefore, the hexagonal four-cabin structure has more advantages than the rectangular pipe corridor.

Table 5. Summary of the calculation results of various and different structural forms.

	Hexagon and four-cabin combined form one	Hexagon and four-cabin combined form two	circular tunnel	Rectangular four cabin Combination pipe gallery	Rectangular four cabin The parallel pipe gallery
horizontal shift /mm	7.2	6.1	9.8	3.2	1.8
vertical displacement /mm	11.5	10.8	14.3	10.3	9.1
pulldown /kN	2012	1839	2117	1950	1777
Inner-side bending moment/kN.m	319	343	147	314	314
Outer bending moment/ kN.m	513	428	122	697	663
shear force /kN	569	707	75	801	750

Note: The vertical displacement is the maximum absolute value in the settlement or uplift value

4 HEXAGONAL UNDERGROUND STRUCTURE TRANSVERSE STIFFNESS EFFICIENCY, AND BENDING MOMENT CORRECTION COEFFICIENT

The hexagonal underground structure determines the value of the horizontal bending stiffness efficiency η through the line loading mode and the comparison with the numerical simulation, and then uses the numerical simulation to calculate the bending moment correction coefficient ζ in the online loading mode of the staggered assembly hexagonal underground structure. The following conclusions are mainly obtained:

(1) In the online loading mode, both the model test and the numerical simulation results show that the change of the structure diameter increases linearly with the increase of the load. The bending stiffness efficiency η of the model test has a large error in the small load and gradually stabilizes with the increase of the load, while the bending stiffness efficiency η of the numerical simulation does not change with the increase of the load^[5].

(2) In the online loading mode, the variation of bending stiffness efficiency η in the through-seam assembly model test is 0.613 to 0.736; the corresponding numerical simulation results is 0.619 to 0.684; the bending stiffness efficiency η of the off-seam assembly model test is 0 to 0.861, and the η variation of the corresponding numerical simulation results is 0.847 to 0.891. The model test is close to the calculation results of the numerical simulation.⁷⁷⁶

(3) In the real loading mode in sand, the resistance of the soil around the structure has a ring effect on the hexagonal underground structure, which will limit the opening of the structural joint and reduce the weakening effect of the joint on the whole structure. Therefore, when the buried depth is greater than 1.5D, the transverse stiffness efficiency η of the misseam and through-seam assembly structure tends to be stable. With the increase of buried depth, the greater the resistance of the soil around the structure, the stronger the hoop effect on the structure, so the lateral stiffness of the structure becomes more efficient η .

(4) The transverse stiffness efficiency rate of the wrong-joint assembly structure η is larger than that of through-seam assembly, but the gap between the stiffness efficiency rate of through-joint and wrong-seam assembly η is gradually decreasing with the increase of buried depth. In the real loading mode in sand, the range of transverse stiffness efficiency of through joint assembly is 0.515~0.806, and the range of transverse stiffness efficiency of through joint assembly is 0.651~0.919. In the actual engineering design, the transverse stiffness efficiency η can be selected according to the research results of this article.

(5) In the real loading mode in sand, after the internal soil of the structure is dug out, the structure of the three assembly modes of misjoint assembly, joint assembly and complete ring will bulge due to the extrusion of the side and the lower part, and this uplift phenomenon will weaken with the increase of buried depth. The complete ring structure has the

least deformation, the through-seam assembled structure is the largest deformation, and the mis-seam assembled structure is in between, which is the same as the deformation law in the line loading mode.

(6) The bending moment of the two adjacent rings of the line loading mode and the misseam assembly structure in the real loading mode changes periodically by 180° along the hexagonal underground structure, which is mainly determined by the bending moment correction coefficient ζ of the misseam assembly structure. When the joint moment correction coefficient of the middle ring is large, the bending moment decay of the middle ring and the increase of the adjacent ring are dominant, while the joint moment correction coefficient of the middle ring is small, that is, when the joint moment correction coefficient of the adjacent ring is large, the bending moment of the adjacent ring and the increase of the bending moment of the middle ring is dominant. The ζ values calculated in this study ranged from 0.19 to 0.4, which is close to the ζ of the existing circular tunnels.

5 CONSTRUCTION METHOD OF HEXAGONAL SECTION AND HONEYCOMB UNDERGROUND STRUCTURE

The construction method of the new hexagonal underground structure system can refer to the conventional circular and rectangular pipe corridor structure. However, due to the particularity of its section form, it should be adjusted on the basis of common construction methods.

The construction of hexagonal underground structure mainly includes two kinds of open excavation method and dark excavation method, open excavation method includes cast-in-place method and prefabrication method, and dark excavation method includes pipe jacking method and shield method. Among them, the open excavation method is suitable for underground structure projects with new urban areas and roads, or with subway, elevated and underground roads; the open excavation method is suitable for urban center or projects with large buried depth, especially if the existing structures are not suitable for open excavation method.

The construction method of the hexagonal underground structure should be decided comprehensively according to the geological conditions of the site, the surrounding environmental conditions, the economic investment of the structure construction, the construction period and the local construction experience.

Based on the shape characteristics of the hexagonal underground structure, can be combined with the inclined pile foundation pit supporting new type of hexagon underground structure system, on the one hand, can combine the shape of the hexagon underground structure and inclined pile, improve the utilization of space, on the other hand also can effectively solve the open foundation pit cost is high, using the support of foundation pit excavation construction inconvenience.

6 PIPE STRUCTURE AND CONNECTION MODE OF HEXAGONAL SECTION AND HONEYCOMB UNDERGROUND ENGINEERING

According to the hexagonal underground structure method described above, it can be found that because this new structure belongs to the special-shaped section, the site pouring operation is difficult, so the most reasonable way is to use the prefabrication method for construction. However, the prefabrication method is limited by the volume of the pipe section, and it is inconvenient to transport and install it when the pipe section is too large and heavy. If the whole pipe section can be divided into several segments for on-site assembly, it can not be limited by the volume of the pipe section and effectively solve the above construction problems.

6.1 Structural type of prefabricated tube segments

precast segment should adopt integrated form, simple structure and high strength, by making the curved segment and “Y” segment with positive hexagonal corner structure, to avoid the splicing surface between prefabricated segment in the corner position, the disadvantages of low structural strength, make the splicing of hexagon underground structure strength is higher, assembling speed is faster. At the same time, by adjusting the length of each side of the curved segment and the splicing method between the segment ring, different connection forms of “open joint connection” and “wrong joint connection” can be realized to meet the design and construction requirements under different circumstances. (Figure 5)

Figure 5. Precast segments assembled into single cabin structure and prefabricated segments assembled into seven cabin structure.

The corner of the hexagonal underground structure is easy to form stress concentration. For prefabricated types and segments, according to the stress characteristics of the structure, the inner sides of the left and right sides of the segments can be treated when making segments, and then assembled in the field to solve this problem.

6.2 Pipe segment connection mode

Bolt holes are opened on the side edge of the prefabricated segments. During assembly, holes are opened on the two sides of the prefabricated segments for the bolt for fixation, so as to form a longitudinal seam and ring between the prefabricated segments.

At the same time, the front and rear ends of the prefabricated segments also open holes for bolt penetration and fixation, so that the connection between the front and back rings to form a ring seam. (graph 6)

Figure 6. Schematic diagram of misjoint assembly.

7 CONCLUSION AND OUTLOOK

The new hexagonal section and its section combination honeycomb underground structure system has obvious advantages in spatial integration. The whole system unifies the planning, design and implementation of underground engineering, reserving precious space for the urban intensive development. The system can combine the left and right lines, the transfer line interval, the comprehensive pipe corridor and other underground space engineering into the upper and lower overlapping system, the left and right parallel system, etc. The honeycomb system of the hexagonal monomer inside the system can also be flexibly arranged and separated, providing the possibility of infinite creative combination for the underground space engineering.

On the basis of this study, more comprehensive model test and field test can be conducted for different size single cabin structure and multi-cabin system, which can further improve the design method of the hexagonal underground structure. In the construction, the matching shield and pipe jacking equipment and auxiliary facilities needed in the construction process should be developed to meet the needs of the hexagonal underground structure system.

Harnessing the potential of underground space for climate-neutral cities: Energy geostructures in metro tunnels

Azad Koliji*, Etienne Garin, Tohid Kazerani, Benjamin Schenk & Jade Senn
WSP BG Consulting Engineers, Lausanne, Switzerland

ABSTRACT: In recent decades, the transition towards sustainable energy has emerged as a crucial challenge in the development of cities and infrastructure. The utilization of eco-friendly technologies that harness renewable energy sources plays a pivotal role in constructing low-carbon buildings and infrastructure. In this regards, energy geostructures present a groundbreaking and versatile technology that can address the challenge. By integrating geothermal heat exchangers in underground structures, energy geostructures offer the potential to serve as heating and cooling systems for various infrastructures. This paper examines the possible incorporation of energy geostructures within the tunnel lining of an under-development future metro line in Lausanne, Switzerland (vd.ch/métros). In general, the urban texture and the proximity of energy consumers provides an opportunity for significant heat recovery, potentially offering a substantial energy source for the surrounding inhabited areas. In the present case, this opportunity needs to be further evaluated with the uncertainties linked to the geology, hydrogeology, temperature variation and the adjacent urban energy consumption. Advanced thermomechanical analyses of the tunnels, equipped with heat exchangers, are carried out to demonstrate the mechanical feasibility of utilizing these structures as energy geostructures. A finite element model with thermodynamic coupling is employed, combining the mechanical forces arising from earth pressure and the expansion of marlstone layers with the thermal forces generated by temperature variation. Conducted in the early stages of the project, these analyses allow determining the additional thermal forces exerted on the tunnel structure, assessing the resulting impact on the supporting structure, and ultimately verifying the feasibility of integrating these geothermal structures into the new tunnels while minimizing costs and construction timelines. The multi-disciplinary study is commissioned by the State of Vaud, the regional authority, which is leading the project in collaboration with the regional public transportation system and the City of Lausanne.

1 INTRODUCTION

In recent years, the global demand for energy has exhibited continuous growth, driven by strong economic expansion and burgeoning populations. As per the findings of the International Energy Agency's World Energy Outlook (IEA's WEO), it is projected that worldwide energy demand will experience a further 10% increase between 2019 and 2030 (IEA 2020). In parallel, it is expected that global CO₂ emissions will not surpass 2019 levels until 2027, despite the anticipation of demand returning to pre-Covid-19 levels in early 2023. This observation underscores the shift in the energy mix, with renewables emerging as resilient components in the post-pandemic recovery.

The initiatives implemented by governments under the Sustainable Development Scenario (SDS) are steering energy systems onto a different trajectory, with the prospect of reducing CO₂ emissions to

below 27 Gt by 2030 (IEA 2020). It is becoming increasingly apparent that an accelerated transition to renewable energy sources, as previously outlined in the "Alternative World Energy Outlook" (Zittel & Schindler 2007), is essential to meet the requirements of sustainable societal development.

In the context of energy considerations, the intelligent utilization of underground space for tapping into renewable geothermal energy sources represents an innovative solution in pursuit of the Sustainable Development Goals (SDG), which have been embraced by all United Nations Member States (UN 2015, specifically SDG no.7, 9, 11, and 13).

Within this context, energy geostructures present an innovative solution that combines the utilization of renewable geothermal energy with the structural components situated in underground spaces (Koliji et al. 2022). In the case of metro lines, the heat generated by the metro traffic could also contribute in

*Corresponding author: azad.koliji@bg-21.com

sourcing thermal energy. The core concept of energy geostructures revolves around integrating the primary heat exchangers of ground-source heat pump (GSHP) systems within the foundation and retaining elements, such as piles and diaphragm walls used for tunnel linings (Soga & Rui 2016).

While conventional shallow geothermal energy systems like geothermal probes are commonly employed in building construction, the use of energy geostructures is a relatively recent development, with its inception dating back to the mid-1980s. Nevertheless, this approach still encounters challenges in terms of planning and construction. Despite a growing number of energy geostructure installations worldwide (Laloui & Rotta Loria, 2019), the paucity of data from real-world installations remains a significant limitation. This dearth of information hampers the formulation of design optimization strategies and guidelines for future installations (Zannin et al. 2020a).

This paper presents a study on the possible incorporation of energy geostructures within the tunnel lining of an under-development future metro line in Lausanne, Switzerland (vd.ch/métros). It looks to different aspects related to the geology, hydrogeology, temperature variation and the adjacent urban energy consumption, and examines the possible thermomechanical effects of geoenergy activation on the structure of the tunnel.

2 ENERGY GEOSTRUCTURES

To gain a deeper insight into the potential contribution of energy geostructures to sustainable societal development, it is instructive to examine energy consumption patterns. Across various sectors within European Union countries, residential and commercial buildings collectively account for approximately 38% of the total final energy consumption (IEA 2017, as depicted in Figure 1). Focusing specifically on residential and commercial buildings, nearly 25% of energy consumption is dedicated to heating and cooling purposes (Eurostat 2018). It is worth noting, however, that only a limited portion of this energy is derived from renewable sources.

When we consider renewable energy sources for heat generation, geothermal energy represents just 7% of the total share (as illustrated in Figure 2, IEA 2017), even though it stands as the Earth's second most abundant primary energy source (Lee, Speight, & Loyalka, 2007). The relatively low utilization of geothermal energy in this context can be attributed to various technical challenges tied to exploration, construction, operation, and energy storage. Consequently, there exists considerable untapped potential for leveraging geothermal energy as a direct source for heating and cooling in buildings. Within this context, energy geostructures emerge as a pivotal player, capable of fulfilling this role.

Figure 1. Total final energy consumption by sector in the EU (data from IEA 2020).

Figure 2. Share of renewable energy sources in heat generation (data from IEA 2020).

Energy geostructures seamlessly integrate the functions of structural support with those of geothermal heat exchange systems within the foundational and shallow subterranean components of infrastructure. These innovative constructs offer a cost-effective, intelligent solution that has demonstrated its effectiveness as a low-emission method for heating and cooling operations in both building and infrastructure contexts (for instance, as highlighted by Sutman et al., 2020). Sterpi et al. (2020) have also presented diverse thermal performance characteristics associated with diaphragms and slabs, shedding light on their versatility.

Furthermore, it is worth noting that the implementation of energy geostructures has resulted in minimal thermally-induced deformations, as evidenced by the observations made at the Lainzer U2 line in Vienna (Brandl, 2016).

3 LAUSANNE NEW METRO LINE

3.1 Project overview

Following the significant economic growth in the Lemanic arc region in western Switzerland, several infrastructure projects have been developed in the region with the purpose of achieving a sustainable

solution for population mobility needs. In a decade, the landscape of Lausanne, a city of 140,000 residents, and the Swiss canton of Vaud will undergo significant transformation. The city's mobility will be revolutionized by the introduction of the new M3 metro line, entirely underground, linking the city's central railway station to a brand-new eco-friendly district that is poised to accommodate 8,000 residents and create 3,000 job opportunities in 10 years (Schneider 2022).

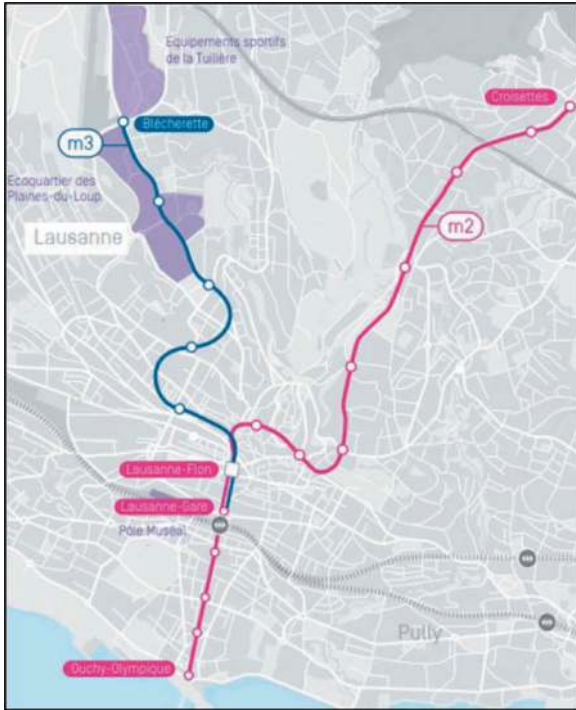

Figure 3. Plan view of the existing m2 (pink) and the new m3 (blue) metro lines in Lausanne (Courtesy of Axes Forts).

Figure 4. Longitudinal profile of m3 tunnel (Schneider 2022).

The new M3 line, spanning 3.6 kilometers, will be a fully dual-track underground route connecting the central station to “La Blécherette”, situated to the north of the town (see Figure 3 & 4). This line is slated to feature a total of seven stations. Its starts from an existing M2 line metro station, passing through an existing cross-station which needs to be expanded to accommodate m3 line, and then

Figure 5. Geological profile of m3 tunnel.

continues its way to the north through new stations. These new stations have been designed with user convenience in mind, emphasizing shallow platforms to facilitate swift entry and exit. In addition, a depot will be constructed at the end of the line to house the train sets.

3.2 Geology & geotechnics

One of the key issues in the study of underground energy geostructures is the geology and hydrogeological condition. The new metro line in Lausanne is located in a mixed geological condition along its alignment. However, the interaction with surface air temperature can be expected.

The geology of the section under study is mainly composed of a surface fill material lying on moraine soil layer, and on higher depth on molassic rock.

4 ENERGY GEOSTRUCTURES ASSESSMENT

4.1 Background

With the aim of promoting sustainable development and use of renewable energy sources, it was decided to explore the possibility of integrating energy geostructures in the tunnels and underground stations of the new metro line in Lausanne.

In this regards, initial feasibility studies were carried out to assess the thermal potential of energy geostructures implementation and the corresponding effects on the structures. Results of the preliminary feasibility studies showed a potential interest in terms of energy production (Meghari 2022). However, integrating heat exchanger systems in the tunnels and underground structures could also have potential construction and structural impacts. Therefore, it has been decided to carry out further advanced analyses to evaluate potential thermo-mechanical effects on the structure and to assess the impacts on the construction methodology, planning and costs.

4.2 Thermo-mechanical approach

Advanced thermo-mechanical coupled analyses are carried out using finite element methods. It combines

Table 1. Thermal material properties.

Parameter	Unit	Concrete	Fill	Moraine	Molasse
Thermal conductivity	$\lambda [W/(m^{\circ}C)]$	1.8	0.6	1.8	2.5
Specific thermal capacity	$C [MJ/(m^3^{\circ}C)]$	880	1.4	2.0	2.1
Thermal dilatancy coefficient	$\alpha [1/^{\circ}C]$	10^{-5}	3.3×10^{-6}	3.3×10^{-6}	2.3×10^{-5}

the thermal induced stresses with those coming from tunnel excavation and swelling effects. The thermo-dynamic approach follows a three-step procedure:

- i. Using a thermal model, the initial thermal condition around the tunnel is set up through internal BC (air temperature inside the tunnel) and external BC (surface air temperature and far field temperature).
- ii. The liquid temperature inside heat exchangers is imposed, allowing heat diffusion inside the pipes, concert and surrounding ground.
- iii. A mechanical model takes the thermal fields and introduce it in the analyses of the stress-strain behaviour. The thermo-mechanical effects are then combined with the mechanical load cases including tunnel sections with and without swelling pressure.

This approach combines the elastoplasticity coming from both mechanical and thermal loading. The total strain increment does reads as follows:

$$\dot{\epsilon}_{ij} = \dot{\epsilon}_{ij}^{Me} + \dot{\epsilon}_{ij}^{Te} + \dot{\epsilon}_{ij}^{Mp} + \dot{\epsilon}_{ij}^{Tp}$$

in which the superscript, e and p denotes elasticity and plasticity; and M and T denote mechanical and thermal part respectively.

5 NUMERICAL MODELLING

5.1 Model set up

The numerical modelling is carried out using finite element code ZSoil. A 2D section of the tunnel is modelled including the tunnel support and lining as well as different geological layers. Concrete is modelled as linear elastic material while elasto-plastic constitutive models are used for soil and rock layers. Figure 6 shows the 2D cross section of the model.

Thermal material properties, reported in Table 1, are taken from previous studies, and are largely based on the literature.

If it is decided to implement geostructures in the project, specific tests are to be carried out in the next stages of the project to confirm or adjust these parameters.

5.2 Modelling phases

Simulations are carried out in three phases:

Figure 6. 2D section of the finite element model.

Figure 7. Tunnel construction with constant air temperature inside the tunnel over 5 years (indicative duration) - distances are given with respect to the tunnel vault.

- a- Initialization of thermal field in the ground by seasonal variation of surface air over 10 years;
- b- onstruction phase during which the tunnel air temperature is constant for 5 years (Figure 7);

c- Geothermal activation with seasonal variation of water inside the heat exchanges pipes over 25 years (Figure 8).

Figure 8. Activation of thermal exchange in the pipes (the first 3 years over 25 years – indicative duration).

5.3 Result of thermal analyses

Results of thermal analyses, in terms of temperature variation in the tunnel lining and the surrounding ground, are presented in the following figure for summer and winter.

In both cases, a temperature gradient can be observed along the thickness of the tunnel. This effect, more pronounced in winter, will result in thermal induced stresses in the concrete.

5.4 Result of thermomechanical analyses

The temperature fields obtained from the thermal analyses of the previous section are taken into mechanical analyses to obtain the thermal induced stresses. The results, in terms of thermal induced stresses are presented in the following figure. These stresses are calculated directly from a thermo-elasticity constitutive model for the concrete. It can be noted that the values of these stresses, themselves, are not very high and still far from the concrete strength. However, these stresses are to be combined with those coming from mechanical analyses and assessed for the critical load cases with swelling pressure of the rock.

Results of the combined thermomechanical analysis for the most critical case with rock swelling pressure shows the concrete stress exceeds the strength on the lower parts of the tunnel wall. Accordingly, additional reinforcement is required in these zones to sustain the loads coming from activation of heat exchangers. It should be noted that the integration of heat exchanger pipes, themselves, results in a reduction of concrete mass which is considered to be insignificant.

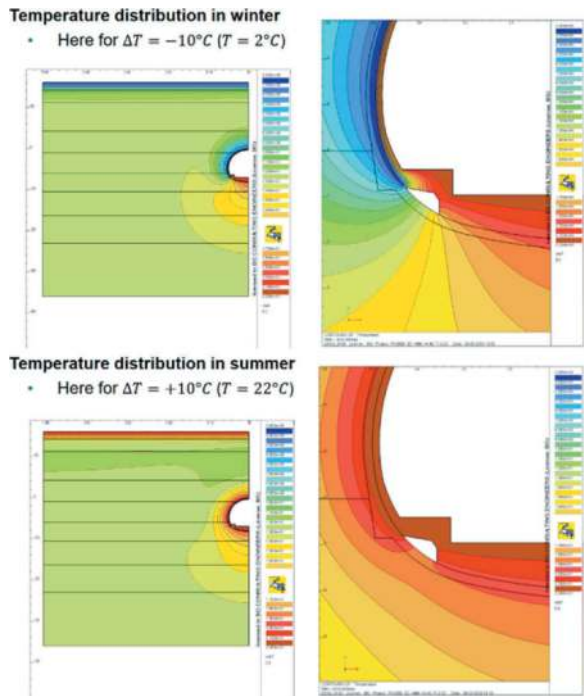

Figure 9. Temperature distribution in the tunnel lining in winter (up) and summer (down).

Figure 10. Thermal induced radial stresses in the tunnel lining in winter (left) and summer (right).

Figure 11. Tunnel support and lining taking the swelling pressure of the rock. Results presented in terms of normal forces, shear forces, bending moment and principal stresses in the concrete.

6 COST AND PLANNING

Results of this study showed that the tunnel lining needs to be reinforced with two layers of B754 mesh ($\phi=12$ mm @ $s=150$ mm), while the support system also requires reinforcement with the same mesh, but only at the base of the walls. For the support system, a mesh layer of 2 meters in height should be installed at the base of each wall. This could influence the total cost and planning of the project. The installation rate for the mesh is 50 square meters per hour with a team of two workers, plus one hour of logistical work per day for approximately 80 days. This work could be conducted in parallel with the lining process, where various workshops follow one another along the tunnel's length. A half-day of production loss should be considered for coordination and coactivity. Based on 12 weeks of lining work for each tunnel, an extension of the overall project duration by 6 days should be expected for each tunnel. On the other hand, the installation of the support reinforcement mesh could not be done in parallel. This would add 5 minutes to each meter of advancement, resulting in an additional 3 days per tunnel. Hence, each tunnel would be expected to experience a two-week extension in the project duration, a relatively short period of time with respect to the total construction time. Moreover, according to these first results, to be confirmed in further studies, the additional costs for reinforcing the civil engineering structures of the tunnels to withstand geothermal-induced stresses are reasonable and relatively low compared to the total construction cost.

7 CONCLUSIONS

This study has shown that thermal constraints vary almost linearly with the temperature variation applied to the heat transfer fluid. The greater the applied temperature difference, the more significant the generated stresses.

Regarding the resistance of the tunnel section, the reduction in surface area due to the presence of heat transfer tubes with a diameter of $\phi=40$ mm and a spacing of $e=40$ cm is practically negligible.

As for the lining, it is subjected to tensile forces during the summer. Therefore, it is necessary to rely on the tensile strength of the sprayed concrete or lightly reinforce the support to ensure structural safety. In both cases, a relatively straightforward solution is available. There is no need to alter the structural system or the thickness of the lining due to the additional thermomechanical stresses.

Concerning the support system, thermal activation during the winter generates tensile stresses. In the short term, considering the contribution of hangers, the support system could accommodate all load combinations for temperatures above $T_{\text{tub}}=2^{\circ}\text{C}$ and ensure structural safety.

In the long term, without taking into account the contribution of hangers for the typical profile, however, the strength is exceeded. In this case, it is also possible to reinforce the monolithic section quite easily, especially by considering the tensile strength of the sprayed concrete lining or using passive reinforcement for the lining. Long-term loads then also remain acceptable. Like the lining, it is possible to maintain the currently planned structural system without changing the thickness of the support.

This study thus demonstrates the feasibility of utilizing thermal energy in tunnels for the given cubic meters, provided that the support and lining are reinforced for tensile strength with fibers or passive reinforcement.

At this stage, the possibility of integrating energy geostructures into the future Lausanne M3 metro tunnels is still under study, with a focus on the benefit-cost ratio. Apart from design considerations, several other issues should be still addressed including the question if this energy project can be ready in time to be integrated into the construction of the M3 metro, or whether an operator interested in running such an energy infrastructure can be found. To date, the final decision by the project owner to implement these geostructures has not yet been taken.

Research on complete technologies for the construction and utilization of super large caverns in Hong Kong

Yifeng Li, Zhengqiang Hong*, Wei Li & Fei Xu

China State Construction Engineering (Hong Kong) Limited, Hong Kong SAR, China

ABSTRACT: In response to land scarcity and the increasing environmental needs in Hong Kong, the construction of public facilities has begun to seek underground space development. One of the first major projects leading the long-term sustainable cavern development in Hong Kong is the Relocation of Sha Tin Sewage Treatment Works to Caverns. The layout and sizes of the caverns must be arranged according to the functionality of the treatment facilities. Taking Sha Tin Caverns as an example, this paper will critically review the main characteristics of underground treatment methods and present the idea of a complete and total solution for the construction of such caverns, focusing on key points such as the construction methodology, implementation of new technology and management for such large caverns. This paper will also discuss the prospects of future relocation of sewage treatment plants to caverns.

Keywords: Complete technologies, Super large caverns, Construction methods, Implementation of new technology, Management method

1 INTRODUCTION

As an important component of municipal engineering, sewage treatment plants play indispensable roles in purifying wastewater, reducing pollution, improving urban ecological environment, and improving residents' quality of life. However, it should also be noted that traditional aboveground sewage treatment plants have negative social and environmental impacts such as excessive land occupation, severe secondary pollution, and negative impacts on the land value of surrounding areas. With continuous development of the economy, cities boundary is gradually expanding, land resources are becoming increasingly scarce, and environmental requirements are becoming more stringent. As such, underground sewage treatment plants (USTPs) have demonstrated clear advantages over traditional STPs in terms of reasonable utilization of underground space, freeing land resources up, odor free, significantly lesser noise pollution, and even somehow making the landscape less attractive - all of which has promoting effects to relocate STP underground. USTP have ushered in new development opportunities.

1.1 *Development of USTPs worldwide*

The development and utilization of underground space has a history of more than 150 years (Bao et al., 2003), and USTPs have also developed well in the past 80 years. So far, there are more than 200 USTPs in stable operation (Wang et al., 2017), which are widely distributed in more than 10 countries and regions, generating enormous economic, environmental and social benefits for the local communities.

Europe has a long history of constructing USTPs. As early as 1932, Finland began constructing of the world's first USTP near Helsinki, and completed the project in 1970 (Herranen, 2001); Sweden leads the world the construction technology and operation experience of USTPs among the world, and all sewage plants in Sweden are USTPs; Norway, Netherland and other counties also constructed lots of USTPs.

In Asia regions, Hong Kong built the first USTP in 1991 in Stanley; other countries and regions started constructing USTPs around 2000 to relocate existing sewage treatment facilities into caverns due to land scarcity.

The current development of USTPs are shown in Table 1 (Tan et al., 2006, and Zhu, 2015).

2016	Futian, Shenzhen	China	Semi-underground
2017	National high-tech Industrial Development Zone, Qingdao	China	Full-underground

1.2 Relocation of Sha Tin Sewage Treatment Works in Caverns in Hong Kong

In order to overcome the problem of land scarcity in Hong Kong, the Civil Engineering and Development Department (CEDD) of the Hong Kong Government has commenced the “Long-Term Strategy for Cavern Development - Feasibility Study” in 2012. And the study has recommended, among others, the formulation of a territory-wide strategy for sustainable cavern development in the form of Cavern Master Plan (CMP). One of the main features of the CMP is the delineation of suitable sites within all areas of Hong Kong for cavern development, termed Strategic Cavern Areas (SCVAs), and the first major projects leading the long-term sustainable cavern development in Hong Kong is the Relocation of Sha Tin Sewage Treatment Works in Caverns (Sha Tin Caverns, STC).

The STC is about 14 hectares, resides within Nui Po Shan, Sha Tin, Hong Kong. Due to the scale of the STC (serving 800 thousand residents, which is 10% of Hong Kong’s population) and unique arrangement of the treatment plants, the layout and sizes of the caverns must be arranged according to the functionality of the treatment facilities, which leads to the largest cavern being 32m high and 32m wide. Drill and Blast Method (DBM) is adopted in this project in order to excavate the largest blast face in Asia.

This paper takes STC as an example to illustrate the construction methods, latest technological applications and management methods applied in the construction process of modern super large caverns.

2 CONSTRUCTION METHODS

The main construction works of STC include the excavation of main caverns, installation of piling works, and buildings of the ventilation facilities and effluent pipelines. The subsequent Chapter 2 of this paper outlined with the construction methods such as blasting and installation of support system of caverns in detail.

2.1 DBM on super large blast faces

The largest blast face inside STC has a width of 32 m and a height of 32 m. The blasting operation of each face has to be divided into three stages, namely the top heading, middle bench, and invert, whose average area of face size reaches 300 m², making it a rare super large cross-sectional blast face in Hong Kong, even globally. And the rest of the main-cavern blast faces all exceed 200 m² (see Figure 1, over 200 blast holes with 8.9m high and 30.52m wide of top heading). Millisecond blasting is applied in the construction of main cavern structure.

Figure 1. Typical blast face.

To apply DBM on these super large blast faces, precise blasting design and calculation were carried out to determine the size and spacing of blast holes, as well as the sequential blast order of selected explosive holes.

2.1.1 Pre-blasting

For DBM, the pre-blasting process mainly involves probing ahead and advanced ductile grouting. The engineering geologists will check and review the ground material from probing (to make sure rock strength is sufficient for blasting), and after confirming that the anticipated ground condition is suitable for blasting, he/she will communicate the findings to blasting engineer, and the blasting engineer will update the blast design accordingly (blast hole pattern, spacing, size, quantity of explosives etc.).

2.1.2 Blast holes design

Two Three-arm Tunnel Drilling Rigs (Jumbo) are used to drill cut holes, production holes, perimeter holes as well as holes for rock bolt installation. Compared with the traditional blast holes drilling method (using pneumatic hammer drills), the diameter of STC’s cut holes and production holes (as well as

perimeter holes) reached 102 mm and 51 mm respectively; The maximum instantaneous charge (MIC) weight can reach 2 kg/m, and the advance length is maintained at approximately 5 m; Simultaneously, all blasting adopts millisecond method, and a blasting surface of about 300 m² can be completely detonated by all explosives within 10 seconds, thus greatly improving the efficiency of construction.

In terms of hole spacing, due to the large diameter of the drilled holes, the quantity of explosives in each hole is also large, therefore the hole spacing need to be larger than that of traditionally drilled holes. The spacing between each production holes is generally over 1 m, and the spacing between perimeter holes is generally over 0.5m. In other words, only one hole is required for every 1.03 m² of the blast face on average.

2.1.3 Explosives

Figure 2. Typical explosive design.

According to the statutory requirements in Hong Kong, the cartridge explosives, bulk emulsion explosives, booster, detonating cords, in-hole delay, non-electric detonators, surface/bunch detonators, electric detonators, electronic initiation system etc. are selected for blasting.

In order to maximize efficiency, enhance economical operation, and control misfire rate, this method only uses non-electric and electric detonators. For any single blasting, electric detonators are only used at the initiation point, and non-electric detonators are used in all subsequent blast holes.

As mentioned in Chapter 2.1.2, the designed MIC for 51mm diameter blast hole can reach 2 kg/m, this is equivalent to 10 kg for one blast hole of 5 m in length, all the while ensuring that environmental impact are within required limits (Section 2.2). Compared to the traditional method of drilling a 38mm diameter blast hole with a length of 3 m, the charge weight for 5 m hole is increased by approximately 3 times.

Figure 2 Shows the typical design of explosives.

2.1.4 Blast delay design

Due to the limitations of the product, the delay device will have a tolerance of about 2 % during blasting. Therefore, when designing the delay of millisecond blasting, the larger the time interval between the outer holes, the more it can ensure that the blasting is carried out from the core to the perimeter. In the design of the maximum blast face, the maximum delay of the outermost perimeter hole is 9,000 ms (i.e. 9 s, see Figure 1). As such, all blasts are guaranteed to be completed within 10 seconds.

2.1.5 Comparison with traditional blast design

The blasting method comparison between the super large blast face in STC and traditional blast face (using air hammer drill) are shown in Table 2.

Table 2. Comparison of blast design.

Parameters	Traditional Design	Design of STC
Dia. of Blast Holes	32~50 mm	51 mm
Spacing of Production Holes	0.7~0.8 m	> 1 m
Blast Holes per Square Meter of Blast Face	1.8	0.97
Length of Blast Holes	< 4 m	5 m
MIC	< 5 kg	10 kg
Explosive Factor	1.2~2.4 kg/m ³	1.2 kg/m ³
Demanded workers	1 per air hammer drill	1 Jumbo operator

2.2 Monitoring system

During the blasting process, two main indicators are measured: peak particle velocity (PPV) and air overpressure (AOP). The outcomes of these two indicators would help to update the next blast design. The thresholds of the two indicators are shown in Tables 3 and 4, respectively.

Table 3. PPV thresholds.

Condition	Threshold
Alert	90 % of the PPV Limit
Action	95 % of the PPV Limit
Alarm	100 % of the PPV Limit

Table 4. AOP thresholds.

Condition	Threshold
Alert	118 dBL
Action	119 dBL
Alarm	120 dBL

After blasting, continuous ventilation is required to ensure the air quality inside the cavern. The concentration of five gases are measured, namely oxygen, methane, hydrogen sulphide, carbon monoxide, and radon. In the meanwhile, 0.5 cm/s of wind speed inside cavern is required.

2.3 Temporary and permanent support with rock bolts

The quality of rock mass for the STC project general ranges between Grade I or Grade II (Grade I being massive, usually unjointed and stable), representing

excellent geological conditions. Hence, for the first time, a new rapid support system was adopted in the construction, which uses a combination of temporary shotcrete, permanent grouted rock bolts, and permanent shotcrete to replace the conventional steel arch support. It has the benefits of cost saving, high efficiency and high flexibility for different blast faces and geological conditions.

2.3.1 Geological mapping

After mucking out, geologists would carry out geological mapping of the blast face to estimate the quality of the rock mass, and specify any prescribed reinforcement measures or require re-scaling according to the mapping result. The Geologists will determine the Q-value of the exposed rock mass based on NGI-Q System (NGI, 2015, see Equation 1) using individual parameters such as the degree of jointing, joint shear strength, and condition of rock active stress

$$Q = \frac{RQD}{J_n} \times \frac{J_r}{J_a} \times \frac{J_w}{SRF} \quad (1)$$

Where *RQD* is Rock Quality Designation; J_n is joint set number; J_r is joint roughness number; J_a is joint alteration number; J_w is joint water reduction factor; and *SRF* is stress reduction factor.

2.3.2 Temporary shotcrete

Safety shotcrete of 50 mm applied to unsupported face immediately after mapping. Temporary support shotcrete installed based on the determined support level.

2.3.3 Rock bolts installation with modified Jumbos

Traditional method of installing rock bolts uses Anchor Drilling Rigs to drill holes, followed by manual handling of the bolts on elevated working platforms to slowly insert bolts into the holes. This method meets the requirements of safety, efficiency and quality on small blast faces.

However, for super large blast faces such as STC, where the size is approximately 20 m wide (maximum 32 m), 10 m high, and 5 m deep, most rock bolts have a length longer than 6.3m. The actual installation process requires two elevated working platforms and four skilled workers to manually handle rock bolts at two heights of 8 m and 6 m; Simultaneously, a banksman is required to conduct unified dispatch and command on the ground (Figure 3). The larger the space, the lower the efficiency using the tradition method.

To address the aforementioned difficulty, Tunnel Drilling Rigs (Jumbos) are modified and used to replace manual handling (Figures 4 and 5). Firstly, input the coordinate and orientation information of rock bolt holes into the rock drilling rig for drilling; Then, replace the drilling rig with installation tools, and automatically insert rock bolts into the drilling hole according to the coordinate and orientation information.

2.3.4 Permanent shotcrete

After the installation of rock bolts, permanent shotcrete construction should be carried out more than 40m away from the blast face to form a complete permanent support structure.

Figure 3. Traditional rock bolt installing method by manual handling.

Figure 4. Modification of Jumbo.

Figure 5. Automatic rock bolts installation by Jumbo.

3 TECHNOLOGY APPLICATION

3.1 BIM technology

BIM is adopted to achieve building information integration, and carries out collaborative work and management throughout the entire lifecycle of STC in design, construction organization design, and construction, achieving the goal of efficient transmission of engineering information, improving work efficiency, and reducing costs and increasing efficiency.

3.1.1 Digital works supervision system

The BIM Digital Works Supervision System (DWSS) used in STC is a self-designed system that includes four modules: Request for Inspection (RFI), Site Diary System, BIM360 Doc and Safety Inspection System.

The RFI system is developed to issue acceptance application for head office's approval and file management. This system greatly shortens the process and file volume, making it easier for both Project Manager and Main-Contractor; The Site Diary System is adopted to help contractors record construction activities, resource logs, data analysis and storage management (Figure 6); The BIM360 Doc visualizes BIM and bind electronic records to BIM components; And the Safety Inspection System helps recording safety issues.

These four systems form the DWSS, creating more flexibility for both Project Manager and Main-Contractor, reducing paper consumption and improving work efficiency.

Figure 6. Site diary of daily labour.

3.1.2 Information technology in management

The information technologies used in the construction management of STC mainly include BIM Deepening Design, BIM Construction Process Management, BIM+Survey and BIM+IoT (Internet of Things).

The BIM Deepening Design conducts structural deepening design and directly converts BIM models into construction drawings (Figure 7); The BIM Construction Process Management sets site planning and layout for each construction stage based on BIM model, and allows the visualisation of the construction process (Figure 8) as well as any technical clarification; BIM+Survey helps the survey team save half of the

time, and provides design information of terrain and site model (Figure 9); And BIM+IoT allows management department aware of the power consumption and lighting control of the site (Figure 10).

CMIT greatly improves the quality of disclosure, the management of drawings and documents, and can also handle the workload of one site clerk.

3.2 Application of DfMA and MiC

3.2.1 Design for manufacture and assembly (DfMA)

DfMA is an acronym for Design for Manufacture and Assembly. In order not to occupy public roads while transporting boulder and rock from blasting, a temporary crane bridge was designed at the site preparation stage of STC for transporting. The temporary steel bridge adopts DfMA method, whose main components are produced and welded in the factory, transported to the site and lifted in place for assembly. This method saved 2 months of construction time and reduced road closure to 2 nights.

Another structure adopting the DfMA method is overhead ventilation ducts (OHVD, Figure 11). After completing all excavation of the cavern, a set of permanent ventilation structures are to be built and handed over to the next stage. The OHVD consists of combination of precast/semi-precast elements and cast-in-situ elements, where the precast/semi-precast parts adopt DfMA method. Due to the large volume of structures to be built, the application of DfMA greatly reduces the construction time compared to conventional cast-in-situ method.

Figure 7. BIM deepening design for MiC.

Figure 8. BIM construction process management.

Figure 9. BIM+Survey.

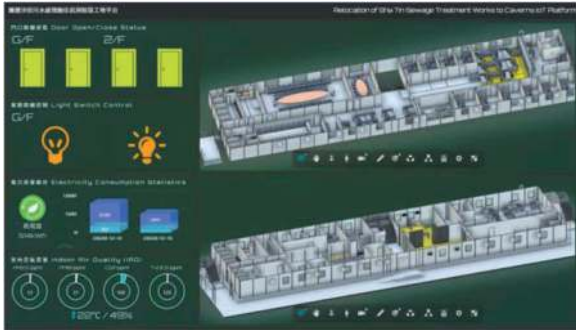

Figure 10. BIM+IoT.

Figure 11. Design of overhead ventilation ducts.

3.2.2 Modular integrated Construction (MiC)

MiC, standing for Modular Integrated Construction, is one of the most important aspects of DfMA, mainly focusing on housing facilities. The Community Liaison Centre (CLC) of the STC project was built using MiC technology. All 14 modules were produced in Zhuhai and transported to Hong Kong. They were lifted and assembled within two days to reduce the impact on surrounding residents. By adopting MiC, it has saved labour costs and achieved early completion within the limited construction period during the COVID epidemic.

3.3 Construction assistance software

Several construction software were adopted during the construction of STC. For example, all Jumbos are equipped with iSure, a computer program which helps tunnelling construction and drill and blast process control. It produces all the data needed for optimized drilling and blasting cycle; For shotcrete, Real-time Spraying monitoring System was used. This system adopts a laser scanner to scan the surface of the shotcrete and generate a point cloud data. The comparison results between the point cloud data and the design surface can be obtained within 2 seconds, guiding the spray operation, reducing material waste and rework, and greatly reducing the workload of the survey team (Figure 12).

Figure 12. Real-time spraying monitoring system.

4 MANAGEMENT

4.1 Establishing 5G/Wi-Fi and IoT system

STC conducts research on the construction of 5G base stations and Wi-Fi networks on site, and established the first on-site 5G base station in Hong Kong to provide networks for the whole cavern (Figure 13). Based on 5G base stations and Wi-Fi networks, STC established Internet of Thing (IoT) System on site, including AI CCTV System, UWB Positioning, AMS System, Intelligent Weight Bridge System, etc, enhancing the efficiency of management.

4.1.1 AI CCTV system

AI detection involves processing image data captured by cameras through a certain algorithm and comparing it with known objects in the database; Next, the algorithm will identify objects that are similar to existing objects in the database and return the results.

The AI CCTV used in STC detects unsafe behaviour, wheel cleanliness, and marks out the restriction area to keep unrelated staff away by sounding alarm (Figure 14).

4.1.2 UWB positioning technology

The Ultra-wideband (UWB) Positioning Technology is a type of indoor positioning technology with high development prospects. It has advantages such as strong penetration, low power consumption, good multipath resistance, high security, low system complexity, and the ability to provide precise positioning accuracy. Therefore, UWB positioning technology can be

applied to the positioning, tracking, and navigation of stationary or moving objects, including people indoor, with very accurate positioning information.

4.1.3 Air monitoring system

Air Monitoring System (AMS) is adopted to detect air flow velocity, temperature, humidity, and level of the usual five confined space gases, namely oxygen, methane, hydrogen sulphide, carbon monoxide and radon, especially after blasting. The thresholds of each kind of index are shown in Table 5.

Figure 13. First On-site 5G Station (Outside/inside Caverns).

Figure 14. AI CCTV Detection.

Table 5. Air quality thresholds.

Item	Unit	Threshold
Oxygen	%	19.5~22
Methane	%LEL	≤ 10
Hydrogen Sulphide	ppm	≤ 10
Carbon Monoxide	ppm	≤ 25
Radon	Bq/m ³	≤ 100
Air Flow Velocity	m/s	≥ 0.5
Wet Bulb Temperature	°C	≤ 27

4.2 Low-carbon construction management

The STC project aims to achieve the goal of reducing carbon emissions during the construction process. To achieve this goal, permanent electricity stations were installed instead of generators; reasonable methods to handle blasted boulders and innovating construction processes were carried out; Simultaneously utilizing automatic sprinkler

systems, environmental monitoring, blasting doors, and reprocessing of environmentally friendly wood into furniture were also put into effect to achieve the goal of reducing waste and pollution emissions during the construction process. In addition, the construction team conducted a carbon emission inventory of the project, seeking feasible paths for ultra-low carbon construction, and realizing the responsibility of the company and the project to society and environmental protection.

5 PROSPECTS OF FUTURE RELOCATION OF SEWAGE TREATMENT PLANTS TO CAVERNS IN CHINA

5.1 Feasibility of constructing USTPs in China

According to the National New Urbanization Plan (2021-2035) released by the National Development and Reform Commission (2022), with the increasingly severe resource constraints and the comprehensive delineation of urban development boundaries, the scale of newly added construction land is controlled to within 29.5 million acres. It is also imperative to transform urbanization development from time oriented to quality oriented. Underground sewage treatment plants fully occupy underground space and efficiently utilize state-owned resources, both of which are in line with the trend of urban development in China.

“Ecological civilization and green health” is one of the guiding principles of urban planning in China. Underground sewage treatment plants not only meet the basic environmental needs of sewage treatment and pollutant discharge standards, they also eliminate the hidden dangers of secondary pollution such as odor and noise. They are an important component of ecological civilization construction.

5.2 Advantages of Cavern-based USTPs

(1) Release ground spaces for multipurpose

The released spaces can be used as a comprehensive office building in the factory area for personal use, as well as to build parks, green landscapes, and other buildings to beautify the environment. It can also be developed into projects such as parking lots etc. Foreign experience can be referenced to build profitable projects to further improve economic benefits.

(2) Reduce secondary pollution

When located in caverns, with the surroundings isolating the noise and odor generated during equipment operation, the sewage plants creates almost no secondary pollution, and zero impact to the environment outside caverns.

(3) Stabilize the operation of sewage plants

Traditional sewage treatment plants are susceptible to variation of temperature, and biological

treatment may not operate properly in low temperatures. The characteristics of thermal expansion and contraction of building materials can also cause pipeline system failures when temperature changes are significant. The sewage treatment plant built in a cavern is underground, with a relatively constant temperature and less affected by the external environment, which can ensure the stable operation of the system. Finland, Norway, Sweden and other countries are located in high latitudes and have cold winter temperatures. Therefore, these are also considerations for vigorously developing underground sewage treatment plants.

5.3 *Disadvantages of Cavern-based USTPs*

The construction of sewage treatment plants in caverns usually requires deep excavation, as well as the construction of pre-construction vehicle access channels, which is relatively difficult and costly compared to traditional aboveground sewage treatment plants; In addition, setting the main body of the factory in cavern will have a significant negative impact on natural ventilation and lighting. In order to ensure the health of underground workers, it is necessary to increase ventilation, lighting and other equipment, thus significantly increases the operating costs after being put into use.

5.4 *Summary*

With the further growth of China's economy and the acceleration of urbanization, urban development planning will start from a higher level. Focusing on the future development of the city, adhering to the principle of adapting to local conditions, selecting the scale and address of underground sewage treatment plants reasonably, developing more underground space usage in the factory area, strengthening integration with the surrounding environment, paying attention to the connotation of sustainable development and ecological civilization construction, promoting the coordinated development of the city's economy, society, and ecology in all aspects. The future

development of sewage treatment plants constructed in caverns is expected.

6 CONCLUSION

This paper first reviewed the main characteristics of underground treatment methods. Taking the Sha Tin Caverns as an example, this paper presented the idea of a complete and total solution for the construction of such caverns, focusing on key points such as the construction methodology, implementation of new technology and management for such large caverns. This paper also discussed the prospects of future relocation of sewage treatment plants to caverns.

Challenges in planning, design, and construction of the underground power plant station cavern Kühtai 2

Alex Morocutti*

Pini Group, Innsbruck, Austria

Peter Wetzlinger

Swietelsky Tunnelbau, Salzburg, Austria

Rupert Steiger

TIWAG – Tiroler Wasserkraft AG, Innsbruck, Austria

ABSTRACT: The new pumped storage power plant station Kühtai 2 including the underground machine and transformer cavern, the new headrace tunnels and the new Kühtai reservoir comprising collection, connection and investigation tunnels produce renewable energy flexibly and on demand and will serve to the intermediate storage of electricity from other renewable sources. The project is situated in the middle of the Alps in Kühtai, Tirol, Austria and is part of the expansion group “Sellrain-Silz” power plants. Once completed, its purpose is to provide autonomous and environmentally friendly renewable energy.

The most important components of the new Kühtai 2 project comprises an underground power station, a headrace tunnel that connects the new Kühtai reservoir with the existing reservoir, the new Kühtai rockfill dam with a usable storage capacity of about 31 mio m³ and the excavation of a 25.5 km long stream adduction tunnel with hard rock TBM.

The focus of this paper is a comprehensive description of the design considerations and the challenges faced through the excavation of the underground power station built completely in a rock cavern, designed for pumped storage operation. The machine cavern has dimensions of length/width/height 65/26/40m and the parallel situated transformer cavern has dimensions of 55/14,5/19m. These caverns were excavated with drill and blast method through different access tunnels different points of attack. This article shows the exciting particularities and challenges that were encountered during planning, design, and construction of the caverns.

Keywords: Cavern excavation design, construction experience, drill and blast, pumped storage

1 PROJECT OVERVIEW

The Austrian company TIWAG-Tiroler Wasserkraft AG that mainly generates electricity from hydropower is currently expanding the existing Sellrain-Silz power plant group with a second upper stage unit, consisting of the Kühtai reservoir, the Kühtai 2 hydropower pump storage plant. First planning and drafting of environmental impact and assessment declaration of the new power plant begun in 2006. In June 2016 the environmental impact assessment has been approved by Tyrolean government and in June 2019 the legal effective has been approved from federal administrative court, so the preliminary work started in September 2019. The main construction works of the plant started in April 2021. The overall facility is scheduled to be commissioned in

the mid of 2026. The project includes headrace and tailrace tunnels as well as a 25 km long water adduction tunnel to the reservoir excavated by an open gripper TBM. The power plant is housed in an underground cavern and will have an installed capacity of 140 MW in turbine mode and 130 MW in pump mode.

The power cavern is situated between the existing reservoir Finstertal and the new Kühtai reservoir, currently under construction, on the orographic right-hand side of Längental. A 1250 m long inclined penstock and a 525m long tailrace tunnel provide the connection between both reservoirs.

The cavern houses the mechanical and electrical plant components for the turbine and pump operation as well as equipment for the monitoring of the power plant.

*Corresponding author: alex.morocutti@pini.group

The size and the shape of the cavern is optimized to meet geotechnical as well as space requirements of the individual components of the power plant.

Figure 1. Project overview.

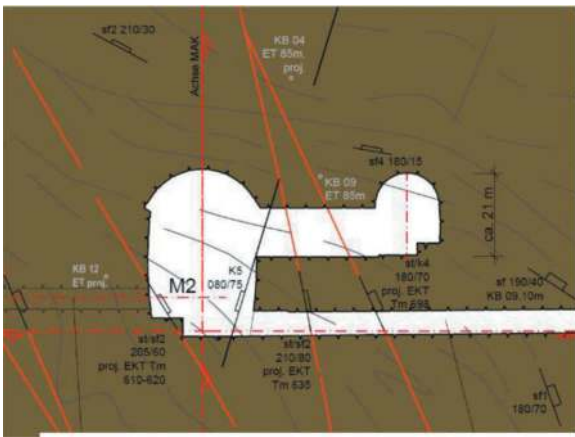

Figure 2. Geological situation.

2 GEOLOGY

The project area is in the Ötztal and Stubai Alps, both of them belong to the east alpine crystalline formation. The prevailing rock mass type in the cavern area is biotite-plagioclase gneiss, which is partly heavily folded. The fold axes generally strike in east-west direction. The three dominant fold systems in the cavern roof are 180/15, 180/75 and 210/80. The distance between the individual folds is approx. 20 to 60cm. Due to the complex rock structure, a changing foliation orientation is present in the cavern area.

3 DESIGN PROCESS

3.1 Study of variants

During the design process for the Kühltal 2 power plant, two cavern variants (single cavern & double cavern) were compared, taking into consideration the geotechnical requirements as well as the requirements for mechanical and electrical system components and maintenance during operation. Furthermore, it was determined that the cavern should have an inner lining to avoid the use of permanent bolting and

permanent shotcrete. The longitudinal cavern axis was selected in such a way that foliation and faulting of the rock mass is orientated transversely to the cavern and unfavorable wedges are avoided.

Variant 1, single cavern solution:

In this variant, all electro - mechanical components such as turbines, transformers and control features should be accommodated in a 72.0 m long, 48.0 m high and 29.0 m wide cavern (Figure 2). In this type of cavern, the two sets of machines are arranged side by side in cross section.

Figure 3. Single cavern solution.

Variant 2, double cavern solution:

In case of the double cavern solution, the machine cavern is 65.0 m long, 40.3 m high and 26.0 m wide. The two sets of machines are arranged side by side along the longitudinal axis of the machine cavern. The transformer cavern has a length of 55.0 m, a height of 17.6 m and a width of 15.5 m. The clear distance between the machine cavern and the transformer cavern is approx. 29 m. The transformer cavern is accessed from the machine cavern via the connection cavern, which is 29.0 m long, 7.5 m high and 6.0 m wide. In addition to the connection cavern, two converter caverns are arranged between the machine cavern and the transformer cavern. The converter caverns are 29.0 m long, 12.0 m high and 9.0 m wide. The size of the remaining rock pillars between the machine cavern and the transformer cavern were selected such, that they are able to resist the concentrated rock pressure. The layout of the double cavern solution is shown in Figure 4.

Figure 4. Double cavern solution.

3.2 Excavation design

3.2.1 Excavation sequences

During the work preparation several variants for the excavation of the caverns were discussed. The task was to work out the most efficient excavation concept based on the geological forecast. This was particularly important for the machine concept as it was not possible to swap selected plants within a short period of time due to the global political and economic environment.

The excavation design supposes that the excavation of the caverns (machine cavern, transformer cavern, converter cavern and the connection cavern) takes place in 5 phases.

- Phase 1: All the tunnels surrounding the caverns (access tunnels, drainage tunnels) are excavated in advance of any cavern in order to avoid unfavourable stress redistribution to the main caverns.
- Phase 2: An exploratory tunnel is driven at the lowest point. The tunnel serves to verify the geological assumptions in detail and as a mucking tunnel for the lowest level of cavern excavation.
- Phase 3: Advancing the top heading of the transformer cavern, followed by the top heading of the machine cavern plus the first bench in the machine cavern and the connection cavern. The next stage is to complete the bench excavation in the transformer cavern and to excavate both converter caverns.
- Phase 4: Concreting and anchoring of the crane abutments as well as casting the concrete lining in the vault of the machine cavern is carried out.
- Phase 5: Finalising bench excavation in the machine cavern.

3.2.2 Support measures

Temporary support measures are applied to avoid progressive loosening of the surrounding rock mass and to retain unstable wedges during the excavation works. The support of the cavern comprising shotcrete and systematic bolting is installed immediately after each round of excavation. The entire cavern complex (machine cavern, transformer cavern, connection cavern, converter caverns 1 and 2) is supported by a 25cm thick shotcrete lining reinforced with two layers of wire-mesh (AQ60) and lattice girders.

Grouted bolts with a length of 9 m, an ultimate load capacity of 440 kN and installed at 1.7 x 1.7 m centres are used in the machine cavern. In the transformer cavern, in the connection cavern and in the converter caverns 1 and 2 grouted bolts with a length of 6 m, an ultimate load capacity of 440 kN are installed at 1.7 x 1.7 m centres. Near the

junctions of the caverns, the bolting pattern is condensed to a spacing of 0.85 x 0.85 m.

Figure 5. Support measures.

Figure 6. Installing GEWI 32 Anchor bolts 9 m.

The excavation process was supported by an extensive instrumentation and monitoring program existing of

- Extensometers with 3, 5 and 25m meters
- Anchor measuring plates.
- geotechnical measurements (Convergence measurements; Extensometer measurements, Anchor force or pressure measurements)

All the Information was daily available to react quickly to changes.

Figure 7. Geotechnical monitoring of rock bolts.

3.2.3 Inner lining machine cavern

The temporary excavation support of the cavern is applied as described in chapter 3.2.2 using shotcrete and systematic bolting. To reduce maintenance efforts during the operation phase, no permanent bolts are installed in the cavern. A 60 cm thick concrete inner lining is placed in the top arch after the excavation of the first bench in the machine cavern instead.

The inner lining consists of 8 individual cast in-situ arch elements with a slot of 50 cm between each element. The slots between the arch elements ensure that hydrostatic pressure cannot build up behind the inner lining. While excavating benches number 2 to 6 in the machine cavern and before the concrete columns are placed under the crane, the elephant's feet and the crane beams, which are situated underneath the top arch, serve as a foundation for the inner lining.

Figure 8. Inner lining works in the machine cavern November 2023.

Figure 9. Slots between the arch elements.

4 CONSTRUCTION EXPERIENCE

A crucial component was the exploratory tunnel which was driven at the lowest point. The exploration tunnel was designed that it could ultimately be used as a drainage tunnel for the five caverns in long term.

In advance, important geological discoveries were made during exploratory drilling and geophysical investigations. These results were then incorporated into the drill and blast concept for the five caverns.

The excavation work started on March 16, 2022, in the transformer cavern top heading. This work was completed on April 06, 2022. Subsequently, starting at the beginning of April 2022 until mid-July, the machine cavern roof, the connecting cavern as well as the first bench of the machine cavern were excavated.

The top heading excavation of the machine cavern, the transformer cavern as well as the excavation of the converter caverns and the connecting cavern was carried out in the classic way (horizontal drill and blast in short excavation rounds like 1.70 m) using standard underground construction equipment.

Figure 10. Machine for geological discovery.

Figure 11. Optical Borehole Imager (OBI).

Due to the geological conditions, it was possible to drill and blast the top heading, which originally was divided into three parts, at once. The covered area of the whole top heading was about 204m² and a round length of 1,7m.

The benches in the machine cavern and in the transformer, cavern was excavated using vertical blasting, similar to the procedure in a quarry.

The required vertical blast holes were drilled with a Sandvik ranger surface drill rig. It turned out that the individual blast holes can be produced very precisely and highly efficiently with this device. The round length/bench height for the vertical benching was until 3.40 m.

The rock mass conditions, and the system behaviour largely corresponded to that anticipated by the design. Only during the excavation work at the elephant's feet in the machine cavern which is later used as an abutment for the crane beam and the inner lining did problems arise due to the sometimes very steep sloping foliation. As a result, parts of the elephant's feet were lost. It was discovered that an elephant's foot is difficult to realize with drill and blast in unfavourable geological conditions. Those parts of the elephant's foot that got lost were subsequently restored using shotcrete and additional bolting. Subsequently bench excavation followed in the transformer cavern, which lasted until the end of August 2022. The excavation of the two converter caverns was completed at the beginning of September. Up to this point, all the construction logistic (mucking and transport of construction materials) was accommodated via the cavern access tunnel.

Figure 12. Excavation works in the cavern in June 2022.

Figure 13. Installing of mechanical part and inner lining.

5 CONCLUSIONS

In the anticipated programme the whole cavern excavation works should be completed in May 2023. In the fact the works were completed in March 2023, so the inner lining works have been started earlier as programmed.

The excavation of the large caverns with notable dimensions in the geological zone of biotite-plagioclase gneiss could be completed without significant problems and in totally safety in according with a sophisticate and detailed planning by the client TIWAG itself.

Demanding preliminary investigation of the geological situation and optimizing size and position of the cavern as described in chapter 2 were also quite important. Also very significant was the optimization of the excavation sequences by contractor in the months of preparatory work before excavation start.

This exciting piece of construction work was only possible thanks to the extraordinary and unique cooperation between client, contractor and site supervision.

The focus actually is on the inner lining and the installation of the mechanical part and equipment of the power plant.

The prospective of the main construction works of inner lining should be completed in second half of 2024.

The use of underground space in greater Kuala Lumpur

Teik-Aun Ooi*

TAO Consult Sdn Bhd, Kuala Lumpur, Malaysia

Chee-Min Khoo

Mass Rapid Transit Corporation, Kuala Lumpur, Malaysia

ABSTRACT: Kuala Lumpur was founded in the late 19th century as a tin mining settlement at the muddy confluence of the Klang and the Gombak Rivers. A century later it has become Malaysia's largest city, its capital and the heart of cultural, financial and economic. It is one of the fastest-growing cities in Asia. Greater Kuala Lumpur, also known as the Klang Valley, extends beyond the boundaries of Kuala Lumpur, it comprises Kuala Lumpur, Putrajaya and 8 districts in Selangor with urban agglomeration of 8.44 million people as of 2020. Given increasing population growth and the rapid pace of development, urban congestion, traffic gridlock and devastating bouts of floodings has become a common phenomenon. The pressing urban phenomenon of metropolis in a developing nation also poses extreme infrastructure needs, which are compounded by inadequate water supply, sewerage and treatment system, and limited parking space, among others. The transformation of Greater Kuala Lumpur into the ultra-modern metropolis has brought along challenges for the town planners and engineers to have innovative underground solutions. This paper discusses the use of underground space in solving the urban problems of Greater Kuala Lumpur/Klang Valley. With a few case studies, it highlights how innovative use of the underground space in Greater Kuala Lumpur can bring more optimal solutions for urban sustainable development and resilience in line with the United Nation's Sustainable Development Goals (SDG).

Keywords: Underground space, Greater Kuala Lumpur, Urban problems, Underground solutions, Sustainable development

1 INTRODUCTION

Kuala Lumpur or KL as it is more fondly called was founded in the late 19th century as a tin mining settlement at the muddy confluence of the Klang and Gombak Rivers. A century later it has become the nation's largest city and serves as the cultural, financial, and economic centre of Malaysia. Rated as alpha world city, it is among the fastest-growing cities in Asia.

Greater Kuala Lumpur extends beyond the boundaries of Kuala Lumpur, it comprises Kuala Lumpur, Putrajaya and 8 districts in Selangor. In 2020, the population of Greater Kuala Lumpur is 8.44 million and it generates about MYR537 billion of the nation's Gross Domestic Product (GDP) (Source: DOSM). This translates to 25 % of the national population contributing more than 40 % of the nation's GDP, proving that Greater KL is indeed the engine of the nation's economic growth. Greater

Kuala Lumpur is ranked 10th in Asia's Top 10 cities in Mercer's Quality of Living 2019 survey while the Global Power City Index 2020 ranked Greater KL 14th on its liveability rankings, second in the Asia Pacific region. Figure 1 shows some of the on-going major developments in Greater Kuala Lumpur.

Worldwide, rapid urbanization in developing countries has produced many urban problems such as the need for more affordable housing, traffic congestion, water and power distribution systems, sewerage systems, lack of green space, reduction of air and noise pollution and other population growth issues. The related problem of sprawl away from the urban core strains the environment by creating more traffic gridlock. Greater Kuala Lumpur have all of them, though not in the scale of other Asian nations. Perhaps, it has its own set of challenges – flash floods.

Since 1990s, urban congestion, traffic gridlock and devastating bouts of floodings has become

*Corresponding author: drtaooi@gmail.com

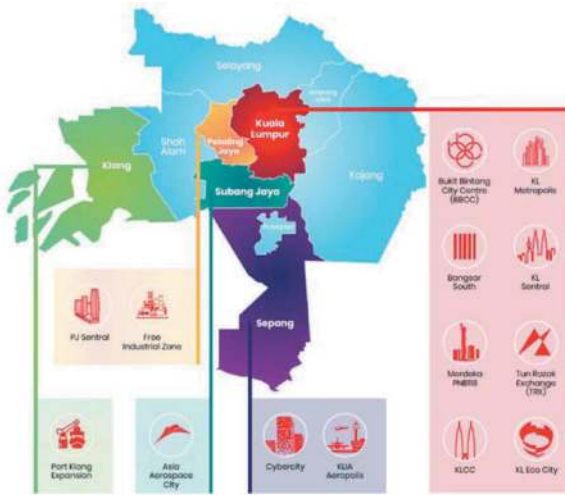

Figure 1. Some on-going major developments in Greater Kuala Lumpur.

a common phenomenon in Greater Kuala Lumpur. On the flip side, we have also seen a lot of major underground space developments especially in transportation (motorways, metros) and public utilities (water supply, sewerage, flood mitigation) in meeting the urbanization needs and challenges, tackling natural hazards and climate change. As a metropolis in the developing world like Kuala Lumpur, ought to take advantage of innovations in engineering and science that will enable them to explore and gain new frontiers in underground spaces as a key element of sustainable development and resilience.

This paper discusses the use of underground space in solving the urban problems of Greater Kuala Lumpur/Klang Valley in view of the rapid growth and unprecedented challenges. With a few case studies, it highlights how innovative use of underground space can bring more optimal solutions for urban sustainable development in line with the United Nation's SDG.

2 STORMWATER RELIEF AND FLOOD MANAGEMENT

Kuala Lumpur (KL) is situated at the confluence of two tributaries of the Klang River and has, from the earliest days, been subjected to flooding. The earliest recorded incident was the flood of 1926 and the largest in recent history was the flood in January 1971 which lasted for 5 days and claimed 32 lives. About 445 hectares of land in the city were inundated to various depths of up to 2 m and the cost of damage was estimated to be in the region of MYR36 million (Abdullah, 2004). The disastrous flood of January 1971 prompted the Malaysian Department of Irrigation and Drainage to establish Kuala Lumpur Flood Mitigation Project which incorporated several engineering options including upstream storage, polder, and pumped drainage, and improving of the

drainage capacity of the Klang River and its major tributaries. The increasing pace of development since 1900s resulted in a three-fold increase in the annual discharge of the Klang River at the city centre. The city has been frequently affected by occurrences of flash floods which descend with hardly any warning and totally upset city routine.

In 2001, the Malaysian Government sought proposals for a more effective solution to flooding, to prevent disruption to the city's centre routine during a typical flood event with a duration of three to six hours. The original idea was for a tunnel that would allow floods to bypass the city centre coupled with temporary storage facilities to keep flows downstream of KL within the capacity of the river channel. However, if the tunnel standing empty for most of the time in a year it will not be economical and justifiable expense at public cost. At the beginning of the design stage, an idea to incorporate a road tunnel within the length of the tunnel was proposed to the government to reduce the contribution from public funds and make the project more attractive and more economically viable. A tolled motorway section was integrated into the system to relieve and reduce traffic congestion at the main southern gateway leading to the city centre.

The above ingenuity gives birth to the first of its kind of dual-purpose tunnel in the world – the Stormwater Management And Road Tunnel (SMART). Under the SMART system, excessive upstream water is diverted at the confluence of Klang River and Ampang River into a holding basin. It was then directed to the Taman Desa storage reservoir downstream via the 9.7 km long and 11.83 m internal diameter by-pass tunnel that acts like an underground river, before being released back in stages into the Kerayong River which is a tributary of Klang River. The discharges passing through the city with and without the SMART tunnel are as shown in Figure 2.

Figure 2. Discharge passing through the city with and without the SMART tunnel (after Abdullah, 2004).

The primary goal of the SMART tunnel was to mitigate flooding caused by heavy rains during the

monsoon reason. By creating a storage tunnel as a release mechanism for the water, Kuala Lumpur can be spared from the expense of flood damages and the retroactive responses to a flood. A second objective of the tunnel was to reduce traffic congestion at the main southern gateway of Kuala Lumpur leading to the city centre. Use of the tunnel also leads to traffic reduction on the above-ground roads. Figure 3 shows an artist's impression of the SMART tunnel. The middle section of about 3 km in length integrates both flood mitigation and motorway purposes.

Figure 3. An artist's impression of the SMART tunnel.

The greatest benefit of the SMART tunnel is that it helps make the city more resilient. In operation for over 15 years now, the SMART tunnel mitigates 45 % of the total flood risks in the Kuala Lumpur, and its activation has saved the city from gridlock and possibly more serious disaster (The Star, 12 February 2022). Because of this infrastructure, areas such as Masjid Jamek area, Dataran Merdeka, Leboh Ampang and Jalan Melaka have witnessed no flooding incidents since SMART tunnel opened in 2007, which has allowed business to operate without interruption. Figure 4 shows the situation before and after SMART activation at Pekeliling area in Kuala Lumpur.

As of December 2021, the SMART tunnel has diverted flood waters on 40 occasions and averted an estimated MYR1.4 billion in public damage (The Star, 22 December 2021). Beyond which, the Department of Irrigation and Drainage's survey concluded that, within the concession period spanning three decades, the SMART tunnel is expected to prevent US\$1.58 billion of possible flood damage and up to US\$1.26 billion savings from traffic congestion (ITS International, 12 September 2012). The savings are likely to be significantly more since these estimates are only for the duration of the concession. The tunnel has a design life of some 100 years.

That said, the SMART tunnel only diverts water around the critical meeting point from one of the contributing rivers. The increase in the frequency

Figure 4. (a) before SMART activation, (b) after SMART activation at Pekeliling area in Kuala Lumpur (The Star, 22 December 2021).

and intensity of major storms due to climate change coupled with the growing development in other parts of the city could not ensure no flooding will take place or thoroughly protect the city centre. Recently, it was reported that Kuala Lumpur City Hall was working with Department of Irrigation and Drainage to build a high-capacity underground stormwater storage tunnel to overcome the issue of flash floods in the nation's capital (New Straits Times, 3 June 2022). This is one of the long-term solutions to solve the problem for good. Time is of the essence for Kuala Lumpur to take urgent action to create more resilient city that is adapted to the impacts of climate change including flooding.

3 URBAN WATER SUPPLY

One of major problems faced by Greater Kuala Lumpur due to rapid urbanisation – there is not enough water for both daily life and industrial use. According to *Suruhanjaya Perkhidmatan Air Negara* (National Water Service Commission), the total water demand for Selangor, Kuala Lumpur and Putrajaya has more than tripled since 1990. The water supply situation in Selangor and Kuala Lumpur was expected to reach critical levels with water demand envisaged to exceed supply as early as 2014 (Ismail, 2009). Development has been moving forward to ensure water resources in Langat River basin in Selangor to deal with the city's rapidly increasing demand of water. However, efforts to secure resources had not always gone as planned, as demonstrated by such problem as the serious water shortage in the region

for approximately half a year from 1997 to 1998 during the dry season that brought in the haze from Sumatra for the first time (The Edge, 20 April 2009). The Malaysian government considered various plans to address this issue and eventually came to the conclusion that, from the perspective of the amount of water needed as well as cost, it would be best to channel water by constructing a tunnel to the state of Selangor from the stage of Pahang, a water-rich region in the central part of the Peninsula.

In June 2009, Malaysia began a project to build the Pahang-Selangor raw water transfer tunnel as illustrated in Figure 5. It is the longest and biggest tunnel in Southeast Asia and the 8th longest water supply tunnel in the world - a 44.6 km long, 5.23 m diameter tunnel starts at Karak, Pahang, running deep under the ground up to 1,200 m below the Titiwangsa mountain range and hot springs (Ooi & Khoo, 2017). The tunnel would convey 1.89 million litres of raw water daily from Semantan River in Pahang to a new Hulu Langat water treatment plant in Selangor. It has the capacity to convey 27.6 m³ of raw water per second. The great advantage of having the water flow in gravity-driven underground tunnel is that it does not evaporate.

Construction works involved excavation using tunnel boring machines (TBM) for 35 km, while the remaining length was excavated by conventional drilling-and-blasting and by cut-and-cover. The upper and lower ends were excavated by New Austrian Tunnelling Method (NATM). This huge tunnelling project was successfully completed in May 2014 and was able to overcome the various

challenges (e.g. Lepoh fault - over 50 m high empty cavern inside a mountain, pressurised spring water that shot out as much as 24.6 cu.m of water per minute, high rock temperature as high as 55 °C, rock burst, etc.) thanks to the strong solidarity of its multinational team consisting of over 1,000 people from 15 countries (Matsumoto, 2013).

In time, this raw water source from Pahang helps to increase the availability of water resources in the basin to meet the high demand for treated water supply and mitigated the water supply crisis by ensuring that the water source in Langat River is at sufficient level and has a low ammonia level as well as complying with the requirements of the National Standard for Drinking Water Quality Malaysia. The immediate beneficiaries are the people, not only the households but the industries, and factories as well as the agricultural producers. It provides water security for the Greater Kuala Lumpur region, which comprises the capital Kuala Lumpur, Putrajaya and the southern half of Selangor. The tunnel solution is a green initiative – the forest reserves in central Peninsular Malaysia have not been touched by the underground works.

4 URBAN SPRAWL AND PUBLIC TRANSPORTATION

As with most capital cities in the world, urban sprawl has also been a trend in Greater Kuala Lumpur due to abundant work and business opportunities in the city centre. Increased urban sprawl, reduced public transport usage, and increased private vehicle ownership led to massive traffic jams in Kuala Lumpur. Traffic jams in 2018 alone led to economic activity inefficiencies and the country suffered between 1.1 – 2.2 % loss in gross domestic product (GDP) in terms of wasted fuel, carbon emissions, delays, and vehicle maintenance (New Straits Times, 2 January 2020). There is ample evidence linking traffic congestion to environmental degradation. According to Mustapa & Bekhet (2015), the transportation sector accounts for 28 % of greenhouse gases emissions in Malaysia, of which 85 % comes from land transport.

Since 1990s, many phases of the transportation systems have been developed. In 2010, in order to further reduce the traffic congestion in Klang Valley, the Malaysian Government spent billions in new urban rail expansion projects including the 35 km LRT extension – Kelana Jaya Line/Ampang Line, 38 km LRT 3 – Shah Alam Line and the development of Klang Valley Mass Rapid Transit (KVMRT) up to 2030. The KVMRT involves construction of a rail-based public transport network, together with the existing urban rail network, will form the backbone of the public transport system in the Greater Kuala Lumpur/Klang Valley. It consists of three lines linking the capital districts with the centre of the city, aiming to develop a modern and efficient urban metro system in Kuala Lumpur.

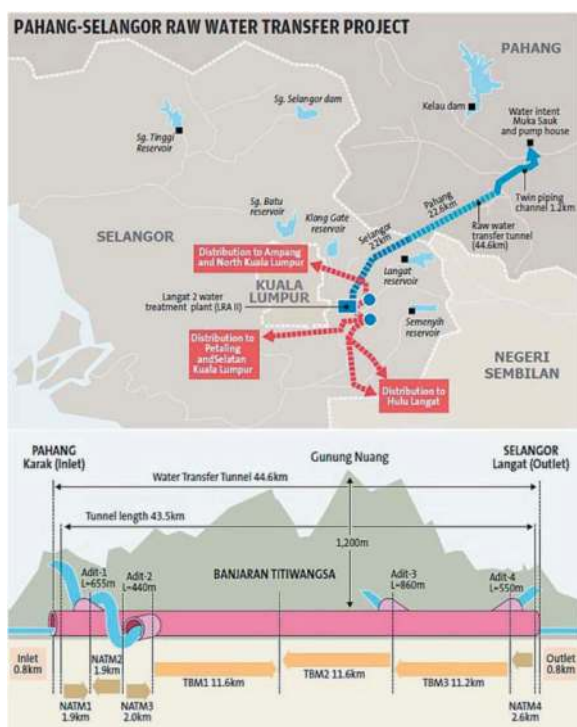

Figure 5. Pahang-Selangor raw water transfer tunnel.

Figure 6 shows the existing integrated transit network that primarily serves the area of Klang Valley and Greater Kuala Lumpur. Like all other metro underground railway designed as part of the urban city, the first MRT line implemented is the 47 km Kajang Line, of which 9.5 km is underground tunnels with 7 underground stations. The second MRT line – Putrajaya Line, began fully operations on 16 March 2023, stretches from Sungai Buloh to Serdang and ends at Putrajaya for a length of 57.7 km, of which 13.5 km is underground tunnels with 10 new underground stations. Line 3 - the Circle Line forms the backbone of the metro as it loops around the business districts of the city, it will serve an important role to tie-up and integrate the currently disjointed LRT, KTM and monorail lines. Construction is expected to commence soon.

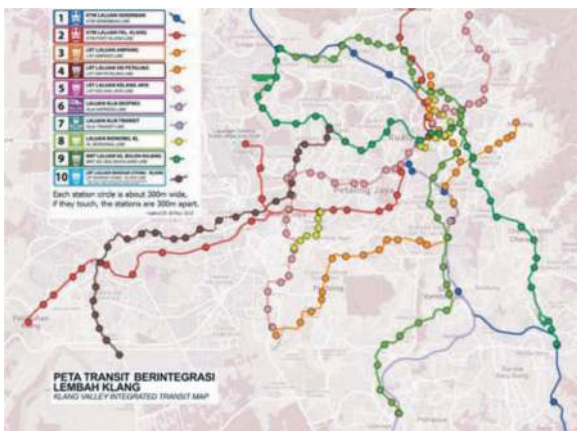

Figure 6. Integrated transit network in Greater Kuala Lumpur.

The completion of the KVMRT Kajang Line and Putrajaya Line not only transforms Kuala Lumpur’s underground but also the heart of Malaysia. It changes the landscape of underground space development in Kuala Lumpur significantly as it will generate a sustainable city with greater connectivity. Urban accessibility will be improved through public transportation. Figure 7 shows an example of the upcoming transit-oriented developments (TOD) in downtown Kuala Lumpur. Typically, it entails development of a microcell of the city directly connected to the metro station with TOD buildings rise over and around the station and tunnel.

5 UNDERGROUND SEWERAGE TREATMENT PLANT

In line with Greater Kuala Lumpur’s socio-economic development, modern sewage treatment plants have also been developed alongside to treat sewage more efficiently and to accommodate the increase in population, which increases yearly. One of the most modern

Figure 7. Transit-oriented developments in downtown Kuala Lumpur.

plants is the Pantai 2 Sewage Treatment Plant (STP), the country’s first and biggest sewage treatment plant as well as the largest in Asia Pacific which was constructed underground and equipped with state-of-the-art green technologies. Previously, the plant used to house an open-air oxidation pond system that could only accommodate 877,000 population equivalents (PE), see Figure 8 (The Star, 22 December 2022). The unfortunate by-products of this service are the water pollution and unpleasant odour that emanate from the facility. Today, the Pantai 2 STP has been upgraded and capable of treating sewage for 1.423 million PE which could cater to a growing population until 2035. The plant can receive sewage flow from a 6,700 hectares Pantai catchment covering central and south-western parts of Kuala Lumpur.

Figure 8. Oxidation ponds at Pantai 2 STP around the year 1984 (The Star, 22 December 2022).

One of the main highlights of the project is that the plant was constructed on the same site as the previous oxidation ponds and comprises two main parts: the fully underground multi-layered sewage treatment facility that goes 17 m deep and the sludge treatment facility above ground developed together with a recreation park right above the underground plant. The park is home to all sorts of sports, leisure and community facilities for the residents and splashers of

lush greeneries and waterways, which spans an area of 12 hectares. The Pantai 2 STP features the use of various green technologies including utilising the skylight concept for the underground plant, effluent reuse, rainwater harvesting and the use of biogas and solar panels to generate electricity. The plant also uses energy-efficient equipment to reduce the amount of electricity consumed. The green technology initiatives adopted help to reduce the carbon footprint and create a sustainable future for all. The overviews of pre-construction and post-construction of the Pantai 2 STP are shown in Figure 9, demonstrating an obvious improvement of the community quality.

Figure 9. (a) Before the construction of Pantai 2 STP, (b) Post-completion of Pantai 2 STP.

With centralisation of sewage treatment at Pantai 2 STP, as many as 140 small plants that produce sub-standard effluent can be closed, reducing pollution into the Klang River. The Pantai 2 STP was built with sustainability in mind, capitalising on renewable resources for energy and water to reduce wastage and pollution. This new state-of-the-art mechanised underground regional sewage plant has proved to be a model for innovation in concept, design, engineering and construction – setting new standards for sustainable sewage treatment in Malaysia and transforming its surrounding environment. Above and beyond, the Malaysian Government has also committed to a substantial investment in underground infrastructure for several years with the expansion and refurbishment of sewerage facilities throughout the country.

6 UNDERGROUND PARKING AND TRAFFIC DISPERSAL

In Kuala Lumpur, the use of underground space for both commercial retail outlets and car parks had also witnessed a big development. In a growing number

of cases, basement car parks are being built for most of the high-rise developments in the city centre. Lately, the trend is observed to be going for large-scale parking towards maximisation of space use and allows complete flexibility in the design of buildings and the disposition of uses and activity at ground level.

The KLCC Underground is noteworthy case study. In the early planning days, the site was earmarked as a “green lung” for the city, with little or no commercial development. However, the enormous potential urban rehabilitation opportunity afforded by the site was also obvious. The compromise was to plan and promote a new city centre surrounding a large park with public amenities. It is the intention of KLCC Master Plan to optimise the land-use treatment for future connectivity and public transportation within the city centre. New planning approach, for example, no provision of podium parking, basement parking wall up to the land boundary lines are specially formulated in the KLCC Master Plan (Figure 10). Notably, the Aquaria KLCC, which has an underwater tunnel, is located just beneath the Kuala Lumpur Convention Centre. KLCC have 5 underground levels of car parks beneath the public park for 5,400 vehicles. In addition, KLCC has also built a few dedicated ingress and egress tunnels to connect the area to the main roads directly, i.e. Jalan Ampang, Jalan Tun Razak. The AKLEH access is unique in the sense that the highway has direct tunnel access to the area’s extensive underground parking lot. In 2013, KLCC commenced to construct the new six levels of basement car parks at North-East located underneath KLCC Park to cater for future development.

Figure 10. KLCC master plan with underground connectivity.

Some other similar on-going new landmark developments are the Tun Razak Exchange (TRX), which spread over 70 acres of land, and the 19-acres Merdeka 118 (KL 118) development, both with six levels of underground basements. Both TRX and

Merdeka 118 can directly connect to underground metro stations, see Figure 7. As a lush green tropical heart to the TRX overall master plan – the world largest rooftop 10-acre public park (see Figure 11) lies above the retail with underground basements of more than 20,000 parking bays. The loop tunnel system planned for the movement of vehicles in TRX would enable traffic to bypass inner city roads altogether and divert the traffic underground. The TRX’s loop tunnel allows seamless access to and from major highways like SMART tunnel and MEX that bypass the heavy above-ground traffic in Kuala Lumpur and relieve the congestion along Jalan Sungai Besi enhancing TRX’s traffic connectivity with the future Bandar Malaysia development.

Figure 11. World largest rooftop public park in Tun Razak Exchange.

The Merdeka 118 development involved construction of the second world’s tallest building, 118-storey 678.9 m tall mega skyscraper sits on a common podium containing retail and car parking space over six basement levels and be directly linked from three major roads via underground tunnels. Figure 12 shows the proposed Belfield tunnel in enhancing the connectivity to the Merdeka 118 development.

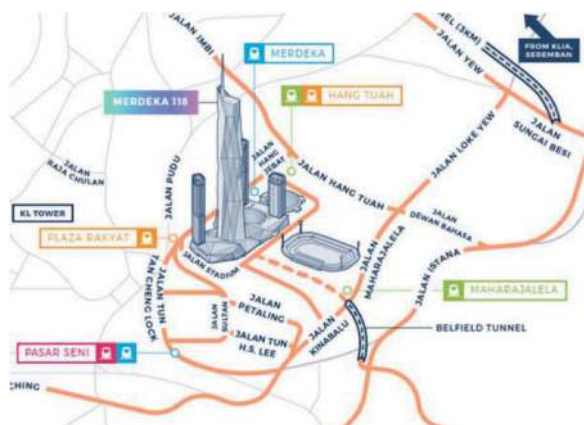

Figure 12. Belfield tunnel connecting to Merdeka 118.

The TRX and Merdeka 118 due for opening soon will set a new benchmark for large scale, mixed use, sustainable integrated urban underground space development in Asia, enhance Kuala Lumpur’s reputation as a highly liveable city.

7 CONCLUSIONS

Since city centre is densely build areas, building underground can relieving pressure on the surface and it can be an attractive solution for solving traffic problems and increasing connectivity. However, use of the underground should not be limited to large scale infrastructure projects. By moving certain facilities below ground, valuable surface area can be preserved for other purposes such as parks, recreational spaces, and commercial developments.

This paper discusses some examples of successful and innovative use of underground space in solving the urban problems of Greater Kuala Lumpur/Klang Valley, yet meeting the urbanisation needs in line with the United Nation’s Sustainable Development Goals. For instance, the SMART tunnel provides great flexibility in terms of climate mitigation and road infrastructure, making the city more resilient and sustainable, i.e. SDG 11 – Sustainable cities and communities, and SDG 13 – Climate action. On the other hand, the Pahang-Selangor interstate raw water transfer tunnel and the Pantai 2 underground sewerage treatment plant respectively deliver universal and equitable access to safe and affordable drinking water and access to adequate and equitable sanitation and hygiene for all under SDG 6 – Clean water and sanitation. The recent conceptualisation of underground tunnels to manage urban stormwater detention underneath the Kuala Lumpur city indicate how is Malaysia faring in its battle against climate change towards a sustainable and resilience development goals.

Resilient public facilities are not just a means of delivering services; it is a critical enabler and guardian of sustainable development. Combination of green and grey infrastructure while creating assets, such as parks over the underground facilities, not only as a sustainable solution to urban growth but also provide public amenities that improve quality of life, as is the case in Pantai 2 STP. For all that, underground parking provides intrinsic environmental and recreation benefits to the city such as the case in KLCC Underground, TRX and Merdeka 118 integrated development which has set unparalleled standards with sustainability at its core.

With the continued development of Klang Valley mass rapid transit, making Kuala Lumpur underground a very important connectivity means through the metro stations. Integration in three-dimension is expected to increase over the years, incorporating underground road tunnels, pedestrian and bicycle tunnels, and public transport facilities like light rail or mass rapid transit systems. The use

of underground space for commercial centres will soon see another wave with active retail development coming along with underground metro network likes Singapore.

SMART tunnel revisited – after 15 years in operation

Teik-Aun Ooi*

TAO Consult Sdn Bhd, Kuala Lumpur, Malaysia

Chee-Min Khoo

Mass Rapid Transit Corporation, Kuala Lumpur, Malaysia

ABSTRACT: Opening on 15 May 2007, the first and one of a kind dual-purpose tunnel in the world – the Stormwater Management And Road Tunnel (SMART) has stood the test of time. It is a nation pride, innovative and a unique solution to the Malaysian capital's long-term traffic and flooding problems. The project was initially incepted primarily to mitigate the recurring floods in the city of Kuala Lumpur since 1971. However, at the design stage, the dual-purpose concept was born from the ingenuity of the project proponents, with a waterway beneath the double-deck motorway tunnel engineered to relieve and reduce traffic congestion at the main Southern Gateway leading to the city centre. The SMART tunnel is touted as a visionary green infrastructure with a sustainable and climate change solution in mind, which helps make the city more resilient. The SMART tunnel clinched the British Construction Industry International Award in 2008 and received the UN Habitat Scroll of Honour Award in 2011 for its innovative and unique management of storm water and peak hour traffic. In April 2015, it was again described by the United Nations as one of the most innovative projects in the world for an urban issue. The SMART tunnel has been listed as one of the top 10 world's greatest tunnels by CNN where the tunnel is expected to prevent billions of dollars of possible flood damage and costs from traffic congestion in Kuala Lumpur's city centre. In operation for more than 15 years now, the SMART tunnel mitigates 45% of the total flood risks in the Kuala Lumpur, and its activation has saved the city from gridlock and possibly more serious disaster. As of December 2021, the SMART tunnel has diverted flood waters on 40 occasions and averted an estimated MYR1.4 billion in public damage, which is expected to continue to save the Kuala Lumpur city from flooding at the time of inclement weather in the foreseeable future. The tunnel has demonstrated the degree of urban underground development Malaysia has achieved and is an example for other developing countries to emulate.

Keywords: SMART tunnel, Dual-purpose tunnel, Innovation, Top 10 world's greatest tunnel, Tunneling in Malaysia

1 INTRODUCTION

Opening on 15 May 2007, the first and one of a kind dual-purpose tunnel in the world – the Stormwater Management And Road Tunnel (SMART) has stood the test of time. It is a nation pride, innovative and a unique solution to the Malaysian capital's long-term traffic and flooding problems.

The SMART tunnel is no stranger to international recognition. The SMART tunnel clinched the British Construction Industry International Award in 2008 and received the UN Habitat Scroll of Honour Award in 2011 for its innovative and unique management of storm water and peak hour traffic. In April 2015, it was again described by the United Nations as one of the most innovative projects in the world for an urban issue. The SMART tunnel has

been listed as one of the top 10 world's greatest tunnels by CNN where the tunnel is expected to prevent billions of dollars of possible flood damage and costs from traffic congestion in Kuala Lumpur's city centre. In operation for more than 15 years now, the SMART tunnel has diverted flood waters on 40 occasions and averted an estimated MYR1.4 billion in public damage, its activation has saved the city from gridlock and possibly more serious disaster (The Star, 22 December 2021). The SMART tunnel is a success. It is unique yet very complex as a whole system though each component has been applied on other projects.

The SMART tunnel is being revisited in this article with a primary objective of re-establishing the associated technical and economic benefits. This article begins with an overview of the project

*Corresponding author: drtaooi@gmail.com

background in the grand scheme of things. The article further elaborated on the tunnel's operations, highlighting the key components and special features driven by opposing needs (alternating wet and dry environments) in the dual-purpose tunnel. Next, construction challenges encountered, and mitigation measures adopted are briefly summarised. It is followed by an appraisal of the technical and economic benefits that have gleaned from this project. The interest in this review is twofold. First, data from the project will be documented and support future research with high-quality information. Second, the experience gained, and lesson learnt could assist the engineers in future projects.

2 PROJECT BACKGROUND

Although a booming city and the nerve centre for Malaysia's economy, Kuala Lumpur was built along the flood plains of the Klang River and thus, from its earliest days, has been subjected to flooding. With heightened land development resulting in increased surface runoff coupled with constrictions along the main rivers running through the city, frequent flooding had brought losses and inconvenience to the business district centre of Kuala Lumpur. The earliest recorded incident was the flood of 1926 and the largest in recent history was the flood in 1971 which lasted for 5 days and claimed 32 lives. About 445 hectares of land in the city were inundated to various depths of up to 2 m and the cost of damage was estimated to be in the region of MYR36 million (Abdullah, 2004). The big flood of 1971 prompted the Department of Irrigation and Drainage to establish Kuala Lumpur Flood Mitigation Project. Over the past decade, incidences of major flooding have become more frequent. In addition, the city has been affected by occurrences of flash floods which descend with hardly any warning and totally upset city routine (see Figure 1).

In 2001, the Malaysian Government sought proposals for a more effective solution to flooding, to prevent disruption to the city's centre during a typical flood event with a duration of three to six hours. The original idea was for a tunnel that would allow floods to bypass the city centre coupled with temporary storage facilities to keep flows downstream of Kuala Lumpur within the capacity of the river channel. However, if the tunnel standing empty for most of the time in a year will not be economical and justifiable at public cost. At the beginning of the design stage, an idea to incorporate a road tunnel within length of the tunnel was proposed to the government to reduce the contribution from public funds and make the project more attractive and viable. One factor in this evolution was that for liability reasons, the tunnel had to run below government-owned land, which led planners to consider locating the tunnel beneath a road. This led to the idea of integrating

Figure 1. Flash flood in Kuala Lumpur.

a tolled motorway into the project. By allowing a portion of the tunnel to be tolled for traffic, private sector participation in a Public-Private Partnership (PPP) could be secured, reducing the costs of the project for the Malaysian Government.

The above ingenuity gives birth to the first and one of a kind dual-purpose tunnel in the world – the Stormwater Management And Road Tunnel (SMART). Under the SMART system, excessive upstream water is diverted at the confluence of Sg. Klang and Sg. Ampang into a holding basin. It was then directed to the Taman Desa storage reservoir downstream via the 9.7 km long and 11.83 m internal diameter by-pass tunnel that acts like an underground river, before being released back in stages into the Sg. Kerayong which is a tributary of Sg. Klang (Figure 2). The whole system has holding capacity of 3 million m³ of stormwater – equivalent to 2,000 Olympic-size swimming pools - and able to retain the water until the flood subsides before discharging the water into the downstream river. The discharges passing through the city with and without the SMART tunnel is shown in Figure 3.

The SMART project was developed as a concession. The concession is to operate and maintain the motorway portion of the tunnel. The Malaysian Government maintains ownership of the land and the tunnel itself. The total cost of

3 OVERVIEW OF THE SMART TUNNEL

The primary goal of the SMART tunnel was to mitigate flooding caused by heavy rains during the monsoon season. By creating a storage tunnel as a release mechanism for the water, Kuala Lumpur can be spared the expense of flood damages and the retroactive responses to a flood. A second objective of the tunnel was to reduce traffic congestion at the main southern gateway of Kuala Lumpur leading to the city centre. Use of the tunnel also leads to traffic reduction on the above-ground roads.

The tunnel was divided into two categories that are the stormwater management system and the double deck motorway for vehicles. Figure 4 shows the middle section of about 3 km in length integrate both flood mitigation and motorway purposes. It is key to keep motorists safe from flood water, while at the same time predicting floods early enough to evacuate motorists and convert the tunnel to flood use before the flood peak arrived.

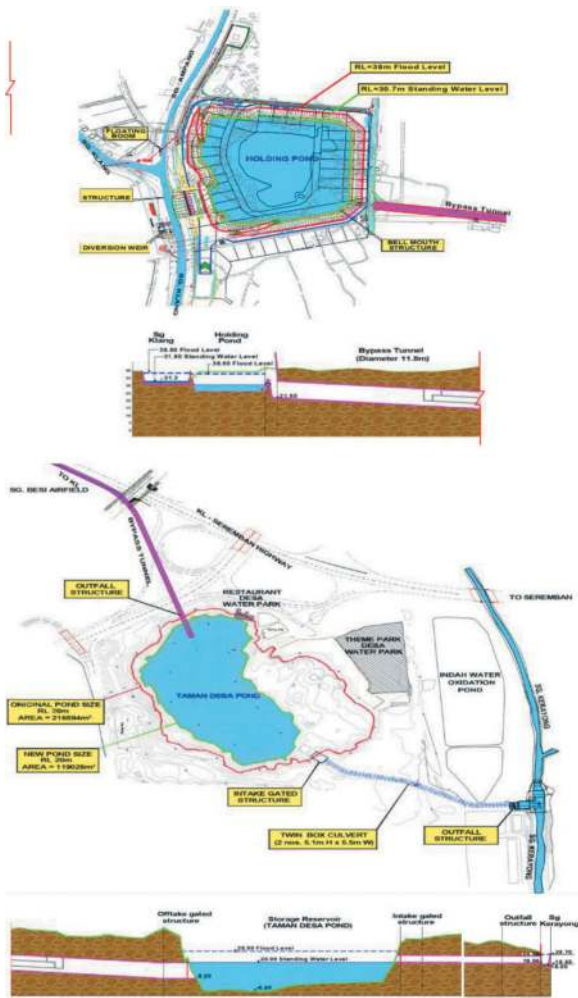

Figure 2. Outline scheme of the flood diversion system.

Figure 4. An artist's impression of the motorway.

Figure 3. Discharge passing through the city with and without the SMART tunnel (after Abdullah, 2004).

the SMART project was US\$514.6 million (MYR1.887 billion). The private sector provided a third of the total funds. In order to recoup the capital investment and operating expenses, the concession charges a toll fee for using the motorway portion of the tunnel.

The motorway traffic is uni-directional, consist of a double decks structure, each carrying two 3.35 m wide traffic lanes and one emergency lane, situated one above other. At each end of the motorway tunnel, there is a Y-junction. One junction allow vehicle to enter/exit the tunnel via ingress/egress section at each end, another junction link to stormwater tunnel (refer Figure 5). The motorway design is only for light vehicles, which is not exceeding 2.55 m height.

For safety reasons, cross-passage decks inside the motorway section placed at 250 m intervals to act as emergency exits, along with ventilation/escape shafts which are placed at 1 km intervals.

3.1 How the SMART tunnel works

The SMART system will be operated based on the relationship between flood discharge at the Klang/ Ampang Rivers confluence and the operation status of the motorway. Basically, its operations can be classified into 4 different modes, as illustrated in Figure 6.

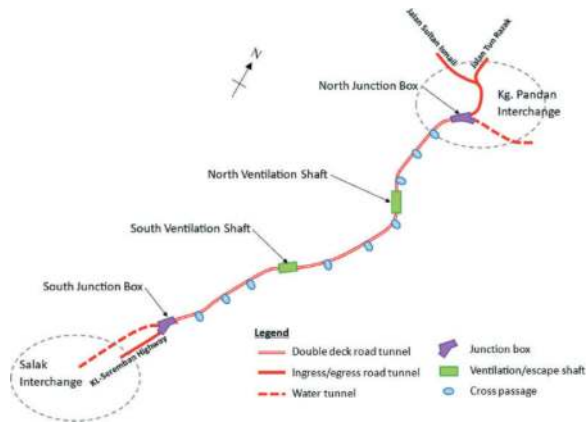

Figure 5. Double road deck motorway tunnel section.

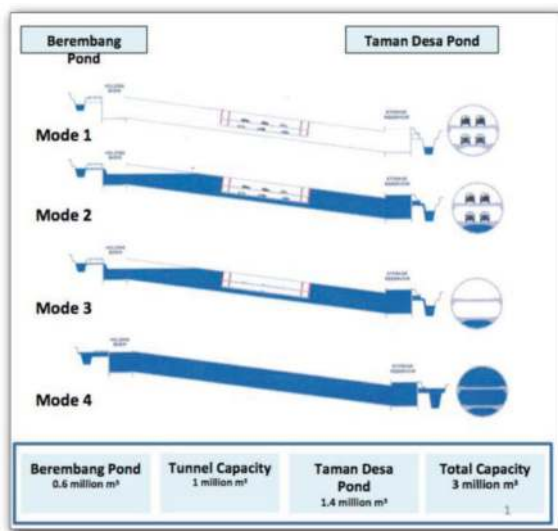

Figure 6. Operation modes (SMART Website).

Mode 1

For most of the time, the road tunnel is opened for traffic under normal conditions (see Figure 7) where there is no storm, no flood water will be diverted into the system.

Mode 2

When the flood discharge exceeds 70 m³/s, the stormwater tunnel is activated to “semi-open” status by allowing the diversion of excess water into the bypass tunnel in the lower channel of the motorway tunnel. The motorway section operates normally and there is no traffic disruption since only the lowest channel is being used at this juncture.

Mode 3

When major storm event occurs and flood model forecasts a flow rate exceeding 150 m³/s, the motorway will be closed to all traffic. Sufficient time will be allocated to allow the last vehicle to exit the motorway. Tunnel is on standby mode for stormwater diversion into the motorway component.

Figure 7. The motorway open to traffic (Mode 1 and 2).

Mode 4

The stormwater tunnel is activated to “fully open” status if heavy rainstorm prolongs, usually will be confirmed 1-2 hour after Mode 3 is declared. After making sure all vehicles have exited the motorway, automated water-tight gates will be opened to allow flood waters to pass through the tunnel (see Figure 8).

Figure 8. CCTV images of the SMART tunnel after activation (The Star, 22 February 2022).

After the flood receded and the weather is back to normal, flood water is pumped out of the tunnel and the tunnel is cleaned of mud and small debris. In normal process of cleaning and inspection of the tunnel condition, the SMART tunnel is reinstated within 48 hours after the water channelisation is made and traffic for the motorway section is allowed back for usage as normal thereafter.

During operations, the upstream monitoring facilities and the retention capacities of the two holding ponds together with the tunnel retention capacity provides the system operators at least an hour of warning for the need to close the motorway to traffic and avail it for flood water diversion. Emptying the road tunnel from traffic user will only take between one hour including closing of the gates and cross

passage doors, conducting a walkthrough check and opening the flood tunnel barrier.

3.2 Key components and special features

The motorway has all the fittings and safety features in compliance with international and local standards. However, some special requirements are unique to SMART. The entire fitting and road furniture in the motorway is designed to cater for the dual-purpose function of the tunnel. The design philosophy adapted for the road tunnel fixtures and fitting is sufficiently robust to withstand water tightness of 2.5 bars hydrostatic pressure and continuous submergence for at least 24 hours. The bracket design shall withstand the water flow of 5.5 m/s (Santhiman & Looi, 2006).

Two major components to make this tunnel “smart”, there are Flood Detection System (FDS) and Traffic Management & Control System (TMCS). FDS is used for forecasting and detect the rainfall and river water at upstream and downstream, it will decide and confirm to close and open the tunnel for flood to bypass. On the other hand, the TMCS is an intelligent system to manage, monitor and control the traffic of the ingress/egress and tunnel.

The status of the primary and essential electrical and mechanical equipment inside the tunnel is continuously monitored, processed, and controlled by SCADA. Having said that, the SCADA monitoring and surveillance system has additional features that are unique in normal motorway tunnel operation. From a central control room which is manned 24/7, over 200 CCTV cameras, linked to an advanced Automatic Incident Detection (AID) system keep watch on every section and can intervene, when necessary, using variable message signs or activation of first responder vehicles and personnel which are on permanent standby (Santhiman & Looi, 2006). The control centre also monitors and operates the 38 sets of air quality monitoring equipment deployed throughout the upper and lower motorway decks. Depending on the equipment returns, four ventilation shafts, each containing 12 number of axial ventilation fans and 2 number of axial pressurized fans, can be activated to provide continued airflow and removal of exhaust fumes (ITS International, 12 September 2012). The ventilation system is integrated with air quality monitoring system and linear heat detection system.

Double set of watertight steel gates at both ends of the motorway, together with surge shafts, were built to prevent damage to the structure caused by surge pressure. As added safety precaution, the opening of flood control gates is not possible without first closing the road gates and vice versa. The two are deliberately interlocked as part of the fail-safe /defect-proof operation. The interlock enabled the dual-purpose operations to be combined safely in a single but dual-purpose structure. Figure 9 shows the upstream stormwater tunnel flood gates at north

junction box. Control of the automated flood control gates is also incorporated within the SCADA system.

Figure 9. Upstream stormwater tunnel flood gates.

3.3 Construction challenges

Construction of the tunnel began on 25 November 2003. According to Special Unit for South-south Corporation’s report (2012), construction of the motorway should have been completed in June 2005 and of the stormwater tunnel a year later, but both portions were not completed until mid-2007. The construction posed a number of challenges, primarily related to the unfavourable and highly variable ground conditions particularly the Kuala Lumpur Limestone and ex-tin mining lands. Kuala Lumpur Limestone is well known for its highly erratic karstic features. For more details the reader can refer to Gobbett (1965), Yeap (1985), Tan (2005).

Figure 10. Geological profile along the SMART tunnel (after Darby & Wilson, 2006).

Briefly, as shown in Figure 10, the tunnel traverses 2.5 km of alluvium starting from north end, continuing into 0.7 km stretch of mixed face of alluvium and limestone rock. After, the tunnel alignment passes through limestone again. Overlying the Kuala Lumpur Limestone is soft alluvium and ground disturbed by tin mining (i.e. mine tailings). The last 200 m stretch at the south end, is in residual soils of Kenny Hill formation. The tunnel was bored at shallow depth with the cover to tunnel varied from 0.8 to 1.8 times its diameter (Yeoh & Klados, 2006). On average, the alluvial deposit is generally 4 to 5m thick; typical rock cover to the tunnel lining in limestone is within 3 to 7 m however at karstic areas the unpredictable rockhead may unexpectedly drop to 20 to 30 m. Groundwater table is relatively high at 1.5 to 2 m. Tan (2006) presented a 3D image of the exposed

limestone surface at north ventilation shaft (reproduced in Figure 11). Figure 12 shows an actual site photo taken during excavation at north junction box.

Figure 11. A 3D image of the exposed limestone surface at north ventilation shaft (after Tan, 2006).

Figure 12. Excavation into limestone at north junction box.

Construction of such large diameter tunnel (13.26 m O.D., almost as tall as a four-storey building) with majority of the boring through the highly weathered and extreme karst was the first-time experience in Malaysia. Tunnelling was very difficult, it gave the contractor plenty of headaches, as dozens of sinkholes and mudflows occurred unexpectedly during the construction. According to Klados (2015), 41 numbers of major ground collapses/sinkholes was reported in the construction of SMART tunnel. To a large extent, these incidents was mitigated through careful and deliberate pre-excavation treatment, which largely entails filling up the cavities and voids with grout before the boring machine passes through that stretch. Extensive soil sampling and geophysical tests were conducted to ferret out the anomalies. Ha (2018) documented the challenges and solutions for tunnelling in Kuala Lumpur karst. On the other hand, the initial construction of the launch shaft had also led to higher-than-expected groundwater inflow into the excavation through solution channels. Systematic “preventive” grouting was designed and purposefully carried out to arrest the problem (Raju & Yee, 2006).

This has proved to be unique from the aspect of construction challenges encountered and mitigation measures adopted, which have provided the tunnelers and engineers with a good learning experience in underground construction involving difficult karstic conditions under Kuala Lumpur.

Figure 12. (a) before SMART activation, (b) after SMART activation at Pekeliling area in Kuala Lumpur (The Star, 22 December 2021).

4 RECORD OF PERFORMANCE AND EVENTS

Soon after the SMART tunnel was opened in operation, it faced its first test at the beginning of September 2007, when the motorway needed to be shut down for a major storm. Authorities at the Stormwater Control Center sent the alert to clear the tunnel when the Klang River registered a reading of $70 \text{ m}^3/\text{s}$. The SMART tunnel was able to keep the water level of the Klang River below the flood level, preventing a disturbance to the city centre.

In operation for over 15 years now, the SMART tunnel mitigates 45 % of the total flood risks in the Kuala Lumpur, and its activation has saved the city from gridlock and possibly more serious disaster (The Star, 12 February 2022). Because of this infrastructure, areas such as Masjid Jamek area, Dataran Merdeka, Leboh Ampang and Jalan Melaka have witnessed no flooding incidents since SMART tunnel opened in 2007, which has allowed business to operate without interruption. Figure 12 shows the situation before and after SMART activation at Pekeliling area in Kuala Lumpur.

As of December 2021, the SMART tunnel has diverted flood waters on 40 occasions and averted an estimated MYR1.4 billion in public damage. The SMART tunnel diverted 5 million m^3 of water on 18 December 2021 due to continuous torrential rainfall in the Greater Kuala Lumpur area, beyond the tunnel’s actual capacity of 3 million m^3 and setting a new record of sorts (The Star, 22 December 2021). This was done by prolonging the diversion period through SMART tunnel and the existing retention ponds, especially the Berembang and Taman Desa retention ponds.

The operation took about 22 hours, some 7 times longer than previous water diversions.

The SMART tunnel is in itself an effective flood deterrent, due to its water capacity and the lag time it creates. It should be noted that SMART tunnel only diverts water around the critical meeting point from one of the contributing rivers. It has no effect on the flow from the other rivers, but it caused the sustained water to flow out. Although the development of SMART tunnel has been considered as successful, however, the growing development in the other parts of the city could not ensure no flooding will take place or thoroughly protect the city centre (Varadharajan & Bailey, 2013).

In terms of its role in traffic relief, SMART tunnel has minimised the journey for cars into Kuala Lumpur city centre from the southern gateway from the normal 20 minutes when using the federal road to only 8 minutes when using SMART tunnel. It serves as traffic dispersal to alleviate the chronic congestion of the southern road arteries of the city. Currently more than 30,000 vehicles use the tunnel daily, helping to ease rush hour traffic by offering an alternative route and cutting driving times (The Star, 11 July 2018).

Putting a financial value to these benefits, the Department of Irrigation and Drainage's survey concluded that, within the concession period spanning three decades, the SMART tunnel is expected to prevent US\$1.58 billion of possible flood damage and up to US\$1.26 billion savings from traffic congestion (ITS International, 12 September 2012). The savings are likely to be significantly more since these estimates are only for the duration of the concession. The tunnel has a design life of some 100 years.

Soon the SMART tunnel will be directly linked to the Tun Razak Exchange underground parking space, which could accommodate 5,000 car parks to boost the upcoming international business district connectivity (The Star, 12 February 2022).

5 CONCLUDING REMARKS

The dual-purpose SMART tunnel: one for storm-water diversion and second as a traffic dispersal scheme has proved to be unique and first of its kind in the world. By using a public-private partnership, the government was able to effectively lower its costs on a much-needed flood relief tunnel, perhaps kill two birds with one stone. Thus far the SMART tunnel has proven to be a success in meeting its primary and secondary objectives.

Construction of the SMART tunnel is not short of its own set of challenges, the geology in which the tunnel snakes through the city is made of extreme karst. The fact that the road tunnel is designed to flood created novel challenges for the design of the mechanical and electrical systems. The amount of redundancy built in for safety and security to ensure

the operation with minimum interruption. Considerable courage, lateral thinking and an entrepreneurial spirit were exercised by all parties to make the concept a success.

Building on the experience gained and technological breakthrough in the industry, the spin-off effects of the SMART tunnel to Malaysia and worldwide tunnelling community were too great to be ignored. Locally, the SMART project has far reaching effect on the development of tunnelling engineering as is evidenced from the innovation of Variable Density TBM (VD TBM), establishment of Tunnelling Training Academy and the local TBM refurbishment plant. This has subsequently led to the in-house development of the world's first autonomous tunnel boring machine (A-TBM), equipped with custom artificial intelligence (AI) control algorithms (New Straits Times, 21 November 2019). Academically, a special session was devoted to the SMART project in the International Conference and Exhibition on Tunnelling and Trenchless Technology 2006 held in Kuala Lumpur in which there are numerous technical papers covering from planning, design, construction to safety issues. There is a wealth of knowledge and experiences shared in the proceedings.

To sum up, the greatest benefit of the SMART tunnel is that it helps make the city more resilient. The SMART tunnel is touted as a visionary green infrastructure built in 2007 with a sustainable, climate change solution in mind. Smart urban infrastructures are included in the United Nation's Sustainable Development Goal (SDG 11 – Sustainable cities and communities), a characteristic intended to be extended to combat climate change. The tunnel has demonstrated the degree of urban underground development Malaysia has achieved and is an example for other developing countries to emulate.

ABSTRACT: The underground surge system of Tanahun Hydropower Project (Nepal) comprises a large span vault (29m by 33m) and an 85.5m-deep vertical shaft, excavated in the Benighat graphitic Slate of the Lesser Himalayan sequence. Geotechnical investigation during the tendering stage, and the excavation of a pilot adit provided the basis for the geomechanical parametrisation of the shaft. The encountered geology consists of thin to narrow foliated Slate with frequent intercalations of sheared bands and localised cleavage. The excavation sequence and the temporary support strategy were designed based on 3D numerical analysis, and the assignment of temporary support adopted the Norwegian Q-system. Considering, the residual degree of geological uncertainty and the tectonised nature of the Slate, the excavation was proven a challenging task. To ensure safe excavation and long-term stability, and maintain deformation within permissible threshold, the construction methodology included an iterative process of real-time investigation, pre-excavation measures, and consistent monitoring. Real-time investigation consisted of probe-drilling sessions with permeability tests and televiewer probing, aiming to detect poor quality zones which might compromise stability. Pre-excavation measures comprised high-pressure consolidation grouting, aiming to pre-stress the surrounding rock mass and improve the properties of the excavated sections in advance; followed by active support measures (i.e. pre-stressed anchors in the vault), focusing to the control of plastic zones. Monitoring included convergence stations, load cells, and multi-point borehole extensometers to assess deformation; all of them aiming to validate the performance of temporary supports. Despite the low progress mandated by difficult ground conditions, the excavation of the shaft was successfully completed by adopting the aforementioned observational and conservative approach.

Keywords: Squeezing ground, High-pressure grouting, Slate, Anisotropy, Surge Shaft, Rock support

1 INTRODUCTION

Tanahu HPP is a medium sized storage type hydropower project currently under construction and located in Gandaki Province (central Nepal). The main structures comprise a 140-metres high concrete gravity dam; a 1.45 Km long headrace tunnel that connects the power intake shaft to the underground powerhouse; and an 85.5-metres deep vertical concrete lined surge system, which consists of a Ø6.0m raiser shaft (the first 16.4 metres) and a large diameter (Ø25.5m) surge tank (69.1m) which ends to a vaulted cavern (28.80m x 35.47m).

The surge system is an integral element of a hydropower project that controls the resonance effect that may occur due the sudden closure of turbine valves, and subsequently mitigates water-hammering effect that might lead to the failure of the vertical water conduit (i.e. bursting of the penstock system). Hydraulic transient modelling and the maximum upsurge and downsurge water levels defined the optimal shaft dimensions to function as water hammering attenuator. The designed maximum pressure aiming to withstand pressure fluctuations is 0.9 MPa.

2 REGIONAL AND PROJECT GEOLOGY

The Project is in the Midlands of Nepal, between the Mahabharat Range to the south and the high peaks of the north, at an altitude of +300m to +500m, above sea level.

The entire Project is constructed in the Lower and Upper Nawakot complex formations, a part of the Lesser Himalayan belt. The Surge Shaft is excavated in the Benighat Slates of the Upper Nawakot group. The Slate series overlay the Meso-Proterozoic series of Dhading formation, consisting of grey to light grey, thinly bedded to massive Dolomites, which were also encountered at the west part of the Project's area.

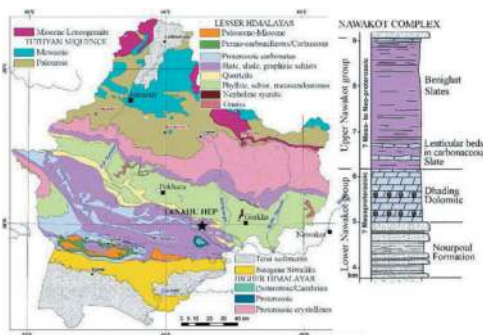

Figure 1. Simplified geological map of the Gandaki region, (after Amatya et al. 1994).

Dhital (2015) describe Benighat Slates as green-grey and light grey, very thinly cleaved, with localised strips of carbonaceous matter, and distinct lamination (from <0.5 mm to 2cm). Cai et al. (2019) consider carbonaceous Slate as special continuous formation, where weak zones parallel to foliation are playing an important role to its anisotropic behaviour.

2.1 Factual geological regime of surge shaft

The structure lies beneath a 250m overburden slope, of a 1040m-high Slate massif. The direction of the maximum stress to the horizontal has been measured to 13.0 MPa, with NNE-SSW trend.

The aforementioned general description coincides with the encountered lithology in the vault and the shaft. Based on observations during the excavation stages, the geological regime of the area corresponds to strong to moderately strong (R4-R3), dark greenish grey to dark grey SLATE, slightly decomposed to fresh (II-I), with small-scale fracturing due to mechanical weathering, and presence of graphite. The formation is very narrow (<6mm) to thinly (<100mm) foliated, with random micro-folding features and sheared zones of variable thickness, mainly parallel to foliation. Foliation constitutes the dominant feature, dipping 35°-50°, striking WNW-ESE. It is very closely to extremely closely spaced (<20mm to 60mm), of low to medium persistence (1-10m), smooth to slickensided undulated (V-VI, JRC: 3-9), with tight to very narrow (0-3mm)

apertures, with quartzite infillings or graphite with stiff to firm components (S4-S3) and fragments of rock (R2). Open joints are found dry to damp (I-II) with localised spots of low seepage (V), whereas filled joints appear damp to wet with occasional drops (II-III). Joint surfaces are partially weathered (PW90/100) to unweathered (UW). The geological regime can be characterised as strongly anisotropic, and heavily jointed. Apart from distinct foliation, two major discontinuity sets (J_1 : 35°-55°, striking NNE-SSW, parallel to σ_H ; and J_2 : 20°-40°, striking ESE-WNW, dipping towards σ_H), and several random joints truncate the excavation. The geo-structural features with respect to the shaft are illustrated in Figure-2, below.

Figure 2. Geotectonic regime of surge shaft.

Furthermore, Alejano et al. (2021) directly link Slate's deformability and strength to the cleavage plane orientations relative to the principal stresses. Sheared zones of various thickness (range between 20-120cm) are mainly expressed parallel to foliation as paraconformities to the normal plane, with micro-scale quasi-folding, distinct moderate cleavage and localised indications of ductility.

3 CONSTRUCTION; CONCEPT AND METHODOLOGY

For the completion of the surge shaft from concept to design and from excavation to support a series of tasks were conducted, as sequential as well as iterative process (whenever this was deemed necessary). At the initial stage for the structure conceptualisation, preliminary information regarding the geological regime was retrieved from the tendering stage desk study, from a number of boreholes and in-situ tests, the detailed geological mapping, and the excavation data from an exploratory adit (i.e. access tunnel). The available baseline information, a collection of investigation data from adjacent vital structures (i.e. underground powerhouse and headrace tunnel), the shaft location,

and the design hydraulic parameters; set the prerequisites for the excavation of the surge system.

With respect to the excavation stages, the anticipated deformability, and the requirements for the temporary support (prior to concrete lining), the design was based on numerical 3D finite element analysis (FEM). For the rock mass classification and the assignment of temporary supports, the empirical Norwegian classification system (Q-value) was adopted. However, considering the anticipated poor rock mass conditions, the geomechanical behaviour of Slate, and aiming to ensure a safe excavation, a series of systematic pre-excavation measures were also introduced. Real-time information was further utilised to adapt temporary support to the needs of the excavated profile. This constitutes an integral part of the observational approach. Such measures included real-time investigation, i.e. vertical and radial probe-drilling; pre-excavation ground improvement with high-pressure grouting; and installation of prestressed anchors (at the shaft's vault). The excavation and temporary support were conducted in stages based on the FEM design; the actual geological conditions; and the response analysis of the surrounding rock mass as this was consistently monitored by a vast instrumentation network. Monitoring evaluation and realistic rock mass classification facilitated the selection of appropriate support which consisted of passive support measures. The aforementioned stages contributed to risk mitigation by improving the surrounding rock mass or by applying confining pressure over the excavated periphery; aiming to form a robust and impermeable uniform shell. Supplementary was the role of pre-excavation grouting, where "supports" focused beyond the excavation boundary.

The observational approach is an iterative procedure that integrates continuous monitoring to the excavation and the support strategy of the underground structure.

3.1 Design stage

For the selection of the most suitable location and the apprehension of anticipated rock mass quality, a 437-metres long D-shaped Access Tunnel) was excavated for exploration and geotechnical investigation purposes. In parallel to the Access Tunnel excavation, boreholes were drilled and a series of geotechnical tests (i.e. hydrofracturing, shear stress tests and compressive strength tests) were conducted. Excavation, investigation, and laboratory data constitute the baseline for the parametrisation and design of the geotechnical model, the excavation strategy and the underground support system. The geotechnical parameters which derived during investigation stage and the excavation of the access tunnel are summarised in Table 1, below.

Considering the anticipated foliated Slate and the rock mass quality (poor to very poor, Q: 4.0 to 0.1), a numerical finite element analysis (FEM) was performed, and the 3D model was generated.

Finite element analysis (FEM) indicated that the distribution of plastic zones is strongly affected by the presence of anticipated weak zones, and also

Table 1. Geotechnical parametrisation for design purpose.

Geotechnical parameter	Value range	Test
Unit weight	25-27 KN/m ³ (avg. 26.3 KN/m ³)	Laboratory
Young's modulus	40 GPa	
Poisson's ratio	0.35-0.25	
Shear stress (average)	3.3 MPa	
Residual stress (average)	1.92 MPa	
Uniaxial Compr. Strength	38 MPa	
Cohesion (peak)	0.52 MPa	Block shear tests
Cohesion (residual)	0.51 MPa	
Internal friction (peak)	38.70	
Internal friction (residual)	30.40	
Vertical stress (σ_v)	9.8 MPa	Hydro-fracturing
Maximum stress at horizontal	13.0 MPa (010 deg.)	
Minimum stress at horizontal	4.8 MPa (100 deg.)	

Figure 3. Finite element model (FEM) of surge tank.

demarcates the extent of the plastic zone, 13m beyond the crown. Moreover, the analysis of stresses in the surrounding rock mass provided the estimate for the expected deformation in the surrounding rock mass, with a maximum vertical displacement of 89mm.

Taking into account the maximum stress concentrations and the resultant maximum deformation, the permanent support of the crown was designed based on the numerical model. With respect to the vertical shaft the numerical evaluation set the baseline for the temporary support

Figure 4. 3D FEM analysis of maximum displacement.

during excavation; whereas the in-situ rock mass assessment and the assignment of support measures adopted the empirical classification system of Q (NGI, 2022).

3.2 Pre-excavation measures

3.2.1 Probe drilling

The excavation of the exploratory tunnel and the subsequent advancing of shorter pilot tunnel ahead of the surge tank area provided adequate clarity with reference to the geological regime that surrounds the vault and set the principles for a safe excavation strategy.

Considering the intrinsic characteristics of Slate, and aiming to reduce geological uncertainty, probe drilling investigation was conducted over the crown, prior to the phased expansion of the vault. To substantiate penetration data and water pressure tests, supplementary information was retrieved from high-resolution imaging with the aid of camera probing (televviewer).

Figure 5. Example of televviewer imaging.

For this stage, 15m-deep probe holes were drilled, to record penetration rates, detect possible weak/shear zones, and assess groundwater regime. In that respect, Lugeon tests were carried out in all 243 holes. During probe drilling sessions, low-pressure ingress (~20 lt/min) was detected at two crown locations. Water pressure tests recorded low to locally very low permeability with values ranging from 0.0 to 3.8 Lu (average 2.4

Lu) which correspond to very tight to tight discontinuities. The average recorded penetration rates range from 0.42m/min to 0.99m/min. The maximum penetration rates were recorded towards the south end part of the crown. Probing penetration rates indicated weak/sheared interlayers in the crown, parallel to the foliation. Provided that the Slate dips with 40°-45°, similar shear zones were expected to be encountered in the shaft, as well.

A similar probing concept (i.e. drilling, recording and testing) was also adopted for the excavation of the shaft, where 20m-long, 20° inclined probe holes were drilled around the shaft perimeter. Each probing session overlapped 5-6m to the next session. Most probe holes in the vertical shaft were found substantially dry, and Lugeon tests indicated very tight to tight conditions (<2.5 Lu).

3.2.2 High-pressure grouting

A systematic high-pressure pre-excavation grouting (PEG) programme was designed before every excavation phase. PEG is a direct ground improvement technique that focuses to the modification of discontinuities properties, contributes to the pre-stressing of the surrounding rock mass, reduces hydraulic conductivity, and attempts to enhance the strength of possible weakness zones. Research and project references presented by Barton (2006 and 2011) where pre-injections have been conducted, provide evidence of the adopted practice (i.e. increase of effective RQD, reduction of effective J_n , and improvement of J_a and J_r). Therefore, considering the available pre-excavation information, PEG was proven essential to mitigate geotechnical risk. The basic PEG design considerations are: i) the stress regime, ii) the surrounding lithology and rock mass quality, and iii) the hydrogeological regime; whereas the grouting process criteria are: i) the groundwater behaviour (i.e. seepage and Lugeon data) of a particular probing phase, ii) the penetration rates, and iii) the encountered rock mass conditions during probing. Based on the aforesaid information, the grouting designer will be asked to decide for: i) suitable grout type material, ii) optimal grout mixes, iii) maximum applicable pressure, iv) possible maximum volume limitations, and v) grouting patterns (i.e. depth, hole spacing design, grout-fan geometry, etc.). In that respect, PEG sessions were conducted for the whole surge system, with the use of hydraulic packers set 1.0-1.5m into rock.

Grouts were injected over the entire crown and its sidewalls in radial patterns of 15m-deep holes. The maximum recorded grout take for the deep segments (5-15m) was 89.5 lit/m, and for the shallow segments (1-5m) 78 lit/m. The average injected volume equals to 23.3 lit/m for the deep segments, and 16.8 lit/m for the shallow, accordingly. These figures are considered relatively low, corroborating the low permeability values. Consequently, the injected mixes mainly contributed to the improvement of the weaker layers within the Slate and the overall

pre-stressing of the crown. Injection for all holes was terminated due to pressure limitations. The grout design and injection outcome for the surge tank vault is summarised in the Table 2, and general grouting layout is illustrated in Figure 6, below.

Table 2. Grout design and summary of surge tank vault PEG.

Grout type	Grout mix	Criteria
Microfine cement (MFC)	1.2 to 0.8 water/ cement	<3.0Lu
Portland cement (OPC)	1.2 to 0.8 water/ cement	>3.0Lu
Admixture	Superplasticiser 0.5-2.0%	
Injection criteria		
Pressure	30 bar (5-15m) 15 bar (1-5m)	Pressure refusal
Volume	4100 lit/15m segment	Volume refusal
Injection strategy		
Staged injection	Primary; 4.0m spacing Secondary; 2.0m spacing Tertiary; 1.0m spacing Control; random spacing	59 holes; 20130 lit 102 holes; 26403 lit 66 holes; 13609 lit 16 holes; 3542 lit
Total injected volume		63.7 m ³

Figure 6. Probing and grouting layout of surge tank vault.

For the injections during shaft excavation, the drilling and grouting of systematic grout fans was adopted. Inclined grout-fans were drilled 20m deep, 1m inside the shaft profile. In order to assure dry excavation for the first 12 metres of the top section, 4 supplementary horizontal radial fans were drilled and grouted, as well. The drilling and injection patterns were linked to the probing results retrieved (i.e. penetration, lugeon tests and televiewer). The vertical spacing between consecutive grout-fans was set to 13-14m (5-6m of overlapping), and the lateral spacing of holes within the same grout-fan ranged

between 2 and 4 metres; considering investigation information and observations made during injection (i.e., grout takes, ingress, and penetration).

Lugeon tests were conducted in two sections: i) from 10m to 15m, and ii) from 15m to 20m. Test results also regulated the selection of appropriate grout mix. The selection criteria for cement suspensions was similar to that of the vault. However, the maximum pressure and maximum volume refusal criteria were set to $P_{max}=50$ bar $V_{max}=5000$ lit/hole, accordingly. Similar to the vault injection outcome, the injection for all shaft holes was terminated by pressure.

The maximum grout takes were recorded close to the highest shaft sections (first 10m) where the average injection was 21.4 lit/m and the injected volume reached 18.2m³ (approx. 0.7% consolidation ratio), and the lowest shaft section (28.1 lit/m). With respect to the whole shaft, and considering a theoretical grouting zone (6m around the excavated profile), the average injected grout per drilled metre equals to 18.81lit/m, with an approximate consolidation ratio for the entire profile, 0.45%. The probing and grouting pattern is shown in Figure 7, and the grouting criteria along with the injection data are summarised in Table 3, below.

Figure 7. Schematic probing and grouting layout of surge tank.

3.3 Excavation and support

3.3.1 Excavation sequence and advancing

Considering the shaft and vault dimensions, in conjunction with the actual poor rock mass quality and the anticipated shear zones, the excavation was proven a challenging task which necessitated a conservative advancing. Thus, after the completion of each PEG

Table 3. Grout design and summary of surge shaft PEG.

Injection criteria		
Pressure refusal	50 bar	
Volume refusal	5000 lit/20m segment	
Grout fan	Injection	Groutability
ST-CG-01 +426.7	42 holes; 5.9m ³ grouts	27.8 lit/metre

session, and taking into account the real-time investigation information, the excavation of the vault was executed in phases, where the timely application of temporary support and short advances were essential limiting factors to undesired occurring deformation.

Four phases consisted of the excavation of the surge vault, which was solely carried out with drilling and blasting.

Figure 8. Excavation sequence of Surge Tank's vault.

The first phase (phase-V1) comprised the excavation of a D-shaped central access tunnel (6m span, 8m height) which crosses the area of the cylindrical shaft.

To acquire more information regarding the properties of the surrounding Slate, the Access Tunnel was further advanced for 23 metres. The rest phases (phase-V2, phase-V3, and phase-V4) relate to the lateral enlargement of the vault which were carried out in parallel with the execution of PEG sessions, and the installation of the permanent support (crown and sidewalls).

Despite the weak nature of the encountered thinly foliated and cleaved Slate, the excavation and installation of permanent supports of the vault (6655 m³ total excavated volume) was successfully completed within 5.5 months, without any recorded failure, overbreak, or signs of deformation.

After completing the vault's permanent rock supports, and the casting of the anchored concrete ring at the vault invert, the next stage comprised the phased shaft excavation.

Figure 9. Excavation sequence of surge shaft.

For the first phase (phase-S1), a 0.2m-diameter pilot hole was drilled with the aid of a raise boring machine. During rotary drilling, penetration rates and groundwater behaviour were also recorded, in order to retrieve supplementary information about the underlying rock mass. The next phase (phase-S2) included the reaming of the pilot hole, from bottom to top; resulting to a 1.4m-diameter shaft that was foreseen to facilitate the mucking activity. The main shaft excavation was executed in one or more concentric phases (phase-S3, phase-S4, and/or phase-S5). The rock mass conditions, and in particular the Slate's strength variation, the presence of shear zones, the foliation properties, and the groundwater regime mandated the number of concentric phases, as well as the excavation method (i.e. mechanical or blasting). Due to the encountered weak rock mass conditions, the majority of advances was executed by mechanical means (approx. 97% of the shaft volume).

3.3.2 Geological regime and as-built support

In situ rock mass quality assessment and classification were carried out for the entire shaft, according to the NGI standards (i.e. Q-system, span size, purpose of structure, and shape parameters). The corresponding temporary rock supports were also assigned considering the NGI principles (as reference support framework) and the numerical stress and deformation

thresholds, always substantiated by the monitoring output. Taking into account the encountered shear zones, the probing output and the behaviour of rock mass during excavation; in order to assure shaft stability, supplementary support measures were installed in few areas. The encountered lithology and the main geological features are illustrated in Figure 10, below.

Figure 10. Geological cross-section of Surge System.

Figure 11 illustrates a typical Slate lithology as this was encountered during the shaft excavation.

Figure 11. Typical Slate encountered at the South shaft-wall.

The entire structure is allocated in the Slates of Benighat formation, and the engineering geological description of the excavated rock mass is presented

in Chapter 2.1. According to the adopted rock mass classification system, rock mass quality is mainly “very poor” ranging between “extremely poor” to “poor” ($Q=0.07\sim 1.25$). The particular assigned rock mass parameters are summarised in Table 4, below.

Table 4. Rock mass parameters according to Q-system.

Parameter	Description	Range	Freq. value
RQD	Very poor (<15%)	10-15	10
Joint set number	Three sets and random joints and locally heavily jointed	12-15	12
J_n	Joint	Smooth undulating to rough planar, locally smooth planar	1.0-2.0 2.0
J_r	Joint	Thin clay/graphite coatings, alteration localised thicker (<2mm)	2.0-4.0 2.0
J_a	Water reduction	Dry with minor localised drippings.	1.0 1.0
J_w	Stress reduction	Medium stress with localised single shear zones	1.0-2.5 1.0

Further to the systematic rock bolts, the surge tank vault was permanently supported with a grid of pre-stressed anchors. With respect to the vertical shaft, the design of temporary support classes comprised a combination of passive measures (i.e. rock bolts, wire mesh, sprayed shotcrete) and confining pressure support types (i.e. lattice girders or H-beams). The permanent rock support of the surge tank vault, and the temporary support patterns for the vertical shaft are summarised in Table 5 and Table 6, accordingly.

Table 5. Design of permanent support for surge shaft vault.

Shotcrete	150mm (fibre reinforced)	
Bolts	Fully grouted passive rock bolts	8.0m Ø32mm 2.0mX2.0m systematic
Anchors	Double corrosion protection pre-tensioned	15.0m Ø47mm; 3.0mX4.0m systematic
Drainage	4.0m, Ø32mm; 4.0mX4.0m systematic	

3.4 Monitoring

Considering the dimensions of the surge system along with the encountered geology, a diligent monitoring strategy during all excavation phases was deemed integral for the construction of the entire surge system. Therefore, monitoring instruments were installed in the vault crown, as well as in the shaft walls, as shown in Figure 12.

Table 6. Design of temporary support for surge shaft.

Q-value	Shotcrete	Rock bolts	Steel ring
>50 (RS1)	50mm (plain)	7.0m Ø32mm; spots	N/A
50-8.0 (RS2)	50mm (fibre)	7.0m, Ø32mm; 2.5mX2.5m systematic	N/A
8.0-2.8 (RS3)	80mm (fibre)	7.0m, Ø32mm; 2.0mX2.0m systematic	N/A
2.8-0.8 (RS4)	100mm (fibre)	7.0m, Ø32mm; 1.75mX1.75m systematic	N/A
0.8-0.28 (RS5)	150mm (wire-mesh)	7.0m, Ø32mm; 1.5mX1.5m systematic	3-element lattice girder
<0.28	200mm (wire-mesh)	7.0 to 9.0m, Ø32mm; 1.0mX1.0m systematic	H-beam

NOTE: Different Excavation Support Ratio (ESR) and downgraded Q-value ranges apply for intersections

Figure 12. Instrumentation setup of the surge system.

In brief, three types of instruments were installed:

- i) Multi-point borehole extensometers (MPBX) equipped with three displacement sensors

(at 2m, 7m and 20m), aiming to monitor displacements and determine the deformation behaviour of the surrounding rock mass.

- ii) Load cells at the vault crown, in order to measure the amount of transferred loads to the support element where the instrumented is mounted to. Load cells were mounted to rock anchors.
- iii) 6-point optical target stations (convergence stations) were installed in the shaft, where routine geodetic survey readings were providing information about the aggregate deformation during all excavation phases.

A summary of all active instruments utilised for the geotechnical monitoring of the surge system is presented in Table 7, below.

Table 7. Surge tank instrumentation.

Instrument	Location	Behaviour	
MPBX	Vault crown; 3 units	Flat trend (max. 7mm) Flat trend (max. 45mm) Flat trend (max. 15mm)	
	Shaft +422; 3 units	Flat trend (max. 8mm) Flat trend (max. 8mm) Flat trend (max. 5mm)	
	Shaft +394; 3 units	Flat trend (max. 15mm) Flat trend (max. 4mm) Flat trend (max. 6mm)	
	Shaft +366; 3 units	Flat trend (max. 8mm) Flat trend (max. 5mm) Flat trend (max. 5mm)	
	Load cell	Vault crown; 3 units	Flat trend (638KN)
		Below alarm (808KN)	
	Convergence station	Shaft +422; 6 targets	Max. converg. 10-20mm
		Shaft +412; 6 targets	
		Shaft +402; 6 targets	Max. converg. 10-15mm
Shaft +391.6; 6 targets			
Shaft +386.6; 6 targets		Max. converg. 10-25mm	
Shaft +381.6; 6 targets		Max. converg. 5-15mm	

During excavation, damp areas and localised minor seepage (max. seepage <1.0 lit/minute) were observed mainly at the south and southwest shaft walls. The overall ingress estimate for the entire shaft is 5 to 8 lit/min/10m shaft.

4 CONCLUSIONS

The anticipated geological conditions in the Surge Tank system were known to some extent from retrieved information during the design stage, and the excavation stage of the Access Tunnel. However, considering the medium- to small-scale variance within the predominant graphitic Slate, and the observed behaviour of Slate during the excavation of the adjacent underground powerhouse (long-term creeping deformation); a diligent re-assessment strategy was adopted, aiming to mitigate geological uncertainty. This strategy comprised medium-scale pre-excavation investigation tasks in parallel with the excavation and support of the Surge system, alongside with consistent real-time monitoring. Investigation included sequential probe drilling with penetration rate measurements, televiewer probing and water pressure tests (Lugeon permeability tests). The precise allocation and the geometry of weak or shear zones, the detection of excessive groundwater activity, or any other adverse stability factor were the main objectives of this parallel investigation approach.

Probing activities revealed a 6m-thick weak zone that trends parallel to Slate's foliation and consists of a 4m-thick heavily jointed layer which transitions to a 2m-thick shear band. The zone appears at the NNE shaft wall, dipping towards SSW with 45°. In general, the shaft is situated in extremely poor to poor foliated Slate, a specific rock mass quality that necessitated the execution of overlapping pre-excavation grouting fans. The relatively low consolidation ratio (0.42%) indicates that high-pressure injections mainly contributed to the prestressing of surrounding Slate, and the overall improvement of discontinuities. Secondly, it also addressed minor seepage.

On the other hand, permeability tests did not reveal any significant groundwater path that might hamper excavation or influence stability. According to the seepage observation records, areas of minor dripping (<0.1 lit/min) were mainly identified at the SSW area, whereas several damp/partially wet areas are scattered in various locations. All seepage issues were addressed with drainage provisions (i.e. deep drainage holes or shallow relief holes). An indicative example of grout penetration through Slate's jointing system is illustrated in Figure 13.

The anticipated as well as the encountered rock mass quality in conjunction with the intrinsic geomechanical behaviour of the particular graphitic Slate (i.e., slow response elastic-perfectly plastic deformation) advocated to a conservative excavation philosophy. In that respect, blasting activity was constrained in order to eliminate blast damage. Consequently the advancing of the shaft was principally carried out by mechanical means. Further to this, in line with the assessed rock mass quality a considerable part of the shaft (approx. 62%) required the installation of numerous steel ring supports (HEB steel beams or 3-element lattice girders).

Noteworthy is the importance of monitoring during the entire excavation and support process that

Figure 13. MFC grout penetration in slate joints (foliation).

may act as early-warning system for possible excavation and/or rock support improvements. The recorded strains of the structure during the excavation stage are negligible with normalized trends, and they do not exceed 0.1%.

The conservative excavation strategy in conjunction with several pre-excavation measures, ensured the safe construction of this large diameter vertical surge shaft. The approach resulted in the reduction of geotechnical risk, a fact which has been also affirmed by the diligent monitoring and careful observation.

1 PROJECT OVERVIEW

Gangxia North Hub is the first hub of the Shenzhen Metro Express network, and the first comprehensive transportation hub in Shenzhen to connect 5 subway lines at one time.

The hub space is mainly divided into five levels: the ground floor is a sunken plaza and ground structures; The mezzanine is an urban crossing corridor (at the same level as the existing Metro Line 2); The first basement floor is the hub transfer station hall, and the underground space of the east, west and south areas; The second underground floor is the east-west platform and rail area of Line 11 and 14, and the equipment area of Line 10; Three basement levels: Line 10 platform level.

Gangxia North underground transfer core area, east, west and south three parts of the underground space. The total length of the hub is about 900 meters from east to west, 620 meters from north to south, and about 235,000 square meters in construction. It is an existing transfer node of Metro Line 2, the newly built Line 10, Line 11 and Line 14, and the commercial development of the underground space of Caitian Road and Shennan Avenue connected by the transfer node, and synchronously connecting the underground space of Line 1 Gangxia Station and Liancheng Xintiandi. Trial operation began on December 28, 2022.

2 THE DIFFICULTIES AND CHALLENGES

Planning and building an all-underground comprehensive transportation hub in the bustling metropolitan area of Shenzhen, carrying the multi-dimensional mission of urban development, while reducing the negative impact on the city during several years of construction, is a major issue facing all participants. As a general contractor of survey and design, CRCC deconstructs the planning and construction goals in different dimensions, and then carries out the logical combination of implementation routes with the goal of high-quality landing, so as to maximize the high-quality completion of the project.

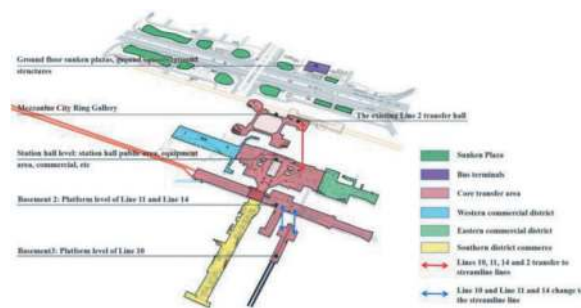

Figure 1. Spatial structure diagram.

*Corresponding author: Qiexuegang@qq.com

2.1 Traffic organization and spatial combination

Rail transit distribution and transfer, bus, slow travel, municipal traffic and other different transportation needs converge here, and the organization of hundreds of thousands of daily passenger flows is the core key of the project. It is necessary to realize the logical undertaking between urban planning, transportation planning and engineering units, and implement the initial requirements to the final engineering practice.

In-depth interpretation of the underground space planning of the central area of Shenzhen, with the help of the planning and construction of the Gangxia North Hub, to build a multi-dimensional urban public space community.

2.2 Urban integration with rail transit as the core

Within the area directly or indirectly affected by rail transit construction, urban municipal roads, bridges, green landscapes, underground spaces, public facilities, infrastructure, etc. will be integrated and integrated to build an integrated urban unit.

2.3 Multi-professional collaborative innovation of comprehensive engineering subjects

Focusing on the goal of urban quality projects, under the guidance of the innovation of planning and architectural schemes, all relevant technical specialties carry out in-depth coordination and innovation work. Structure, mechanical and electrical equipment, fire protection, civil air defense and other related technical majors carry out cutting-edge exploration in their respective fields, and carry out comprehensive coordination under the overall planning of the project center objectives.

2.4 Pay attention to systematic industry leadership and pioneering demonstration

On the basis of the innovation of planning and design schemes, this project should also explore the technological development of the industry, explore and demonstrate the overall innovation of subsequent projects, and reflect the urban spirit based on urban characteristics.

2.5 Define the cultural and artistic attributes of important public spaces

Under the mission of realizing the transportation function and promoting urban development, as an important public space in the central area of the city, especially the large-scale underground hub space, the corresponding cultural and artistic attributes should be given through design, so that the public can have a higher quality space experience in the process of traffic travel.

3 INNOVATION HIGHLIGHTS

3.1 Build a new multi-dimensional urban public space network

Gangxia North Hub is generally located on the east side of the center of Shenzhen, the central area of Shenzhen. The construction of the hub will connect the surrounding underground space to form a complete underground space network, which will become an important urban public space in Shenzhen.

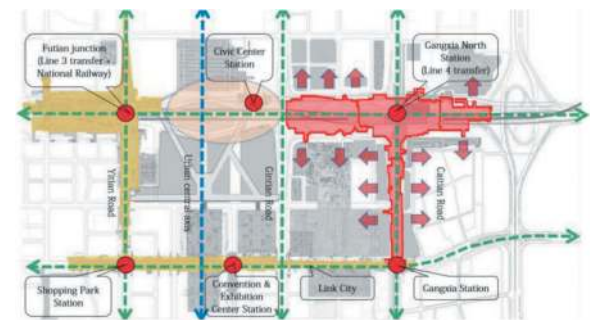

Figure 2. Schematic diagram of underground space planning.

On the basis of building multiple interchange stations, a networked three-dimensional urban space is organized simultaneously. Urban municipal traffic public ring corridor and street passage; Seamless networking of underground space; Sunken plaza and landscape excessive gray space sequence.

3.2 The design model of “sunken square + underground corridor” was proposed

As an urban unit without precise boundaries, the exploration of design patterns has been successfully explored in this project, completing the coordinated combination of different sequences. Urban roads have been reconstructed and optimized, the amount of overpasses has been upgraded and upgraded, conventional green belts in the road have been transformed into urban public roadside gently sloped gardens, subway stations are convenient to access and transfer, and underground space and supporting facilities are integrated to form urban units.

Form a hub “connection” city and realize the integrated hub method of road-bridge-station-park-city.

Figure 3. Separated traffic.

3.3 *The largest span underground hub in china, heavy-duty steel beams and concrete slab composite structure*

The three new lines are all stations of the 8A marshall, and the scale of the central hall is beyond the norm based on the need for quick and convenient transfers. According to the special needs of function and space, a structural span of 51.2mX48m was designed. In order to realize the 51.2m underground structure, which is the world's largest span, compatible with the special-shaped space of the daylight, the middle main force member of the super-large span underground structure needs to consider the continuity after disconnection; in addition, the hub is located at the intersection of the main road of the city, and the intersection cannot be severed during the construction process, and the structural system conversion needs to be carried out during the construction. Comprehensively considering different factors, Tsinghua University and Harbin Institute of Technology have carried out a large number of technical and economic comparison work. Finally, considering the influencing factors such as investment control, modeling design, mechanical analysis, implementation difficulty, and adaptability to traffic dredging, it was determined that the flat-plate structure two-way beam steel-concrete composite system was selected as the large-span structural system of Gangxia North Hub.

Figure 4. Structural integral model.

Figure 5. Photos of long-span structure on construction site.

3.4 *Developed the glass tunnel system of the platform rail travel area*

Since the opening of the first subway in 1863, the subway has been a weapon to solve urban transportation, with a sense of technology and the future. The industry has been diligently using the language of the times to continue the original characteristics of the subway. Gangxia North Hub has made joint efforts in different dimensions such as material research and development, product customization, structural construction, and design research, and finally realized the glass tunnel in the rail travel area. The traveling process of the train is directly perceived, and at the same time ensures multiple conditions such as earthquake resistance, fire resistance, and pressure resistance. It provides a valuable demonstration of subsequent subway, intercity, railway and other forms of transportation.

Figure 6. Station hall atrium effect diagram.

3.5 *The large-scale underground hub decoration method integrating chinese and western cultural concepts was proposed*

In line with Shenzhen's open and inclusive urban spirit, combined with the special architectural design of Gangxia North Hub, the decoration design creates a conceptual scheme with the theme of "Shenzhen Eye". Implement the design concept of "introducing sunlight into the subway space", and create an

Figure 7. Site atrium effect diagram.

underground space of rail transit hub that can not only reflect Shenzhen's humanistic care but also carry the characteristics of Shenzhen's "convergence, inclusiveness and internationalization". Using the mathematical principle of "Fermat spiral" to design a ceiling design scheme endowed with visual tension, the white spiral converges to the "eye of the sky", reflecting the international style.

4 ENLIGHTENMENT

Human civilization has always been closely related to the development and utilization of underground space, and there are different ways of effective exploration around the world, especially in large cities. Based on the construction process of the subway, Gangxia North Hub has carried out multi-dimensional innovative exploration of planning and design, aiming to expand new ways and methods of development and utilization in the field of underground space. Hundreds of thousands of passengers gather and disperse here every day, and there are also general citizens who carry out various activities in different areas of the underground space. The passage of time never stops, so that people

Figure 8. Station hall scene photos.

traveling in underground space have a better travel experience, and it is the industry's continuous pursuit to extend more and more suitable activities in underground space. In the continuous iteration of the industry, we will definitely have a better transportation space and lifestyle.

Contract Korsvägen - part of the new Westlänken Commuter Rail Project in Gothenburg, Sweden.

Challenges of drill & blast Tunnelling and cut & cover construction in heterogeneous ground conditions

Klaus Rieker*

Wayss & Freytag Ingenieurbau AG, Frankfurt am Main, Germany

ABSTRACT: The West Link Project in Gothenburg is an 8 km long double track railway line. About 6 km of the section run through a twin-tube tunnel under the city center. An escape/service tunnel, which is accessible for vehicles through access tunnels, runs parallel to the track tunnel in the mined section. There are also three new stations located throughout the city center. Widening from two to four tracks within the stations will make rail operation as efficient as possible. The Korsvägen contract is a 3.2 km long section. It runs through heterogeneous ground conditions, alternating between hard rock and soft soil. The construction elements are therefore: a 700 m long Cut & Cover section, a 1 km long Tunnel, a 300 m long Cut & Cover section, Korsvägen station (constructed partly in an open box and partly within Drill & Blast Tunnel sections) and another 1 km long Tunnel. The joint venture Westlink Contractors (WLC), consisting of construction companies NCC from Sweden and Wayss & Freytag Ingenieurbau AG from Germany were awarded the contract in December 2017. The total bid sum, which also represents the first target price, is the sum of the unit price BOQ of the rock tunnel and the Design & Build price of all other cut & cover structures. The presentation will focus on the drill & blast tunnelling works with cross sections of up to 45 m with a cover of about 8 m only, will highlight the challenges of the open cut & cover temporary works (using different retaining structures) connecting very soft clay to hard rock in the transition areas and touch briefly on the interesting target price model.

Keywords: Tunnelling, Cut & Cover, Target Price, Challenging Geology, Inner City, Design & Build

1 PROJECT OVERVIEW WEST LINK

The West Link aims to increase the transport capacity of the commuter and regional train system, to create more travelling possibilities, to ease passenger flow at the Central station and to eliminate weak links in the current system. Besides the extension of the Central station, two new underground stations will be built - Haga and Korsvägen. This paper however deals further on with the construction section Korsvägen only, highlighted in yellow on the bottom half of Figure 1. The alignment and geology are presented for the whole West Link Project (Figure 2), whereby Korsvägen is on the right hand side.

The Client for the project is the Swedish Transport Authority Trafikverket.

2 KORSVÄGEN CONSTRUCTION SECTIONS

2.1 Overview

The Korsvägen project is an approximately 3.3 km long section spanning from the municipality of Mölndal to Lorensberg, a district of Gothenburg. This is also where the boundary line to the Haga construction section lies. The various sections with the project are shown in Figure 3.

Coming from the Mölndal direction, the alignment of the new West Link Tunnel initially runs in Almedal above ground parallel to the European motorway E20 and an existing railway line. In this area, the connection to the existing railway network will be via a trough and tunnel structure. This section is about 700 m long.

*Corresponding author: Klaus.Rieker@wf-ib.de

Figure 1. Overview of West Link Project, Gothenburg.

The next section of the project is the 1,000 m long Örgryte Tunnel, which runs under the European motorways E20/E6 and passes under the residential areas Skår und Örgryte. Just before the transition to the Liseberg cut & cover section, the tunnel passes as well below the Gårda Tunnel, a railway tunnel in operation.

Within the 300 m long Liseberg area, the rock horizon dips down requiring replacing mined tunnelling with cut & cover. Since this area runs through an amusement park, some buildings, including a sports hall, a car park, an access bridge, and various small buildings of the amusement park, had to be demolished first. The Liseberg Amusement Park is the largest in Scandinavia. The excavation pit in this section lies in the Mölndalsån river valley, which is filled with Lera clay.

From Liseberg the construction method changes back to a mining method. This 100 m long section is the trumpet-shaped eastern part of the Korsvägen Station and as well located under the Liseberg

Figure 3. Main construction sections and details.

Amusement Park. At this point, the double-track tunnel changes into a four-track section. Tunnel excavation will be carried out from an access tunnel using the drill & blast method.

The eastern trumpet is followed by the Korsvägen excavation pit. Like the Liseberg excavation pit, it is in a valley filled with Lera clay. The about 100 m long excavation pit will be constructed in two phases by means of secant bored pile walls and steel piles whilst operation of the Korsvägen traffic junction continues on a temporary bridge.

Drill & blast excavation methods will be used for the construction of the second half of Korsvägen station in the direction of the Lorensberg district. After about 100 m the cross section narrows from four to two tracks in the western trumpet-shaped area of the station. In this area caverns for ventilation systems and other technical installations as well as a ventilation shaft and tunnel plus an adit serving later as an entrance gallery to the station must be constructed. The follow-on approximately 1,000 m long Lorensberg Tunnel, which has a double-track cross-section, ends at the boundary line to the Haga construction section. All mined tunnelling in this area will be done from an access tunnel.

Each section (Figure 3) and its challenges will be described in more detail in the following paragraphs.

2.2 Almedal ramp

The temporary retaining structure for the trough and tunnel construction consists of about 3,000 sheet piles driven to rock level. Rock dowels and grouting secure the interface. To ensure water tightness everywhere, rock curtain grouting had to be carried out as

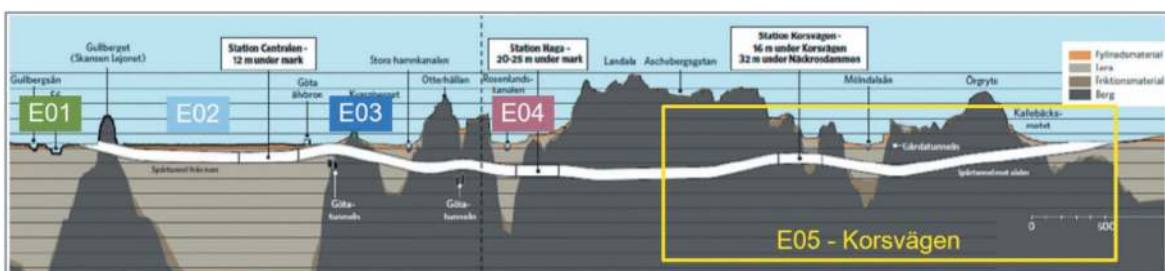

Figure 2. Simplified geotechnical longitudinal section of Gothenburg West Link.

well. Due to the soft soil conditions, the whole area had to be stabilized first by lime-cement soil treatment. Prior to that the existing railway tracks had to be shifted to allow construction to take place. The ramp is squeezed over the entire length between the tracks and the E6 motorway on the other side. The excavation pit was secured by up to three levels of strutting (Figure 4).

Figure 4. Almedal trough and tunnel section.

2.3 Örgryte tunnel

The Örgryte track tunnel is excavated via Service Tunnel 209 located just outside the city center of Gothenburg in the Skår residential area. 209 is the intermediate starting point for the construction of the 1,000 m long Örgryte track and a parallel running service tunnel (Figure 5). Both, the track tunnel with an excavation cross-section of approx. 130 m² and the service tunnel with an excavation cross-section of approx. 100 m² will be driven northwards and southwards simultaneously, i.e., four tunnel fronts are operational in

Figure 5. Örgryte track and service tunnel.

this area. Tunnelling works on Service Tunnel 209 started in November 2020. The tunnel section passes as well under sensitive buildings, such as the E-routes 20/6 and the existing railway tunnel Gårda. Granite with strengths of up to 300 MPa are encountered in this section. To-date the southbound Track and Service Tunnels are completely excavated (Figure 6). The northbound excavation is about 80 % complete.

Figure 6. Interface Almedal Ramp/Örgryte Track Tunnel.

2.4 Liseberg cut & cover

The challenges to overcome in the Liseberg Park area include the existing ramp to the motorway E6 and the historic buildings as well as the Mölndalsan river crossing. The ramp to the motorway had to be demolished and the so-called Rondo, an about 100-year-old building used year-round for performances, had to be partially flattened on one side to make room for the construction pit. An existing restaurant had to be demolished and rebuilt a few meters away to make room on the other side (Figures 7 and 8).

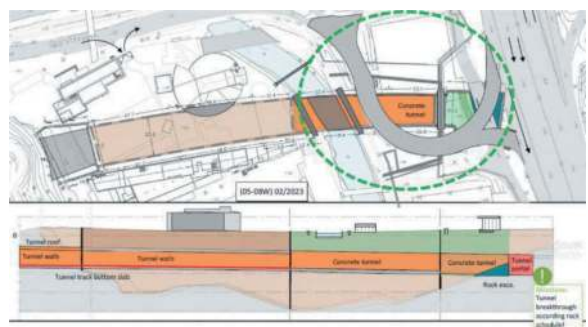

Figure 7. Ramp to E6, Rondo, Restaurant and Mölndalsan River.

Due to the very challenging geology different special foundation techniques came into play over about 300 m in length. Going from East to West, those are: 900 mm interlocking steel pipes, 1,472 mm interlocking steel pipes in the area, followed by diaphragm walls and sheet piles further on. In all areas, watertightness at the toe of the retaining structure must be

Figure 8. Liseberg Cut & Cover Section (grey).

achieved. Rock curtain grouting must be carried out where the rock on either end rises above the final excavation level. The transition to the Liseberg rock tunnel will be achieved with a 25 m long NATM/SCL excavation from within the Eastern Trumpet. Since the river, crossing the alignment, cannot be diverted, blocked or otherwise, a steel trough was manufactured off-site, assembled on site and lifted as one component into place. It rests on a sealing system and the previously mentioned 1,472 mm pipes.

2.5 Korsvägen station

Korsvägen station consist of three parts - Station East, Station Mid and Station West (Figure 9).

Figure 9. Station West (left), Station Mid (red), Station East (right).

Station East and West must be excavated via 400 respectively 500 m long access adits with an excavation cross-section of 80 m². Tunnelling works on the city-center access tunnels 206 and 207 began in autumn 2018. With only two blasting times per working day and strict vibration and noise criteria, the excavation cross-section of 80 m² was first subdivided into eleven sections and excavated with a round length ranging from 1 to 2 m. The sensitive buildings in the immediate vicinity (shown in Figure 10) such as the tram line, the Carlanderska Hospital, the Universeum Museum of Natural Science with rare species of fish in large aquariums and other residential buildings directly adjacent to the tunnel portals did not permit longer round lengths. Only after the tunnelling works had successfully commenced, was it possible to optimize the blasting process and change from partial-face excavation to full-face excavation and increase the round lengths to 5 m.

Figure 10. Portals and site installation area of service tunnels 206 (left) and 207 (right), access to Lorensberg and Liseberg.

Figure 11. Abutment walls of access tunnel 206 with the Carlanderska Hospital in the background.

These round lengths, common in Sweden, can be achieved since all tunnel sections built using the drill & blast method are in hard rock.

The subsoil in the mined tunnel sections consists mainly of gneiss with uniaxial compressive strengths between 200 and 300 MPa (Figure 11) shows exemplary the subsoil conditions at access tunnel portal 206, where two of the three portal walls were cut with wire saws to keep noise and vibration loads as low as possible.

Station East

From access tunnel 207, the eastern trumpet was excavated. Due to the large cross-section, 3 pilot tunnel had to be driven towards Station Mid. Prior to taking out the remaining 2 rock pillars, concrete columns must be built in the center pilot tunnel. The construction of these pillars can be seen in Figure 12. Due to the slopping rock level towards Liseberg, the remaining 25 m will be excavated applying NATM/SCL principles from within the trumpet.

Station Mid

The excavation for the mid-section of Korsvägen Station, which lies in Lera clay, will be retained by a combination of a secant pile wall and interlocking 900 mm steel piles (see Figure 13). Some of the surrounding buildings are based on wooden piles, requiring a constant groundwater level of 2 m below ground level. To keep the groundwater level constant

Figure 12. Pillars in the Center Pilot.

during construction the water inflow interrupted by the retaining structure will be pumped out on one side of the excavation and fed back into the soil on the side facing away from the hillside. Permanent water ways will be established within the bottom slab of the station.

Figure 13. Korsvägen station mid construction layout.

Excavation was completed in mid-2023. Currently uplift anchors are being installed and preparation for casting the first section of the base slab are ongoing (Figure 14).

Station West

Station West is being excavated from access tunnel 206. As Figure 9 shows numerous other caverns and tunnels must be excavated in addition to the trumpet and the track and service tunnels running west towards Haga. Some of the caverns are up to 35 m in height. Due to the large cross-section required by the 4 tracks, three pilot tunnels had to be constructed first. As in Station East, concrete pillars have now to be installed in the center pilot prior to taking out the remaining rock pillars. Due to the low overburden in some areas, 6 to 8 m only, intensive grouting works had to be carried out and numerous anchors as rock support had to be installed. Excavation of the service and track and tunnel towards Haga will be completed before respectively after the end of this year.

Figure 14. Korsvägen station mid construction pit.

3 DESIGN

The design for rock tunnelling is provided by the Client. The design for all open excavation is provided by a consultant appointed by the joint venture. As a part of the 3D design of the Design & Build contract, which is carried out concurrently with the construction work, the individual specialist models are joined to form a coordination model that serves to identify discrepancies between the individual specialist designers. Due to the parametric structure of the specialist models, design changes can be implemented efficiently, since the 2D drawings to be derived are automatically updated as views and sections from the model. Once the specialist models have been created using the corresponding authoring software, they are uploaded to BIM360Glue, combined, and automatically converted into the native Navisworks format NWC within the complex software landscape. Finally, detailed attribute and collisions checks are performed via Navisworks. The attributes provide information about release status, calculation reference and quantity of individual components, among other things.

Visualizations support decision-making and create a uniform understanding of the envisaged construction project during the execution phase. The model, which is divided into viewpoints, is also available to site management team members who are away from the site via tablet PCs.

4 TUNNELLING IN ROCK - THE SWEDISH WAY

4.1 *Tunnel cycle*

The working stages on Swedish tunnelling projects are basically the same as on any other conventional tunnelling project. The biggest difference, however, is in the tunnel lining. Normally an in-situ concrete inner lining is used, which is designed as a watertight concrete construction or provided with a sealing layer between the sprayed concrete outer

lining and the inner lining. This type of lining is generally not used on Swedish tunnelling projects. The Swedish tunnelling philosophy is based on using the rock as the final lining as far as possible. To reduce the groundwater and tunnel water inflow during the construction phase, but also permanently in the final state, as far as possible, the tunnelling activities are accompanied by discontinuous cement mortar grouting. The usual tunnelling cycle, consisting of drilling, charging, blasting, ventilating, mucking, scaling, installing of rock support and surveying is extended by operations that are necessary for pre-excavation grouting. The additional operations vary depending on the grouting class. In grouting class 3 the additional operations consist of

1. Drilling the first grout curtain holes
2. Injecting the first grout curtain
3. Drilling the second grout curtain holes
4. Injecting the second grout curtain
5. Drilling for water loss measurements
6. Measuring the water loss in the borehole
7. Evaluation
8. Decision: tunnelling/new injections

As a rule, an injection process is carried out approximately every 15 to 18 tunnel meters. Accordingly, the injection process takes place after every third round in the case of a regular round length of 5 m.

Each grout curtain consists of at least 30 boreholes, depending on the cross-section of the excavation. The boreholes are approximately 30 m long so that the grout curtains overlap. Figure 15 shows the drilling works.

Although the rock prevailing in Gothenburg consists mainly of very competent gneiss and has relatively few fault zones, sealing the fissures and cracks with cement injections as mentioned above is a very complex procedure, which can also have an extreme effect on tunnelling. For example, temperature has a great influence on the curing time of the grouting material, so that the usual curing time of six hours in winter must be extended considerably. In addition, the tunnel grouting process is on the critical path of the tunnelling. If the strict water tightness criterion is

Figure 15. Drilling a grout curtain.

not met when measuring the success of the grouting operation, the additional grout curtain has a direct effect on the duration of the tunnelling works.

4.2 Requirements on watertightness

Since the existing rock is used as a permanent structure and designed with a service life of 120 years, high demands are made on the tunnel lining. The strict water loss criterion should be mentioned in this connection. Once a grout curtain has been completed, six to twelve boreholes are drilled into the working face, depending on the excavation cross-section. Then packers are placed at the borehole and exposed to water pressure. The water loss per borehole must not exceed 0.05 l/min and borehole meter while applying 1 MPa. The total amount of water lost per grout curtain, however, must not be more than 4 l/min.

To meet the requirements, the borehole grout must be capable of withstanding the injection pressure for ten minutes. In addition, a very low injection pressure (approx. 1-10 bar) is specified, which is to prevent the fissures in the rock from splitting apart (see Figure 16). The strict criteria are intended to avoid a permanent lowering of the groundwater level and above-ground settlements that may occur as a result thereof and to reduce the water ingress as far as possible.

Figure 16. Grouting unit during the injection of a grout curtain.

5 PARTNERING

A special feature agreed between the Client Trafikverket and the West Link Contractors Joint Venture is partnering, a collaborative management approach both parties wish to use on the construction project. At the outset of the project, the parties jointly developed a collaboration model comprising five key elements: health & safety, innovations, impact on the surroundings, a common project culture, construction costs and construction time (see Figure 17).

Figure 17. One project culture.

These five keywords represent the goals that each project employee is to incorporate consciously into his or her daily work. One example is the common project culture. Project days are held at regular intervals and everybody from miners to suppliers and external consulting engineers to the project manager are invited to participate.

In addition, team building is also greatly encouraged by the long coffee breaks that are common in Sweden.

The collaboration even goes to such lengths that the Client and the Contractor share the construction offices. Care is taken to ensure that persons having the same position on Trafikverket's side and on the WLC's side share one room. This keeps lines of communication as short as possible and increases cooperation.

6 CONTRACT MODEL

Within the contract, based on the Swedish ABT06 standard, two contract models and two payment mechanisms are used - whereby all open cut structures are executed under a Design & Built Model with a Target Price payment mechanism and all tunnel works are executed under a Built-only model with a re-measured Bill of Quantity payment mechanism.

The total direct and indirect costs of all works are considered variable costs. On top of that, a fixed remuneration is paid. This fixed part must cover some specified costs plus overhead and profit.

Conditions prior to tender submission stipulated that the Fixed Part must not exceed 12 % and that the costs for the tunnels (BoQ-part) must not exceed 30 % of the total variable costs.

Finally, the whole reimbursement model does include a pain/gain mechanism of 80/20. Should the final costs exceed the final target, the overrun would be shared between the Client and the Contractor according to the percentages mentioned, likewise any saving would be shared on the same percentages.

7 SUMMARY

The project mentioned is using a pre-grouting method in the rock tunnel section. The grouted rock formation is the permanent lining for a 120-year life cycle. The conclusion can be drawn that these activities need to be carefully executed to ensure that the requirements are met. Otherwise, groundwater could still infiltrate the tunnels, affecting the settlements of the older properties in central Gothenburg. Due to the complexity of the works and the methods to be carried out, especially considering the varying geology throughout the alignment, a number of challenges had to be met. As of today, all open construction pit retaining structures are completed, rock tunnelling is well under way and constructing the permanent structures in Almedal and Korsvägen Station Mid are underway/have started.

The contract model with a combination of Built-only and Design & Build with different payment mechanisms for the rock tunnel sections and the open excavation areas embedded in a target price payment model poses some manageable challenges.

The cross river rail project as a PPP model in Brisbane, Australia. Experiences in cavern construction for 3 underground stations and tunnelling with double shield machines

Klaus Rieker*

Wayss & Freytag Ingenieurbau AG, Frankfurt am Main, Germany

ABSTRACT: Cross River Rail is a new 10.2 km long railway line, comprising of twin 5.9 km tunnels (excavated by TBMs and roadheaders) under the Brisbane River and the city center. It encompasses in addition 4 new stations (3 underground in 280 m long caverns excavated by roadheaders) and ramp structures at both ends as transition points to the existing rail system. Most of the route lies in stable rock such as sandstone, tuff or phyllites. Because of this, and to minimize the impact on the city center during construction, mining methods have been used wherever possible. On 2 stations, temporary access shafts were constructed next to the tunnel alignment due to existing railway lines and pedestrian zones respectively and fully enclosed by temporary buildings to reduce noise and enhance safety. Two station caverns were fully excavated by the time the TBMs reached respective locations. In the third station cavern, only the top heading was excavated and the TBMs mined through the lower cross section. The station caverns will be accessible via entrances located adjacent and will be connected by short tunnels. Construction is being carried out within the framework of a PPP model. The contract was awarded on 1 July 2019. To date, all tunnelling and inner lining works in the caverns are completed; rails in the running tunnels are installed and fit-out works in the stations and tunnels are well underway. The presentation will focus on tunnelling, cavern and shaft construction and the innovative method of casting and installing the mezzanine slab made of precast beams within the caverns.

Keywords: Tunnelling, Caverns, TBMs, Roadheaders, Lining, Precast

1 PROJECT OVERVIEW

As the population of South-East Queensland grows, the current rail network is reaching its capacity limits and is also constrained by a single river crossing in Brisbane and only four inner-city stations. This creates a bottleneck that limits the ability to run more trains.

A new rail link is therefore being built under Brisbane's city centre with the Cross River Rail project. Cross River Rail is a new 10.2 km long railway line from southern Dutton Park to northern Bowen Hills, comprising two 5.9 km tunnels under the Brisbane River and the city center [1]. The main components are four new stations and the associated single-track tunnels as well as the ramp structures at the transition points to the existing rail system (Figure 1).

Most of the route lies in stable rock such as sandstone, tuff or phyllites. Because of this, and to minimize the impact on the city center during construction, mining methods have predominantly been used. Approximately 4 km of the tunnel tubes were driven with two double shield machines. The

remaining tunnelling sections, as well as most of the station caverns, were excavated with roadheaders.

At the Albert and Roma Street stations, the TBMs were pushed or driven through the previously (partially) excavated caverns. The access shafts at the individual stations were all enclosed with large sheds to reduce noise emissions and to have as little impact as possible on the surrounding area and enable 24-hour operations.

Furthermore, four caverns at the Boggo Road, Woolloongabba, Albert and Roma Street stations were excavated using roadheaders as well as blasting and rock hammering. Especially at the Albert and Roma Street stations, the mined construction method was necessary to reduce the impact on the densely populated surrounding areas.

The construction project is being carried out within the framework of a PPP model by a joint venture of CPB Contractors, BAM International Australia (with Wayss & Freytag Ingenieurbau AG as internal partner), Ghella and UGL Engineering (CBGU JV).

*Corresponding author: Klaus.Rieker@wf-ib.de

Figure 1. Overview of tunnel excavation. Roadheader tunnels from Woolloongabba to Boggo Road. TBM tunnels from Woolloongabba to Northern Portal.

The contract was awarded on 1 July 2019.

2 STATION CAVERNS

2.1 Excavation and support

The caverns of the Albert and Roma Street stations as well as the launch caverns at Woolloongabba were designed with the same internal cross-section. The main differences are the primary and permanent lining as well as the tunnelling and excavation methods used, depending on the station configuration and prevailing ground conditions. Furthermore, the overburden, the location and configuration of the station structure as well as the planned surface development were considered.

All station caverns were excavated using roadheaders. In areas of stable rock, the heading was divided into two sections. In areas with lower strength or where fault zones were present, the excavation of the heading was divided into three sections. Fiber shotcrete and rock bolts were used as support measures. In some support classes, reinforcement mesh was also installed.

2.2 Roma Street Station

Roma Street Station is the central connection point for train and bus services in Brisbane and the surrounding area and connection for Suncorp Stadium and the future Brisbane Live arena, both venues for the 2032 Olympic Games. The new station building is being constructed next to the existing bus station, whose operations are maintained during construction. At the beginning of construction, an existing

multi-story carpark was demolished, and an acoustic shed was constructed around the temporary access shaft ahead of cavern excavation (see Figure 2). Here, too, the tunnelling work was physically separated from the progressing demolition work and construction of the station buildings.

Figure 2. Roma Street cavern and access adits.

The excavation of the cavern took place with roadheaders in the heading, as well as drill and blast in the bench, invert, and the access adits. Here the ground consists of the NFG group with decreasing strength in the northern section of the cavern. After completion of the excavation, the TBMs were pushed through the cavern on rails with a skidding system. The inner lining was then constructed while TBM tunnelling continued. This required a great deal of coordination of the logistics flows within the cavern. For this purpose, one of the existing tunnel tubes was temporarily closed and the supply of the TBM limited to one tunnel by means of multi-service vehicles. Due to the required supply lines and the conveyor belt, only the invert slab could be constructed.

2.3 Albert Street Station

Albert Street Station is in the center of Brisbane in a heavily built-up area with many high-rise buildings. Subsequent access to the underground station is via two station buildings that blend into the surface development. During construction, a temporary access shaft with an acoustic shed was built (Figure 3 - Lot 2). In this way, the construction, and logistics processes of excavating the cavern and construction of the station buildings could be physically separated. Due to the confined space in Brisbane's city center, sections of Albert Street were closed to road traffic and a pedestrian gantry enclosure was constructed under the elevated site facility. In this way, pedestrian throughfare could be maintained.

Figure 3. Albert Street cavern and access adits.

The acoustic shed of the cavern's access shaft contained, in a compact space (see Figure 4), the temporary storage and removal of spoil, delivery of all required materials (for example shotcrete, reinforcement), a water treatment plant, a workshop and general storage areas. As the only access point for the excavation of the cavern, the access shaft was a logistical challenge. Material and construction equipment as well as the skip bin for the spoil were lifted into the shaft with the help of a gantry crane inside the hall.

Figure 4. Lot 2 – access shaft to Albert Street cavern and acoustic shed.

The excavation of the cavern in Albert Street is done in sections heading, benching, and invert. In this process, the heading is divided into two sections in the southern cavern and into three sections in the northern cavern. The heading was excavated using roadheaders. The predominant ground was the Neranleigh-Fernvale group (NFG), consisting of phyllites interbedded with quartz layers. The varying rock strength results from the different degrees of weathering of the rock.

The permanent shafts for the station buildings were secured with bored piles and excavated with excavators and drill and blast. The simultaneous blasting in the shaft of Lot 1 with excavation of the cavern and advance of the TBM around and in the Albert Street cavern led to an increased coordination effort between the different teams. In addition, the excavation depth of the Lot 1 shaft had to be limited to ensure the stability of the adjacent rock between the shaft and the tunnel and cavern during the advance of the TBM through the cavern.

2.4 Woolloongabba start-caverns

The station in Woolloongabba is the connection of the Gabba Stadium, another venue for the 2032 Olympic Games, to the train network. As the starting point of the mined and TBM tunnels, the construction site facility in Woolloongabba had the largest area. In addition to the logistics areas of the TBM tunnels, the roadheader tunnels and the station

building, it included the station box with a temporary access ramp for access to the tunnel drives. After completion of the excavation work and concreting of the base slab, the lower station wall was erected to separate the work on the station building from the logistics of the tunnel drives.

The excavation of the caverns was done with split heading, bench, and invert with roadheaders and with rock hammer. The excavation here was mainly in NFG and Brisbane Tuff in the northern cavern. Defects in the rock of the invert had to be excavated in the area of the later railway line and replaced by concrete.

As shown in Figure 5, mined tunnelling was started in the southern cavern. The TBMs were assembled and started in the northern cavern.

Figure 5. Woolloongabba cavern and station box.

3 MINED TUNNELS

The tunnels from Woolloongabba south to Boggo Road Station were excavated using conventional construction methods with the aid of roadheaders. The primary support of the mined tunnels consists of Swellex anchors and PP fiber shotcrete.

As in the other stations and the start caverns, the predominant ground at the beginning of the excavation is the NFG group with very high strengths in areas with increased quartz veins. In these sections, the excavation method was changed from a pure roadheader excavation to excavation with rock hammer. Here, the profile continued to be trimmed using the roadheaders after the cut length had been reached.

The ground first changed to sandstones and conglomerates and then to Brisbane Tuff. These have significantly lower strengths, so that tunnelling could be carried out entirely with roadheaders. In the NFG area, cut lengths of five meters were achieved, and in Brisbane Tuff 2-5 meter cut lengths were achieved.

The mined tunnels were connected with a total of three permanent cross passages spaced at approximately 250 meters, and three additional temporary cross passages, which were used as logistical hubs during excavation to enable the subsequent construction of the inner lining in the southern cavern and the tunnels.

4 TBM TUNNELS

4.1 Main drives

The two 4.2 km long tunnels from Woolloongabba to the Northern Portal were excavated with two double shield machines with an excavation diameter of 7.23 m. The two Herrenknecht machines were already used in the Sydney Metro 2 project with a slightly smaller diameter and were adapted to the required excavation diameter with a new shield and cutting wheel for the Cross River Rail project. The tunnel section includes the two approximately 300 m long station caverns as well as the cross passages 4-16.

From a geotechnical point of view, the excavation can be divided into four sections. The launch at Woolloongabba and the first section were in Brisbane Tuff rock with a strength of up to 175 MPa. Before cross passage 6, there was a fault zone at the transition from Brisbane Tuff to the sandstone and conglomerates with potential water inflow from the Brisbane River and thus marks the starting point of the river crossing. The section of the river crossing extended through the low point at cross passage 7 to the next transition before cross passage 8. From there on, tunnelling was in the NFG grouping. Other

features of tunnelling included crossing the Albert Street cavern with little to no overburden, advancing the TBM in the Roma Street cavern using a jacking system and tunnelling towards and at the northern portal with reduced overburden below the tracks of the existing railway network.

The tunnel lining consists of six segments per ring with a large keystone. The main part of the tunnel lining consists of steel fiber segments. Reinforced concrete segments were only used around the cross passages and in the area of the station portals. In addition, highly reinforced segments were installed in the tunnel of the first drive where significant load surcharges were anticipated.

The annular gap was filled with a two-component grout. The segments were equipped with grouting sockets at which a hole could be drilled into the segment shell to further grout the annular gap under pressure at a later stage, if required. These grouting sockets would then be sealed watertight with suitable caps.

Driving in double shield mode allowed simultaneous excavation and ring building. As a result, advance rates of more than 60 m per day were achieved with the TBMs. Due to the fracturing of the layered rock in the NFG, high advance rates were achieved despite high rock strengths. Despite the high quartz content, the wear and tear of the

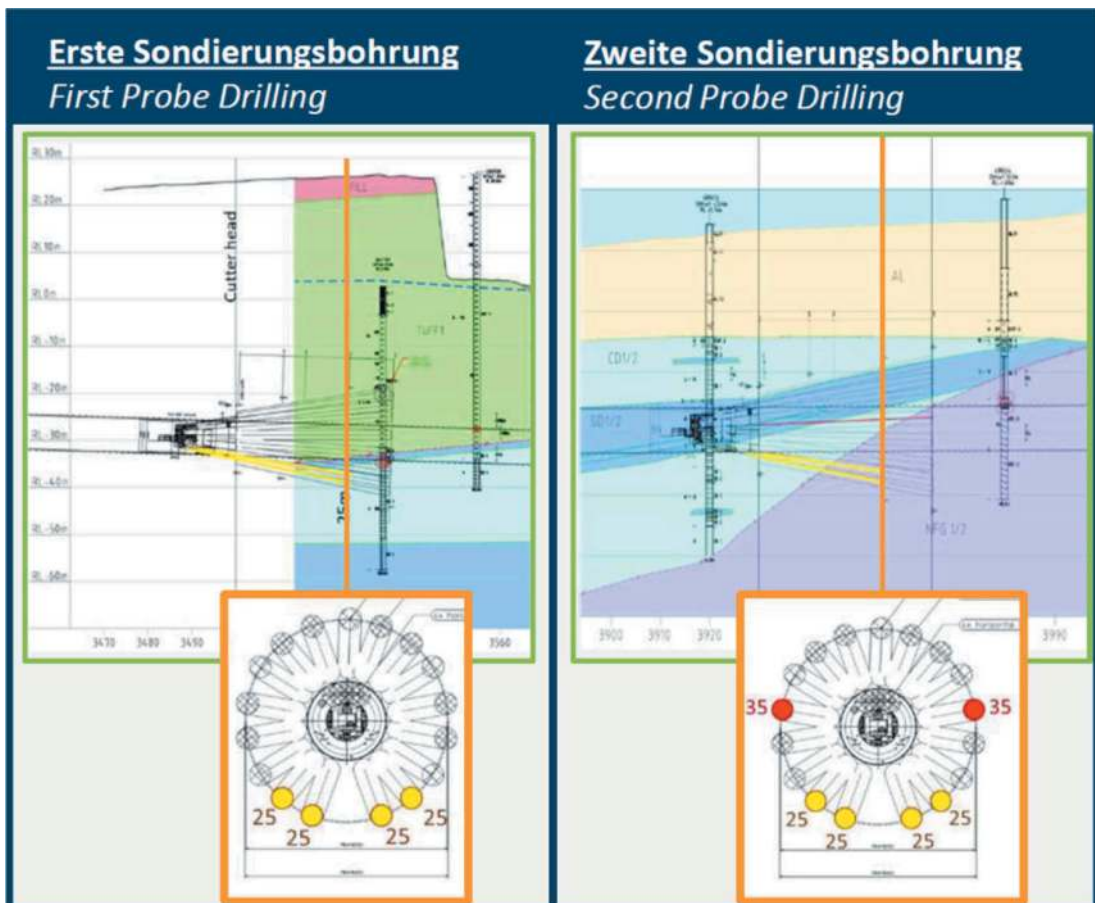

Figure 6. Probe drilling in both fault zones.

excavation tools was also low, with 1-2 maintenance stops per week.

4.2 Brisbane river crossing

Prior to confirming the methodology to cross the Brisbane River, the team undertook intensive risk assessments and detailed modelling to ensure all risks could be effectively mitigated. The river crossing was carried out with an open dewatering system. The geotechnical report showed two excavation sections with an increased risk of larger water inflow in the area of the river crossing (see Figure 6).

The first section was in the fault zone at the transition between the Brisbane Tuff and the Aspley Formation consisting of sandstone and conglomerates at the beginning of the river crossing. The second section was located at the end of the crossing between the Aspley Formation and the NFG grouping. Both sections carried the risk of water pathways to the Brisbane River with water inflows of more than 40 liters per second.

Based on the expected water volumes, a multi-stage concept for dewatering during the river crossing was developed:

1. Increased dewatering capacity on the TBM and at the tunnel low point including an emergency dewatering system consisting of additional pumps, pipelines, and an additional sediment pond.
2. Probe drilling in the fault or transition zones.
3. Grouting of the ground to seal the fault zones in the event of increased water ingress from the probe boreholes.
4. Sealing of the TBM: telescopic shield, gripper shoes, muck ring.

Two additional submersible pumps with a pumping capacity of up to 50 liters per second were installed on the TBMs. These were connected to two additional DN150 pipes that drained directly into the sediment pond. One of the pumps was

installed in the front shield of the TBM, the second was attached to the Gantry 1. However, the water inflow that occurred was low enough and was pumped out with the standard dewatering.

During tunnelling with TBM 1, probe drilling was carried out up to 35 m in front of the cutterhead at both fault zones. As both fault zones were expected to be at an upward angle to the face, probe drilling was mainly carried out in the bottom of the TBMs (see Figure 6).

In both cases, the drilling parameters and the borehole flushing water showed clear signs that the fault zone had been encountered. In both cases, however, no significant water inflow was measured from the probe boreholes. In addition, during excavation through the two sections and throughout the river crossing, only a small increase in water inflow was detected, which could be managed using standard dewatering. Grouting of the ground and sealing of the shield were therefore not necessary.

4.3 Albert Street cavern crossing

The cavern heading was 90 per cent excavated at the time the TBMs arrived, so TBM excavation in the cavern took place with little or no overburden. Figure 7 (left) shows the cross-section of the cavern with the actual state of the excavation depth of the heading.

The low cover caused the rock to break up into large blocks (Figure 7 - right). These were removed as far as possible from the surface with the help of an excavator to prevent damage to the conveyor belt. The ventilation system was adapted during excavation to increase its capacity, with the help of water curtains and scrubbers.

5 MEZZANINE BEAMS AND INSTALLATION

In the three station caverns at Roma and Albert Street as well as at Woolloongabba, the mezzanine level was constructed with precast concrete beams.

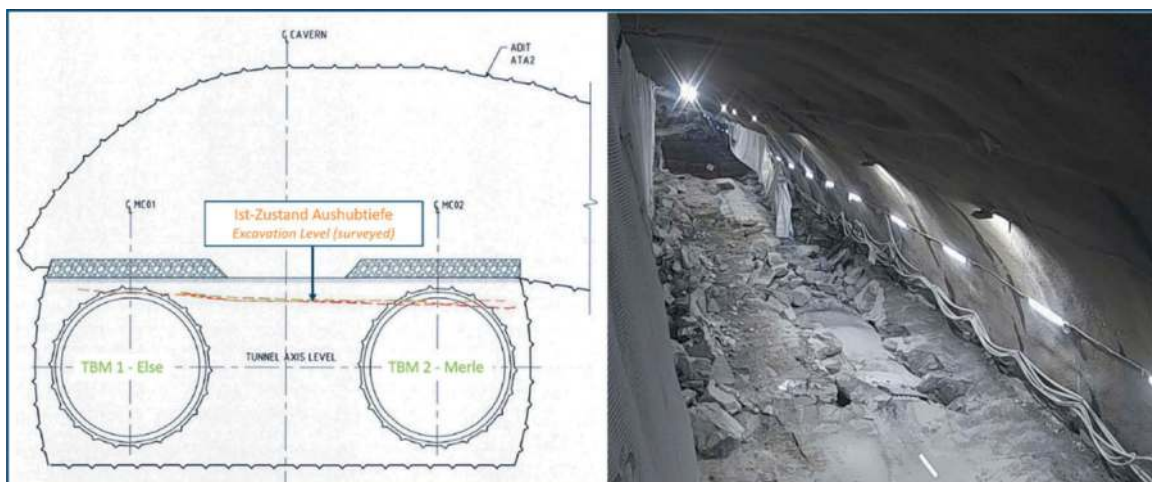

Figure 7. Cavern excavation level. Break-up of cover in Albert Street cavern during TBM excavation.

6 CURRENT STATUS

Figure 8. Mezzanine precast beam factory.

Figure 9. Loader for mezzanine beam installation.

The manufacturing of the beams took place about 400 km south of Brisbane in a dedicated precast yard (Figure 8). Due to the span width of about 20 m and large openings in the mezzanine slab for escalators, an innovative match-cast system was used. Each beam was cast directly against the previous and later installed in the same sequence. Since the beams had to be transported into the caverns via the temporary access shafts, each beam consisted of three sections. For the installation, 2 special loaders (Figure 9) and transport vehicles were manufactured and employed.

TBM Tunnelling on the Cross River Rail project was commenced in early 2021 and completed before the end of the year. All remaining excavation was completed in 2022 in line with project planning. Extensive settlement measurements were carried out in the zone of influence of the tunnel drives. Especially in the heavily built-up inner-city area, the influence could thus be monitored and minimized. Settlements measured in the stations caverns above the alarm values were examined in more detail with all parties involved and no damage was detected throughout tunnelling.

In the Albert Street and Roma Street areas, pedestrian flows were successfully rerouted and enclosed, minimizing the impact in the heavily trafficked inner-city areas. In addition, noise levels and vibration measurements were taken at the surface in the heavily built-up areas. Based on this data, the working hours for certain activities were adjusted. In addition to minimizing the impact on the environment, very great importance was attached to the integrity of the population and neighboring buildings, as well as to occupational safety during construction. Despite the large number of employees and subcontractors, the project had no major incidents.

As of October 2023, all station caverns are fully lined with cast-in-place concrete, all mezzanine precast concrete beams are installed and the fit-out works in the caverns are well underway. Within all tunnels, the tracks are laid and the installation of cables, water mains and safety walkways are well underway. Within all station buildings, fit-out works are ongoing. At the southern end of the project, near Boggo Station, a pedestrian bridge with a cable suspension section in the middle was erected over live railway lines. The northern ramp was already handed-over and overall works are proceeding in line with having 1st Train in the tunnels from there to Roma Street Station in April 2024.

Mechanized shaft sinking with VSM: Developing underground space for U-Park[®] systems

Peter Schmä^{*}, Stefan Frey & Marc Peters
Herrenknecht AG, Schwanau-Allmannsweier, Germany

ABSTRACT: In view of the increasing number of megacities worldwide and the growing population living in urban areas, space on the surface is becoming increasingly scarce and correspondingly more expensive. To ease the inner-city parking situation, new space can be developed underground. The Herrenknecht U-Park concept is a combination of mechanized shaft construction using VSM technology and the subsequent installation of an automated parking system with the associated technical equipment.

As a new mechanized solution, the Vertical Shaft Sinking technology (VSM) has been developed to overcome challenging mixed ground conditions, high groundwater tables or economic limits in greater depths. For almost twenty years, the VSM technology has been in operation worldwide to build shaft structures for ventilation, tunnelling operations or mining applications. More than 100 circular shafts have been completed, mainly in difficult, groundwater-bearing soil, in depths of up to 115 meters. The VSM is completely remote-controlled from the surface and covers a diameter range from 4.5 to 18 meters. It meets the key requirements for shaft construction in inner cities: no complex groundwater lowering; maximum production accuracy and safety, both for the site crew and for surrounding buildings; and flexible arrangement of site equipment.

The advantages of mechanized shaft construction with VSM becomes more apparent the deeper the shaft is sunk. Shaft diameter and depth of a Herrenknecht U-Park system are planned and designed according to local requirements in terms of capacity, underground conditions and economic considerations. In Nanjing, the world's first underground parking garage built using Herrenknecht's proprietary VSM mechanized shaft sinking technology went into operation in 2022. This U-Park concept included the construction of two shafts (diameter 12 m, depth 65 m) and the installation of the automated parking system for a total of 200 vehicles on 25 levels.

Keywords: Shaft sinking, drilling, foundations, underground parking

1 INTRODUCTION

The Vertical Shaft Sinking Machine (VSM) was originally developed by Herrenknecht for the mechanized construction of deep launch and reception shafts for microtunnelling. After starting design and testing in early 2004, the first Herrenknecht VSM equipment went into operation in Kuwait and Saudi Arabia in 2006. The machine concept, fully remote-controlled from the surface, as well as its implementation on site proved to be an efficient solution right from the start for the safe and fast construction of shafts especially in difficult, inner-city environment without lowering the groundwater table. Deep shafts can also serve, for example, as ventilation shafts for metro systems, maintenance or collector shafts for sewage, or for underground parking systems as shown in Figure 1. With an increasing number of successful reference projects worldwide, the technology is becoming more

and more well-known. The mechanized approach opens up a new technical solution for demanding shaft and foundation construction projects, to the benefit of project owners and planners.

Figure 1. Overview of different applications for VSM.

The latest application of the mechanized shaft sinking with VSM is the construction of deep shafts for underground parking systems, called U-Park[®]. This automated solution for underground car parking system is ideal for cities with high density population, where the availability of parking places is limited and therefore expensive.

2 BENEFITS OF MECHANIZED SHAFT SINKING WITH VSM

Shaft construction companies often encounter difficult geological conditions such as high groundwater tables combined with layers of hard and soft material. The VSM technology can be used in almost all geological formations: from sand and clay to gravel and rock with compressive strengths of up to 140 MPa and below groundwater level with a hydrostatic pressure of up to 10 bar. It masters the main challenges associated with inner-city shaft sinking: safe working conditions for surrounding buildings and the environment, especially regarding potential ground settlement. There is an increased requirement to avoid the lowering of the groundwater level during the construction of shafts in order to avoid the associated settlement, which can affect a wide area. As with using the VSM the water level in the shaft is maintained close to the groundwater level outside the shaft, water flow is prevented which otherwise could cause ground movement. Furthermore, recultivation measures caused by groundwater lowering are not necessary anymore.

In addition, deep shafts and foundation structures need special attention for the safety of the operating personnel. All installations, including the lining erection, are remote-controlled from the surface. No personnel has to enter the shaft until it has reached the final depth and is fully secured. In general, mechanized shaft sinking requires less personnel and machinery on site, which leads to minimized risk exposure.

Simultaneous excavation and shaft lining facilitate high advance rates and shortened overall project duration. At the same time, continuous performance ensures overall high planning reliability for all stakeholders. The lining of a VSM shaft consists of either precast segments or cast-in-situ concrete. As the lining installation is completed on the surface, high quality installation can be accomplished, leading to greater accuracy of the whole shaft structure. In most cases, a secondary, time-consuming lining is not required, resulting in a reduced wall thickness of the shaft and, thus, less soil excavation.

Furthermore, each VSM type is very flexible as its excavation diameter can be adjusted within a specific range. A VSM12000, for example, can cover shafts with inner diameters ranging from 5.5m to 12.0m and is, therefore, a one-time investment for multiple use.

3 VSM EQUIPMENT AND SHAFT SINKING PROCESS

The VSM consists of two main components (Figure 2): the excavation unit and the lowering unit. The excavation unit systematically cuts and excavates the soil and consists of a cutting drum attached to a telescopic boom that allows excavation of a determined overcut. The lowering unit on the surface stabilizes the entire shaft construction against

uncontrolled sinking by holding the total shaft weight with steel strands and hydraulic jacks. When one excavation cycle is completed, the complete lining can be lowered uniformly and precisely.

Figure 2. VSM components of equipment.

A slurry discharge system removes the excavated soil with the help of a submerged slurry pump which is located directly on the cutting drum casing. It transports the water and soil mixture through a slurry discharge line to a separation plant on the surface. The whole operation is controlled by the operator from the control container on the surface, without the necessity to view the shaft bottom or the machine. Power supply for the submerged VSM is secured by the energy chain. After reaching its final depth, the VSM is lifted out of the shaft by the recovery winches and the jobsite crane. All installation steps are shown in Figure 3.

Figure 3. Installation steps of shaft sinking with VSM.

3.1 The shaft lining

In most cases, the shaft lining consists of precast concrete segments installed at the surface. The ring building process is comparable to segment lining in tunnelling. The ring is built at the surface with support of a crane. The number of segments depends on the shaft diameter. Ring building work includes the proper connection of the rings by anchors and bolts, which can be handled from outside the shaft. The excavation process of the VSM is not affected by the ring building process. This increases the shaft sinking performance significantly.

Alternatively, in-situ concrete casting of the shaft walls is another solution, especially for larger shaft diameters where segment handling becomes more difficult. In this case, the progress of shaft construction works is slowed down by the necessary time to

build the formwork and the setting time of the concrete structure. The benefit of in-situ casing is the “continuous” structure without joints and the possibility to integrate entire entry and exit structures, e.g. for microtunnelling activities in the shaft walls.

3.2 Jobsite arrangement in inner-city conditions

Depending on the space conditions on site, the VSM components can be positioned flexibly to suit local circumstances (Figure 3). As most sites are located in heavily built-up urban areas, the access for logistics, e.g. trucks, ring segment stock or soil disposal, is limited. Special concepts to relocate components such as the separation plant already exist for this purpose and can be discussed if required.

Figure 4. Exemplary layout of a VSM jobsite.

In 2019 and early 2020, a VSM machine has been in operation to sink a total of three shafts in extremely confined space conditions in Barcelona, the capital of Catalonia, Spain. The three shafts with an inner diameter of 9 meters and an outer diameter of 9.8 meters reached a depth of 43.5, 41 and 50 meters. A detailed planning of jobsite logistics was necessary to allocate the key components of the shaft sinking equipment in traffic surroundings and to assure continuous progress at the same time.

Figure 5. VSM Jobsite arrangement in Barcelona.

3.3 Noise emissions

An important point to be considered on inner city jobsites are the noise emissions impacts of the construction equipment and the process itself. On a general basis it can be stated, that shaft construction with VSM causes a significantly lower level of noise emissions compared to conventional shaft construction methods. During shaft construction, the main components of the VSM equipment work under water and are supplied with electrical power. Instead of using diesel generators, the electrical power for the VSM jobsite can be provided by the municipal power grid. Thus, a considerable reduction of noise emissions can be achieved.

Within the VSM system the components which create highest acoustic levels are the separation plant and the diesel generator. The flexibility of this equipment makes it possible to place it at a larger distance from the main system components if required, which makes it an advantage highly appreciated not only by contractors but also by residents in these areas.

3.4 Mobility

When a VSM is supposed to sink shafts on different construction sites within a city, a quick and smooth mobilization and demobilization of all VSM components and detailed logistics planning can be considered, not only before the construction start of the first shaft, but also for disassembly, transport and installation of the VSM equipment on subsequent locations. After completion of the shaft, disassembly and assembly of the equipment on next location can take place simultaneously, because of the flexibility and compact design of the VSM equipment.

4 THE U-PARK® CONCEPT

In view of the increasing number of megacities worldwide and the growing population living in urban areas, space on the surface is becoming increasingly scarce and correspondingly more expensive. For this reason, urban planners see the future of infrastructure and logistics underground. This applies not only to supply and disposal networks in major cities, but also to the further development of sustainable traffic infrastructure.

To ease the inner-city parking situation, new space can be developed underground – with positive effects on the environment and on people’s quality of life. The smart Herrenknecht U-Park concept is a combination of mechanized shaft construction using VSM technology and the subsequent installation of an automatic parking system with the associated technical equipment. The number of parking lots per system depends on the diameter and depth of the shaft and on the expected car sizes (Figure 6).

Shaft inner diameter	Ø 11m		Ø 11-13m		Ø 16m		Ø 18m	
Shaft depth	50m	70m	50m	70m	50m	70m	50m	70m
Total no. of parking spaces in shaft	75	105	100	140	150	210	200	280
No. of parking levels	25	35	25	35	25	35	25	35
Parking spaces per level	3		4		6		8	

Figure 6. Shaft sizes and exemplary U-Park[®] capacities.

In order to use the available space as economically as possible, the shaft diameter and depth of a U-Park system are planned and designed with the respective local requirements, environmental conditions and user-friendliness in mind. Building the deepest possible shafts is a key factor in enabling maximum parking space capacity per U-Park facility and meeting cost-effectiveness requirements.

4.1 Benefits of the U-Park[®] concept

Shifting stationary traffic underground not only alleviates congestion but also offers a multitude of benefits. It effectively eliminates the need for drivers to endlessly circle in search of parking spaces, significantly enhancing the quality of life and safety for both motorists and residents.

This innovative approach also minimizes space requirements, opening up exciting new design and utilization possibilities for above-ground areas, particularly in locations where ground space is exceptionally limited and costly. This concept is particularly advantageous when repurposing outdated parking garages, transforming them into modern, underground parking systems.

Figure 7. Exemplary use of the U-Park[®] as foundation structure.

4.2 Shaft construction

The mechanized shaft sinking approach enables a compact and efficient jobsite setup during construction, as described above, even in tight spaces and densely built-up urban areas. Thanks to the safe

mechanized shaft sinking technique, it can be executed in various ground conditions, including high groundwater levels. This makes it a versatile and practical solution for urban mobility challenges. The advantages of mechanized shaft construction become more apparent the deeper the shaft is sunk.

4.3 Installation of the automatic parking system

As soon as the shaft is completely finished, the automatic parking system and the technical equipment can be installed. Only the entrance and exit will later be at ground level: in the ground-level reception booth, the intelligent, computer-aided system receives the vehicle from the driver before the driverless car then glides down to a free space in the parking shaft. Matched to the overall capacity of the parking system and arrangement of the platforms, the system manages the parking and removing of vehicles with maximum efficiency and safety. The installation of charging stations for electric vehicles and the integration of car sharing services are also possible.

Access to the parking levels is not necessary and is therefore reserved for service personnel. This reduces the costly installation of lighting and ventilation systems to a minimum. The ground-level access and the simple handover of the car to a closed system not only benefit those with disabilities, but also significantly reduce the risk of property damage or other crimes in some older parking areas.

Figure 8. Surface installations and access design.

The design of the entrance and exit on the surface depends primarily on the size and capacity of the U-Park system. Reception booths can be integrated into new or existing buildings or building complexes and connected to local traffic management. The drive-in booths can be designed to be independent or integrated into building concepts as desired.

4.4 U-Park reference project Nanjing, China

The world's first underground parking system built by a VSM mechanized shaft sinking machine went into operation in Nanjing in 2022. The Herrenknecht U-Park for Nanjing concept included the construction of two shafts and the subsequent installation of the automated parking system. The system of two shafts (diameter 12 m, depth 65 m) can accommodate a total of 200 vehicles on 25 levels.

The first shaft was completed in February 2021, the second in May 2021. Installation of the parking system was completed by the end of 2021.

Figure 9. Overview of Nanjing U-Park[®] concept for 200 cars.

4.5 Lack of space as major challenge

The major challenges in Nanjing were the lack of space for placing the equipment, the risks of settlements since several infrastructures, such as offices buildings, were very close to the shafts to be built. Furthermore, a high accuracy of verticality of the shaft installation was required, since the distance between the two shafts was around 5 m.

Figure 10. VSM Jobsite arrangement in Nanjing.

With the implementation of VSM technology, all these challenges could be overcome. Its design was based on the most frequent challenges that clients and contractors face when constructing large-diameter deep shafts in highly populated areas. The modular configuration of some components of the VSM system allow to play with their placement on the jobsite, giving the advantage of reducing the final required footprint, avoiding the necessity of lowering the groundwater level, reducing the risks of settlements and therefore, the risk of damage the infrastructure in the area. Finally, its guidance system together with the lowering system to control each unit individually, allows the system to achieve a very high accuracy of the shafts.

5 CONCLUSION

The current and worldwide trend to construct more and more infrastructure underground, e.g. metro,

Figure 11. VSM lowered into start section of the first shaft.

Figure 12. Final U-Park[®] Building, Nanjing.

road and railway as well as a large variety of utility lines, promotes a growing demand for the construction of shafts. With increasing shaft depths and groundwater levels, conventional shaft construction methods reach their technical and economical limits. The efficiency and benefits of mechanized shaft sinking in terms of budget, construction time and occupational safety have led to a total of more than 100 VSM projects where shafts have been successfully sunk. The VSM equipment design has been continuously further developed and adapted to a serve a growing range of applications, with ever larger diameters and in increasing depths.

The future of underground parking facilities in large cities is poised for a remarkable transformation. With the integration of advanced digital processes for parking management, the hassle of finding a parking spot will become a thing of the past. Drivers will be able to effortlessly navigate to available spaces, reserve spots in advance, and seamlessly complete the parking process, all through their smartphones or vehicle systems.

Additionally, charging stations will be integrated into the infrastructure, providing convenient and accessible options for electric vehicle owners to recharge their vehicles while parked.

This synergy of smart technology and sustainable mobility solutions will not only ease urban congestion but also contribute to a cleaner and more efficient urban landscape, shaping the cities of tomorrow.

ABSTRACT: Snowy 2.0 is a major hydro power project currently under construction in Australia. This new development will increase the capacity of the existing Snowy Mountains hydro power scheme by 2200 MW, making it the largest source of renewable energy in Australia and one of the largest pumped-storage projects in the world.

The Snowy 2.0 Power Station Complex is excavated at about 720 m depth in high in-situ stresses and fair to good rock mass conditions. During the construction of the two underground caverns, the geological conditions at the basis of the design are systematically and continuously verified thanks to in-situ geological investigations, detailed geological mapping and monitoring measurements, in accordance with the so-called “observational method”, allowing to perform design adjustments if and when the actual conditions would be differing beyond the expected design scenarios in a short time.

This article presents the main features of the observational method with a focus on the development of a “twin numerical model” of the Power Station Complex, to be regularly updated during the construction as more information becomes available from the continuing investigations and monitoring.

The development of the “twin numerical model” has for main objective to anticipate the behaviour of possible geological critical areas where the displacement of the rock mass is likely to locally yield the rock bolts which constitute the main support elements of the caverns. Once the possible critical areas are identified, specific monitoring instruments are installed in the most effective way, to identify the rockbolts that may exceed the design criteria.

Finally, depending on the actual monitoring results, remedial measures such as re-bolting may be necessary to comply with the design requirements.

Keywords: Large caverns, monitoring, twin digital model

1 INTRODUCTION

Snowy 2.0 is a pumped-storage hydro project that will generate 2200 megawatts to cover the peak demand of the network connected to the Snowy Mountains Scheme. The project links two existing reservoirs, namely Tantangara and Talbingo reservoirs, through around 27 km of tunnels and an underground Power Station Complex (PSC) at around 720 m depth (Figure 1).

Figure 1. Snowy 2.0 – project alignment.

*Corresponding author: pier-luigi.tonioni@tractebel.engie.com

During low demand hours, the excess of generated energy will be used to pump back the water from the lower reservoir (Talbingo at the western part of the PSC) to the upper reservoir (Tantangara at the Eastern part of the PSC), ensuring the storage of hydro-energy for peak demand hours. Emptying the upper storage reservoir from its full capacity at Full Supply Level could provide approximately 350 GWh of energy.

2 GENERAL CONTEXT

The project is developed and financed by Snowy Hydro Ltd, the owner and operator of the emblematic Snowy Mountain hydroelectric and irrigation scheme. The project construction was appointed to Future Generation, a Joint Venture between WeBuild (formerly Salini Impregilo), Clough and Lane Construction, under an Engineer, Procure and Construct (EPC) contract. Tractebel, together with partners, were contracted by WeBuild to develop the design of the civil works and Voith Hydro to design and procure the electro-mechanical equipment. Within the civil works design consortium, Tractebel is in charge of the design of the Power Station Complex.

The Power Station Complex (PSC) is an underground powerhouse housing six Francis reversible pump-turbines which can operate both in turbine and pumping modes. It includes the following structures: two main caverns, i.e., the Machine Hall (MH) at the eastern part of the complex and the Transformer Hall (TH) at the western part, six Busbar galleries (routing the connection cables between the generation units and the transformers) and six Draft Tubes tunnels (Figure 2).

Figure 2. Power station complex (in blue) - general layout.

Other tunnels surround the caverns for waterway, main access, ventilation, emergency egress as well as construction purposes. The main excavation cross sections of the Machine Hall and Transformer Hall are shown in Figure 3.

The maximum length, width and height of the MH are about 250m, 32m and 52m respectively, and for the TH these are about 220m, 20m and 46m respectively. The distance between the two caverns is about 60 m. The six Busbar galleries are

Figure 3. Power Station Complex cross-section.

perpendicular to the longitudinal axes of the MH and TH. The distance between two adjacent Busbar galleries is between 18 m and 19 m. The Busbar galleries are 10m wide and ~14.5m high. The Draft Tube tunnels are ~ 6m wide and ~6.5m high. Two main tunnels (Main Access Tunnel and Egress, Cables and Ventilation Tunnel) provide permanent access to the PSC. Both are excavated from the surface with two TBM of ~10 m diameter. From these main tunnels, Drill & Blast construction tunnels are carried out for the excavation works of the caverns.

3 GEOLOGICAL CONTEXT

The project area is situated within the south-eastern portion of the Lachlan Orogen (Fold Belt) of New South Wales (NSW), which comprises a suite of early Paleozoic Era (550-350 Million years ago) sedimentary, igneous and metamorphic rocks that have developed during several orogenic periods. These periods are associated with extensive faulting and have formed major geological structures through the area.

The Power Station Complex is situated at a depth of about 720 m below ground surface in the Ravine Beds Formation (Figure 4). The main lithology consists of interlaminated to interbedded siltstone/sandstone. Siltstones are predominant.

The rock mass is considered impervious with an average permeability of approximately 10^{-8} m/s.

The main geomechanical parameters considered in the development of the design are given below. They were derived from the outcomes of an outstanding, high quality campaign of geotechnical investigations carried out from the surface:

In-situ stress: the in-situ stresses were defined from over coring and hydro-fracturing/hydro-jacking tests carried out from the surface. The vertical stress at the location of the PSC is around 20 MPa, basically corresponding to the overburden. The major stresses are horizontal, with average values of K_H and K_h of 2.3 and 1.5 respectively.

Unconfined Compressive Strength of the intact rock (UCS): The main parameter governing the UCS value is the lithology. The siltstone being predominant, an UCS characteristic value of ~ 60 MPa was adopted.

Geological Strength Index: The GSI was evaluated from the observation of the boreholes at the

PSC area. Based on the statistical analysis, the average GSI value is equal to 72.

Other parameters such as intact rock modulus (E_i), Poisson ratio and m_i were estimated to be 35 GPa, 0.25 and 8 respectively. The joint sets consist of two main families: (i) the bedding joints – almost sub-horizontal –, strongly prevalent, spaced approximately every 2 m, and (ii) tectonic joints – almost subvertical-, more widely spaced. The two joint sets include pre-sheared joints with low friction angle – 25° to 30° - spaced approximately every 10 to 20m. The joints are generally closed. The pre-sheared joints, bedding or tectonic joints, are considered weakness planes. A structural model's scheme of the rock mass is given in Figure 4.

Figure 4. Structural model's scheme of the rock mass.

4 DESIGN APPROACH & CRITERIA

As mentioned in the previous section, the design of the rock support and global stability of the caverns is based on the geotechnical investigations (GIP 2019, 2020 and 2021) available during the design phase (i.e. the PD phase and the DD phase). Design assumptions were made regarding the geological and geomechanical model derived from the investigations.

On the basis of these design assumptions, the Detailed Design was developed to verify the global and local stability of the caverns, as well as the integrity of the rock support, mainly the rockbolts.

The design of the rock support for the PSC was based on the New Austrian Tunnelling Method (NATM), the resistance of the rock mass being preserved and increased by means of point-anchored, fully grouted rock-bolts, reinforcing the rock mass shear strength and multiple layers of steel fibres reinforced shotcrete.

No relevant Code or Standard exists for the design of such large deep underground caverns as the geological and geotechnical conditions govern the stability. Specific design criteria, compatible with the overarching principles of the Australian standards, were therefore defined and agreed with the

Employer. The retained design criteria covered the following technical issues:

- i. the general rock mass behaviour,
- ii. the rock pillars stability,
- iii. the rock wedges stability,
- iv. the performance and durability of the rock-bolts.

The first three issues are not addressed in this paper. Readers may refer to [7] for a comprehensive discussion of these items.

The verification of the performance & durability criteria of the rock-bolts is developed therein and constitutes one of the main purposes of the “twin digital model”.

4.1 Performance & durability of the rockbolts

Displacements of the rock mass under high stresses is likely to locally yield the rockbolts, in tension but also in shear when crossing weak geological joints. Rockbolts are verified for their structural integrity and durability. The long-term protection of the rockbolts is ensured by a “double corrosion protection” system, composed of HDPE sheath around the bar and grouting of the gap between the rockbolt and the borehole. After a series of tests, the following design criteria for the rockbolts were specifically defined:

- Maximum elongation strain: 2.5% for the primary rockbolts and 1.5% for the permanent rockbolts, based on an A_{gt} of 7.5%.
- Maximum admissible shear displacement at: 18 ~ 20mm for durability of permanent rockbolt (CT-M24 or CT26WR respectively) and 35 mm for structural integrity of both primary and secondary rockbolts.

5 THE OBSERVATIONAL METHOD

During the construction, the design assumptions are verified based on specific in-situ geological investigations during construction and actual observations (detailed geological mapping and monitoring measurements), also known as the “observational approach” during construction.

The main objectives of the observational approach are:

- to confirm (or update) the geological conditions and model;
- to confirm the validity of the design (for the actual geological conditions and model)
- to provide design adjustments if the actual conditions are differing beyond the expected design scenarios.

This observational approach is based on two processes:

- collecting during construction the geological, geotechnical and monitoring data;

- carrying out a “back analysis” process that involves the analysis of the design components (mainly the mechanical properties of the rock mass and joints, the in-situ stress, the displacements of the rock mass and joints, ...) in order to confirm or update the numerical model and if required the design.

In general, the monitoring of the convergences of the caverns constitutes the most significant source of information of a behaviour of the structure during the excavation. To a large extent, the monitoring scheme of the PSC is devised to quantify those kinds of displacement including the direct and undirect measurements of the displacements of the joints and rockbolts. The measurements will be compared to the results of the numerical model of the PSC, potentially leading to adjust some of the geotechnical parameters introduced in the model.

In particular, depending on the actual shear displacement of the rockbolts and joints, re-bolting of some secondary rockbolts may be necessary to guarantee the durability of the support.

5.1 Design verification by control points

As part of the observational approach, design control points - **Witness points (WP)** and **Hold Points (HP)** - are defined along the excavation procedure of the caverns and the IPB galleries. The definition and objective of these design control points are presented below:

Witness points

WP are scheduled at specific stages of the excavation where detailed information must be provided to the designer. Relevant tests and monitoring data must therefore be formally documented and provided by the Contractor to be able to follow up the behaviour of the cavern. At this point the construction can continue as planned.

Hold points

HP are scheduled at critical stages of the excavation where specific detailed information must be provided to the designer to check the design and to release those HP to continue the excavation works. Release of the HP by the designer means that the design can be executed *as is* with regards to the actual geological/geotechnical conditions as well as actual monitoring. Construction can proceed only if such confirmation is given by the Designer.

It should be noted that a Witness Point (WP) could become a Hold Point, i.e., in case of identification of unforeseen geological conditions or unforeseen behaviours of the rock mass which would necessitate an immediate adaption of the design at the referred Witness Point. In other words, the principle of the observational method is to be reactive to the actual conditions encountered and therefore, the detailed definition on the HP/WP presented thereafter may be adapted in function of the actual conditions found at site.

A scheme of the HP/WP localization along the excavation staging is given in Figure 5.

Figure 5. HP/WP along the caverns' excavation staging.

6 TWIN NUMERICAL MODEL & DESIGN ADJUSTMENT

The twin numerical model provides the digital modelling of Power Station Complex. Its main scope is to predict the opportunity of design adjustments at any stage of the caverns' construction. It will also be a powerful tool to assist the Contractor regarding the specific “delayed” sequence of installation of the rockbolts, which has been designed to avoid excessive shearing of the permanent rockbolts.

The level of details of the twin model may vary depending on the analysis to be performed, as well as the type of model itself. In the framework of the Snowy PSC design, a first level of analysis was performed to investigate the spatial relationship between certain parts of the PSC and the main discontinuities detected on site by the geo-structural mapping. This type of analysis was carried out by a “Twin model”, developed with Rhino (Figure 6). At the time of writing, this model is continuously updated with the data progressively collected from the detailed geological mapping of the excavation.

Figure 6. Twin numerical model on Rhino.

A second type of analysis, aimed at identifying the rockbolts exceeding the design criteria, is based on a “Twin model” developed by 3DEC, with a level of detail such to represent both the primary and the secondary rockbolts as well as the main pre-sheared joints at their exact position and orientation (Figure 7).

6.1 Example of “twin model” for design assumptions verification

In the framework of the PSC design, a particular attention was given to the intersection between the

Figure 7. Twin numerical model for rockbolts analysis.

main access gallery MAT01 (ϕ 11m TBM tunnel) and the two main caverns. The project features both caverns to be connected by MAT01 during the construction and the service phases. Circulation inside MAT01 must be guaranteed as long as possible during the excavation of the caverns (Figure 8) and surrounding galleries, requiring a robust support design.

Figure 8. Circulation above MAT01 during cavern excavation.

The numerical model developed for the Detailed Design is a 3DEC model of the whole PSC, which considers the presence of the main joint sets (Figure 9).

Figure 9. 3DEC Model - geometric hypothesis – 3D view.

Two pre-sheared joint sets, among the 5 joint families, are explicitly represented in the model:

- Bedding joint set: 35° dip, 75° dip-direction and 10 m spacing.
- Tectonic joint set: 75° dip, 125° dip-direction and 20 m spacing.

The remaining joint families were implicitly taken into account, lumped in rock mass parameters.

While developing the 3DEC model of the zone surrounding the MAT01 junctions, the joints positions were adjusted so that a bedding joint and a tectonic joint cross the rock slab in-between Central Heading Tunnel in both MH and TH and the underlying MAT01 (Figure 10).

Figure 10. Pre-sheared joints between CHT and MAT01.

This conservative approach, introduced in the numerical model, was adopted as a precautionary measure to maximize the possible rock mass displacements and the wedges dislocation in the surrounding of MAT01 (Figure 11).

In other words, the existence of two joints (bedding and tectonic joints) crossing each other in correspondence of the rock slab in-between the CHT and the underlying MAT01, has to be considered as a sort of “worst case” condition, to be verified in the framework of the HP/WP procedure.

Figure 11. Exaggerate MAT01 displacements induced by MH excavation.

The circumstance described above was the object of a specific Hold Point (HP1a) to confirm that the in-situ geological conditions of the rock

slab in-between the Central Heading Tunnels and the underlying MAT01 are consistent with the hypothesis assumed for the design (Table 1).

Table 1. Description of the HP01a scope.

WP/HP	Main Objectives	Input required	Home Office Output
HP 1a During the excavation of CHT	Verification of the joint sets intercepting the rock slab in-between the Central Heading Tunnels and the underlaying MAT01.	Routine geological survey focused on the Joint sets.	The output of HP1a shall consist of an “HP1a PSC Report” related to the design of the MAT01/PSC intersection (MH01.3) The report shall confirm that the in-situ geological conditions of the rock slab in-between the Central Heading Tunnels and the underlaying MAT01 are in-line with the conditions assumed for the detailed design (Ref. S2-CIV-PX-MHA-REP-3703) and that the Design Package MH01.3 can be executed <i>as is</i> .

The first stage of the verification procedure consists in the joints mapping along the area affecting MAT01.

Due to the joint sets’ orientation, the face mapping had to be extended well beyond the area strictly overlaying MAT01 to capture all potential discontinuities passing through the rock slab.

A step further of the verification procedure was based on the data obtained from a long horizontal borehole (250m) drilled all along the TH’s central heading tunnel, thus crossing the area of interest above MAT01.

The borehole also allowed to recognize the lithology of the concerned area, as well as the rock mass resistance via several Point Load tests.

Figure 12. Borehole along TH and area of interest for HP1a.

The development of a “Twin model”, using the available data from site, allowed the designer to validate that the actual on-site conditions are consistent with the design hypothesis, so that the “Hold Point 1a” was fulfilled smoothly, without any disruption to site activities.

6.2 Example of “Twin model” for verification of the rockbolts.

The re-bolting of the rockbolts is dictated by shear displacement of significant joints, mainly along the pre-sheared bedding joints or tectonic joints.

A preliminary assessment of the required re-bolting was performed by means of a 3DEC full staged PSC “Twin Model”, simulating the whole excavation process and the explicit installation of the rockbolts.

At the time of writing, this preliminary “Twin Model” already includes the main pre-sheared joint sets deduced from the previous geological investigation’s campaigns. However the final Twin Model is expected to be updated with the joint sets data actually observed on site during the caverns’ excavation.

The “Twin Model” analysis suggests the presence of some possible critical areas where re-bolting shall occur because of exceeding the design shear criteria, at the upstream side of the MH, extended between the vault and the sidewall at location of weak pre-sheared joints.

The mentioned critical areas are numbered from 1 to 6 in the following Figure 13.

Figure 13. Example of the critical areas assessment.

The results of the in-situ investigations and the data from the monitoring will be considered for updating the PSC Twin Model numerical model, which will be re-run at several stages during cavern excavation – as part as the HP/WP – allowing an early identification of rockbolts (number and location) potentially exceeding the design criteria.

It is expected that rockbolts exceeding the design criteria are related to pre-sheared joints or discontinuities, thus the correct identification of such pre-sheared elements during the excavation process will require special attention and effort.

It is finally noted that even if the general deformation pattern of the PSC is modelled, it is difficult to calibrate the whole PSC numerical model so that all the measurements are in line with each other. Hence, local “Twin Models” are foreseen to be developed, fitting the data collected by the monitoring system in a given area of the PSC through back-analysis in acceptable computational time.

7 CONCLUSIONS

The Snowy 2.0 Power Station Complex is being excavated at about 720 m depth in high in-situ stresses and fair to good rock mass conditions in Australia. During the caverns construction, the geological conditions at the base of the design assumptions are systematically and continuously verified thanks to specific in-situ investigations and monitoring measurements during construction, in accordance with the “observational method”, providing time to design adjustments if the actual conditions are differing beyond the expected design scenarios.

The article draws attention on the development of a “Twin Numerical” model of the Power Station Complex, to be regularly updated during the caverns’ construction, and allowing to predict the need for design adjustments at any stage of the caverns’ construction in a short time.

The level of details of the Twin Model may vary depending on the analysis to be performed; and two cases of application of the Twin Model implemented in the first phase of the Snowy 2.0 caverns’ construction are reported as examples.

ACKNOWLEDGMENTS

The authors would like to acknowledge all the peers from Tractebel who contributed to the design of the Snowy 2.0 Power Station Complex over the years.

Authors would like to thank Snowy Hydro Ltd and Future Generation Joint Venture for the intensive and valuable technical discussions that were held along the development of the design.

ABSTRACT: Rock engineering plays a pivotal role in Sweden's critical infrastructure sectors, including mining, hydropower, and railways. This article provides an overview of the significance of rock engineering in these domains and highlights Sweden's expertise in harnessing the power of its geological formations for sustainable development. Sweden's mining industry relies heavily on the country's rich mineral deposits, particularly iron ore, copper, and zinc. Rock engineering is fundamental in ensuring safe and efficient extraction from underground mines. Sweden's commitment to sustainable mining practices has led to the development of cutting-edge rock reinforcement techniques, ground control strategies, and advanced monitoring systems, making it a global leader in responsible mining operations. Rock Engineering is essential for tunnelling through the country's rocky terrain, enabling reliable transportation even in challenging landscapes. Sweden's rail engineering innovations, including tunnelling methods and rock support systems, ensure the safety and functionality of the railway network and heavy haul transports e.g. iron ore. Due to demand from the mining industry and railway sector Sweden's abundant water resources have made hydropower a cornerstone of its clean energy strategy. Rock engineering is critical for constructing and maintaining hydropower infrastructure, including dams, tunnels, and underground power stations. Swedish expertise in geological mapping, rock mechanics, and tunnelling technologies has enabled the harnessing of hydroelectric potential while minimizing environmental impacts. In conclusion, rock engineering in Sweden is integral to the success of its mining, hydropower, and railway sectors. Sweden's commitment to sustainable practices, coupled with its expertise in geology and engineering, has positioned it as a global leader in these critical industries, serving as a model for responsible resource utilization and infrastructure development all over the world.

Keywords: Sustainability, Tunnelling, Metals, Hydrogen storage, Environmental code

1 INTRODUCTION

In the last century the technique of rock blasting has developed from a manual occupation in which personal skill and intuition plays a great part into a technical science that today can be taught to student's, engineers and workers. A lot of methods and technologies used today worldwide have been development in Sweden according to Langefors, and Kihlstrom, 1978.

The introduction of drills with tungsten carbide bits and modern drilling machines played an important part in the transition to a more automated process. This development accelerated in 1946 as a collaborative

effort among large Swedish steel companies to develop materials for rock drilling. The result was the establishment of an association and over time, it expanded its focus to serve the broader rock blasting industry and technology related to underground construction in rock. In 1957 the association changed its name to the Rock Blasting Committee and in 2017, the name officially changed to the Swedish Rock Engineering Association following an expanded collaboration with the Rock Engineering Research Foundation (BeFo).

The Swedish Rock Engineering Association is a non-profit organization that brings together companies involved in the design, construction, and operation

*Corresponding author: pervedin@hotmail.com

of underground facilities and mining, as well as manufacturers of relevant machinery and equipment. Their primary activities is to host conferences on rock engineering and rock mechanics and share insights on various topics, and provide information to the public and members free of charge. The association monitors the field of rock engineering accumulating valuable knowledge for the industry and decision-makers.

2 SWEDEN IN BRIEF

Sweden, Figure 1, is a constitutional monarchy with a parliamentary system of government. It covers an total area of about 447 000 square kilometres which makes it the largest country in Northern Europe. Sweden has a population of approximately 10.5 million people and the capital Stockholm is the largest city.

Figure 1. The country of Sweden located in the north of Europe.

In Sweden Education is free and compulsory for all children between the age of 6 and 16 and there is a universal healthcare system that provides healthcare services to all residents. Sweden has one of the highest life expectancies in the world with an average of over 83 years.

Sweden is known various things, awarding the Nobel Prizes, including the Nobel Peace Prize, which is presented annually in Stockholm city hall. When you visit Sweden, you should know the word “Fika”. It is a Swedish tradition of taking a coffee break with a snack, often accompanied by socializing.

In northern Sweden, the phenomenon known as the “Midnight Sun” occurs during the summer months, where the sun remains visible throughout the night. This is also the location of the largest iron ore mines in the country.

2.1 Geology

The rock underlying much of Sweden is highly suitable for building tunnels and rock caverns. The rock in Sweden comprises of three main units: the Precambrian crystalline basement, the remains of a sedimentary rock cover, and the rocks in the Scandinavian Caledonides mountain range.

The basement is part of a palaeocontinent, Baltica, and comprises of rocks formed during the Precambrian eras approximately 2800-545 million years ago. Most of the sedimentary rocks overlaying the basement to the east of the mountain range were formed in the period from the Cambrian and into the Tertiary period 545-55 million years ago. The sedimentary rocks are fossil-bearing and overlie the crystalline basement. The Scandinavian Caledonides are the remains of an old mountain range 510-400 million years ago when Baltica collided with Laurentia (North America—Greenland). Super-regional thrusts forced up older rocks from the west to form a long mountain range.

2.2 Sustainability

Sweden is committed to environmental sustainability, with recycling and eco-friendly practices being common. Sweden is working toward achieving the Sustainable Development Goals outlined in the United Nations’ 2030 Agenda. These goals encompass various aspects of sustainability, including poverty reduction, environmental protection, and social equity.

Sustainability goals in Sweden are aligned with global objectives and reflect the country’s commitment to environmental, social, and economic sustainability. The sustainability goals reflect a holistic approach to addressing all these challenges. The goals are supported by policies, regulations, and initiatives that aim to make Sweden a model for sustainable development and a leader in addressing global sustainability issues.

In 2022, nearly 98 % of the energy consumption in Sweden came from fossil free energy sources and nearly 70 % of the total energy consumption came from renewable energy sources. Sweden has made significant investments in renewable energy sources, particularly wind and hydropower. The aim is to increase the share of renewable energy in the national energy mix, reducing dependence on fossil fuels.

3 THE ENVIRONMENTAL CODE AND RAILWAY TUNNELS

3.1 *The Hallandsås Tunnel project*

The Hallandsås Tunnel project, initiated in 1992 with an open-face tunnel boring machine (TBM), encountered immediate issues, prompting a shift to traditional drilling and blasting methods. Subsequently, a more significant problem arose as substantial groundwater inflows disrupted the northern tunnels, leading to lowered groundwater levels and well water.

Efforts to seal the tunnel revealed that none of the tested grouting agents could effectively penetrate and seal the finest cracks. Eventually, a chemical grouting agent, widely used in global tunnel projects, was experimented with. This agent contained acrylamide components, initially toxic but rendered harmless through polymerization, making it suitable for sealing fine cracks due to its water-soluble nature.

In October 1997, complications arose as some of the acrylamide failed to polymerize due to abundant groundwater flow and high-water pressure. Consequently, this unreacted acrylamide contaminated nearby streams, resulting in fish mortality and paralysis in cattle that consumed the water. Concerns also extended to local drinking water quality and tunnel workers' safety.

The project came to a standstill in 1997 upon the discovery of acrylamide discharge issues. Further assessments indicated that the drill-and-blast method would introduce substantial water inflows during construction, necessitating a solution. The conclusion was to line the tunnels with enclosed concrete and employ a shielded tunnel boring machine. A vital lesson learned was the importance of prioritizing environmental considerations, control, and public information, BeFo Rock Engineering Foundation and Swedish Rock Engineering Association, 2018.

3.2 *The Environmental Code*

The Environmental Code, implemented in 1999, consolidated various environmental laws with the primary goal of fostering sustainable development, ensuring a healthy and favourable environment for both current and future generations.

Within the Environmental Code, there are overarching regulations concerning responsible planning and execution of subterranean initiatives. These encompass guidelines for land and water management, safeguarding crucial ecological zones, and setting environmental quality standards.

One illustrative instance covered by the Environmental Code involves the extraction of water from tunnels and subterranean caverns, necessitating a permit. A core tenet dictates that all construction endeavours involving groundwater must be formally reported. Furthermore, activities linked to noise and dust emissions during the construction and operation of subterranean facilities can fall under environmentally hazardous classifications in accordance with the Environmental Code.

The Hallandsås Tunnel project serves as a case study illustrating the intersection of infrastructure development, environmental regulations, and the importance of environmental considerations and risk management in large-scale construction projects in Sweden, in accordance with the Environmental Code.

4 HYDROPOWER

Sweden doesn't have much coal and oil, so the focus has been to use more renewable energy sources, being environmentally friendly. This has made Sweden good at finding clean energy solutions. Hydropower has traditionally served as a pivotal pillar in Sweden's industrial progress.

Electricity generation is almost evenly divided between the government, represented by the Swedish

State Power Board (Vattenfall), and power companies owned by various entities such as industries, municipalities, and non-governmental bodies. These entities collectively form the Swedish Power Association, established in 1909.

Today, every household in Sweden enjoys access to electricity, and a comprehensive 400 and 220 kV grid system connects Sweden and the Nordic countries. Notably, cooperation among these countries is advantageous due to their distinct power generation mixes.

The design of hydropower stations is contingent upon local natural conditions. Swedish rivers, characterized by flat watercourses and expansive valleys, rarely offer suitable sites for high dams. Consequently, the focus shifts to moderate heads of water from relatively low dams. Favourable geological conditions have made underground power stations coupled with extensive tunnels more cost-effective than multiple above-ground dams and stations along the river.

As a result, a majority of Sweden's hydropower is generated within rock caverns. Depending on circumstances, these underground power stations are positioned near the dam, with water returned to the river through a tailrace tunnel. In some cases, it proves more efficient to place the machine hall downstream to facilitate shorter access tunnels or more favourable transportation gradients.

Economic considerations necessitate minimizing the size of structures and caverns, tailoring machine halls and other rooms to meet maintenance and equipment requirements. The cross-section of tunnels and ducts is chosen to minimize annual energy loss costs due to head losses and reduce initial investment expenses.

Some tunnels are notably expansive, such as the 4-kilometer tailrace tunnel at Stornorrfors with a cross-sectional area of 390 square meters or the tailrace tunnel at Harsprånget, boasting an area of 325 square meters. Power tunnels typically remain unlined, receiving support only in areas with weak rock. Strengthening efforts typically have amounted to 10% to 30% of the tunnel excavation costs. Therefore, for economic reasons, unlined tunnels with larger cross-sectional areas often present a more favourable choice than smaller, concrete-lined alternatives, Winqvist and Mellgren, 1988.

5 MINING IN SWEDEN

5.1 *Sweden's pioneering role in mining*

Mining has deep roots in Sweden, dating back to the Middle Ages when iron ore extraction began in earnest. Today, Sweden boasts a diverse mining sector that includes iron ore, copper, zinc, lead, silver, gold, and other minerals, Table 1. This sector has played a pivotal role in Sweden's industrial development and global economic contributions. Several international mining companies, including Boliden, LKAB, and Lundin Mining, have a significant presence in Sweden, contributing to the global mining industry.

Established in 1637, the Swedish Board of Mines, under royal authority, played a pivotal role in shaping the Swedish mining industry. Initially, it served as an inspection body, overseeing metal production processes. Additionally, the board took on the responsibility of recruiting and training individuals for crucial roles within the mining sector.

Table 1. Production of metals in Sweden in relation to the EU and the World. [Liljenstolpe, C et al].

Type of metal	Production of metals [tons]	Part of production in EU [%]	Part of production in the World [%]
Iron	28 500 000	93	1,2
Lead	79 700	39	1,2
Zinc	250 500	33	1,8
Copper	84 300	11	0,39
Silver	460	20	1,8
Gold	7,2	25	0,23

During the mid-18th century, private mine and works owners united to create a national entity known as the Swedish Iron Masters' Association, which remains active to this day. These two organizations collaborated to synchronize evolving mining techniques. Furthermore, the Swedish Board of Mines played a key role in setting guidelines for the optimal utilization of technology across all mines in the country, Hedström J-O, 2012.

5.2 Mining innovations and collaborations

Sweden's mining innovations have global significance. The advancements made in sustainable mining practices, automation, and environmental stewardship are shared with the world. Swedish mining equipment and expertise are in demand internationally, making Sweden a hub for mining innovation and knowledge exchange.

What sets Swedish mining apart is its unwavering commitment to sustainability and environmental responsibility. Swedish mining companies have embraced the challenge of minimizing their environmental footprint and ensuring that mining activities do not harm the delicate ecosystems of the region. This commitment has led to the development of cutting-edge technologies and innovative practices that are transforming the mining industry worldwide.

Swedish mines are at the forefront of automation and digitalization. Mines employ autonomous vehicles, drones, and sensor networks to improve efficiency, safety, and accuracy in exploration and extraction, Liljenstolpe C et al. 2022.

5.3 Hydrogen storage advances fossil-free steel

A pioneering project in Sweden, referred to as HYBRIT, has reached a significant milestone by

inaugurating the world's first rock cavern storage facility for fossil-free hydrogen gas in Lulea. This marks a groundbreaking development in the journey towards establishing a comprehensive value chain for fossil-free iron and steel production.

The facility has undergone successful pressure tests and demonstrated the ability to operate at a maximum pressure of 250 bar, ensuring the stable and reliable supply of hydrogen for industrial use. By leveraging fossil-free wind power production, this technology addresses the intermittency of renewable energy sources, ultimately contributing to a cleaner steel industry with the potential to store up to 100 GWh of electricity in the form of hydrogen gas.

The HYBRIT initiative, initiated in 2016, is at the forefront of reducing carbon emissions in the global steel industry, pioneering a fossil-free future for steel production. Swedish mines are transitioning towards renewable energy sources. Wind, solar, and hydro-power are increasingly used to power mining operations, reducing greenhouse gas emissions.

6 METHODS AND TECHNOLOGIES

The Swede Alfred Nobel and his dynamite played a crucial role in tunnel construction during the late 19th century, notably in the St. Gotthard Alpine railway tunnel from 1872-81. This innovation in rock engineering revolutionized blasting techniques. Pneumatic rock-drilling machines, mounted on rail "jumbos," were further improved, and locomotives driven by compressed air were introduced to remove broken rock.

Despite significant advancements, challenging rock conditions sometimes caused delays and safety issues. Various tunnels, including the impressive Simplon tunnel (19,540 meters) connecting Italy and Switzerland, were constructed during this golden age of railway development. The main tunnel featured a cross-section of 28 square meters and was designed for a single track. A smaller tunnel ran parallel to provide fresh air, with connecting tunnels every 200 meters to maintain a tolerable work environment for laborers.

The construction process involved initially blasting a small section in the main tunnel, followed by widening behind the pilot gallery's face while simultaneously constructing the permanent lining. While rock-drilling machines were employed for the pilot gallery, hand drilling was still necessary elsewhere. The Simplon tunnel's completion in 1905 marked it as one of the most remarkable achievements of the era in tunnel engineering.

Alfred Nobel's dynamite and innovations in tunnelling techniques were pivotal in the development of complex railway tunnels during this period, setting the stage for future advancements in rock engineering. In recent years, Sweden has witnessed several innovations in rock engineering, particularly in the field of underground construction and tunnelling.

7 COOPERATION BETWEEN STAKEHOLDERS

In Sweden, there exists a longstanding tradition of fostering a strong working relationship among the client, consultant, and construction teams, regardless of whether construction is carried out in-house or through contracts. This collaborative approach involves continuous discussions throughout the entire construction process, enabling the adaptation of design and methods to enhance both the project's timeline and cost-efficiency.

In the context of constructing underground power stations, tunnelling plays a crucial role, often dictating the overall project's construction duration. Therefore, it is of paramount importance to seek optimal solutions not only in terms of hydraulics but also regarding tunnelling techniques. This includes adjusting the width/height ratio to match the equipment used and the prevailing rock stress conditions.

Moreover, the selection of the number of tunnel headings is strategic to prevent delays caused by unfavourable rock conditions. To minimize rock damage, overbreak, and head losses, the approach typically involves employing smooth-wall blasting techniques. This comprehensive approach ensures efficient and effective construction processes in Sweden.

8 CONCLUSIONS

Sweden's prominent role in subsurface technology is attributed to a collaborative spirit among all stakeholders, driven by a focus on meeting customer needs and addressing specific challenges. Notable initiatives in this regard include the Swedish Rock Blasting Committee, established in the 1940s, fostering an open exchange of information within the rock construction community.

Today, rock drilling primarily utilizes wheeled or rail-frame jumbos, with hydraulic machines largely replacing compressed-air ones, resulting in quieter operations. Tunnel boring machines (TBMs) have become a permanent fixture for creating circular tunnels. Safety and efficiency have improved with safer blasting agents, ignition methods, and mechanized loading, often employing purpose-built vehicles. Computers play a crucial role in precise work planning, leading to significant improvements in workplace conditions.

Sweden's mining industry is a testament to the potential for environmentally responsible resource extraction. Its commitment to innovation and sustainability has not only contributed significantly to the nation's economy but has also positioned Sweden as a global leader in mining technology and practices. As the world grapples with the challenges of resource scarcity and environmental preservation, Sweden's mining sector offers valuable lessons and inspiration for the mining industry worldwide.

Integration of stations and cities plan and research on technological innovation of Shenzhen Dayun comprehensive transportation Hub

Ming-sheng Wang*, Chang Liu, Rui-zhen Fei & Wen-ruì Liu
China Railway Design Corporation, Tianjin, China

Yong-yu Fu & Yong-zhong Deng
Shenzhen Metro Construction Group Co.,Ltd, Shenzhen, China

ABSTRACT: The transportation facilities of Dayun Comprehensive Transportation Hub have been integrated into development land. In order to break the traditional concept of a clear boundary between rail transit and adjacent commercial buildings, achieve a new hub mode while stitching the land plots on both sides of Longgang Avenue, and further expand the radiation range of the hub, Dayun Comprehensive Transportation Hub requires new ideas, new concepts, and new techniques to achieve true new hub mode of integration of stations and cities, including planning concepts, architectural design, aboveground and underground design of large heterogeneous structural system, and large-scale renovation of existing Line 3 station.

Keywords: Shenzhen Dayun, Transportation Hub, New hub mode, Heterogeneous structural system, Renovation

1 HUB PROFILE

Dayun Comprehensive Transportation Hub is located in Longgang District, Shenzhen City, Guangdong Province, China. It is a large-scale modern comprehensive transportation hub integrating intercity railway, subway, road traffic, bus and slow traffic system, and a fourth-line transfer hub of rail transit. The universiade hub as a passenger “extension” urban infrastructure key nodes, the design of the hub itself and the hub around the “space” and “time” to reconstruct, avoid rail transit hub “island” and urban construction, eventually form the universiade hub super blocks, let the passengers’ perception has obvious continuity. The average daily passenger flow of the hub is forecast to be 434,000 person-times per day. Construction is scheduled to start in March 2019 and put into initial operation in October 2022. The total construction area of Shenzhen Universiade comprehensive transportation hub is about 162,200 square meters, with a total investment of about 4.9 billion yuan.

Figure 1. Dayun Hub slice view.

2 HUB PLANNING AND ARCHITECTURAL DESIGN INNOVATION

2.1 Hub positioning

Dayun Hub is a comprehensive transportation hub in the eastern region of Shenzhen and an important node

*Corresponding author: Wangmingsheng@crdc.com

on the link between the eastern and western urban agglomerations in the Greater Bay Area. Meanwhile, relying on Dayun Software Town to link Baolong Industrial Park and Apollo Industrial Park, it is an innovative wisdom hub center and an exchange center for gathering industries and talents.

2.2 New hub mode

The traditional mode of interconnection between rail transit and surrounding plot development is set independently, and the channel connection is adopted between the two with obvious physical division. The current popular mode, although rail transit is embedded in the development plot, there is still obvious boundary and the connection is still not close enough. Dayun hub adopts the mode of integrating transfer space into the plot development, which makes the rail transit and plot development integrated to achieve mutual nesting and common development.

Figure 2. Traditional model comparison chart.

2.1.1 Hub-based suture space

The design of the hub makes the main road of Longgang Avenue sink together with the underground structure of the hub. Through the entrance and exit of the first floor, the paid area of Line 3 and the platform of the non-paid area span the Longgang Avenue. The two measures effectively sew up the east and west sides of the plots separated by Longgang Avenue.

2.1.2 The Line3 will not suspend when the expansion platform is building

To meet the long-term passenger flow demand of the hub, the hub design built two side platforms while the two sides of the original island platform of Line 3 were not suspended. At the same time, the original canopy was removed, and a large hyperbola canopy covering the platform and the platform of the second floor of Line 3 was built.

2.1.3 Integration of hub buildings and plot buildings

In order to break the traditional separation boundary between rail transit and land development, the hub design uses the urban core as an effective separation between rail transit and adjacent commerce, so that the passengers in the commercial land can transition to the traffic core through an urban space, so as to achieve mutual nesting and seamless connection.

Figure 3. Renderings after renovation of line 3.

Figure 4. Sliced diagram between urban core and traffic core.

2.1.4 Vertical transfer of the hub

The design of the hub adopts vertical traffic core to solve the problem of inconvenient transfer between the elevated Line 3 station and the underground 14,16 and Shenzhen-Dalian intercity stations, effectively improving the comfort of passenger transfer and significantly shortening the transfer time. The height of the elevated transfer is 25m, only 5 minutes.

Figure 5. Scenery photo of traffic core.

3 HUB UNDERGROUND STRUCTURE INNOVATION

3.1 Underground structure problems that need to be solved to realize the building intention

For longgang avenue municipal tunnel into the hub construction during the same period, the new line

14,16 Dayun station shall adopt 22m large span roof force conversion, board span nearly 3m soil load but also need to lift nearly 20000 kN axial canopy column on the ground, the roof area also need to in the foundation pit Ming dig construction stage and relief road and construction site, design condition is complex, need to solve the load under the action of load system design problem.

The new foundation pit of lines 14 and 16 is 27~30m deep, 597m longitudinal and adjacent to the Dayun Viaduct station of the existing Line 3. The net distance between the foundation pit and the existing line is only 2.1m, which needs to solve the deformation control problem of the existing lines.

3.2 Study on the force conversion structure of the joint construction section of the station and the above-ground structure

The large span structure of the excavated section of the 1-34 shaft cover of Shenzhen Dayun Comprehensive Transportation Hub Project includes the structural part of the conversion section (20-32 axis) bearing the load on the column and the non-conversion section structure (remaining axis) without the load on the column. The scope of this study is the large span structure of the 20-32 axis conversion section, as shown in Figure 6.

The station 20-32 axis of line 14 and Line 16 is built together with the ground structure column with the design scheme of 22m large span beam. The superstructure column is concrete filled steel tube column with a diameter of 1300mm. The layout position of the column is close to the side wall and about 5.1m away.

Figure 6. Section diagram of the large-span structure.

Under the premise of selecting the steel concrete beam-column structure system for the stress system of the conversion section, consider the influence of different large span beam conversion nodes on the overall structure, and make the structure design more economical, safe and reliable on the premise of ensuring the strength, stiffness and stability of the structure. Six kinds of large span beam conversion nodes are proposed to be studied: type steel concrete beam scheme, section steel concrete inclined column conversion scheme, steel truss conversion scheme, concrete box beam scheme, steel box combined beam scheme and type steel concrete beam end addition scheme.

All the above schemes can meet the requirements of structural strength, stiffness and stability, but in practical engineering, the influence of structural design on economic conditions, construction difficulty and building effect should also be considered. The advantages and disadvantages of the six schemes are summarized as follows, as shown in Table 1.

Table 1. Comparison table of each conversion scheme.

Project	Plan 1	Plan 2	Plan 3	Plan 4	Plan 5	Plan 6
Description	Girder with rolled steel section encased in concrete	Inclined column + section steel concrete beam	Steeltruss	Concrete box girder	Steel box-type steel composite girder	Section steel concrete beam with arm
Primary beam section	Wide 3m and high 2.5m	Beam width is 2m and its height is 2m	The total height of the steel truss is 3m, and the truss height is 2.2m	The beam height of 3m	The beam height of 3m	Wide 3m and high 2.5m
Merit	Simple stress; Reliable connection;	Direct force transmission, the beam bending moment is greatly reduced; the bearing capacity is the best.	In light weight; fabricated	In light weight	Advantages of the combined structure; Reduce the beam weight.	Simple stress; Reliable connection; High bearing capacity
Shortcoming		Great influence on B1 chamber; connecting structure Make slightly complex.	The truss height is small, the chord is stressed; the conversion column foot joint connection is difficult;	The connection of beam-column end is complex; the reinforcement is large.	The beam end node connection is complicated; the deflection is relatively large.	Some effect on the B1 room;

As shown in Table 1, the secondary transmission force is the most direct, greatly reduces the internal force of the beam and column, has the best bearing capacity, the best safety and economy, but has a great impact on the indoor function, affecting the overall architectural effect, and the connection structure is slightly complex. Scheme three, scheme four, scheme five although is a new type of conversion structure form, can reduce the structure weight, give full play to the material characteristics, but there are the same design shortcomings, namely the node connection is more complex, construction is difficult, and the existing calculation results show that the beam weight only accounts for 8.5% of the total constant load, so by reducing the trabecam weight to reduce the structure of bending moment, the effect is not obvious. Scheme and six belong to the conventional scheme, but can be seen from the calculation results, through reasonable reinforcement and section design, the bearing capacity, deformation and crack width are meet the requirements of the range, scheme six axillary is further improve the carrying capacity of the structure, and reliable node connection, construction technology is relatively mature, therefore, from the safety, economy and the use of function comprehensive consideration, recommend these two schemes.

In the original structural load composition, the large span beam of the conversion section bears two columns, the load of column A is 7000 kN, and that of column B is 20000 kN. In order to improve the bearing capacity of the large span beam in the lower conversion section of the B column, scheme 6 (steel concrete beam end) is selected as the conversion node of its large span beam, and the load of column A is small, so scheme 1 (steel concrete beam) is

Figure 7. Location of the structural components of the final scheme.

Table 2. Size of final solution.

selected as the conversion node of its large span beam.

In the current structure load composition, the large span beam under column load into a kind, namely C column load is 15050 kN, compared to before the B column load reduced, so the above six large span beam conversion node scheme and the current column load, choose a scheme (steel concrete beam) as the conversion section structure of large span beam conversion node. The final location of structural members and the dimensions of structural members are shown in Figure 7 and Table 2.

3.3 Research on the deformation prediction of adjacent existing lines in deep foundation pit construction

Near the existing Line 3 viaduct, the Dayun Hub is located on the west side of the elevated bridge of Shenzhen Metro Line 3, with a clear distance of about 2 meters, the main foundation pit is constructed by open excavation. The foundation pit of the part of the 1-7 axis at the small mileage end of the station is constructed by cover excavation, and the traffic core is constructed by cover excavation. The retaining structure adopts the supporting form of ground connecting wall, drilling and bite pile (whole meat, meat and vegetable) + inner support, and four supports (three or five partial supports) are set in the foundation pit. The auxiliary structure is constructed by open excavation method or dark excavation method. MIDAS/GTS. In order to eliminate the boundary effect, the length of the soil was 3 times the length of the foundation pit, taking 1200m X, 500m Y and 60m Z. The soil, bridge deck, pier and cap adopt the solid unit, the soil adopts the modified Moore-Kulun constitutive model, the structure adopts the elastic constitutive model; the retaining structure (into equivalent thickness plate), cover plate, floor plate, side wall and side wall adopt the beam unit; the column pile adopts implanted beam unit; the bridge pile; 138501 nodes, 168635 units. The computational model is shown in Figure 8.

Based on the finite element calculation results, Dayun Hub is near the viaduct of Metro Line 3, After excavation of the main foundation pit, horizontal and vertical displacement of cap bridge pile and horizontal and vertical deformation of bridge deck track, The maximum settlement value and the

Figure 8. Elevated calculation model of the main foundation pit of Dayun hub near subway Line 3.

maximum horizontal displacement of each construction step cap bridge pile are shown in Figure 4; The maximum settlement value and maximum horizontal displacement of bridge deck piers for each construction step are shown in Figure 5; Taking the representative nodes 711802,711807 (lateral), and 711904 (track) in the model, In accordance with Figure 9, the vertical displacement value on the track should be observed. Subsequently, the change curves for the settlement value, rail deformation difference, and lateral settlement difference should be graphed relative to the construction step . See Figure Figure 10, The calculation results of the pile displacement, pile foundation tilt value, bridge deck pier displacement and track deformation of line 3 in the main construction step are shown in Table 3.

Figure 9. The maximum displacement result diagram of the cap bridge pile of Metro Line 3.

Figure 10. The imum displacement of bridge piers of Metro Line 3.

Figure 11. The existing track deformation measurement points of subway Line 3.

Figure 12. The existing track deformation results diagram of Metro Line 3.

Since AT01~AT12 of Dayun Station of Line 3 is a continuous beam bridge, it is relatively sensitive to the differential settlement between the bridge spans, so the vertical displacement and differential settlement between the bridge spans in each construction stage should be mainly analyzed.

The construction of foundation pit in the open excavation section of large and small mileage has little impact on the vertical settlement of AT01~AT12 piers of Dayun Station. The maximum settlement of cap pile foundation is 1.8mm, which occurs at the bottom of the AT12 pile closest to the foundation pit in the open excavation section of large mileage; the maximum difference settlement of adjacent cap is 0.2mm of AT11 and AT12, the maximum settlement of bridge deck is 1.3mm, and the

Table 3. Summary of the calculation results (cumulative value) of the displacement (deformation) of the viaduct of Metro Line 3.

Displacement	Operating mode	The foundation pit is excavated to the bottom of the pit	The foundation pit of the station is excavated to the bottom of the pit	Traffic core and Longgang foundation pit excavation to the bottom of the pit	The foundation pit at the open excavation entrance is excavated to the bottom of the pit
Subway line 3 viaduct pile cap displacement	Maximum settlement (mm)	2.06	2.81	2.96	3.62
	Maximum horizontal displacement (mm)	1.27	2.27	2.70	2.49
	Maximum adjacent cap Settlement difference (mm)	0.46	0.63	0.65	0.60
Metro Line 3	Horizontal Displacement/ Pile length (10-5)	3.2	5.7	6.8	6.2
	Maximum settlement (mm)	2.23	2.92	3.08	3.77
Displacement of the viaduct pier of Metro Line 3	Maximum horizontal displacement (mm)	1.87	2.74	3.11	2.93
	Maximum adjacent bridge piers Settlement difference (mm)	0.43	0.64	0.65	0.67
	Monorail longitudinal deformation difference (mm)/10m	0.2	0.2	0.4	0.4
Dedformation of subway line 3	Horizontal height difference (mm)	0.5	0.7	0.5	0.6

maximum difference settlement of adjacent piers is 0.2mm;

The impact of the construction of foundation pit in the station section on the vertical settlement of AT01~AT12 piers is large but uniform. The settlement of cap bridge piles is not different, the maximum settlement of cap pile foundation is 2.3mm (cumulative value), the maximum difference settlement of adjacent caps is 0.1mm, the maximum settlement of bridge deck is 2.3mm (cumulative value), and the maximum difference settlement of adjacent piers is 0.1mm;

After the completion of the foundation pit and the foundation pit on the east side of Line 3, the vertical settlement of AT01~AT12 piers increases slightly, the maximum settlement of cap pile foundation is

2.4mm (cumulative value), the maximum differential settlement of adjacent caps is 0.1mm, the maximum settlement of bridge deck is 2.5mm (cumulative value), and the maximum differential settlement of adjacent piers is 0.1mm;

The construction of foundation pit at the open dig entrance and exit has a great impact on the vertical settlement of AT01~AT03 piers adjacent to the entrance and exit. The maximum settlement of cap pile foundation is 3.0mm (cumulative value), the maximum differential settlement of adjacent caps is 0.2mm, the maximum settlement of bridge deck is 3.0mm (cumulative value), and the maximum differential settlement of adjacent piers is 0.1mm.

In conclusion, the vertical displacement and settlement difference of each construction stage are

within 5mm of the control value, and the horizontal displacement is also within 5mm of the control value.

The track displacement of existing Line 3 is basically synchronized with the bridge deck, and the monorail longitudinal deformation difference occurs in the construction stage, which is located in the area above HT 43 ~ AT 01 piers, the maximum value of monorail is 0.4mm/10m. The maximum transverse elevation difference occurs in the construction stage of foundation pit of the station, is located in the area above HT 36 piers, and the maximum transverse elevation difference is 0.7mm, which meet the deformation control index.

4 HUB ABOVE GROUND STRUCTURE INNOVATION

In the aspect of hub roof design, in order to make the shape of the roof more beautiful and delicate, the twisted space grid structure system is proposed, and a complete set of analysis and design process is formed, and a new type of joint bearing is applied. In terms of the reconstruction of the existing Line 3, in order to realize the shelter function of the whole process of the transformation of the existing station, it is planned to build a new canopy first, and then dismantle the existing canopy. Special construction method should be adopted to meet the requirements of the protection of the existing stations and the demolition of the existing canopy at the same time.

4.1 Steel structure system of complex twisted space grid

The canopy of the Dayun hub is hyperbolic, and the top and side of the roof are gradually transformed in different areas. The vertical lateral force resistance member adopts Y type or straight column type circular steel pipe column, the main beam adopts round steel pipe, and the secondary beam adopts inverted ladder box beam. The columns and the main and secondary beams all present the different section form along with the roof shape, which is light and chic, and perfectly reflects the roof design concept of "Dance of the Bay Area". Each component is made

Figure 13. Housing structure composition of the Dayun hub.

of Q390GJC steel, and the maximum span of the structure is about 36m, as shown in Figure 13.

Due to the distortion and fluctuation of the canopy form, each structural rod has both the bending force characteristics of the conventional frame structure system beam and the space force characteristics of pressing (pull) bending. It is difficult to find the complete corresponding type of this structure in the division of existing structure forms, so the structure system is defined as "twisted space grid structure" according to its spatial form and force characteristics of components.

In addition, the large canopy beams and columns of the hub are connected by the joint bearing support to release the rotational constraints. In order to realize the "clear purlin" design required by the building shape, the lateral constraint of purlin on the secondary beam is not considered. These special factors all bring greater challenges to the structural design.

According to the shape and stress characteristics of the canopy structure, the overall static analysis, stability analysis, node and support analysis are carried out, and the wind tunnel test is carried out to form a complete analysis and design process to ensure the safety and reliability of the structure design.

In the overall static analysis, the structural stress, deformation calculation and continuous collapse analysis; in the stability analysis, the characteristic buckling analysis and nonlinear buckling analysis were conducted using the finite element analysis software; in the wind tunnel test, considering the recent no interference and future interference, considering 36 wind angles to measure the extreme wind pressure, and the equivalent static wind load is obtained through the wind response calculation and used for the design analysis, as shown in Figure 14.

Figure 14. Wind tunnel test.

4.2 Application of the new joint bearing support

The canopy of the Dayun hub chose the scheme of using the centripetal joint bearing support and the angular contact joint bearing support, as shown in Figure 15. These two kinds of joint bearing bearings are different in appearance, but they both belong to the universal hinge, which can release the three-way

(A) centripetal joint bearing support

(B) Angle contact joint bearing support

Figure 15. Schematic illustration of both joint bearings.

bending moment and only restrain the three-way translation.

One model is selected: XGJZ-3500-700/1200-0.06, The bearing capacity is 3500 kN, Pull tensile capacity 1200 kN, Axial horizontal shear bearing capacity of 700 kN, The maximum rotation angle of the rotating shaft bearing is 0.06 rad; Two models exist: JGJZ-5300-700/1100-0.06 and JGJZ-3800-700/1300-0.06, 5300 (3800) kN, Axial upward tensile capacity of 1100 (1300) kN, Horizontal shear bearing capacity is 700 kN, The maximum rotation angle of the rotating shaft bearing is 0.06 rad.

The new joint bearing bearing has the following advantages:

- 1) The beam and column connection is hinged, which can release the bending moment of the junction node and effectively optimize the section size of the nearby rods;
- 2) The hub canopy spans the existing Dayun Station, and the columns fall on the landscape platform or platform on the east and west sides respectively. There are differences between the two in terms of foundation form, stiffness and settlement, and the uneven settlement problem can be solved through the joint bearing support.
- 3) The canopy column form is divided into two categories: tree branch type and straight column type. Combined with the shape characteristics, the centripetal joint bearing support and the angular contact joint bearing support are adopted respectively, so as to make it organically combined with the column shape.

Therefore, the use of various forms of universal hinge support on the same canopy steel structure not only solves the stress requirements of the structure

itself, but also takes into account the aesthetic effect of the building. The design technique of the support is novel, which provides a new idea for the selection of canopy steel structure support in the future. The site diagram of Dayun hub bearing bearing is shown in Figure 16.

(A) centripetal joint bearing support

(B) Angle contact joint bearing support

Figure 16. Field diagram of two joint bearings.

4.3 Construction method of mobile protective shed

The new canopy of Dayun hub is a twisted space grid structure, with many types of rods, complex structure and large weight, so it has high requirements for lifting accuracy. Due to the new canopy across the existing operating elevated station, small parts, small instruments, welding slag and welding sparks may fall in the construction process of high-altitude assembly and welding, and there is a large construction safety risk. In order to ensure the normal operation of the existing Metro Line 3 and the normal operation of the ground traffic on Long-gang Avenue, corresponding protective measures must be taken.

To this end, combined with the spatial location relationship, construction requirements, protection requirements and construction period requirements, the construction method of the mobile protective shed is specially designed, as shown in Figure 17. A single mobile protective shed is 22.4m long and 12m wide, and the basic form is arched, with a total of 3 vertical frames. Lay pressed steel plates on both sides and

Figure 17. Schematic diagram of the mobile protective shed of the Dayun hub.

above to play a protective role. Mechanical and electrical equipment are set up at the bottom of the rigid frame column for the function of sliding. At the same time, the track is laid on the two sides of the platform and the extension platform of the new construction, and the mobile protective shed can slide longitudinally along the track. Just the frame is also equipped with lifting hooks, with lifting function.

Two mobile protective sheds are set up in this project, which can cover 22.4m 24m on the plane. On the one hand, the construction technology can form the protective measures of the Dayun station of the existing Line 3, and on the other hand, the canopy of the existing station can be removed, lifted and transported.

The construction method combines the function of the existing station and the demolition of the existing

canopy, simple structure, saves materials, avoids the frequent shutdown of existing lines, effectively shortens the construction period, can provide idea and reference for the construction protection of similar reconstruction and expansion projects in the future.

Comprehensive development and utilization of underground space of Xiangya Road River-crossing Tunnel project in Changsha City

Hailin Wang, Junqiu Ma*, Xin Zhang & Mi Zhou

Hunan Provincial Communications Planning, Survey And Design Institute Co, Ltd, Changsha, China

ABSTRACT: The Xiangya Road River-crossing Tunnel is an important pathway crossing beneath the Xiangjiang River in the northern part of Changsha City. A 14.5-meter large diameter shield was used to dig the river section of the tunnel, and open cut method was adopted to the river embankment section. This paper aimed to introduce the innovation of the project regarding the comprehensive development and utilization of underground space as follows:(1) The collaborative design and construction problem of long-distance overlapping municipal tunnels and subway tunnels in the urban core area was solved. The open-cut sections of this pathway overlapped vertically with two subway stations. The tunnel was set on the basement floor of the subway station, which makes the best use of underground space. (2) Two underground parking lots (with about 400 spaces) were constructed in the backfilling space above the open-cut tunnel foundation pit, which greatly eased the parking difficulty in the central urban area. (3) The site selection problem of tunnel management building in the central urban area was solved by constructing a semi-underground structure in the Yinpenling Park, which not only met the needs of tunnel maintenance and rescue, but also remained the green area of the park. (4) A multi-point distributed ventilation and emission mode was adopted in this tunnel project, avoiding erecting high wind towers, and realizing the coordination between tunnel environmental protection and urban landscape. The green space of the Yinpenling Park was rationally used, in which 8 decentralized hidden exhaust pavilions were designed.

Keywords: Underground space development, Intensive utilization, Shield tunnels, Foundation pit engineering

1 INTRODUCTION

The Xiangya Road River-crossing Tunnel starts from the intersection of Tongzipo Road and Yuehua Road in Yuelu District in the west to the intersection of Xiangya Road and Furong Middle Road in the east, with a total length of about 4.18 km, which is an important east-west crossing of Changsha City. The geographical location of the project is shown in Figure 1. The Tunnel connects the east and west banks of the Xiangjiang River, and is located in the north comprehensive development belt of Chang-Zhu-Tan city group and on the industrial axis of Chang-Ning-Liu city group in Changsha. The completion of the tunnel would relieve river-crossing traffic pressure in the northern city to a greater extent, specifically in the Yinpanling Bridge to the north and Yingpan Road tunnel to the south of this tunnel, which would connect the isolated lines and surrounding areas, shorten the spatial and temporal distance, improve the quality of the nearby land, and produce economic and social benefits.

Specifically, the Xiangya Road River-crossing Tunnel starts from 290 m to the east of Yuehua Road, and split into 2 sub-lines in the river section. The

Figure 1. The location of the Xiangya Road River-crossing Tunnel.

north line ends at 80 m to the west of Caie Road, and the south line ends at 240 m to the west of Furong Road. The total length of the north line and the south line is 3348 m and 3680 m, respectively. The design speed of the main line tunnel is 50 km/h. A pair of ramps was set up in the west section, the north line exit transferred to the right of Yinshuang Road via

*Corresponding author: 253484901@qq.com

Figure 2. The overall layout of the Xiangya Road River-crossing Tunnel and the section of the shield tunnel.

Xiangyue Road, and the south line entrance was arranged parallel to the east of Yinpan South Road. In the east section, the north and south sub-lines were each equipped with one ramp to connect with Huangxing North Road, and the ramps were arranged parallel to the west of Huangxing North Road. The total length of the four ramp tunnels is 1601.11 m, and the design speed is 35 km/h. The connecting roads of the east and west banks of the tunnel are Xiangya Road and Tongzipo Road, both of which are urban trunk roads with a design speed of 50km/h. The middle section of the tunnel adopted a 1400 m long shield tunnel with an outer diameter of 14.5m and an inner diameter of 13.3m (six lanes in both directions), and with a minimum tunnelling radius of 840 m. The shore section was constructed by open excavation method (four lanes in both directions). The maximum longitudinal slope of the tunnel section was 5%, and the section passing through the subway station adopted 0.3% longitudinal slope. The minimum longitudinal slope of the shield section in the middle of the river adopted 0.3%. The minimum cover depth of western and eastern section was 10 m and 8.73 m, respectively. The section of the shield tunnel and the overall layout of the project is shown in Figure 2.

The main challenges of the exploitation and utilization of underground space during the construction of this project can be attributed to: (1) The construction conditions around the project are complicated, as the whole line of the project and Changsha Metro Line 6 have many common and interweaving lines. (2) The tunnel is located in the downtown area of Changsha with precious land resources. (3) The project has high requirements for surrounding environmental protection with plenty of air environment sensitive areas such as parks, hospitals, schools, residential areas and scientific research institutes near the entrance of both sides of the tunnel. Therefore, the impact of the project on the environment was strictly controlled.

Based on the above challenges, this project had carried out some innovations in the comprehensive development and utilization of urban underground space. Firstly, for the collaborative design and construction problem of long-distance overlapping

municipal tunnels and subway tunnels in the urban core area, co-construction scheme was exerted. Secondly, the natural formed space above the deep foundation pit of the tunnel was utilized to build a two-story underground parking lot, which alleviated the parking difficulty in the core area of the city. Thirdly, the semi-underground structure in combination with the park landform was adopted to set up tunnel management buildings, which solved the problem of building tunnel management buildings under the land shortage in the central urban area. Fourthly, considering the urban core area and environmental sensitive areas, a multi-point distributed ventilation emission mode was implemented to optimize the air quality at the tunnel entrance, avoid setting high wind towers, and realize the coordination between tunnel environmental protection and urban landscape.

2 THE INNOVATION IN THE COMPREHENSIVE DEVELOPMENT AND UTILIZATION OF URBAN UNDERGROUND SPACE

2.1 *The co-construction of this project and metro stations*

The relative locations of tunnel and subway in this project are shown in Figures 3 and 4. It can be seen the location of this project is similar to Changsha Metro Line 6, and there are many lines interweaving. The Liugoulong Station, Wenchangge station, and the section between The Third Xiangya Hospital Station and The Xiangya Hospital Station of Metro line 6 almost overlap this project. Moreover, this tunnel crosses Liugoulong Station and Wenchangge Station of Metro Line 6, respectively, occupying the space of basement level 1 of them.

As presented in Figure 5, the section from The Third Xiangya Hospital Station to Liugoulong Station of Metro Line 6 is located below the project, with spacing of 13.8 m~31.6 m. The thickness of the lightly weathered slate cover the subway section is 4~9m. In the construction of this project, the layered utilization of underground space should be taken into account.

Figure 6. presents the co-construction scheme of this project and Liugoulong Station of Metro line 6.

Figure 3. The plane diagram of relative locations of this project and subway.

Figure 4. The profile diagram of relative locations of this project and subway.

Figure 5. The cross-sectional relationship between the tunnel and metro line 6.

Liugoulong Station is located at the intersection of Tongzipo Road and Yinpan South Road, which is a island station with two underground floors. Moreover, it is also the transfer station for Metro Line 4 and Line 6. The project intersected vertically with Liugoulong Station at the intersection and occupied the basement level 1 (B1) of the station. The B1 of Liugoulong Station had reserved 6 lanes.

As shown in Figure7, co-construction scheme was also exerted between this project and Wenchange Station of Metro Line 6. Wenchange Station is located to the east of the intersection of Huangxing North Road and Xiangya Road, along Xiangya Road in an east-west direction. Moreover, it is a three-

Figure 6. The co-construction scheme of this project and liugoulong station.

storey underground island station with a width of 14 m, which is also a transfer station for Metro Line 6 and Line 1. This project is parallel to Wenchange Station of Line 6, located on the B1 of Wenchange Station. The ramp on the north side of the project is above the station and reserved for eastward extension. There was a 2 m mismatch between Wenchange Station and the south side of this tunnel project. According to the consultation with the Metro Company, the south structure of Wenchange Station expanded by 2 m to meet the construction requirements of the co-construction.

Figure 7. The co-construction scheme of this project and wenchange station.

The tunnel of this project was arranged along the east-west corridor with Changsha Metro Line 6. The cut-and-cover section on shore of this project and two subway stations were co-constructed and the tunnel is located on the B1 of the subway station. The overlapping sections were arranged by upper and lower layers, and the shield tunnel section adopted separate layout. This project solved the problem of collaborative design and construction of municipal traffic tunnel and subway overlapping long distance in the core area of the city. Furthermore, the multi-layer intensive utilization of the inner space of the narrow traffic corridor in the city was realized.

2.2 Underground parking lot in the backfill space of the foundation pit

There was a large demand for parking lots due to the dense population and large traffic flow near the project. However, the project is located in the core area of Changsha City, and the land resources are precious. The development and utilization of above-ground and underground space is one of the main measures for urban land conservation. This project considered the backfill space of the foundation pit above the tunnel to set up two-layer underground parking lot.

The underground parking lot of Xiangya Road River-crossing Tunnel Project is located in the west section of the river, under Tongzipo Road and Yinpenling Park, and above the cut-and-cover section of Xiangya Road tunnel. The east side of the project is close to the scenic belt along the river and Yuxiang Factory of yarn, the south side is the land to be developed, and the west side is Liugoulong Station of Metro Line 4, and Youth Palace of Yuelu District. The project served as a non-profit underground parking lot for minicars and small cars. The total construction area of the parking lot is about 17424.2 m², which can provide nearly 400 parking spaces. It is a large parking lot with two vehicle entrances, 7 groups of wind pavilions, 5 safety exits and 3 barrier-free elevators. In order to reduce the impact on the Tongzipo Road, the north side of the Tongzi slope was set to 4 lanes. The renderings of the underground parking lot are shown in Figure 8.

Figure 8. The renderings of the underground parking lot.

This project changed the traditional backfill scheme of open-cut deep foundation pit, and established a comprehensive utilization and development mode of underground space. The natural space formed above the deep excavation foundation pit of the tunnel was utilized to build an underground two-story parking lot (about 400 parking spaces), which reduced the soil covering load of the deep excavation tunnel, optimized the tunnel structure size, reduced the project investment, saved the construction cost of the underground parking envelope, and alleviated the parking shortage in the core area of the city.

2.3 Tunnel management building of semi-underground structure

The tunnel management building of this project is located near Yinpenling Park. In order to protect the ecological environment of the park, the project considered the current situation of the park and the underground parking lot and chose semi-underground structure for the tunnel management building. On the premise of meeting the needs of tunnel maintenance and rescue, the construction scheme saved ground and did not affect the overall planning of the park and the area of green space. The plane diagram of the tunnel management building is shown in Figure 9, and the profile diagram of the tunnel management building is shown in Figure 10.

Figure 9. The plane diagram of the tunnel management building.

Figure 10. The profile diagram of the tunnel management building.

According to the requirements of centralized monitoring and management, the land use and the distribution of tunnels, tunnel management building combined with Yinpenling park was designed as covered buildings. The entrance and exit of the building start from the Tongzipo Road, and the roof of the building is covered with about 2-meter-thick soil.

The whole site landscape was integrated into the landscape system of Yinpenling Park. The architectural shape adopted a smooth and soothing style, and

the natural terrain was rationally used in the local area. The plant configuration was further combined to enrich the site landscape. As for the facade design of the building, the environment of the surrounding Yinpenling Park was combined, and the building was fully integrated into the environment by the design of the earth covered building, which reduces the impact on the park. Under the premise of economic rationality, the design was strived to be novel, beautiful, elegant, and modern. The facade adopted a modernist approach with materials of stone, tiles, glass curtain wall, and rainproof louvers. Through a variety of measures, such as virtual-real contrast, rhythm and change, to express the modern, simple and atmospheric characteristics of the building. The diagram of tunnel management building is shown in Figure 11.

Figure 11. The renderings of tunnel management building.

In combination with the landscape of the park, semi-underground structure was adopted to set up tunnel management buildings, which solved the problem of building tunnel management buildings under the land shortage in the central urban area. Located in the park, the tunnel management building with semi-underground structure created a quiet office and living space for users, while reducing the impact on Yinpenling Park and becoming a model of adapting to local conditions.

2.4 Multi-point distributed ventilation

Ventilation system is an important part of tunnel. Under normal traffic conditions, the ventilation system should be able to dilute the exhaust gas (CO and smoke) emitted by driving cars, and provide standard ventilation and health conditions for the passenger and maintenance personnel. In the case of a fire accident, the ventilation system should exhaust smoke, control the diffusion of smoke and heat, and provide a certain amount of fresh air for passengers and firefighters staying in the tunnel, so as to facilitate safe evacuation and fire-fighting. In the design of tunnel ventilation, the proper ventilation mode should be selected under the premise of ensuring ventilation effect and energy-saving operation, and saving project investment.

The ventilation mode of urban cross-river tunnel mainly depends on the tunnel length, longitudinal

slope, traffic volume and traffic mode. In addition, the environmental protection of the entrance, tunnel construction methods, and fire safety requirements should also be considered. The length of the closed section of Xiangya Road River-crossing Tunnel Project is 3038 m in the north, 3347 m in the south, and 1400 m for shield section in the middle of the river, respectively. There are two ramps on the east and west banks, and the length of the closed sections are 537 m for C ramp, 348 m for D ramp, 204 m for E ramp and 182 m for G ramp, respectively. According to the calculation result of air demand, longitudinal ventilation mode and full longitudinal jet fan were adopted in this project.

There are several environmentally sensitive buildings such as hospitals, schools, residential areas and scientific research institutes near the entrance to both sides of the tunnel, and the concentrated emission from the entrance is bound to affect the surrounding buildings. As shown in Figure 12, in order to reduce the impact of concentrated emissions from the tunnel entrance, eight decentralized exhaust pavilions were set up in the green area of Yinpenling Park on the West Bank, which covered an area of about 150m² on the ground. Each exhaust pavilion was equipped with an exhaust fan with air volume of 40 m³/s and power of 45 kW. In order to ensure that the length of the smoke exhaust section of the tunnel is not more than 3 km, a smoke exhaust room was set up in the shield shaft of the West bank. Three smoke exhaust fans with air volume of 120 m³/s and power of 160 kW were arranged in the room, which are responsible for the smoke exhaust of the ramp of the West Bank and the entrance of the main line, as well as the entrance ramp of the main tunnel and the east bank.

Figure 12. Eight decentralized exhaust pavilions were set up in the green area of yinpenling park on the west bank.

In this project, considering the environment of urban core area, the tunnel adopted a multi-point distributed ventilation emission mode to optimize the air quality at the tunnel entrance. The optimized design avoided setting high wind towers, and realized the coordination between tunnel environmental protection and urban landscape. The tunnel entrance is close to the environmentally sensitive buildings. The tunnel ventilation design reasonably adopted the multi-point decentralized emission mode, and eight decentralized concealed exhaust booths were set within the green space of the park to deal with the

diffusion of tunnel pollutants. The emission concentration of pollutants at the exit of the tunnel was controlled, and the risk of affecting the surrounding air environment caused by the centralized emission at the entrance of the main line was effectively avoided.

3 DISCUSSION

The 21st century is the century of underground space development and utilization (Qian, 2007). Vigorously developing and utilizing urban underground space has great strategic significance to address many problems in the urbanization process such as urban land shortage, traffic congestion, and environmental pollution (Cui et al., 2021). Many cities around the world have developed and utilized underground space reasonably, and the development of urban underground space has been a general trend.

Firstly, the development of urban underground space is beneficial for alleviating urban land shortage. The land resources in urban central areas are relatively short, the intensity of land development is relatively high, and the population is concentrated. Therefore, the demand for various urban functions is relatively high, and it cannot be met through ground construction alone, which leads to the imbalance of land supply and demand. Therefore, it is necessary to use underground space to supplement the ground space of urban central area and realize urban redevelopment.

Secondly, the development of urban underground space is beneficial for alleviating urban transportation conflicts. The number of cars in major cities in China continues to grow in recent years, and the huge traffic pressure has caused serious urban congestion, which directly affects the efficiency of social operation. Rationally planning and constructing underground roads can improve the structure of the road network, solve the traffic bottleneck, improve the travel efficiency and relieve the pressure of surface traffic (Jia, 2016).

Finally, the development of urban underground space is beneficial for environmental restoration. Urban central areas are densely built and lacking green space. Through the renewal and utilization of underground space, large facilities such as substations, refuse transfer stations, high-voltage equipment and public transportation platforms can be placed in the underground space to release the public space on the ground and transformed into leisure space, park square and so on. It is conducive to creating living areas filled with bright light and green plants in the ground space, providing a comfortable experience for urban residents (Audi et al., 2020).

On the basis of reasonable protection of various functional spaces, this project focused on the intensive comprehensive development and utilization of underground space, which improved the comprehensive utilization rate of underground space, saved engineering cost and urban land resources, and

played a significant role in protecting and coordinating the surrounding environment and landscape. Firstly, the whole line was co-built with the subway, and the technologies such as layered utilization, synchronous co-construction and reserved sub-construction were adopted to solve the collaborative design and construction problems of overlapping and interweaving municipal underwater traffic tunnel and subway in urban areas. Secondly, the underground parking lot scheme saved project investment and provided about 400 underground parking spaces, which greatly alleviated the parking shortage of the surrounding commercial plots and the scenic belt along the river. Thirdly, combined with the Yinpenling Park and the underground parking lot, the tunnel management building was built as a semi-underground structure by using the site height difference in the park, which directly saved land resources of about 2000 square meters. The problem of construction of tunnel management building in the central city was then resolved. Finally, 8 decentralized concealed exhaust pavilions were set up in the green area of Yinpenling Park to avoid setting high wind towers, which realized coordination between tunnel ventilation system and urban landscape.

4 CONCLUSIONS

This project realized the intensive comprehensive development and utilization of underground space by co-construction with subway stations, using the pit backfill space to set up underground parking lot, setting up tunnel management buildings with semi-underground structure by using the elevation difference, and using the park green space to set up dispersed hidden exhaust pavilions. On the basis of guaranteeing all functional spaces, the comprehensive utilization rate of underground space was improved, engineering cost and urban land resources were saved, and the surrounding environment was protected as much as possible.

ABSTRACT: The northern New Territories is being planned for development into one of the important development nodes in Hong Kong. While the flat alluvial plain landform in that region can facilitate future developments, to further optimise the development potential of the new development areas, the mountains flanking the alluvial plain can offer rock cavern development opportunities as an alternative form of land supply to support the overall development, as demonstrated by cavern development in Hong Kong over the past decades. These mountains are composed of the Lok Ma Chau Formation, a meta-sedimentary rock formed in the Palaeozoic period. However, in the past cavern development history in Hong Kong, most of the large-span caverns were built in either granitic rock or volcanic rock. There is also only limited tunnel design and construction experience in the meta-sedimentary rocks and hence the effect of common characteristics of this geology on cavern engineering, such as potentially lower rock strength as compared to that of the igneous rocks, planes of weakness along bedding, high variability in material characteristic over short distances, etc., are largely unexamined in the past.

Given the strategic location, the cavern development potential in the northern part of Hong Kong is expected to gain weight in the future. A broad review of the cavern engineering approach in the meta-sedimentary rocks has therefore been carried out to examine the cavern development potential in this geology with a view to opening up the opportunity for cavern development in meta-sedimentary rocks in the future. The paper presents the findings of the review, which includes a preliminary geotechnical assessment, appraisal of cavern engineering considerations and broad parametric assessment of cavern design, with a particular focus on the feasibility of rock reinforcement approach in the meta-sedimentary rock in the study area.

Keywords: Cavern, Meta-sedimentary rock, Hong Kong

1 INTRODUCTION

The northern area in Hong Kong is one of the important development nodes in the coming future. Near the Hong Kong–Shenzhen Innovation and Technology Park and the San Tin Technopole under planning, the cavern development potential in the mountains flanking these major development nodes is expected to gain weight in the future. These mountains are composed of the Lok Ma Chau Formation, a meta-sedimentary rock formed in the Palaeozoic period. However, the general understanding of this geology is that the rock strength varies widely, with preferred weak planes along the beddings (GEO, 2007), and the general rock strength is potentially lower as compared with granitic/volcanic rock (Arup, 2008). As there was no precedent cavern development in the geology of meta-sedimentary rock in Hong Kong and the

available ground information in this area is scarce, the cavern engineering approach in this geology was largely unexamined in the past.

Ho et al. (2020) provided a comprehensive review of rock cavern development and the paradigm shift of the cavern engineering approach in igneous rock geology in Hong Kong. In the past, the most dominant form of permanent support for caverns was the cast in-situ reinforced concrete lining. Yet there is a drive for the use of the rock reinforcement approach, in the form of permanent pattern rock bolt and sprayed concrete, in lieu of the traditional cast in-situ concrete lining in the recent cavern projects. By relying on the formation of reinforced rock arch at the crown of caverns (Bischoff and Smart, 1977), the rock reinforcement approach is considered to be much more cost-effective than the cast in-situ concrete lining (Grøv, 2013) and, therefore, the

*Corresponding author: leslietsang@cedd.gov.hk; David.mak@aecom.co

applicability of the rock reinforcement approach in the concerned meta-sedimentary rock has a significant implication to the cavern development potential from the financial perspective. Nevertheless, the experience of applying the rock reinforcement approach was all in the volcanic/granitic rock in Hong Kong and it is uncertain whether it is suitable in the meta-sedimentary rock commonly found in this area.

To unlock the cavern development potential in the northern area in Hong Kong, a broad review of the cavern engineering approach based on some recent ground investigation (GI) results in the meta-sedimentary rocks has therefore been carried out, which includes a preliminary geotechnical assessment, appraisal of cavern engineering considerations and broad parametric assessment of cavern design, with a particular focus of the feasibility of rock reinforcement approach in the meta-sedimentary rock in the study area.

2 GEOLOGICAL CHARACTERISTICS OF THE STUDY AREAS

The study is conducted on two hilly areas, namely the Lok Ma Chau study area and the Tai Shek Mo study area, as shown in Figure 1, under meta-sedimentary rock conditions in the Northern District of Hong Kong. The Lok Ma Chau study area is situated in the northeast-trending ridge from east of Lok Ma Chau with a maximum height of +143 mPD at the crest and the Tai Shek Mo study area is located in the north-trending ridge of Tai Shek Mo with a maximum height of +163 mPD at the crest.

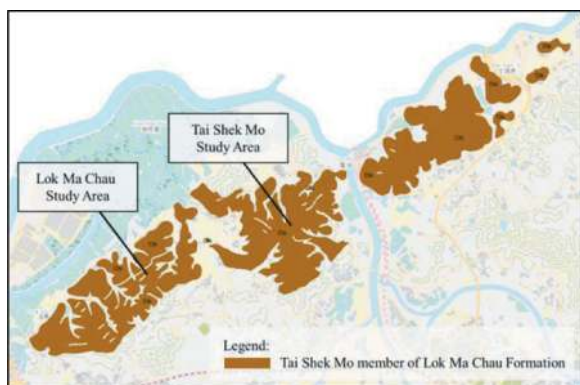

Figure 1. Location plan for the study.

2.1 Geological characteristics

Based on the 1:20,000 geological map, the Lok Ma Chau and Tai Shek Mo study areas are predominantly underlain by Tai Shek Mo member (Cts) of the Carboniferous Lok Ma Chau Formation, which comprises meta-sandstone with meta-conglomerate and phyllite.

In reference to the 1:100,000 geological map (GEO, 2016), the Lok Ma Chau and Tai Shek Mo study areas are predominately bounded by the NE-

SW and NW-SE trending faults. In addition, some fault gouge materials are also encountered in a few boreholes. The rock head depression and the presence of these fault-related materials shall be indicative of possible fault zones in the study areas. The predominate NE-SW and NW-SE trending with locally N-S trending photolineaments are delineated based on the aerial photo interpretation of the study areas, which may induce potential weakness zones.

In addition, a relatively less persistent and highly anisotropic orientation of foliation and cleavage are observed in the sedimentary rock at a few spots of the study areas in the 1:20,000 geological map (GCO, 1989 and GCO, 1991). Foliation may result in anisotropy rock mass strength, which may lead the shear strength along the foliation to be relatively low, but a higher shear strength perpendicular to the plane of foliation. As a result, there is a possibility to encounter a comparatively large spectrum of shear strength values in the tests. Nonetheless, this is generally local in size and site specified (orientation and excavation scale) concerned.

2.2 Geotechnical properties

Based on the geological map and available GI data, meta-sandstone would be the dominant rock type within the study areas. The information from laboratory tests on rock specimens has been reviewed. Based on the laboratory testing results, the uniaxial compressive strength (UCS) of specimens, which are eligible for this test, with material failure identified, elastic modulus and joint shear strength on intact rock specimens have been summarised in Tables 1-3.

Table 1. Summary of uniaxial compressive strength.

Rock Type	Uniaxial Compressive Strength, UCS (MPa)			
	No. of test	Min.	Max.	Avg.
Meta-Siltstone	23	8	164	86
Meta-Sandstone	6	41	220	102

Table 2. Summary of elastic modulus.

Rock Type	Elastic Modulus, E_i (GPa)			
	No. of test	Min.	Max.	Avg.
Meta-Siltstone	17	8	69	49
Meta-Sandstone	3	53	74	64

Table 3. Summary of peak joint friction angle.

Rock Type	Peak friction angle, ϕ_p (Deg)			
	No. of test	Min.	Max.	Avg.
Meta-Siltstone	113	19	56	37
Meta-Sandstone	30	17	49	33

The above available GI data did not differentiate the testing direction in the laboratory testing. Therefore, the above results represent the material strength in a random direction and the anisotropic behaviour due to the foliation/bedding of the meta-sedimentary rock could not be revealed.

The UCS and elastic modulus with the other common rock types in Hong Kong, such as granite and volcanic rocks, have been compared in Table 4. It should be noted that the weathering classification of meta-sedimentary rock is a subject under review recently in Hong Kong. The below table presents all the data of meta-sedimentary rock retrieved at the site without assigning a weathering grade. It can be seen that the maximum and minimum rock strength of the meta-sedimentary stretched considerably but the average rock strength is comparable to that of granitic and volcanic rocks.

Table 4. Comparison of UCS between common rock types in Hong Kong.

	Granite*		Volcanic*		Meta-Siltstone	Meta-Sandstone
	Grade II	Grade III	Grade II	Grade III		
UCS (MPa)	60 to 179	10 to 85	110 to above 300	10 to 120	8 to 164 (avg. 86)	41 to 220 (avg. 102)

3 BROAD ASSESSMENT OF POTENTIAL FAILURE MODES

Martin et al. (1999), based on Hoek et al. (1995), have worked on the potential failure mode in excavations, as shown in Figure 2. Failure modes in caverns are determined by the characteristics of the rock mass, which is dependent on the strength of the intact rock and Rock Mass Rating (RMR) (Bieniawski 1989), as well as the in-situ stresses.

3.1 Estimation of Q-value in the study area

The RMR is estimated based on the approximate relationship between the Q-value and RMR proposed by Bieniawski (1984). The NGI Q-system for rock mass classification and its relationships to tunnel supports were first developed by Barton et al. (1974) and updated by Grimstad & Barton (1993). To characterise the ground condition for cavern design and construction, a range of Q-values have been interpreted in Table 5 using the available existing bore-hole information.

The Q-value is formulated by multipliers of six rock mass parameters in Equation 1.

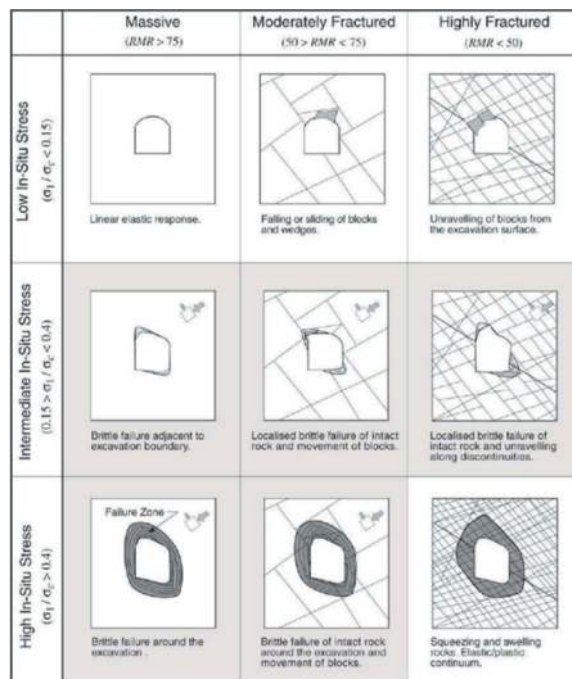

Figure 2. Modes of failure (Martin et al, 1999).

Table 5. Range of Q-value based on ground investigation.

Depth below rockhead	Q<0.1	0.1≤Q<0.4	0.4≤Q<1	1≤Q<4	4≤Q<10	Q≥10
<20 m	12%	13%	16%	51%	8%	0%
≥20 m	8%	1%	2%	48%	28%	13%

$$Q = \frac{RQD}{J_n} \times \frac{J_r}{J_a} \times \frac{J_w}{SRF} \quad (1)$$

The first component (RQD/J_n) describes the relative size of rock blocks. The second component (J_r/J_a) describes the shear strength of inter-block discontinuities. The third component (J_w/SRF) describes the stress conditions.

Further breakdown and examination reveal that the Q-value between 0.7 and 12 would cover about 80% of the estimated ground conditions for depth below rockhead ≥ 20m. By adopting the approximate relationship between Q-value and RMR, the RMR of the meta-sedimentary rocks in the study areas is estimated to be in a range between 40 and 65.

3.2 Estimation of failure modes in the study area

According to Table 1, the average UCS of meta-siltstone and meta-sandstone are 86MPa and 102MPa respectively. As discussed in Section 2.3, the laboratory data could not provide the anisotropic parameter and therefore, for the purpose of this broad review, a conservative UCS of the meta-sedimentary rock (UCS = 50MPa) was adopted in the assessment. Although there is no available data about the

principal rock stress ratio, it is conservatively assumed to be 2.5 based on some regional studies (Alan et al. 2012). As a result, the ratio of the maximum principal stress to the UCS would be less than 0.15 at the depth of the assumed cavern crown level in the study areas (i.e. around 70m below ground level) for the above range of principal stress ratio.

Based on the above observations, structurally controlled failures, including falling or sliding of blocks/wedges and unravelling of blocks from the excavation surface, are considered the dominating types of instability for caverns in the study areas in general as the stress level relative to the rock mass strength is generally low, except where localised weaker rock is encountered due to high variation of rock strength. The failure modes of caverns in meta-sedimentary rock in the study areas are estimated to be similar to that in granite and volcanic rocks in Hong Kong in general conditions.

4 CAVERN STABILISATION DESIGN IN HONG KONG

4.1 Rock reinforcement approach

Over 80% of the hilly terrain in Hong Kong is underlain by hard igneous rocks with a comparatively higher compressive strength than concrete. The concept of the rock reinforcement approach in cavern design relies on the formation of a rock arch at the cavern crown. The inherent strength and thrust capacity of rock mass are utilised by applying confining stress via systematic bolts. Permanent rock reinforcements in hard rock caverns comprise rock bolts and sprayed concrete. Systematic rock bolts are the main reinforcement and sprayed concrete supports rock wedges between rock bolts (Barrett and McCreath, 1995). On the other hand, spot bolts are installed to stabilise individual blocks and wedges.

4.2 Deriving support with the NGI Q-system

For a given combination of Q-value and Equivalent Dimension, the support requirements, such as the required shotcrete thickness and systematic rock bolt spacing for a given rock support class, can be obtained from the NGI Q-system (NGI, 2015) in Figure 4.

The formula proposed by Barton et al. (1977) in Equation 2 is used to determine the initial systematic rock bolt length. Spot bolts for rock wedges shall be assessed separately.

$$L = 2 + \frac{0.15B}{ESR} \quad (2)$$

where:

L = bolt length in metre.

B = cavern span for crown support in metre (could use the cavern height H for wall support).

ESR = excavation support ratio (safety requirement).

Figure 3. The Q-system rock support chart (NGI, 2015).

Based on Figure 4, for a cavern span of up to 20m in meta-sedimentary rock, rock reinforcement using permanent sprayed concrete and rock bolts would be sufficient to stabilise the ground, while the individual rock blocks would be supported by spot bolts as necessary. Although caverns with a span of more than 30m are becoming very common in Hong Kong, in this assessment, the cavern span is assumed to be 20m, which is considered to be sufficient to accommodate various development needs. This initial cavern supporting system derived from the NGI Q-system and the adopted material capacities are summarised in Tables 6 and 7.

Table 6. Initial rock bolts support for prototype cavern.

Systematic Rock Bolts (Crown)		Systematic Rock Bolts (Wall)		Ultimate Bolt Capacity*
Length	Spacing	Length	Spacing	(kN)
5 m	1.6 m	5 m	1.6 m	482

* The ultimate capacity of a fully grouted bolt, which is required to be 2 times of the working load

Table 7. Initial shotcrete support for prototype cavern.

Shotcrete Thickness (mm)		Shotcrete Strength (MPa)	
Crown	Wall	Flexural	Compressive f_{ck}
130	100	5	37

5 VERIFICATION USING NUMERICAL ANALYSES

On the basis of the methodologies discussed in Section 4, an initial cavern stabilisation system can be reasonably obtained for a single cavern excavation. To further examine the supporting performance under the conditions of multiple cavern excavations, cavern supports derived by the NGI Q-system are verified using numerical analyses. Based on numerical modelling, the permanent rock bolts are checked against their design capacities.

5.1 General configuration of the prototype caverns

According to To et al. (2021), the permanent support requirements for rock caverns are more stringent with increasing cavern spans and multiple parallel excavations. Three parallel caverns with 20 m width rock pillars (i.e. 1 × cavern span) between each cavern were assumed in the prototype design for verification. Also, as shown in Figure 5, the cavern in the prototype is assumed to be 20 m (span) × 20 m (height), with a 4 m high roof arch plus a -16 m high straight wall.

Based on the topological setting of the study areas, the ground level is approximated to be +130 mPD. According to the available GI data, the rock-head level is approximately 40m below ground level at +90 mPD. It is considered to have sufficient rock cover of 30 m (i.e. 1.5 cavern span) for the cavern development of a 20 m wide span.

Figure 4. Prototype cavern design (not to scale).

Based on the knowledge from the available data on the rock samples as discussed in Section 2, the geotechnical parameters adopted in the prototype design are summarised in Table 8.

Table 8. Parameters adopted in the prototype design.

Rock type	Q	UCS (MPa)	E _i (GPa)	ν
Meta-siltstone	0.7	50	30	0.3
Meta-sandstone		50	65	0.3

5.2 Verification using numerical simulation

The commercial 2D finite element method programme (RS2 by Rocscience) was used to conduct the design verification of permanent rock supports for the caverns in moderately to highly fractured ground, as shown in Figure 5.

The rock material (grey in Figure 5) was simulated using the isotropic elastic perfectly plastic model with Generalised Hoek-Brown (GHB) failure criterion for rock mass, which is assumed to be meta-sandstone as it is the dominant rock type with the study areas as discussed in Section 2.3. Rock bolts and shotcrete were modelled using linear elastic structural element. Various modelling stages were assigned to simulate the

Figure 5. Numerical analysis for multiple caverns excavation.

rock excavation and support installation as illustrated in Figure 6 and Table 9.

Table 9. Modelling stage of the numerical analysis.

Stage	Remark
1	Initial stress generation.
2	Core replacement method to mimic the 3D effect of tunnel face support to the surrounding rock mass by retaining portions of the original stress field.
3	Installation of permanent rock bolts and fibre reinforced shotcrete.
4	Full excavation along the rock caverns.

Figure 6. Modelling Stages in numerical analysis.

The estimated maximum bolt force is 111.0kN, which is much lower than the allowable bolt force of 241kN. This indicates that the initial cavern stabilisation design is acceptable in the concerned geology. Nevertheless, due to the characteristics of meta-sedimentary rock (e.g. varying rock quality, rock bedding, etc.), parametric studies have been conducted against different critical parameters which may affect the design of the cavern supporting system.

6 PARAMETRIC STUDIES OF CAVERN DESIGN UNDER META-SEDIMENTARY ROCK CONDITIONS

To further understand the cavern design under different meta-sedimentary rock conditions and allow greater flexibility for subsequent planning, the

design methodology discussed in Section 4 were further examine with the variation of following factors:

- i. Rock Mass Quality (Q-value)
- ii. Uniaxial Compressive Strength (UCS)
- iii. Rock Layering Arrangement

6.1 Rock mass quality (Q-value)

Rock mass quality is a critical parameter affecting the support design. The fundamental difference between the use of permanent rock reinforcements and the cast-in-situ concrete lining is the reliance on the strength of in-situ rock mass.

The selected range of rock mass quality for the parameter study in Table 10 is on the conservative side to test the feasibility of rock reinforcement approach.

Table 10. Parametric studies of rock mass quality.

Span	Height	Q-value	UCS
20 m	20 m	0.4	50 MPa
		0.7	
		4	

The maximum bolt forces as shown in Figure 7 reveals that the utilisation of the cavern supporting system drops significantly when the Q-value increase from 0.4 to 0.7 (very poor to poor rock quality). The decreasing trend of bolt force becomes steady when Q-value is greater than 0.7 (fair rock quality).

Figure 7. Bolt forces for varying rock mass quality.

6.2 Uniaxial Compressive Strength (UCS)

Similarly, UCS is a critical factor in the design of permanent cavern reinforcement. With reference to Table 4, UCS of meta-sedimentary has a wide range from 41 MPa to 220 MPa, and the UCS used in the prototype design is 50 MPa (Table 8). Hence, a range of ± 30 MPa was adopted to study the impact when the UCS varies from 20 MPa and 80 MPa respectively, as presented in Table 11.

The maximum bolt forces are shown in Figure 8 that structural forces decrease whilst UCS increasing. It shows that utilisation of bolt at walls is sensitive to UCS, which is similar to the behaviour as observed in Figure 7 for the changes of rock mass quality.

Table 11. Parametric studies of uniaxial compressive strength (UCS).

Span (m)	Height (m)	Q-value	UCS (MPa)
20	20	0.7	20
			50
			80

Figure 8. Bolt forces for varying UCS.

6.3 Rock layering arrangement

Compared with granite or volcanic rock in Hong Kong, sedimentary rock has the characteristic of rock layering. A study was carried out to examine the impact with respect to the thickness of strata layers and the dipping. To simulate the possible combination of rock layer interfaces crossing the rock bolts at different cavern locations (crown and walls), 5 m and 8 m thick strata layers were assumed based on the available GI data. Based on the published geological map, an average dipping of 30° was noted. For the dipping, horizontal rock layers with 0° and inclined rock layers with 30° were selected for the study. The general arrangement of four numerical models with varying thicknesses and dipping of strata layers are presented in Figures 9-12.

Figure 9. Horizontal and 5 m thick rock layering.

Figure 10. 30° Inclination and 5m thick rock layering.

According to Figure 13, the maximum bolt force in the meta-siltstone model is higher than that in the meta-sandstone model. This is because meta-siltstone has lower GHB engineering properties than

Figure 11. Horizontal and 8m thick rock layering.

Figure 12. 30 ° Inclination and 8m thick rock layering.

meta-sandstone. With the presence of alternative layering of meta-sandstone and meta-siltstone in various 5 m/8 m thickness and 0°/30° inclination, the corresponding maximum rock bolt forces lay between the upper bound value (meta-siltstone model) and the lower bound value (meta-sandstone model). This outcome reveals that the rock layering arrangement did not significantly affect the utilisation of the cavern supporting system. The homogenous meta-siltstone model would serve as the conservative design case covering the various layering scenarios.

Figure 13. Bolt forces for alternative rock stratum layering.

Nevertheless, amongst the alternative layering models, it is noted that an inclination of 30° incurs is a more critical case. The cavern supporting system requires a higher utilisation. Yet, there was no clear trend observed regarding the impact of 5m/8m thickness.

7 CONCLUSION

An assessment has been undertaken to review cavern engineering considerations and the feasibility of the

rock reinforcement approach. A prototype design for cavern development in meta-sedimentary rock was conducted. The performance and utilisation of cavern supports in the prototype design are all within the acceptable range. In addition, parametric studies were conducted with the critical parameters which may bring significant impacts to the cavern support, such as the degree of utilisation of bolt force. It provides a broad understanding of cavern design in meta-sedimentary rock and allows a greater flexibility for subsequent planning and design in the next stage. Nonetheless, the study was carried out based on limited existing GI data without differentiation of testing direction, together with the large variations in meta-sedimentary rocks, including rock strength and bedding arrangement. It is recommended that a more extensive ground investigation and further study on the project site location are required to identify any adverse features in the cavern area.

To conclude, the broad review reveals that, subject to local heavy weathering/fracturing, the rock reinforcement approach is generally feasible for the meta-sedimentary rock in the two concerned study areas, even for ground conditions with special characteristics such as rock layering. Although the cavern engineering conditions in meta-sedimentary rock is still considered to be more complicated as compared to that in the igneous rocks, this review opens up the cavern development potential in this area as it implies that the cavern engineering approach in this geology in general would be similar to those adopted in other igneous rocks in Hong Kong.

ABSTRACT: Shen-Zhong Link is another bridge-island-tunnel combination project in China after the Hong Kong-Zhuhai-Macao Bridge. The project construction conditions are complex and technically difficult, mainly including a main span of 1666 meters suspension bridge, two artificial island and 6.8 km tunnel, the east artificial island, is China's first large underwater interchange, highway is the construction environment is extremely demanding near both operating highway deep foundation pit engineering, the main line using two-way eight lane highway technical standards. East Artificial Island is a large underwater interchange to realize the traffic transformation between the Shenzhen-China channel and the expressway near the river. It is realized through multiple changes of the structural section. The construction environment is extremely complex. The deep foundation pit project involves the complex external conditions of sea, land, air, passenger terminal, multiple channels, expressway, tight construction period, complex organization and high construction requirements of water environment. Through technical scheme optimization, technical management, site construction management and other technical and management means, the project has formed the technology of the adjacent bridge reclamation, the deep foundation pit protection technology of the existing bridge, and the construction technology of the existing bridge and tunnel. A batch of suitable construction equipment has been developed to form the key technology of tunnel construction of large underwater interchange near and under the existing operating expressway, to provide reference for the construction of the same type of projects.

Keywords: Shenzhen-Zhongshan Link, suspension bridge, subsea tunnel, artificial island, deep foundation pit

1 PREFACE

Deep channel is after the Hong Kong-Zhuhai-macao bridge China another bridge island tunnel cluster engineering, project construction conditions is complex, technical difficulty is big, mainly including the main span 1666 m suspension bridge, two artificial island and 6.8 km long tunnel, the east artificial island, is China's first large underwater interchange, highway construction environment is extremely demanding near both operation of highway filling sand island and island tunnel deep foundation pit engineering, the main line with two-way eight lane highway technical standards.

East artificial island land area of 343,800 square meters, the island with tunnel engineering, rescue wharf, power supply and distribution facilities and

Figure 1. Line bitmap of the deep and middle channel.

related ancillary facilities, the tunnel works include 480 m long weir section tunnel, 855 m long main tunnel on the island, and the four ramp tunnels for traffic conversion. The construction environment is extremely complex, under the existing expressway. East Artificial Island is the gateway project of Shenzhen end, located in the south of Shenzhen Bao'an

Airport, adjacent to Fuyong Airport Terminal, connected to the east of the project, and the complex external conditions of China, including passenger terminal, multiple channels, white dolphin reserve, air pipeline, air route and other water environment. Combined with the characteristics of the project, through technical scheme optimization, technical management, site construction management and other technical and management means, the problems of anti-seepage control and uniform backfill control in the construction stage of deep soft foundation, ultra-deep and ultra-wide foundation pit cluster in the sea area were solved, and the problem of deep foundation pit construction against the small deformation of the structure was solved.

Figure 2. Layout plan of the east artificial island.

2 CONTROL THE DEFORMATION OF THE EXISTING ADJACENT BRIDGE PIERS

The construction of east artificial island is faced with prominent difficulties in large project scale and high environmental protection requirements, and the operation of existing projects such as Baoan Airport and Guangzhou-Shenzhen Yanjiang Expressway cannot be affected in the construction process. The engineering geology is mainly composed of silt and silt soil layer with a small amount of silty clay, 8.0~15.0m thick, backfill sand layer and deep silt layer are distributed in the field, and riprap layer exists in the local area, and it is easily affected by tide, typhoon and rainfall. Under the existing Guangzhou-Shenzhen expressway along the Yangtze River, about 3 million cubic meters of sea sand should be filled within the 40-span pier cap sea area. The ownership unit of the expressway along the river requires that the displacement and settlement of the bridge pier of the expressway along the river shall not exceed 5 mm, which can be said that the control indicators are extremely demanding.

Figure 4. Geological profile of the east artificial island.

2.1 Carry out special studies on safety evaluation

According to the characteristics of the implementation of the east artificial island and the island tunnel, the special Study on the safety Evaluation of the impact of the East artificial Island and the Island Tunnel along the Yangtze River was carried out. The proposed plan of the east artificial island project is connected with the existing Guangzhou-Shenzhen high-speed bridge along the River, and the connecting section is originally sea area. In the later stage, the coarse sand and the island wall embankment are constructed to realize the normal use elevation of the artificial island, so as to meet the connection between the buried tunnel and the land viaduct and open tunnel. According to the design, the filling height reaches 7~8m, and the soft soil layer is below the surface of the project area, and the thickness of the soft soil reaches about 10m. Large area sand filling of artificial island, island wall embankment construction, and later building construction in the island will have extremely adverse effects on the adjacent bridge foundation. Large surface overload in sea soft soil area will produce negative friction resistance in the pile foundation, increase the axial force of the pile body, and reduce the vertical bearing capacity of the pile. Meanwhile, large side sand filling will produce additional stress in the soil to move the soil on the side, so that the pile body and even the whole bridge substructure produce additional stress, cause large additional deformation and bending moment of the pile foundation and reduce the horizontal bearing capacity of the pile foundation. Moreover, a large area of sand filling will cause the horizontal and vertical displacement of the bridge substructure, and the large displacement may cause the damage of the bridge substructure, and on the other hand, it may affect the normal use of the superstructure engineering. Project for the above problems, considering the artificial island blowing sand filling process in the pile side, island wall dike construction, island wall inside large sand filling building construction, and the island, and the ramp and the main tunnel foundation pit construction, according to the east artificial island construction of the existing wide expressway bridge pile foundation influence and prevention needs, research: (1) for Ming built sea artificial island and adjacent along the river highway engineering characteristics, clear artificial sand filling on adjacent bridge safety displacement control standard, further guide the project artificial island filling construction and bridge protection. (2) The protection design scheme of the expressway pier along the river adopts the steel plate pile scheme, and the height

difference around the pier is not more than 1m in the process of island building. Analyze and evaluate the highway safety along the river under this working condition. And put forward relevant suggestions for the protection scheme. (3) The island wall structure at the southern end of the east artificial island is located below the expressway along the river. The island wall structure adopts the cement mixing pile composite foundation treatment scheme to analyze and evaluate the safety of the expressway along the river under the working conditions. And put forward relevant suggestions for the protection scheme. (4) Within the range of the concentrated structures on the east artificial island, the stacking prepressure is used for the foundation treatment to analyze the safety of the highway along the river under the working conditions. (5) According to the influence results of different working conditions of the artificial island construction on the adjacent Guangzhou-Shenzhen expressway bridge along the Yangtze River, the key monitoring parts and monitoring and early warning indicators of the Guangzhou-Shenzhen expressway bridge along the Yangtze River are put forward. (6) Through the simulation analysis of the ramp foundation pit construction, according to the calculation results to judge whether the foundation pit excavation affects the adjacent bridge pile foundation, if there is an impact, the degree of impact (mainly from the analysis of the bridge pile deformation and additional bending moment). (7) Through the simulation results of foundation pit excavation and the ultimate additional deformation and additional bending moment value, judge whether the proposed supporting structure of the foundation pit and the bridge pile foundation protection structure can meet the safety requirements of the bridge. (8) According to the position relationship between different ramps and bridge pile foundation, reasonable suggestions are put forward in combination with the design scheme and simulation results. In view of some key technical problems existing in the impact of the large area filling of the east artificial island on the adjacent bridge pile foundation, the appropriate suggestions for bridge protection are put forward.

In order to solve the practical problems in the project and guide the design and construction, based on a large number of theoretical analysis and numerical calculation, the research results consider the engineering practice, combined with the characteristics of the project, focus on the study of the impact of beach siltation, seabed migration, road construction on the adjacent ramp bridge foundation. Finally, according to the simulation analysis of the adverse conditions in the island, such as the sand filling and the dam construction, it is concluded that: (1) due to the soil filling on both sides of the pier alternately, the horizontal displacement of the bridge pile in the sand filling direction will also change alternately, while the horizontal displacement on the other side will increase with the increase of the sand filling thickness. Compared with the calculation results of the unbalanced sand filling between the transverse bridge and the transverse

bridge, we find that when the maximum height difference between the left and right sides is always 1m, the sand filling along the bridge has a more significant impact on the adjacent bridge piles. (2) When taking the steel plate pile reinforcement, the steel plate pile is filled first, and then the sand filling outside of the steel plate pile is more conducive to the protection effect of the adjacent bridge pile. The maximum horizontal displacement of the steel plate pile along the bridge is 12mm, while the maximum horizontal displacement along the bridge can reach more than 20mm outside the steel plate pile. It is suggested to fill the steel plate pile with sand first. (3) When the sand is filled in the steel plate pile, the displacement is even greater than 10mm along the bridge, and the impact of the sand filling on both sides of the bridge is much less than 10mm. In the actual construction process, it is suggested to fill sand on both sides of the horizontal bridge, that is, symmetric backfill on both sides of the bridge line. When the backfill thickness reaches 4m, the filling rate should be strictly controlled in the subsequent sand filling process, and it is suggested that the height difference of filling should be appropriately reduced. (4) take steel plate pile first filling sand, one side of the sand filling thickness is greater than 3m, and the other side of the height difference 1m, should strengthen the adjacent pier displacement monitoring, monitoring and warning displacement can be controlled for 5mm, more than 5mm is suggested to stop filling, adjust the filling process or isolation and corrective reinforcement measures, the displacement change of larger condition should reduce the height difference on both sides of the filling, control the balance sand filling construction as far as possible. (5) For the axial force of pile, due to the negative friction resistance, the axial force of pile increases and then decreases with the depth. However, because the piles along the expressway bridge along the river are all rock-embedded piles, the axial load of the pile meets the requirements of compressive bearing capacity. (6) take steel plate pile filling first, for pile bending moment, with the increase of filling thickness, the pile moment is increasing, along the bridge to the thickness of 7m, the other side of 6m pile bending moment, but through the maximum moment section check found that the maximum moment position pile cracks are less than 0.1mm, meet the requirements of engineering safety. (7) take steel plate pile outside filling first, for pile moment, with the increase of filling thickness, the pile moment, along the bridge to both sides or the bridge filling in thickness of 7m, the other side of 6m pile moment, but through the maximum moment section check found that the maximum moment position pile cracks are greater than 0.1mm, does not meet the requirements of engineering safety. (8) By taking the 48 # pier as the typical island pier, during the filling process of the island, after the steel plate pile strengthens and protects the pier, when 7m is filled according to the height difference thickness of 1m, the maximum side shift of the adjacent bridge pile is 5.0mm, and the filling height of one side is 7m and the other side is

6m. Considering the overload of 1~3m, the filling height can reach 8~10m, the maximum horizontal displacement can reach 5.3~6.7mm, and less than 10mm displacement control standard, which can meet the safety requirements of bridge engineering. (9) In the southern end of the island wall area, when steel plate pile is adopted to reinforce the pier, the foundation treatment depth is shallow and the treatment range is small, the dam filling and sand filling have a significant impact on the adjacent 71 # ~75 # piers, and the horizontal displacement is greater than 10mm, and the safety is low. (10) In the island wall area of the southern end, when the steel pipe pile is drilled to reinforce the pier, the foundation treatment depth reaches above the medium weathered rock and the treatment range is from 70 # ~76 # pier area, the dam filling and the adjacent 71 # ~75 # pier are less affected, and the horizontal displacement is less than 10mm, meeting the requirements of 10mm displacement control standard. (11) Due to the geological differences of different piers near the southern island wall, it is suggested that the settlement and horizontal displacement monitoring of the adjacent piers should be strengthened during the island wall construction and sand filling construction in the island, and the filling rate and process should be timely adjusted to ensure the filling balance around the piers as far as possible. It shows that under the action of the dam pile load, the pile foundation of the pier at the embankment corner is subjected to large lateral extrusion pressure, so the multi-layer protection and reinforcement measures of the pier at the embankment corner position should be carried out according to the monitoring results and the actual situation, such as the row pile reinforcement measures.

The results are demonstrated through the study: the horizontal displacement of the backfill in the pile is reduced by 21%, the horizontal displacement of the horizontal bridge is reduced by 61% compared with that of the backfill in the forward bridge, and the horizontal displacement is reduced by 62.5% compared with the 0.5m thick 1m, and the horizontal displacement is increased by 12.5% per 0.1m increase on average.

2.2 Technical solutions

Field area exists deep silt layer (8~15m), the physical and mechanical indexes of sea silt formation is poor, high water content, low bearing capacity, easy to touch, easy flow, high compressibility characteristics, backfill construction prone to large area arch, gushing phenomenon, such as directly in the pier and both sides of the backfill, silt layer strength and the resistance to deformation is too low, backfill loading process, will produce the larger range of shape deformation area in foundation soil, make the foundation of too large settlement and lateral displacement. The lateral displacement of soil is an important cause of the additional bending moment and deformation of pier pile foundation. When the additional bending

moment and deformation are greater than the allowable value of pile foundation, the pile foundation will stagger and change, reduce the bearing capacity, and the pile foundation will break and destroy in serious cases.

Combined with the research results, it is necessary to take measures to limit the deformation of the silt layer at each pier to avoid the safety risks caused by the island backfill construction and affect the normal use of the piers. From the technical scheme, it is clear that the steel plate pile or steel pipe pile are protected around the pier cap within the influence area of the island, and grasp the data and analyze the development trend, and take timely countermeasures. For symmetrical layered filling on both sides of the existing bridge piers, the force must be uniform, otherwise it is easy to cause partial load, which leads to the displacement of the bridge pier. To solve the bridge area filling sand cannot real-time dispersion of short-term stress concentration problem, innovation adopted the island filling process' sand is method for filling operations, using sand pumping pump will backfill sand filling into the film bag, uniform filling into sand is, a layer a layer evenly spread around the piers, effectively solve the problem of deep silt layer backfill partial load.

Figure 5. Sand backfill process.

Figure 6. Drainage consolidation.

2.3 Technical management and construction control

Through the study, the backfill principle is summarized: according to the horizontal bridge to the backfill, first the inside and outside, the steel plate (pipe) pile, filling to layer, symmetrical, uniform, stratification thickness is strictly controlled at no more than 50cm, the height difference between the left and right sides is controlled at no more than 100cm.

The backfill under the bridge adopts the sand separation device of the sand distributor, and the "7" shaped hole pipe backfill the transverse bridge to the corresponding area. By suction ship + 2 Φ 300mm main pipe for backfill sand long distance transportation, each main branch for 2 Φ 240mm vice pipe for sand diversion, in the auxiliary pipe port installed sand separator device, both sides are 200mm wide sand, two 100mm wide sand outlet, can effectively ensure the uniform stability of backfill construction, reduce accumulation thickness, all the bottom of the pump pipe are easy to convert backfill working face, a single sand separator

blowing range of 2.5m. 4 Φ 550mm hole pipes are used at the pipe head of the sand blowing pipe, with 4 Φ 150mm sand outlet opened for each pipe. The hole sandblasting distance is 3-5m. The pipe head is fixed by cable to prevent left and right swing. It can control the thickness of a single filling more accurately, and has strong applicability to the backfill construction around the existing bridge structure.

Figure 7. Backfilling of sand division unit.

Figure 8. Backfilling of sand division unit.

The protective steel plate pile of the expressway pier along the river is constructed by static pressure planting pile or without resonance. First, the first steel plate pile is driven into the soil, and then the second steel plate pile is welded with the first section. After the quality of the weld is checked, the whole steel plate pile will be driven to the design elevation.

Figure 9. Hydrostatic pressing pile planting.

Figure 10. No-resonance drilling process.

Drainage is consolidated into an island. After the completion of sand filling island, plastic drainage plate is applied for consolidation and settlement, and then loaded to the design elevation through the combination of blowing, land transportation and direct unloading, and the vibration is washed into the island.

3 DEFORMATION CONTROL OF THE DEEP FOUNDATION PIT OF THE EXISTING HIGH-SPEED BRIDGE

After the completion of the east artificial island, the island involves the main tunnel and two ramp tunnels under the existing high-speed bridge. In the main tunnel construction, the deep foundation pit about 70m long, 46m wide and 18m deep should be excavated, and the nearest place is only 1.17m from the existing bridge cap. The engineering geology of the site is mainly filled with a small amount of silty clay,

8.0~15.0m thick. There is a riprap layer in the local area, and it is easily affected by tide, typhoon and rainfall. Under the existing Guangzhou-Shenzhen expressway along the River, it involves three times through the existing expressway bridge. The excavation boundary of the tunnel is 62~350cm away from the bridge cap, and the excavation depth of the foundation pit is 8~16m. The ownership unit of the expressway along the river requires that the displacement and settlement of the foundation pit excavation on the expressway pier along the river shall not exceed 5 mm, and the control indicators are extremely demanding.

In the construction process of the ramp tunnel under the east artificial island, H and F ramp and the main tunnel need to pass through the completed main bridge along the river respectively. The open-dug foundation pit of the G and E ramp is also in parallel with the main bridge pier along the riverside expressway, and the local ramp structure is only about 2m away from the pile cap of the bridge along the river. The construction of the ramp foundation pit will cause the imbalance of soil pressure on both sides of the pier pile foundation, leading to the transverse displacement of the pile foundation, and causing certain risks to the normal passage of the expressway along the river. It is necessary to carry out detailed calculation and analysis to determine the protection measures and relevant control standards of the substructure of the main bridge along the river in the tunnel area.

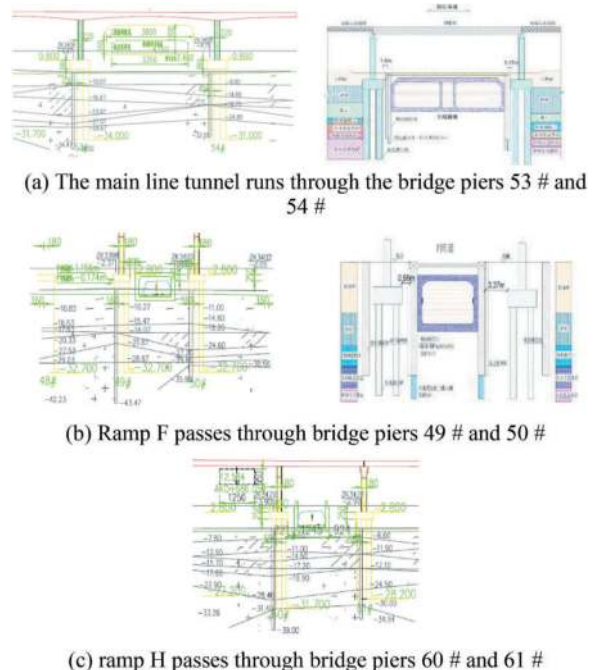

Figure 11. Bridge section of the ramp and the main tunnel.

3.1 Conduct special research on safety evaluation and safety evaluation

Considering the Shenzhen channel east artificial island and both deep bridge along the river, artificial

island four ramp two parallel with the existing bridge, the main tunnel and the other two ramp under the existing bridge, foundation pit supporting structure distance bridge cap edge, foundation pit excavation depth is larger, excavation of foundation pit excavation is bound to affect the existing bridge, threat to bridge security. In order to ensure the safety of the existing bridge, it is necessary to analyze and evaluate the influence of the ramp foundation pit excavation on the existing bridge, evaluate the support effect and protection effect of the foundation pit supporting structure and the bridge pile foundation protection structure, and put forward reasonable suggestions.

Simulation analysis from the following aspects: (1) according to the existing E ramp foundation pit excavation design drawings, design drawings of high-highway bridge pile foundation and design drawings of bridge foundation protection, the impact of E ramp (parallel bridge foundation) foundation pit excavation on the existing bridge is analyzed. (2) According to the existing F and H ramp foundation pit excavation design drawings, Guangshen and riverside bridge pile foundation design drawings and bridge foundation protection design drawings, the impact of foundation pit excavation of F and H ramp (under bridge foundation) on the existing bridge is analyzed. (3) According to the existing G ramp foundation pit excavation design drawings, Guangzhou-Shenzhen Yangtze River bridge pile foundation design drawings, bridge foundation protection design drawings, the impact of G ramp (parallel bridge foundation) excavation on the existing bridge is analyzed. (4) According to the design drawings of the excavation of the main tunnel, the design drawings of the foundation and the design drawings of the protection of the bridge foundation, the influence of the excavation of the main tunnel (underpass bridge foundation) on the existing bridge is analyzed.

Through the above study, the existing design meets the bridge safety according to the design results, and the reasonable suggestions are as follows:

(1) Calculation and analysis results of piers spanning 53 # and 54 # in the main tunnel project. After review, the compression bearing capacity of the positive section, vertical bearing capacity of pile foundation and pile bearing capacity of the main tunnel pier all meet the requirements. And the following conclusion: ① construction according to the current design, the maximum side of pile foundation cap is 5.84mm, if not considering the cap retaining steel pipe pile, the maximum side of 6.50mm, the displacement increased slightly, the vertical displacement of pile foundation cap is small, the maximum vertical displacement of 4.42mm. The small displacement, consider the retaining steel pipe pile on the vertical displacement, pier and cap displacement overall within the safety range. ② The maximum tensile stress of the pier and pile foundation cap is 0.94MPa, the maximum compressive stress is about 3.95MPa, and the maximum shear stress is 0.53 Mpa, which is within the safety range. ③ The steel pipe pile plays an important role in preventing the lateral deformation of the soil. The maximum lateral

deformation of the steel pipe pile is 11.03mm, and the deformation is to the inside of the foundation pit, showing the overall “drum belly” deformation, and the maximum horizontal displacement is near the excavation surface. ④ Four supports, the axial pressure of the third and fourth steel support is the largest, the maximum axial force of the third support is 1518 kN, the maximum axial force of the fourth support is 1430 kN, the overall pressure of each support is within the safe range. The pressure of the lattice column is about 736.2kN, which is also within the safe range. ⑤ According to the calculation results, after the construction of the main line tunnel, considering the precipitation influence of the foundation pit precipitation, the maximum settlement of the surface outside the pit in the model boundary area reaches 1.16cm, which meets the standard requirements, and the maximum uplift at the bottom of the foundation pit reaches 7.77cm. In the actual construction, the detection of the foundation reinforcement effect should be strengthened. ⑥ In order to ensure that the deformation and force of the existing expressway pier and cap pile foundation along the river meet the requirements, the drainage conditions of steel pipe piles on both sides are considered for numerical calculation, and the calculated main structural deformation is taken as the construction limit value, and the warning value is 80% of the limit value. The normal working condition calculation value, standard value, limit value and early warning value are listed as shown in Table 1 below. ⑦ The bearing capacity of the pile foundation of the pier and cap is checked respectively. The bearing capacity of the positive section of the pier is 92499 kN, which is greater than the load of 20785 kN. The bearing capacity of single pile foundation is 80031 kN, and the bearing capacity of pile body is 67682 kN, greater than the load of pile top 8676.5kN. All meet the requirements. The maximum horizontal displacement allowable value of the pile top calculated according to the bearing capacity of the pile foundation is 28.33mm.

Table 1. Construction estimate.

name	Bearing table side shift/mm	Side shift of steel pipe pile/mm
Normal calculation value	5.84	11.03
Drainage on both sides	10.97	11.71
Specification value		27.0 (0.18% depth of foundation pit excavation)
Construction limit value	10.97	11.71
Construction early warning value	8.78	9.37

(2) Calculation and analysis results of F ramp crossing 49 # and 50 # piers. After review, the pressure

bearing capacity of the positive section, vertical bearing capacity of pile foundation and pile bearing capacity of F ramp tunnel all meet the requirements. And concluded as follows: ① as plate support, through the numerical simulation analysis of F ramp shows that the cap will cause stress concentration of cap pile foundation, and lead to the generation of large tensile stress, based on the conditions of 1 and 2 with cap bearing stress is 1.94MPa, greater than 0.5MPa. Large tensile stress may crack the pile foundation and affect the structural safety. In the absence of plate support, the maximum lateral displacement of the pier and pile foundation cap is 8.18mm and 3.59mm respectively, which are still within the allowable range. Compared with the application of plate support, the lateral displacement is only 0.22mm and 1.31mm increased respectively. Therefore, applying the plate support is not the most reasonable construction scheme. ② The maximum transverse deformation of pier and foundation pit. Through calculation and analysis, the maximum transverse deformation of pier under the action of plate support (working condition 1) is 7.96mm respectively, without exceeding the displacement standard value of 25.98mm; the maximum transverse deformation of crown beam and steel pipe pile is 2.42mm and 2.91mm respectively, which does not exceed the displacement standard value of 18.66 mm. After the foundation pit construction, the maximum surface settlement of the soil is distributed on both sides of the pile foundation cap, and the maximum settlement value is 7.68mm, which does not exceed the displacement standard value of 14.00mm. ③ The lateral displacement monitoring warning value of the key parts of the foundation pit of F ramp is set at 80% of the construction limit value. For the horizontal displacement of the steel pipe pile, cap and crown beam top, when the monitoring value reaches 3.73mm, 7.22mm and 2.6mm respectively, the warning should be reminded. ④ The bearing capacity of the pier and cap pile foundation is checked respectively, and the bearing capacity of the pier in the moment plane and perpendicular to the moment plane are 44910 kN and 31919 kN, greater than the load of 5840 kN. The bearing capacity of single pile foundation is 33332 kN, and the bearing capacity of pile body is 27429 kN, greater than the load of pile top 4077.8kN. All meet the requirements. The maximum horizontal displacement allowable value is 35.13mm when the pile foundation section reaches the bearing limit state.

(3) Calculation and analysis results of H ramp crossing 60 # and 61 # piers. After review, the pressure bearing capacity of the positive section, vertical bearing capacity of pile foundation and pile body of H ramp tunnel all meet the requirements. The following conclusions are drawn: during the construction of ① foundation pit, the maximum lateral displacement of the pier top is 8.8mm, and the maximum transverse displacement of the cap is 6.1mm; the maximum vertical deformation of the pier and cap is 1.94mm, which appears on the inside of the cap. The maximum tensile stress of the pier and cap pile foundation is about

0.48MPa, the maximum compressive stress is about 3.30MPa, and the maximum shear stress is about 0.31MPa, all within the safety range. ② The plate support plays a certain role in the displacement control of the cap. The lateral deformation of the cap is reduced by about 0.73mm, but the deformation at the pier can not be well controlled. On the contrary, a large secondary stress is generated in this process, resulting in the large tensile stress and shear stress at the cap. The calculation results of ramp H crossing piers 60 # and 61 # are shown in Table 2. ③ During the construction of the foundation pit, the maximum lateral deformation of the steel pipe pile in the envelope structure is about 7.69mm, the maximum axial tensile stress of the steel pipe pile is 0.65MPa, and the maximum axial compressive stress is 0.79MPa, which is within the safe range. The surface settlement is about 19.42mm, and the maximum lateral deformation of the surface soil is about 20.76mm. ④ In the process of foundation pit construction, the maximum lateral deformation of the crown beam is about 7.42mm, the maximum vertical deformation of the crown beam is about 10.83mm, and the value is small. The maximum tensile stress in the axial stress of the crown is 0.75MPa and the maximum compressive stress is 0.52MPa. The maximum axial compressive stress of the first support is 1.125MPa, and the maximum axial compressive stress of the second support is 11.31MPa. The maximum tensile stress of the main structure is 0.65MPa, and the maximum compressive stress is 2.25MPa. The maximum vertical deformation of the bottom plate is 11.03mm, and the maximum lateral deformation of the side wall is 5.43mm, which is within the safe range. ⑤ It is suggested to give an early warning when 80% of the control standard is reached. The construction limit value and the early warning value are shown in Table 3. ⑥ The bearing capacity of the pier and cap pile foundation is reviewed respectively: the bearing capacity of the pier in the bending moment plane and perpendicular to the bending moment plane is 46659 kN and 34698 kN, greater than the load of 5528 kN. The bearing capacity of single pile of pile is 34374 kN, and the bearing capacity of pile body is 27720 kN, which is greater than the load of pile top and 4044 kN, all of which meet the requirements. According to pile foundation specification and road and bridge code, the maximum horizontal displacement of pile top is 29.3mm.

(4) through the inversion analysis monitoring results, finally suggested as follows: ① because the envelope structure (filling) pile and rotary spray pile of good supporting wall, can effectively control the deformation around the soil to the pit, therefore, should ensure the construction quality of the envelope structure, strengthen the construction quality of testing work, prevent the cross section of the pier pile foundation and the surrounding soil deformation expansion, ensure the safety and stability of the foundation pit. ② The horizontal support of the envelope structure can effectively control the horizontal deformation of the soil. It is suggested that the horizontal support should be performed as soon as possible, and that the

Construction early warning value	7.5	9.8	8.6

horizontal deformation monitoring of the soil around the foundation pit should be strengthened. ③ Although the bottom plate has been reinforced before the excavation, the uplift of the pit is still relatively obvious after the excavation of the foundation pit. Considering the adverse factors of the high water level of the artificial island, it is suggested to strengthen the detection of the reinforcement effect of the floor, and strictly carry out the construction monitoring of the floor uplift displacement. ④ The foundation pit precipitation has a great impact on the stability of the retaining structure and the surrounding soil, so the reinforcement and drainage scheme during excavation should be scientifically designed, and the effectiveness of the rotary spray reinforcement measures outside the pit and the bottom of the pit should be effectively guaranteed. It is suggested that the precipitation of the foundation pit should be controlled within 1-3m at the bottom of the pit, and the precipitation rate should not be too fast. ⑤ Strengthen the construction monitoring and measurement of foundation pit retaining structure and pile foundation of expressway pier along the river, adjust the construction process and supporting design parameters according to the monitoring results of deformation and stress; strengthen the monitoring of water and soil pressure and groundwater during the construction of working well. When necessary, the slope monitoring of the envelope steel pipe pile should be carried out, and the monitoring measurement forecast and early warning should be strengthened. ⑥ In order to

avoid excessive displacement or settlement of the expressway pier along the river, it is recommended to adopt the automatic survey method of measuring robot during the construction period, and give early warning at 80% of the construction control standard, and serve as the basis for the preparation of basic deviation correction and reinforcement process plan. ⑦ Through calculation, the preliminary design of the pier cap and pile foundation surrounding a steel pipe pile as protection, the actual effect is not obvious (such as the main tunnel, as a steel pipe pile and only foundation pit side for steel pipe pile and rotary spray pile, the maximum deformation only 0.66mm), therefore, can consider to reduce the reinforcement strength and parameters (such as steel pipe pile layout sparse or slightly away from the cap, 3m outside), or consider only in close to the foundation pit. ⑧ In the control of F ramp and H ramp foundation pit and along the highway bridge cap lateral deformation, it is recommended that when control deformation measures (such as servo system, support jack or high pressure rotary jet), to strictly strengthen the cap and retaining structure of the lateral deformation monitoring, to ensure the safety and stability of the highway pier and foundation pit along the river retaining structure. ⑨ The force and deformation results of the foundation pit crown beam show that there is some optimization possibility, this calculation, the process, the mechanical parameters and permeability of the foundation reinforcement is given by experience analogy, the next further research based on the field test process sampling analysis, and according to verify the reinforcement parameters on the safety of the existing bridge structure and determine the final process parameters and supporting axial force system.

3.2 Technical solutions

The protection design of the affected 49,50,53,54,60 and 61 #. After the completion of the filling of the east island, the foundation pit of F ramp, main tunnel and H ramp will be excavated. According to the supporting scheme of ramp and tunnel foundation pit, the composite pile structure of steel pipe pile + (pouring) pile (in the steel pipe pile) will be adopted. Due to the limitation of construction space near the pier, in order to avoid mutual interference between different construction processes and reduce the construction difficulty, protection measures need to be taken for the pier during island filling and foundation pit excavation, and

the lock steel pipe pile is considered. The specification and depth of steel pipe pile are determined according to the needs of foundation pit support.

Figure 12. Location of the piers of the deep-middle passage and the Yangtze Expressway.

Figure 13. Design schematic diagram.

The 53 and 54 # piers affected by the island filling and the excavation of the main tunnel, steel pipe piles with 1.4m lock diameter and wall thickness of 20mm; 49,50,60 and 61 # piers affected by the island filling and the excavation of F and H ramp tunnel, lock steel pipe piles with a diameter of 1.5m with a wall thickness of 16mm. The steel pipe pile is set along the bridge pier, and the horizontal support is set on the inside to form the combined retaining structure of the locked steel pipe pile + the inner cast-in-place pile + the pile; the silt layer in the bottom and the upper silt layer and the high pressure rotary jet pile are used to monitor the supporting shaft force and the deformation of the foundation pit, control the support shaft force and comprehensively control the safety and deformation of the foundation pit and the protected objects.

Figure 14. Steel pipe pile protection diagram.

Figure 15. Soil reinforcement in passive area.

Figure 16. Steel support servo system.

3.3 Technical management and construction control

Enclosure structure technology, in the early island of sand lock steel pipe pile bridge protection measures for steel drum, low headspin drilling hole construction, hole into the lower steel cage using section hoisting measures, after the completion of the bored pile for water stop high pressure rotary spray pile, achieve the purpose of pile water stop, eventually formed lock steel pipe pile + set pile + pile between water stop spin spray pile composite envelope structure, realize "a multi-purpose".

The soil reinforcement technology in passive area affects the scope of foundation pit excavation level of deep silt formation (greater than 3 times the excavation depth). The silt layer at the bottom of the foundation pit and the 15m foundation pit on both sides of the viaduct is strengthened by high-pressure rotary jet pile. By improving the physical and mechanical properties of soil, improving the resistance of soil in the passive area, reducing the deformation of foundation pit supporting structure and enhancing the stability of foundation pit.

The foundation pit support safety scheme is solved by increasing the support axial force servo system. It integrates numerical control hydraulic technology, automatic monitoring technology and Internet of Things technology to monitor the real-time support shaft force and foundation pit deformation. It can regulate the support shaft force according to the foundation pit deformation data, and control the safety and deformation of foundation pit and protection objects in an all-round way. Foundation pit support axial force servo system through the active loading inhibition foundation pit deformation, through the travel of servo system and oil pressure two indicators of double control and timely compensation, can better avoid ordinary steel support in the process of excavation axial force loss, after the envelope structure horizontal displacement has obvious recovery, control effect is more significant.

Figure 17. For monitoring data.

Displacement compensation and dynamic deviation correction technology. Make full use of the unloading effect of foundation pit, reasonably adjust the construction sequence to realize the horizontal displacement compensation; active displacement side, rotary jet tracking grouting for the dynamic correction and the deformation limit of the bridge.

Automatic monitoring technology. Leica TM50 automatic monitoring robot is used for all-weather automatic monitoring. In order to reduce the impact of the island on the stability of the observation station, two offshore measuring platforms are set up in the north and south sides of the east artificial island as automatic observation stations.

4 CONCLUSION

1. The deformation control of the piers of the existing adjacent bridge is controlled by the reclamation island. Through targeted project research and actual control, the deformation control index of the reclaimed bridge piers of the existing adjacent bridge is within 5mm, and the measures such as backfill principle and sand separation device should be adopted are effective for the deformation control.
2. Under the both high-speed bridge deep foundation pit deformation control, through the project safety evaluation research and safety assessment and the field more technical control, realized the existing high speed bridge deep foundation pit deformation control index reached 5mm, appropriate use of steel pipe pile, rotary pile water stop, passive area soil reinforcement measures and support axial force servo system way, is effective for control deformation.
3. For the subsequent calculation of soil and water pressure of similar foundation pit supporting structure design in the Pearl River Delta region, it is suggested to comprehensively consider the regional characteristics and influencing factors in order to obtain the quality and stability that meet the requirements.

ABSTRACT: An extraordinary assessment plan, performed on 365 km of motorway tunnels, has been carried out in Italy since 2020 starting with detailed inspections and testing. Hundreds of laser scanning kilometres and ground-penetrating radargrams, thousands of concrete compressive strength tests, endoscope inspections and flat-jack tests have been performed so far. Tens of thousands structural defects were detected and several square meters of temporary safety measures installed as well. This allowed to acquire a significant amount of knowledges about the current condition of the asset.

According to the process defined by the new Italian Regulations, the dataset analysis provides an insight into the condition of the asset, guiding the entire maintenance process. The visual and detailed inspections frequency is driven by the simplified risk analysis outcome and further safety evaluation are designed based on multidisciplinary criticality.

A comprehensive approach, based on in-depth knowledge of the characteristics of the existing tunnel, has been engineered for structural risk, with a focus on tunnel “history” (excavation stages and techniques, construction materials, etc.), design and dimensioning approaches (e.g. Kommerel’s graphical method), identified as standard methods for the tunnel construction period from literature review. Additional analyses are carried out for likely local structural failure modes of tunnel lining (punching and flexural strength of residual concrete layers, spalling hazard of concrete thickness anomalies due to temperature variations).

When re-lining is needed, the design of a new shell aimed to ensure at least the same structural performance of the original one is addressed, including seismic loads that were neglected in the original design.

The tunnel assessment, from inspections to re-lining works passing through risk analysis, is an on-going process open to be improved in the upcoming years within a wider asset management strategy.

1 INTRODUCTION

Italy has a complex transport system mainly due to its geography and orography. Moving people and goods in the most safe, fast and efficient way is nowadays crucial and strategic at the same time. Road transport mode is historically the most widely adopted in the Country.

In this picture the resilience of the motorway is one of the main objectives that Autostrade per l'Italia S.p.A. (ASPI), the main motorway Concessioner in Italy, is pursuing.

ASPI is actively involved in the maintenance and operation of the asset on behalf of the Ministry of Transport. The main purpose is to ensure travellers, as well as employees, safety and continuity of the operations within a competitive level of service.

An extraordinary assessment plan was launched in 2020 on the road tunnel side, triggering about 365 km of ASPI network (595 tunnels). In 2020, the assessment program was mainly characterized by a reactive approach to maintenance due to few adverse events, one of which is unfortunately well known.

*Corresponding author: lapo.baccolini@tecneautostrade.it

Tunnels were visually inspected and tested through laser scanning (LSC) and ground-penetrating radargrams (GPR) as well as cored to compressive strength of 50 m each.

Many tunnels were visually inspected simultaneously along the motorway. At that time, due to the pandemic, the level of traffic was the lowest ever recorded since many decades and this facilitated construction sites, minimizing the effect on users of the infrastructure.

The reactive maintenance was leading to treatment of structural defects in a short time frame (3 to 6 months) opening several construction sites at the same time, increasing the user related traffic risk when approaching the sites.

A transition from reactive to preventive maintenance approach was then needed among the Organizations and partially promoted by the new Guidelines:

- 23rd August 2022 “Guidelines for existing tunnel’s risk and safety evaluation and monitoring system installation”, referred to as “LLGG” in the following sections.

The new code comes spread in layers (1 to 4) characterized by an increasing level of detail:

- **Level 0** – Asset information such as location, length, lining material, construction age etc.;
- **Level 1** – Asset conditions in terms of scored defect detected during the visual inspection. In this phase, extension (k_1), magnitude (k_2) and severity (G) of the defects are collected in forms for further analyses;
- **Level 2** – The levels 0 and 1 gathered information feeds a process whose purpose is to assign a simplified risk score to each 20 m long segment of the tunnel for each thematic area (structural global and local, geological, seismic, hydraulic and transport related). The score can be low, mid-low, mid-high or high. The six thematic areas (except for hydraulic) are then combined into a global risk rate. Level 2 defines the visual inspection frequency of the asset, by the risk rate associated to structures (both for global and local mechanisms).
- **Level 3 & 4** – Whenever risk rate coming from level 2 is mid-high a preliminary safety evaluation is performed to better investigate the parameters which lead to such rate of risk in the specific thematic area. If the risk rate is confirmed engineering judgement and calculation are put in place to identify the mitigation measures, or eventually monitoring systems, needed to keep the risk acceptable (Level 4). When the risk rate is higher Level 3 is glossed over. At Level 4, the engineered process to residual level of safety evaluation includes calculation and approaches, in some cases, directly derived from the past.

The LLGG multilevel approach helps Organisations like ASPI, with a very large asset portfolio, in prioritizing maintenance and expenditures.

In the following sections the assessment program is described starting from the guidelines approach going through the treatment strategies with an insight to the asset management.

2 ASSET INFORMATION

Risk evaluation and treatment prioritization start from a deep knowledge of the asset. Level 0 is the first step of the assessment process where tunnels affected by the guidelines are analysed to collect the minimum amount of information about (but not limited to) location, owner, designer, length, number of lanes, construction age, structure layout and materials, surrounding conditions of the soil, average number of vehicles per day, percentage of commercial vehicles etc.. Data are collected and printed in standard spreadsheet (Figure 1).

Figure 1. Standard printout data for Level 0.

The amount of data required is quite large, more than 600 parameters, but the level of detail can be coarse at this early stage. The set of data gained at this stage will be deepened during the subsequent levels. Some of the parameters are directly involved in the simplified risk evaluation of the asset promoted by Level 2 and in the safety analysis of Level 3 and 4.

The Level 0 activity does not require the fulfilling of the 600 requested parameters in a row, it can be accomplished by subsequent runs of digging for knowledge.

3 FIRST INSPECTION

When it comes to Level 1, of the multilevel approach, a first visual inspection is carried out on the asset.

The purpose of the first inspection is to confirm and deepen the data collected at the Level 0, gather further information about the actual geometry and structural characteristics of the tunnel, in addition to assess the degree of deterioration of the liner.

First inspection starts with high pressure water cleaning of the lining surface. In fact, the inner road

tunnel environment is quite aggressive and the exposure of the liner to vehicles smog makes hard to notice any possible evolution of structural defects. Any screen and water-sheet are dismantled in order to have free access to the surface of the concrete (or to inspect the masonry in some other cases).

The inspection is not limited to the tunnel lining only, the access areas of the tunnel and non-structural support elements are analysed as well.

Before Engineers inspect the tunnel, some tests are performed:

- Ground-Penetrating Radargrams (GPR) – a transmitter is used to generate electromagnetic waves across the concrete liner. Waves travel time is measured and distances from obstacles or anomalies inside the concrete detected. The test is used to evaluate the thickness of the liner, the presence of voids or steel rebars and the presence of hidden defects.

The test is performed by longitudinal sections (Figure 2). across the tunnel in central top position and on the sides. A minimum of 3 sections are required for two lanes tunnel, 5 for three lanes one.

- Laser Scanner (LSC) – the travel time of the light emitted by a source, hitting the lining surface and coming back to the receiver is recorded. The output is a cloud of points representing the actual geometry of the tunnel (Figure 3).
- coring for concrete strength – concrete is cored and specimens collected each 50 meters for simple compression testing. The strength of the liner has an impact on the evaluation of the simplified structural risk for local mechanism as well as for the subsequent safety evaluations.

Figure 2. GPR section layout.

During inspection, defects are recorded by position, relative dimensions k_1 (from 0 to 1), intensity k_2 (0.2 – 0.5 – 1.0) and severity G (from 1 to 4).

Defects are listed in a spreadsheet (Figure 4) and represented into a 1 m by 1 m grid plan layout (Figure 5).

k_1 and k_2 are assigned during the inspection whilst G is under the Engineering judgement responsibility who will tag a defect with high severity ($G=4$) when this could lead to collapse of the structure, mid-high severity ($G=3$) when leading to an out of service of the asset.

Figure 4. Annex C2.

Figure 5. Defect representation.

Defects are then grouped by type in each tunnel element¹ evaluating the size and intensity of the cluster as follows:

$$k_{1,t} = \sum_{i=1}^n k_{1,i} \quad (1)$$

$$k_{2,t} = \sum_{i=1}^n (k_{2,i} \cdot k_{1,i}) / k_{1,t} \quad (2)$$

1 A tunnel is usually broken down into 20 m long elements unless geological or structural discontinuities are identified.

$$G_t = \sum_{i=1}^n G_i \cdot k_{1,i} / k_{1,t} \quad (3)$$

These parameters are then combined, at Level 2, to have a vulnerability rate (low to high).

4 PRELIMINARY RISK ANALYSIS

The background of knowledge coming from Level 0 and 1 is analyzed at Level 2 to have a simplified indicator of the risk. The preliminary risk rate (CdA) of the tunnel is computed combining hazard, vulnerability and exposure of six different disciplines:

$$CdA = H \times V \times E \quad (4)$$

global structural and geotechnical risk (SGG), local structural risk (SLO), seismic risk (SIS), landslide risk (GEO), transportation risk (STD) and hydraulic risk (IDR). To do so about 60 indicators (primary and secondary) are gathered and combined. Primary and secondary parameters are characterized by a rate (low, mid-low, mid-high, high).

The specific disciplines risk rates are then consecutively combined according to (5) to have the representative risk of the tunnel.

$$CdA = \{[(CdA_{SGG} + CdA_{SLO}) + CdA_{GEO}] + [(CdA_{SGG} + CdA_{SLO}) + CdA_{SIS}] + CdA_{STD} \quad (5)$$

Hydraulic stands separately (Figure 6).

Figure 6. CdA.

The overall risk of the tunnel is represented by the worst one among its sections. The percentage of sections in a specific risk rate classification is calculated and called “*index of diffusion*”.

Level 2 allows to preliminary shortlist tunnels based on specific risks. Mid-high to high values of risk lead the disciplines involved to undergo safety evaluation respectively in Level 3 and 4.

In both cases a detailed inspection, including testing, is planned within a year.

Level 3 is focused on the re-evaluation of the CdA concentrating on deepening the board of knowledge gathered at Level 2 whilst, in Level 4, accurate

evaluations are carried out to estimate the safety factor of the involved risk disciplines.

During these activities (Level 3 and 4) the asset, is constantly monitored proportionally to its structural criticalities (briefly SGG+SLO CdA) which drive the subsequent visual inspection frequency (both ordinary and detailed).

LLGG also includes a Level 5 analysis, which only applies to strategic tunnels. At this stage, advanced models are put in place to evaluate the resilience of the infrastructure considering the logistic importance of the tunnel itself, analysing the interaction between the tunnel and the transport system of the geographic area and finally studying the consequences of a closure on the social and economic context.

5 DETAILED INSPECTION AND SAFETY EVALUATIONS

5.1 Detailed inspection

Detailed inspection has characteristics similar to visual first inspection; nonetheless, it includes some tests previously requested by the company in charge of the activity and results are gathered before entering the tunnel.

Testing is mainly addressed in deepening the knowledge of the areas suspected of hidden deterioration of the concrete liner. Heritage from Level 1 is driving test plans including:

- endoscope (VE) - when GPR provides clues for potential defects under the concrete lining, VEs are then performed by drilling small diameter holes through the liner down to the rock surface. A cctv equipped probe and a tape measure are used to report the layers where concrete, voids or deteriorated concrete are encountered;
- flat jack - stress state of the liner is a needed information for further safety analyses. The concrete surface is cut to measure the displacement of the edges. The original edges position is then restored by applying a flat-jack load;
- pacometer test - a digital tool enabling the detection, the direction and the diameter of the rods in the reinforced concrete in a non-destructive way. It consists of a probe generating a magnetic field and a controller measuring the power dissipated by the metallic object as result of the magnetic induction from the probe. This test can be used to confirm the presence of rebars in specific tunnel sections.

During detailed inspection on site, if any criticality is detected, additional tests and an accurate safety evaluation may be requested to the Process Owner².

Level 3, based on the detailed inspection results, investigates deeper the parameters which led to a mid-high specific level of risk.

² Supported by the Engineering Judgement.

If the risk is confirmed Level 4 is activated for further safety evaluation. In the following sections some of the methods adopted for structural global and local risk are described.

5.2 Global safety evaluation

The methods to evaluate the residual safety factor associated to a global mechanism of failure of the structure is strictly linked to the context (presence/absence of primary concrete liner, geological conditions etc...). When the tunnel liner is unloaded, the surrounding soil has good properties (sound rock) and the cross-sectional model is almost symmetric an historical approach to assess liner performance can be adopted. Conversely, finite element analysis is needed to replicate the actual condition of the liner in terms of stress and strain. Here the historical method of “Kommerell” is presented, which was widely adopted before '70 to design tunnels in Italy. It is based on a graphic procedure to evaluate the load, and its eccentricity, among the arch sections (Figure 7).

Figure 7. Kommerell method.

The method is based on three main assumptions:

- symmetry of the model (load and geometry);
- sides distributed reaction of the surrounding soil to balance the vertical loads;
- compression of the arch only – the load shall be included in the central $t/3$ where t represents the thickness of the lining.

The method has been implemented in a user-friendly spread sheet to iterate the calculation increasing vertical loads to the highest compatible with the structure. The thus found load is then compared with the expected one (Figure 8) based on rock mass quality designation (RQD) (Bieniawski).

When the expected load is lower than the maximum one the performance of the lining is adequate and the global failure mechanism unlikely.

Figure 8. Terzaghi's rock load classification (2, 3 lanes tunnel).

5.3 Local safety evaluation

The methods to evaluate the residual safety factor associated to a local mechanism of failure of the structure is strictly linked to the local condition of the lining (construction and exogenous defects). Three methods are used to assess the influence of the anomalies of the concrete lining:

- punching check on the residual thickness;
- bending check on the concrete plate;
- critical temperature variations influence (Aiello et al.).

Figure 9. Under thickness of the concrete.

In all cases a thin concrete layer is investigated for likely failures mode and mitigation measures consequently prescribed. Furthermore, that a more comprehensive approach is adopted by the Engineer who is in charge of evaluating the level of deterioration of the asset. Defects distribution, presence of cracks or water leakages and their combination feed

a more complex engineering judgement process that leads to the definition of a monitoring and/or treatment plan on the tunnel.

6 TUNNEL INTERVENTION STRATEGY

Level 4 purpose is to highlight the criticalities and possible solutions in terms of monitoring systems or intervention strategies. Tecne S.p.A., engineering company of Autostrade per l'Italia S.p.A., tends to group intervention strategies with the effect these have on asset conditions:

- IMS – is the treatment approach closer to extraordinary maintenance “*Intervento di Manutenzione Straordinaria*”. The aim is to reduce vulnerability for mainly local mechanisms of failure without increasing the strength of the structure.
- IRS – stands for structural reinforcement “*Intervento di Rinforzo Strutturale*”. In this, the aim is to reduce vulnerability for global mechanisms and increase the structural strength of the system.
- TRS – stands for “Tunnel Renewal Strategy”. The renewal solution is aimed to extend the tunnels life cycle of at least additional 50 years, through the construction of new lining, able to replace the structural function of the existing one and to ensure waterproof condition and suitable performance under seismic events.

The optimal solution to be implemented mainly depends on Organization culture about preventive maintenance, existing lining conditions, impact on traffic, time, costs, waterproofing effectiveness, job-site organization, reusability of the solution, propensity to innovation.

On a higher organizational level, decision making on tunnel maintenance strategy is moving to a more robust asset management approach also by developing a dedicated tool to compare several alternative intervention scenarios in terms of risk, costs and residual value of the asset.

7 TUNNEL RENEWAL STRATEGY

Due to the early stage tunnel assessment experience mainly based on reactive maintenance, the TRS approach was developed since end of 2021 by the following main steps:

1. analysis of the assessment program and technical solutions applied during 2020/2021;
2. collection of existing tunnel industry state of the art, including bibliographic research, looking for solutions adopted around the world for tunnel rehabilitation both in continuity of operation and closure;
3. definition objectives and requirements of relining works (§7.1);
4. definition of a set of typological interventions and related design methods and verification criteria (§7.2);

5. involvement of construction market to develop mechanized and technologically innovative solutions (§7.3);
6. organizing field tests and application of pilot projects (§7.4);
7. standardization and recurrent applications based on return of experiences coming from pilot projects (§7.4);
8. continuous improvement (§7.5).

7.1 Objectives and requirements

The main objectives and requirements defined in the TRS context are:

- safety for operation, especially in case of alternation of works/traffic operation and works during traffic operation;
- safety for workers (protection, mechanization);
- minimization of impact on traffic (protection, mechanization);
- quickness of intervention (mechanization);
- high structural performance (pre-casting operations, high-performing concrete mix);
- installation of an effective and durable waterproofing system;
- sustainability and conservation of the asset by recycling, use of green machine and materials.

Key role to ensure safety conditions and reduce time and traffic impact is played by the minimization of the existing concrete milling, especially when a not negligible stress state is detected in the lining during detailed inspection. This allows also to reduce the supports and soil treatment needed to fulfill the required safety standard during concrete demolition, maintaining low uncertainties regarding rock mass stability.

The minimization of existing concrete milling can be obtained by lowering the road pavement and reducing new lining thickness resorting to high performance materials.

Once the new lining is built, the maintenance of its structural capability is ensured by the mandatory installation of a waterproofing system and drainage system is mandatory to take out water from deterioration root causes during the operational stage.

Every project is accompanied by environmental performance of the works, assessed by LCA methodology, which has become an additional item for designing and choosing between engineering solutions.

7.2 Typological interventions

Nine different typological interventions were defined:

- A. complete demolishing of existing lining and cast in place of new concrete shell;
- B. partial existing lining milling and concrete relining casted in place by precast concrete shell formworks (Figure 10);
- C1. C1.partial existing lining milling and relining by high performance shotcrete (Figure 11, Figure 12, Figure 13);

- C2. partial existing lining milling and concrete relining by casted in place by modular steel formwork (Figure 14);
- D. shallow existing lining milling and relining by implementation of liner plates (Figure 15);
- E. existing lining milling and relining by implementation of precast concrete segments (Figure 16);
- F. steel liner coupled to existing lining;
- G. installation of steel ribs and shotcrete, with or without existing lining milling;
- H. platform remodulation (lowering) to avoid existing lining milling combined with inner lining based on previous typological interventions.

Each intervention has been detailed evaluated to define its proper field of application based on a pros and cons analysis and the specific design methods and verification criteria are developed correspondingly.

7.3 Involvement of construction market

As part of TRS, the construction market was approached by engaging specialized players by issuing the challenge regarding the development of innovative solutions.

The search for these solutions was mainly directed in the area of materials, seeking innovative materials with high structural performance, as well as in the area of mechanization for the installation of the components of the new lining shell. Not Disclosure Agreements have been signed with the selected companies and suppliers to ensure the exclusive use of the information shared in the design phase, then followed by specific agreements in order to manage future patent developments of original solutions as well.

7.4 Testing, pilot projects and recurrent applications

Less than two years from the statement of TRS main steps, all the typological interventions have been preliminary tested and the application of the related pilot projects completed or ongoing.

Deep involvement in the design and testing stage have been extended to members of Construction Company and all the technicians included in the process. It is also demonstrated mandatory training sessions and the availability of detailed method statement for each innovative technologies introduced by the design.

In addition, the daily technical support ensured by design teams during the progress of the works has been crucial to refine typological interventions, fix issues, record feedback and improve products and application processes. In this regard, it is worth to be noticed that the Construction Standards do not provide any facilitation for pilot projects, therefore the process entails unavoidable technical refinement during the works and possible related additional costs.

To date, seventeen TRS projects are under construction and almost half of them are already recurrent applications of the corresponding pilot project.

Figure 12. “Manfreida” tunnel construction site – relining by high strength shotcrete.

Figure 13. Relining by high strength shotcrete - Pilot application at “Manfreida” tunnel.

7.5 Continuous improvement

The next developments of TRS are aimed to the following main goals:

- implementation along the second tube of “Colle Marino” tunnel of shields system, to ensure

8 CONCLUSIONS

Tunnel assessment is an on going process for Autostrade per l’Italia S.p.A. The amount of information and experience acquired by its Engineering company

(Tecne S.p.A.) and all the Operators involved in the activities, is constantly growing.

The monetary and economic value of the asset make any effort needed and worthy.

The reactive approach to maintenance has been overtaken and the Tunnel Renewal Strategy is now starting the standardization and recurrent applications stage to extend the tunnels life cycle of at least additional 50 years.

Beyond that, the company is looking forward to embrace a comprehensive tunnel asset management approach including data management, asset condition evaluation and tunnel tailored best intervention strategy going from corrective to preventive maintenance approach.

ABSTRACT: The present work deals with the structural safety assessment of existing tunnel masonry linings. Until the introduction of reinforced concrete, masonry linings were the common solution for railway, metro, and road tunnels. As a result, there are still many tunnels with masonry lining that have been in service for more than a century. After such a long time, masonry linings may show signs of degradation due to ageing and the long action of water infiltration may have reduced their strength. For this reason, the safety assessment of existing tunnels is becoming increasingly important, in order to timely identify the criticalities and plan the necessary rehabilitation interventions, but specific regulations are still lacking.

This paper addresses this need by proposing a methodology for the global and local static verification of masonry-tunnel-linings, describing the issues to be addressed and proposing a procedure to define the mechanical properties of the masonry, calibrate the partial safety factors, identify the local vulnerabilities and their priority order. In this process, the scientific literature and normative references developed for cultural heritage masonry structures are taken into account, considering that these tunnels have features and problems similar to old masonry constructions (bridges, porches, vaulted buildings) and that the interventions planned should also have a conservative approach, since these structures represent indeed an important element of the history of our architectural and technological evolution.

Keywords: Cultural Heritage, Masonry infrastructure, Planned conservation, Safety assessment

1 INTRODUCTION

1.1 *Assessment and strengthening of masonry tunnels*

This paper focuses on masonry tunnels, which were the predominant typology in Europe in the 19th and early 20th centuries, before the development of reinforced concrete. For instance, many subway tunnels in Paris and London, as well as the Simplon and Frejus railway tunnels in the Alps, are made in masonry.

Usually, the masonry is made of solid clay bricks, but stone masonry is often used, especially in the lower parts, which are potentially subject to damage by moisture. Brick or stone masonry was the material of choice for the construction of the lining for two

main reasons: firstly, because the raw material was often obtained from the excavated material during tunnel construction; and secondly, because bricks have the advantage of being made up of small, easily transported and handled regular units, which were suitable for the construction of arches in confined spaces. However, in order to achieve the required lining thickness, it was usually necessary to construct several layers of brickwork in the side walls and arches with multiple rings, and to use a relatively large quantity of mortar, since the proportion of mortar in brickwork is generally much higher than in good quality ashlar masonry. The thickness of the lining was determined by simple rules of thumb, depending on the type of soil, with light soils generally considered to be self-supporting and heavy soils as requiring support (McKibbins et al., 2009). The

*Corresponding author: roberto.pittalis@tecneautostrade.it

geometric section of the tunnel and subsequent lining were usually related to the excavation and shoring techniques. The thickness and geometry of the lining, therefore, did not descend from structural mechanics but from practical guidance, often described in manuals and regulatory guidelines.

This type of construction has been widely used in Italy since the second half of the 19th century. Currently, due to its morphological conformation (the Alps in the north and the Apennines along the peninsula), Italy has the largest number of road tunnels in the Trans-European Transport Network (TEN-T). Specifically, Italy has well over 1,200 km of tunnels in the ANAS road network, 500 km in the motorway network and 1,200 km in the rail network, with 34 tunnels longer than 5 km (Tunnel, 2023). The problems associated with their preservation and safety are therefore of particular importance, considering their age, which is often a centenary or even more.

In fact, there are numerous scientific studies related to tunnel collapse cases, considering both the census of tunnel damage (Sousa, 2010; CEDD, 2015; Zhang et al., 2016) and the related statistical analysis (Špačková et al., 2013). However, these studies mainly consider two types of causes (Spyridis et al., 2021): the collapse during construction or the damage related to transport accidents followed by a fire. Instead, the present study intends to focus on the analysis of the risk of collapse or damage, both global and local, in masonry tunnels during operation. In fact, many accidents of this type have occurred recently, both nationally and internationally: e.g. Ciclopi, Tenda and Tre Madonne tunnels in northern Italy; Vierzy and Rove tunnels in France. At present, monitoring systems and preventive maintenance activities specific to these infrastructures play a very important role in reducing this type of risk. For this reason, the safety verification of existing tunnels was recently requested in some countries. For example, in Italy, the recent “Guidelines for the classification and management of risk, safety assessment and monitoring of existing tunnels” (DM 247, 2022) require the study of existing tunnels with a multilevel approach that starts from the geometric survey and, depending on the problems found, can reach the static assessment. For the static assessment of masonry tunnel-linings, there are no specific standards, and it is necessary to refer to the code standards for new masonry buildings (DM, 2018) or those for historical buildings (D.P.C.M. 09/02/2011), which, moreover, were mainly developed for seismic problems. In the case of existing bridges, instead, there are specific guidelines for both reinforced concrete and steel (CSLLPP, 2021), or masonry bridges (CNR, 2015), which can also be a useful methodological reference for the static assessment.

In general, the guidelines aim to adopt a preventive approach, both to avoid potentially dangerous situations and to plan maintenance works without having to operate under emergency conditions with long road closures, but there are no clear indications on the quantification of the safety levels and the priority of the interventions.

1.2 Aims of the research

Starting from the instructions contained in the DM 247 (2022), written for infrastructures of all ages and types, this research aims to integrate them with approaches derived from the field of architectural conservation and existing buildings static assessment. In fact, at the theoretical level, it is now established that strengthening, when applied to an asset recognised as having historical and/or artistic value, is an essential part of the discipline of architectural conservation and not something separate and autonomous (Di Stefano; D.Lgs. 22/01/2004). For this reason, the analysis will borrow concepts developed for the approach to historical structures (D.P.C.M. 09/02/2011), both from a global point of view, intended to assess the overall structural capacity, and from a local point of view, concerning the material-pathological conditions of the surface. In the first case, the concepts of the Masonry Quality Index (Borri et al., 2019), the Confidence Factor (D.P.C.M. 09/02/2011; D.M 17/01/2018) and, more generally, the methods for defining the mechanical characteristics of an existing masonry are taken up and adapted to the specific case of tunnels, which are characterised by thick masonry built with a curved shape and with a single free face. The local vulnerability associated with surface deterioration (UNI 11182, 2006), which defines a possible risk of detachment of parts of the lining that may interact with the road network, shows similarities with the problems encountered in historic buildings. Similar safety issues were highlighted in all their importance in October 2017, with the fatal accident in the Basilica of Santa Croce in Florence, which triggered a wide-ranging campaign to check the stone facings of monuments in the Tuscan capital (Salvatici et al., 2020; Ceppetelli, 2022). Although there are obvious differences, both in terms of value and operational complexity, in the knowledge and intervention phases, this research aims to propose a possible specific protocol for the study of criticalities in historic masonry tunnels currently in use, for the assessment of their global and local stability conditions and, therefore, for the definition of targeted interventions to resolve criticalities that may pose a risk to vehicle safety, also taking into account the conservation needs of elements recognised as valuable.

The proposed protocol will be tested on two tunnels along the “Genoa-Po Valley Motorway” in Italy, which date back to the 1930s. Since their construction, the works carried out to ensure road safety have been in line with the usual maintenance operations for this type of structure, taking into account only the technical aspects, sometimes to the detriment of the conservation of the material and the perception of the asset. The recognition by the operator, Autostrade per l’Italia, of the specific nature and value of these historic tunnels is now laying the foundations for a different approach to their management.

1.3 The analysed case study

1.3.1 Historical overview of the motorway tunnels

Aware of the strategic role - both economic and social - played by road communications, the Fascist regime promoted the construction of major infrastructure projects. Among these was the “Genoa-Po Valley Motorway” (*Autocamionale*), which was intended to solve the problem of heavy traffic between the port of Genoa and the hinterland. On August 31, 1932, the preliminary project for the entire motorway between Genoa and Serravalle Scrivia was completed. The works, for a total cost of 218 million lire, were put out to tender on 6 October 1932 and took three years to complete, divided into 22 sections (Pini, 1936).

The motorway had the most modern features for a mountain road at the time and therefore represents an interesting testimony of the evolution of road and tunnel technologies.

1.3.2 Main features and constructive techniques

In the Motorway there are 11 tunnels with a total length of 3,002 m, about half of which are in the first 8 km close to Genova. The carriageway is 10 m wide, with two lanes and a platform width of 9.42m, plus margins. The tunnel profile is a horse-shoe shaped with an invert. The construction method used for the tunnels is known as “heading and bench”, which involves excavation of a top pilot adit, widening to create space for the vault, excavation of the lower bench, and then construction of the invert (Figure 1).

The thickness of the wall linings varies according to the pressure exerted by the ground, ranging from 0.94 m to 1.60 m for the shell and abutments, and from 0.67 m to 1.07 m for the inverted arch. The linings themselves were constructed using brick masonry for the vaults and inverted arches, and

a combination of rubble and brick for the abutments. Only in the central section of the “Littorio” tunnel was a structure of squared stone blocks used.

In the areas where water infiltration occurred on the vault surfaces, waterproofing was carried out by injecting cement mortar under pressure to seal any remaining voids and to divert the water as far as possible towards the abutments. The surfaces were then coated with an external plaster of cement mixed with waterproofing agents (Pini, 1936). The façades were designed with the utmost simplicity: corniches, projections and decorative elements were eliminated, and only a variety of coloured stones were used for decorative purposes. In the “Littorio” and “28 Ottobre” tunnels, the only architectural element is a large Fascist symbol called the *Fascio Littorio* (Figure 2).

1.3.3 The first tests on two galleries

The paper focuses on two tunnels built along the “Genoa-Po Valley Motorway”: the Campora and Giovi tunnels, 509 m and 910 m long, respectively, both opened to traffic in 1935.

Unfortunately, there is no historical documentation on the design of the Campora tunnel, and for the Giovi tunnel it is incomplete, especially regarding the technical-constructive features of the masonry vaults. In fact, for the Giovi tunnel, the available historical information is derived in part from design drawings for the entrance and exit sections, ventilation shafts, fenestrations and mine work and location of the niches. Construction details are also available but are limited to the basement of the piers.

Additional data have been obtained from the documentation of surface rehabilitation works for the degraded area of both tunnels and related first aid interventions, dating back to the early 2000s (Figure 3). In particular, it was found that the vaults are made

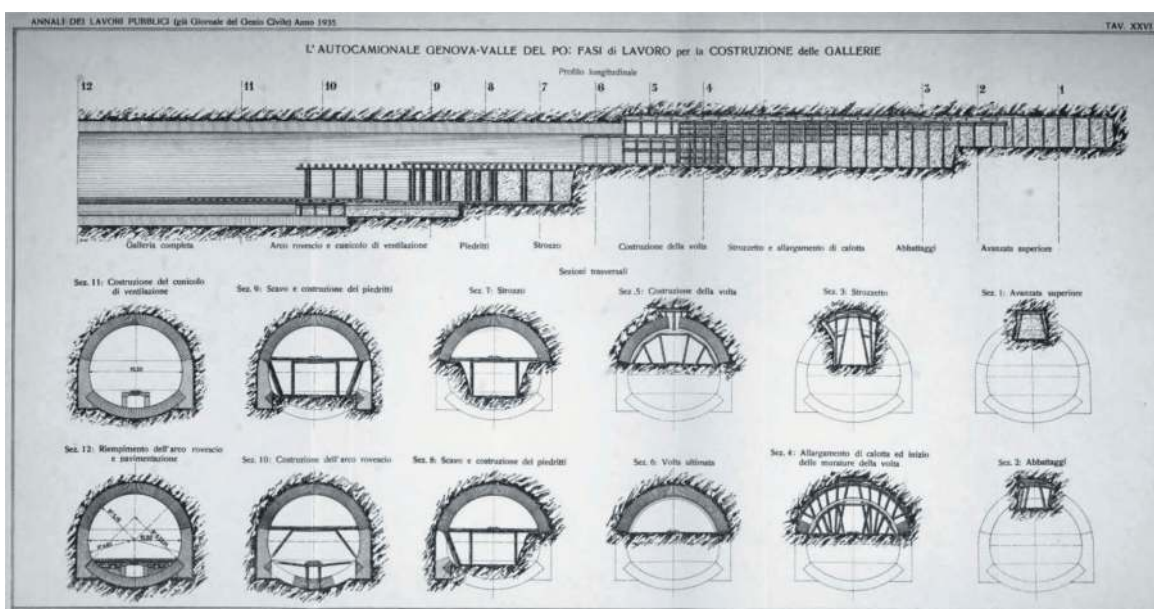

Figure 1. Construction of the masonry lining (CSLLPP, 1935).

Figure 2. Portal of the Maltempo and of 28 Ottobre tunnels (CSLLPP, 1935).

Figure 3. Detail of the masonry vault and of the first aid intervention.

entirely of brick masonry, plastered in some sections, while the sidewalls are composed mainly of stone masonry.

In 2023, a series of tests were carried out to provide information on the state of conservation of the coating of the two tunnels: laser scanner surveys, thermography, video-endoscopy, single and double flat jacks.

Laser scanner surveys and thermographies provided preliminary and important geometric and diagnostic information about the inspected surfaces. On the vaulted surfaces, there are widespread moisture phenomena that have caused efflorescence, plaster detachment, mortar disintegration and a widespread crack pattern (Figure 4).

Figure 4. Survey of materials and decay of the Giovi tunnel.

In addition, a settlement in the crown of the vaults was surveyed (Figure 5). Regarding the piers in the Campora gallery, observed degradation is limited only to the plastered surfaces, while in the Giovi gallery there is also widespread mortar deterioration and exfoliation of the stone elements.

On the basis on the above-mentioned surveys, inspection points were chosen for video-endoscopies, which showed the use of full bricks through all the cross section, with no evidence of problematic situations. On the contrary, tests with flat jacks revealed points with a stress state worthy of attention. In fact, for the Giovi tunnel, some tests showed an asymmetric stress state, with compressions on the left haunch and tension on the vault and right haunch, consistently with the asymmetrical geometric deformation surveyed with the laser scanner (orange line in Figure 5). Regarding the Campora tunnel, high stress values are present on the left side of the tunnel and no tension on the crown in two sections (like in normal arches, gravitationally loaded).

Figure 5. The laser scanner survey highlighted an asymmetrical settlement in the vault of Giovi tunnel.

The inspections described provided qualitative indications and priorities for the inspection activities to be carried out, but the present study aims to integrate these results with more quantitative data to guide the intervention choices.

2 MECHANICAL PROPERTIES OF THE MASONRY

2.1 Double flat jack tests

Lining masonry works predominantly in compression, so its safety is determined by the compressive strength of the material. Estimating the compressive

strength of existing masonry is still an open problem. Destructive methods have been proposed in the literature, such as the compression test on undisturbed walls extracted from the masonry, the compression test on cores of appropriate size, and the double flat jack (RILEM 2005, ASTM C1196 2009). In the present work, it was decided to use double flat jacks, as data were already available for the analysed tunnels. For safety reasons, the test was stopped when the measured stress-strain curve began to bend, i.e. before the masonry cracked (Figure 6).

Figure 6. Double flat jack stress-strain curve: for safety reasons, the test was stopped when the measured curve began to bend.

In this case, the test provides a conservative estimate of the compressive strength and the value of the elastic modulus of the masonry E_M . From the latter, the masonry strength f can be estimated using formulae of the type $f = E_M/c$. Using the relationship suggested by EC6 (EC6, 2005), $c = 1000$, and considering a coefficient 0.85 to transform mean strengths into characteristic strengths, gives $f = E_M/850$. It should be noted that the flat jack used in this campaign had a thickness of 200 mm and acted on the intrados of the lining, which has a global thickness of 1200 mm. For this reason, the masonry behind the flat jack constrains the loaded masonry and causes the modulus of elasticity E_M to be overestimated. For this reason, Alecci et al. (2021) proposed a correction factor K for the modulus of elasticity that depends on the ratio between the thickness of the jack and that of the wall. The resistance obtained in this way is still subject to several uncertainties. Firstly, some authors suggest values of c between 250 and 1200 for a solid brick wall, indicating that the correlation between the modulus of elasticity and the strength is not so certain (Costigan et al., 2015). Furthermore, EC6 refers to a secant modulus, whereas flat jacks measure an unloading and reloading modulus, which is generally higher. For this reason, it was decided to estimate masonry strength using also other approaches and to compare and validate the results.

2.2 Tests on bricks and mortar

Masonry cores with a diameter of 150 mm were taken from the masonry to characterise the constituents, mortar and bricks. Bricks or parts of bricks were taken from the cores, stoned from both sides and then cut into cubes of 50 mm side. In this way a larger number of samples were obtained, all of the same size, to avoid size-effects (Cabané et al., 2022). The cubes were tested in compression according to EN 772-1 (2011). The normalised strength $f_{b,N} = \delta f_b$ was calculated using the shape factor δ given in EN 772-1 (2011).

The mortar bed joints are approximately 20 mm thick. XRD analysis has shown that the mortar is composed of lime and cement. The mortar was characterised on site using a Gucci penetrometer (Gucci, Barsotti, 1995). Mortar samples of approximately 50 mm x 50 mm x 20 mm were taken from the cores to measure the compressive strength using the UIC double punch test (UIC 778-3R, 2011).

The average strengths of mortar f_m and bricks $f_{b,N}$ can be used to estimate the characteristic strength f_k of masonry using tables or equations. As this is industrial masonry, the power equation proposed by EC6 (2005) for solid bricks and cement mortar $f_k = 0.55 f_{b,N}^{0.7} f_m^{0.3}$ has been used: several authors (e.g., Ferretti, 2020) have shown that this equation also gives reliable results for masonry built with mixed lime-cement mortar, such as the one in question.

Again, the factor of 0.85 proposed by EC6 (2005) was used to divide the characteristic strength f_k to obtain the average strength f . To take into account the fact that masonry consists of several layers, EC6 multiplies the strength by a coefficient 0.8. This coefficient was proposed by EC6 (2005) for buildings and is not necessarily good for the very thick walls of tunnel linings, but cathedrals and towers may also have the same problem.

2.3 Masonry quality index for tunnels masonries

The structural behaviour of masonry is influenced not only by the strength of its components, but also by the construction technique of the masonry within its thickness, the texture of the brick (or stone) work and by deterioration: more generally, by compliance with the so-called “rules of the art”. In this study, the empirical approach defined by Borri et al (2015) for calculating the Masonry Quality Index (MQI) is used to rapidly assess the quality of masonry tunnel linings. This is achieved by measuring parameters that indicate whether certain conditions related to the correct and effective construction of the masonry have been met.

The seven parameters to be examined, which can be identified by visual and/or manual inspection, are: (a) the shape of the load-bearing elements, (b) the presence of cross-bonding elements, (c) the horizontal alignment of the layers, (d) the strength of the elements, (e) the size of the elements in relation to

the wall thickness, (f) the offset of the vertical joints and (g) the quality of the mortar. The application of this method to the specific case studies makes it possible to calibrate these parameters in order to take into account the differences in behaviour between vertical thin masonry walls, for which the MQI method was defined, and the curved thick structures of masonry tunnels. In the latter case, the influence of the vault texture (Boni et al., 2022) and the different importance of some parameters under different loading conditions must be taken into account.

Further calibration will be carried out by comparison with the described in-situ tests, in order to refine the formulae proposed by Borri (2015) and to guide the determination of the mechanical parameters of the tunnel masonry, whose parameters can be very variable depending on the technical details analysed in the MQI. The implementation of this method is proposed as a tool to support both the assessment of the safety level of existing tunnels, the definition of the possible inspections needed, and the indications of the necessary reinforcement interventions, also allowing a rapid evaluation of their effectiveness.

2.4 Decay phenomena

2.4.1 Decay phenomena involved in structural weakness

The alteration of the physical and chemical properties of the materials, such as the disintegration of mortar and the spalling of bricks, is a risk factor for the safety of the tunnel (increasing the possibility of detachment of individual elements) and can have a negative effect on the mechanical behaviour of the masonry, reducing its strength. According to the illustrated glossary of the ICOMOS-ISCS International Scientific Committee for Stone (2008) and Cultural Heritage - Natural and artificial stone Description of the alteration - Terminology and definition (UNI 11182, 2006), the main types of deterioration that affect the properties of the masonry and the risk of detachment of bricks from the tunnel lining can be identified as follows: (a) biological colonization (algae, lichens, moss, mould, plants); (b) deposit (crust, efflorescence, encrustation); (c) material loss (alveolization, erosion); (d) detachment (blistering, bursting, disintegration); (e) cracks (fractures, hair cracks) and (f) deformations.

2.4.2 Decay survey and in situ analysis

In the specific case of tunnels, the presence of such deterioration is detected by the evaluation procedure outlined for Level 1 of the 2022 Guidelines (D.M. 247:2022): the catalogue of defects (Annex B) includes the defects associated with the identified deterioration, evaluated in terms of extent (k1), intensity (k2) and severity (G), in order to determine the attention class of the tunnel under investigation.

After an initial qualitative assessment of the existing pathologies, further checks can be carried out

using specialised instruments and chemical analyses. In particular, the assessment of the state of deterioration of the masonry, in terms of the reduction of its mechanical properties and consistency, can be carried out by means of rapid investigations such as visual inspections to locate areas of deterioration and define their characteristics; acoustic inspections using mechanical tapping of the surface to detect hidden defects such as detachments, cavities or fractures; and manual inspections to define the surface consistency (i.e. mortar disaggregation). These can be complemented by more detailed investigations such as laboratory chemical analysis to identify materials and degradation agents, georadar and/or thermographic inspections to locate hidden defects, photogrammetric and dynamic laser scanning surveys to check deformations, and pathological material surveys.

One of the objectives of this research is to define an operational protocol for assessing the safety of masonry tunnels through the implementation of a rapid method. Following the approach proposed by CNR-DT 213/2015, the aim is to establish a coefficient for the reduction of the strengths associated with the presence of deterioration and to define the degree of urgency for strengthening interventions in the different areas. This coefficient will be calibrated by comparing the results of in-situ masonry strength tests (single and double flat jacks, drilling energy tests on mortar, and brick sampling for compression test) with expert judgement on the level of deterioration present in the study areas. This makes it possible to estimate the effect of material deterioration on the strength of the masonry and on the risk of detachment.

3 SAFETY ASSESSMENT

3.1 Global safety

The original design reports of the lining could not be found. In those days, empirical methods such as Ritter's method and Kommerell's method were used to calculate thrusts (Steiner, Einstein, 1980). Given the actions, the masonry lining was verified using graphical statics methods derived from Mery's method. Today, verification can be conducted by means of non-linear finite element analysis or limit analysis (Tralli et al, 2014). In the latter case, a portion of the lining is studied as if it were a masonry arch. Unlike masonry arches, however, the possible interaction between the lining and the overlying rock can change the collapse mechanism and the position of the plastic hinges, like shown by the laser scanning surveys, in some cases with a possible beneficial effect on the load-bearing capacity. The stresses calculated in this way can be compared with in-situ stress measurements performed with a single flat jack in order to validate the modelling.

For the ultimate limit state assessment, appropriate partial coefficients on actions and material strengths γ_M must be considered. For compressive

strength, the Italian National Annex of EC6 (2005) prescribes a γ_M coefficient between 2 and 3. The value $\gamma_M = 3$ is often too restrictive for existing masonry tunnels. However, this coefficient was defined for the design of walls of new buildings and has no clear probabilistic basis (Lulić et al., 2023). For a sound assessment of tunnel masonry linings, the partial safety factor should be defined taking into account material variability, model uncertainty, and geometric uncertainties. Model uncertainties should include not only the uncertainty arising from the EC6 (2005) equation used to estimate the compressive strength of the masonry, but also the uncertainty of the model used for the global analysis of the arch.

The calculation should be performed for an assigned probability of failure evaluated for an assigned reference period T_R using the reliability index β . This obviously is different for tunnels than for new buildings. By reducing the reference period T_R , for example by prescribing periodic inspections and safety assessments, the β coefficient and consequently the coefficient γ_M can be reduced as already proposed for existing reinforced concrete bridges (CSLLPP, 2021).

3.2 Local safety

While ensuring the overall safety of the tunnel, it's important not to overlook the local risk, which corresponds, for example, to conditions of detachment of materials that may interact with the carriageway but do not pose a global instability risk to the structure. The Guidelines (D.M. 247, 2022) provide a procedure for evaluating the level 2 local attention class of structures on portions of tunnels which are 10 m long.

In addition to this procedure, this research aims to define a specific investigative method for assessing in a more detailed way the type and level of risk of detachment of individual elements in masonry tunnels, in order to plan focused rehabilitation interventions to prevent blocks from falling. This proposal draws on the methodologies suggested by Salvatici et al. (2020), Ceppetelli (2022), and Mariotti et al. (2023) for stone masonry facades in monumental buildings: through the visual analysis of the stone surface, the detachment hazard index is determined, allowing for a rapid assessment comparable to that obtained through in-situ investigations. In the case of tunnels, the parameters contributing to the definition of the detachment hazard index should be tailored to the specific case, with primary consideration given to the effects of water, the main cause of deterioration in these structures.

4 CONCLUSIONS AND FUTURE DEVELOPMENTS

The present paper presents a new approach to the local and global safety assessment of historical masonry tunnels, starting from the analysis process proposed in the Italian guidelines for tunnels and integrating some aspects derived from the Italian guidelines for bridges, the Italian guidelines for

cultural heritage in seismic areas, and data from the scientific literature in the field of historical masonries mechanical properties, and of monumental façades conservation.

The aim is the quantification of the urgency of the interventions, both from a global structural point of view, and also considering the impact of local degradation and material deterioration. The assessment of the masonry strength has been defined adopting equations and coefficients proposed in EC6 for industrial masonry, considering the presence of large thicknesses and multiple brick layers, applied to the strength of bricks (or stones) and mortars obtained through in situ tests. A possible calibration of the Masonry Quality Index specific for the tunnels conditions was also proposed, to take into consideration not only the blocks and mortars properties but also the effects of the texture and other qualitative parameters that were proved for old buildings to have a high impact on the mechanical behaviour of ancient masonries.

A discussion about the material partial safety factor γ_M to be adopted was also made, considering the possibility of reducing it by prescribing periodic inspections and safety assessments, in line with the prescriptions for Italian RC bridges.

Finally, a proposal was made for the assessment of the level of risk of local detachments, starting from the survey of the materials decays and integrating the data with some on site tests, following a method already used for historical buildings subjected to similar risks of local material detachments.

The results obtained with the proposed method will define a priority list for the interventions and possibly a link between the type and level of risk with the type and urgency of the re-habilitation required, also considering the nominal life of the construction.

Considering these tunnels not only as an important operating infrastructure, but also as a specific typology of historical construction, has made it possible to merge different approaches into a single procedure with one aim: plan the conservation activities on these artefacts in order to preserve them in the best possible conditions, for their future use and for the testimony they represent.

ABSTRACT: The *Colle Marino left* project, along A14 Bologna-Taranto highway, is the first case, in Italy, of complete reconstruction of existing tunnel final-lining, from invert to crown, over the entire length (960 m). The technical complexity due to the invert demolition in clayey geological context, with overburden of up to 70 m and adjacent tunnel open to traffic, required firstly an extensive geotechnical-survey campaign and systemic concrete-structures investigations, from which significant linings working rates emerged, especially at maximum overburden in higher plasticity clays. The project therefore provided for a careful planning of invert demolition and reconstruction operations, arranged by segments of various lengths at proper spacing, with the adoption of specific demolition-technologies for early-assessment of invert actual working-conditions and structural-disturbance minimization. Specific monitoring procedures and emergency measures have been also established to counteract deformations and existing lining damaging. After complete invert-reconstruction using PP macro-fibers reinforced concrete, temporary re-opening to traffic preceded crown-piers reconstruction adopting pre-cast arch slabs with SCC back-pouring fully waterproofed by TNT+PVC membrane. Construction works, carried out during several H24 tunnel-closure periods (almost 7 months of net activity), included considerable road platform lowering (65 cm) thanks to the absence of altimetric constraints at portals. This solution reduced milling-depth at crown thus strongly mitigating risks associated to demolition of existing concrete lining extensively guarded by temporary steel nailing. General speeding-up of production was therefore achieved. Industrialization of construction processes was ensured thanks to knowledge framework completeness and efficient site-organization. This valuable know-how allowed to plan similar works on adjacent tunnel by granting daily traffic opening, introducing significant technical optimizations for both invert and crown structures. The innovative TLRG system (Tunnel Renewal Work Train) will be adopted to meet workers-safety and automation of main construction processes (milling, waterproofing and high-performance concrete pouring), while ensuring appropriate level of service for highway users.

Keywords: Tunnel linings retrofitting, invert reconstruction, existing tunnel waterproofing

1 INTRODUCTION

The modernization of the Colle Marino left tunnel constitutes the first case of a tunnel in the Italian motorway

network subjected to complete demolition and reconstruction of the original definitive linings, from the inverted arch to the crown, over the entire length of the bore. The tunnel, built in the early 1970s, is located

*Corresponding author: bruno.spigarelli@tecneautostrade.it

along the northbound carriageway of the A14 Bologna – Taranto motorway, in the section between the Atri-Pineto and Roseto degli Abruzzi junctions. The intervention implemented is part of Autostrade per l'Italia's Tunnel Assessment Plan aimed at modernizing infrastructural assets and, in particular, represents one of the most significant pilot projects scheduled for the two-year period 2022-2023 on certain tunnels of the network for testing of the so-called Tunnel Renewal Strategy (TRS): this strategy responds to the objective of providing motorway tunnels with a new definitive lining that is structurally autonomous and independent from the original one, renewing the nominal life of the work by a further 50 years.

The scope of application of the TRS interventions specifically consists of tunnels whose original final lining is affected by widespread infiltration phenomena and/or by a structural defects framework and a state of concrete deterioration such as not to guarantee the satisfaction of the minimum performance requirements envisaged by current legislation in the load conditions expected over the life of the work, with particular reference to the effects caused by the action of the earthquake. A salient design element of the TRS interventions consists of the installation of a waterproofing system integrated with all the necessary devices for intercepting, collecting and disposing of infiltrating ground water.

The TRS intervention therefore has the objective of definitively resolving (corresponding to the Vn 50 year scenario) the static critical issues of the tunnel, returning the infrastructure to the operating standard specific to new constructions. The waterproofing of the tunnel involves the elimination of the infiltration phenomena previously present and constituting one of the main causes determining the evolution of the degradation of concrete. The introduction of a new structural shell is usually associated with the complete renovation of the carriageway platform with the creation of a new water collection network (where provided), as well as the installation of all the necessary plant equipment in compliance with the most recent sector regulations (e.g. preparation of underground cable routes with adaptation to the new CEI 64-20 regulation) and network integration needs (e.g. installation of cable ducts for fiber optic networks for telephone operators).

The tunnel is also subjected to a geometric regularization of the intrados profile, with homogenization of the free spaces and elimination of any under-profile resulting from imperfections in the construction of the original definitive lining.

Since the first half of 2022, TECNE has started the planning of pilot TRS interventions to be applied on specific tunnels of the network identified among those most in need of a complete lining renewal operation and at the same time located along motorway sections characterized by traffic volumes compatible with the total interruption (24 hours a day) to traffic over minimum time windows of 2/3 months each, the latter being a necessary condition to actuate the experimental design solutions for the complete reconstruction of tunnel crown as well as, as in the specific case of the Colle Marino left, of the invert.

As part of the TRS strategy, TECNE has developed a series of intervention typologies based on the adoption of different construction solutions for the new definitive lining of the tunnels, making use in particular of technologies recently developed in the underground market, both for the choice of structural materials and waterproofing techniques. By way of example, reference is made to the use of modular elements in galvanized steel for liner plates constituting the new lining, to the use of structural shotcrete with high mechanical performance or of high-resistance fibre-reinforced concrete cast on site, to use of prefabricated structural segments.

In the specific case of the Colle Marino left tunnel, for the new final lining (crown/piers) the solution was identified consisting of an arch of 3 prefabricated slabs with completion casting on the back carried out with high-performance self-compacting concrete. The arch is connected to the invert made of

fiber-reinforced concrete cast on site, through a special shear-key joint reinforced with pre-assembled steel cages.

The following contents retrace the process that led to the development of the design solution, provide a description of the extensive geognostic and structural investigation campaign carried out on the tunnel, illustrate the basic concept of the solution and the dimensioning process and verification of the structures, the most interesting evidence collected during construction is summarized. Finally, the technical-technological contents currently being developed for the modernization project of the adjacent tube, i.e. the right Colle Marino tunnel, are anticipated, the field of application of the “fully operational” TRS strategy resulting from the complete return of experience relating to the pilot intervention conducted on the left tunnel. The structural renewal project of the right bore represents a prototype intervention of works with continuous construction operations, foreseeing the closure to traffic at night and the opening of the tunnel during the day with transit of vehicles underneath a system of shield gantries capable of carry out certain processes simultaneously with the use of the tunnel by users, resorting as far as possible to the automation of the processes.

2 DEFINITION OF THE INTERVENTION ON THE LEFT TUNNEL

The left Colle Marino tunnel, almost entirely made up of the natural section excavated in the consistent clays belonging to the Mutignano Formation (Plio-Pleistocene marine deposits), extends for a total of 960 m, presenting maximum overburden of 70 m. The tunnel, in July 2021, was the subject of a thorough inspection conducted in compliance with the New Inspection Manual issued by the MIT (Italian Transportation Ministry) during the year 2020. From this inspection a severe picture emerged in terms of structural degradation of the original

definitive linings for the presence of widespread and persistent cracks in the crown as well as a general state of deterioration of the concrete also determined by the presence of defects which occurred during the casting phase. Furthermore, a good part of the tunnel crown was already protected with previously installed steel wire mesh, precisely because of defects pattern that had emerged over the years. This condition led, in the immediate future, to the use of temporary interventions on the final lining consisting of welded wire mesh coupled in several layers fixed with chemical anchors and, locally, in the most critical sectors, by metal ribs hung from the crown intrados again by chemical anchors (L 450 mm). At the same time, in anticipation of a subsequent and more lasting intervention to resolve the defects, a specific campaign of geognostic investigations was conducted both in the tunnel (continuous core drilling with recovery of undisturbed samples aimed at the geotechnical characterization of the mass as well as the assessment of the mechanical properties of the concrete of the final covering in place), and from ground level (refraction seismic laying with $V_p + V_s$ acquisition, extended to cover the entire longitudinal development of the work). The series of core samples obtained from the invert revealed a critical scenario determined by the modest thicknesses detected (significantly lower than those deduced from the original design documents) and, in particular, by the poor compressive resistance of the cement conglomerate (cylindrical resistance values close to 5 MPa).

The preliminary structural analyzes for the static evaluation of the existing linings confirmed the need to equip the tunnel with a new invert in order to meet the minimum performance requirements required by current legislation, in the specific context of intervention characterized by medium-high seismicity and modest characteristics geomechanics of the soil interacting with the work. Demolition and reconstruction of the invert were therefore included in the design plan for the renewal of the tunnel’s definitive linings, according to the logic of the Tunnel Renewal Strategy. Precisely in light of the complex conservation conditions of the tunnel crown subject to the extensive application of temporary protection interventions, the design solution identified by TECNE pursued the objective of significantly reducing the impact of milling operations in the crown sector (confining it between kidneys and the base of the piers), drastically mitigating the potential risk associated with phenomena of uncontrolled detachment of portions of concrete, beyond the theoretical milling profile, triggered by the mechanical demolition/milling of the covering portions incorporating the anchors chemicals for deep fixing of hanging nets and ribs - particularly pervasive in this tunnel - especially in the sections affected by underthickness of the original lining. Furthermore, the deep anchoring bars would have constituted an obstacle to the correct functioning of the milling head, with the possibility of damage and risk of machine downtime.

The total elimination of milling in the central sector of the crown, with the inscription of the new intrados geometry within the profile of the original lining, was achieved as a result of the design choice to implement a significant lowering of the motorway platform (average value 65 cm in roadway axis), permitted by the absence of altimetric constraints at portals (i.e. structures such as bridges, viaduct abutments, underpasses). This option, in the specific case of the Colle Marino sx tunnel, introduces extra costs that are not significant in economic and temporal terms, precisely due to its inclusion in the context of a design solution already contemplating the demolition and reconstruction of the invert. The lowering of the platform made it necessary to design platform altimetric connections with a development limited to within a hundred metres, at each tunnel portal.

3 TECHNICAL CHARACTERISTICS OF THE ORIGINAL TUNNEL

Prior to the development of the design solution, a careful examination of the original design documentation of the tunnel was conducted, as mentioned dating back to the late 1960s, preserved in the Autostrade archives. It was possible to analyze a large number of documents relating to the construction phase of the work, in particular accounting drawings representing in detail the temporary linings (ribs and spritz), the carpentry of the different type-sections applied for the natural tunnel, artificial tunnels and portal (carpentry and armor works). Of particular importance is the availability of the calculation reports of the final linings of both the natural section and the artificial tunnel, from which it is possible to trace the dimensioning and verification approaches of the aforementioned linings, and of the Works Journal useful for the reconstruction of the succession of the construction phases of the the work as a whole, the methods of excavation of the two arches, and any critical issues that occurred in the progress of the works. From this analysis it was possible to deduce how the excavation of the left tube (object of the intervention) was attacked on the Bologna side, anticipating the start of the adjacent tube, adopting the full front advancement technique with systematic installation of reticular ribs (spacing 0.8 /1.00 m) incorporated inside a shotcrete shell 15/20 cm thick, probably among the first examples in Italy of full-section excavation considering the year of construction of the work.

The construction sequence therefore included the casting of the walls, the excavation and casting of the invert (unreinforced, thickness 70 cm), the completion of the lining with the crown castings (unreinforced, thickness varying from 70 to 90 cm, depending on the section-type applied). From the examination of the *Giornale Lavori* there are no particular critical issues during the excavation phase on both arches. The artificial section on the Pescara side

extends for approximately 22 m; the work, according to accounting drawings, appears to be entirely reinforced (crown/pier/inverted arch) for the first 14 m, the last 8 m feature exclusively crown reinforcement. The artificial section on the Bologna side, with a total length of 120 m, required very significant excavation excavations. The significant thickness of the filling determined the use of massive structural sections, with crown thicknesses of 120 cm and abutment thicknesses of up to 150 cm at the base. According to the original design documentation, the crowns of the artificial tunnel are reinforced everywhere, while the piers and the inverted arch are reinforced only on the 50 m section starting from the entrance. It is interesting to note the presence of a notch on the valley side of the inverted arch, evidently introduced to counteract the asymmetrical thrust of the earth filling/covering.

4 STRUCTURAL INVESTIGATION CAMPAIGN PREPARATORY FOR EXECUTIVE DESIGN

The tunnel was the subject of a vast campaign of structural investigations preparatory to the detailed executive design of the intervention, in particular to the safe management of the demolition and reconstruction operations of the inverted arch and deep milling of the tunnel piers. The need to have a particularly accurate cognitive framework of the actual thicknesses of the linings (crown/piers and inverted arch), of their work rate, of the physical-mechanical characteristics of the concrete is dictated by the specificity of the intervention context, interacting the tunnel with an averagely consistent clay formation, locally characterized by mechanically poorer sectors from the examination of the results of the extensive geophysical investigation campaign conducted from the surface, precisely in the central part of the tunnel which corresponds to the maximum coverage in crown. This plan consisted in the preparation of approximately 40 investigation sections, placed at a distance of 24 m, where the following tests were carried out:

- N.2 flat jack tests in inverted arch performed inside trenches made on the platform; in particular, the test located on the adjacent tunnel side (hypothesized to be more stressed due to the construction history of the tunnel) was carried out using an innovative method which involves the measurement of the strain value on the surface in correspondence with subsequent cutting steps, with the aim of detect the evolution of the detensioning as a function of the cutting depth. On the opposite side of the inverted arch, traditional tests were conducted (single cycle tests, loading/unloading, with determination of the recovery pressure).
- N. 2 traditional flat jack tests, on the abutments (left/right), at a height of approximately

- 1.50 m from the pavement level (single cycle tests, loading/unloading, with determination of the recovery pressure);
- N. 2 core drillings passing through the piers (left/right), at a height of approximately 1.50 m from the pavement level, pushed up to the interception of the clay mass, with recovery of concrete samples of the final covering and of the constituent shotcrete the first phase lining (including stratigraphic reconstruction with identification of the thicknesses of the two types of lining).

Throughout the development of the work, ground penetrating radar systems were therefore carried out at the height of the piers, with a specifically defined spectral content for the purpose of reconstructing the thickness of the definitive lining and the pre-lining (since the presence of the reticular ribs was known), also being able “calibrate” the GPR interpretation on the dense series of direct acquisitions consisting of structural core drilling carried out on both the left and right sides with a 24 m spacing.

5 RESULTS OF THE STRUCTURAL INVESTIGATION CAMPAIGN

From the investigation campaign an extremely detailed cognitive picture of the final linings of the natural tunnel emerged. With a frequency of 24 m it was possible to reconstruct the tensional regime acting in the piers and in the inverted arch (associated with similar data already available for the crown sector, key section and kidneys, on the basis of the flat jack tests conducted during the inspection phase in the year 2021), correlating the same to the overburden and the mechanical quality of the soil/rock mass interacting with the tunnel (obtained from the continuous data returned from the surface seismic tests, integrated and calibrated with the evidence of the direct geognostic investigations conducted in the tunnel), as well as the actual concrete thicknesses. To confirm the expected scenario, different sectors of the tunnel were identified with abutments and inverted arches subject to a non-negligible work rate and clearly higher than the tension level associated only with the self-weight of the final linings, a symptomatic situation of a rock mass-structure interaction that has occurred during the excavation phase and, presumably, considering the construction methods deriving from the Work Journal, during the years following the tunnel construction (evolution attributable to the partial physical-mechanical decay of the temporary linings as well as to possible phenomena of stress-strain release in the time, of a viscous nature, occurred in the clayey passages characterized by greater plasticity of the material (and corresponding reduced mechanical characteristics), clearly detectable by the analysis of the V_p - V_s tomographies processed by the seismic refraction survey conducted from the surface.

Of particular importance are the results of the GPR investigations conducted along the piers, as it was possible to identify numerous tunnel sectors with significant under-thicknesses evidently determined by the compensation of tracking errors during the excavation phase. In certain areas, reductions in thickness of up to 50 cm have been recorded compared to the theoretical derivable from historical design documents. The compressive strength of the piers concrete was found to be affected by a modest variability along the development of the tunnel, averaging around 15 MPa (cylindrical strength). Of note is the good quality level of the first phase shotcrete sampled in the core sampling campaign; the simple compression tests returned an average value of 35 MPa.

This evidence significantly guided the process of identifying the design solution and, specifically, the articulation of the operational phases and the scanning of the so-called elementary fields of works-progress of the inverted arch and crown/pier reconstruction.

6 GENESIS OF THE DESIGN INTERVENTION AND ADOPTION OF SPECIFIC TECHNICAL SOLUTIONS

The typical section of the intervention on the natural tunnel was conceived according to the specific construction phases of the work. In particular, the annual arrangement of the windows permanently closed to vehicular traffic, in the reference section (A14, Atri-Pineto/Roseto degli Abruzzi) constituted the main constraint for the organization of the complete renewal works of the definitive coverings of the Opera. This motorway section along the Adriatic coast is affected by particularly intense vehicular flows during the entire summer season and during the main national holidays (Christmas, Easter, All Saints' Day and the Immaculate Conception). The Management of Section 7 has therefore defined the need to guarantee the reopening of the tunnel in the aforementioned periods, consequently determining the distribution and duration of the periods of permanent closure of the tunnel useful for the implementation of the intervention. The most significant time windows in terms of continuous days of closure to traffic of the left tube (northbound) were therefore identified as a priority, for carrying out the intervention with the greatest static commitment of the renewal project, i.e. the demolition and reconstruction of the inverted arch over the entire length of the natural tunnel and approximately 80 m of artificial tunnel, for a total of approximately 900 linear m. This operation was divided into two macro-phases of work: November 2022 (70 m of inverted arch reconstructed on the artificial Bologna side) and January-March 2023 (830 m of inverted arch reconstructed on the entire length of the natural tunnel and on the artificial side Pescara). At the end of the reconstruction of the inverted arch, for the Easter holidays, the Trunk Management requested the reopening of the fornix to vehicular traffic.

The design solution was therefore conceived to allow the return of the work to operation albeit with a partial structural renewal intervention, limited to the inverted arch only: the demolition of the existing inverted arch was therefore carried out with methods aimed at preserving the structures of crown and abutment, making sub-vertical cuts in the base portion of the abutment, extending longitudinally over the entire development of the fornix, both on the right and left side, as well as transversal cuts in an inverted arch, spaced correspondingly to the length established for the elementary field of progress of the works, in order to contain the propagation of the vibrations induced by the mechanical action of the demolition hammer acting on the inverted concrete. The elementary advancement range for inverted arch workings was defined as 6m or 12m based on the evidence of the structural and geotechnical investigation campaign, as well as the results of the longitudinal cutting operations carried out well in advance to pay attention to any resealing phenomena cuts symptomatic of the structures' work rate.

The new inverted arch has a thickness of 45 cm (increased to 60 cm in the tunnel sectors on which a more significant work rate of the linings was measured, in particular in the original inverted arch), and is made with fiber-reinforced concrete casting having Rck 45 MPa (locally reinforced in correspondence with the sectors mentioned above for the application of the increased thickness section).

In order to restore the structural continuity of the coverings during the temporary reopening to vehicular traffic, in the minimum terms of confinement at the foot of the abutment structures freed from the longitudinal cutting and demolition operation of the existing inverted arch, special temporary curbs were introduced connection cast in place against the surface of the longitudinal cut of the abutment and the recess of the cutting key present on both sides of the inverted arch. The interposition of EPS panels and metal sheets on the lateral surfaces of the curbs is functional to the preservation of the concrete of the definitive inverted arch during the demolition operations of the temporary curbs, necessary to proceed with the construction of the new crown covering.

The shell cladding was designed with the aim of minimizing the structural thickness to just 35 cm, adopting prefabricated lattice slabs with lowered geometry to allow easier handling during launching and arch formation. The back casting is made of class C40/50 self-compacting concrete. The waterproofing layer is made up of a layer of 500 g/m² geotextile and a 2.0 mm thick PVC layer. At the foot of the abutment there is a micro-cracked pipe DN 110 mm, intercepted every 12 m by transversal drains which deliver to the DN200 collector located under the pavement.

A less invasive intervention was adopted on the artificial tunnels, as the original linings were

reinforced, the latter condition causing greater difficulties when milling. The coverings were first subjected to extraordinary maintenance interventions with the aim of resolving all structural defects (remediation of construction defects, sealing of cracks). In order to restore a work with an aesthetic effect in line with that offered by the new crown coverings of the natural tunnel, it was decided to install an internal lining in galvanized steel sheet panels (stiffened with appropriate ribs to achieve suitable rigidity of the elements in launch phase).

7 INTERVENTION DESIGN CRITERIA

The new lining of the crown and inverted arch was sized and verified through detailed numerical modeling which firstly reconstructed the construction phases of the original tunnel (simulating the full face excavation operations followed by the inverted arch excavation) with the aim of calibrating the stress state of the final linings reproduced in the FEM model on the real work rate recorded in the tunnel by the flat jacks installed in the preparatory investigation phase for the executive design of the intervention. The new lining was then subjected to load conditions corresponding to theoretical scenarios identified with a conservative approach, hypothesizing, for example, the total mechanical decay of the concrete of the residual original lining portions after milling, as well as the de-functionalization of the pre-linings (ribs and spritz), i.e. the total absence of load on the new coverings and the concomitant shear deformation generated by the seismic action.

8 MAIN EVIDENCES FROM THE EXECUTION OF THE WORKS

The main evidence returned from the construction phase consisted in the verification of geometries of the existing inverted arch different from those reported in the historical archive documents, frequently revealing under-thicknesses compared to the theoretical value as well as lowered intrados profiles and only partially abutting the walls (with consequent penalization of the theoretical confinement action at the foot of the piers). These results confirmed the strategic layout of the design solution for the integral reconstruction of the inverted arch to respond to the most stringent regulatory requirements in terms of structural performance of the tunnel linings under seismic action. The demolition operations of the inverted arch were accompanied by extensive manual topographic monitoring of the deformations that occurred at the foot of the abutment following the demolition of the inverted arch itself. The design forecast of interception of tunnel sectors interacting with rock mass sectors characterized by more demanding conditions in terms of interaction with the structures was essentially confirmed. This evidence confirmed the validity of the choice to implement an extensive

campaign of structural investigations preparatory to the detailed executive planning of the intervention, thanks to which it was possible to reconstruct a detailed cognitive framework on the basis of which to identify the most critical tunnel sectors, guiding the field work and carefully planning the use of protective devices such as the contrasting metal strut.

The synergy between the design group, works management and contractor made it possible to achieve the ambitious objective of demolition and reconstruction of approximately 900 m of inverted arch in the limited time span of 3 months (Jan/Feb/Mar 2023), the first case in a motorway tunnel of the Italian network. The reconstruction work on the crown, which is expected to be completed by March 2024, confirmed the flexibility of the construction solution based on the adoption of prefabricated slabs as disposable formwork, being able to attach multiple work fronts at the same time, to guarantee high production (approximately 350 m of shell in 2 months of work).

9 COLLE MARINO RIGH TUNNEL FUTURE PROJECT DEVELOPMENTS

On the basis of the feedback from the experience gathered from the work carried out on the left tube, the executive project for the similar integral reconstruction of the final linings on the right tube was developed. The intervention involves significant technical optimizations, consisting of the adoption of new inverted arch geometries that are smaller and similar to a slab placed on the intrados of the original building, pursuing the objective of minimizing the demolition of the existing structure (which in any case is totally defunctionalized once the new base slab is completed). The shell lining is made of a cast HPC concrete characterized by the addition of steel and polypropylene fibres, with very high mechanical performance. The main innovation associated with the intervention being designed on the right tube, however, consists of the adoption of a construction system based on work trucks under which vehicular traffic passes during the daytime hours when it is open to traffic.

This technology, experimental and in its first application on the motorway network, is aimed at carrying out the works in temporal continuity, regardless of the needs of motorway operations which impose frequent interruptions of the works with associated diseconomies and extensions of the completion times of the interventions and, above all to the increase in safety conditions for users by always being able to guarantee a traffic lane during the day on the roadway on which the tunnel

affected by the works is located in the face of the total closure of the fornix to traffic adopted so far for the execution of structural interventions of such importance that it determined the operation of the adjacent barrel in bidirectional mode. The train of wagons consists of a special wagon for milling with dust extraction, a wagon for the automated installation of waterproofing, a wagon with integrated formwork for casting high-performance fibre-reinforced concrete. The train is completed by an invitation wagon which guarantees the correct direction of traffic within the shield, in compliance with the safety conditions established by the technical regulations. The application of this technological solution is expected, on the right tube of the Colle Marino Tunnel, in the first months of 2025.

Encarnación Quesada Ruiz

Marketing Director, Gijón, Spain

ABSTRACT: Longitudinal ventilation plays a crucial role in ensuring safe and efficient operation of underground tunnels. Over the years, Zitron has encountered and overcome various challenges associated with longitudinal ventilation systems in tunnels. This paper presents a comprehensive analysis of the lessons learned from these experiences and explores innovative solutions using Computational Fluid Dynamics (CFD) tools.

The study addresses several critical questions that arise during the design and installation of longitudinal ventilation systems. Firstly, it investigates the optimal spacing between jet fans in tunnels with wide cross-sectional areas. Secondly, the paper investigates the impact of placing information panels in the proximity of jet fans and provides insights into mitigating potential issues. Additionally, it explores the most suitable longitudinal distribution between fan banks to minimize electrical cable usage while maintaining effective ventilation. The feasibility of installing jet fans at tunnel portals is examined, considering the trade-offs between tunnel length, fan quantity, and overall ventilation performance.

Furthermore, it also addresses the challenge of insufficient longitudinal ventilation in existing tunnels through a case study of a tunnel, highlighting successful strategies for improving airflow distribution and enhancing safety.

The results demonstrate the effectiveness of CFD-based tools in optimizing longitudinal ventilation designs, ensuring proper airflow distribution, and validating the performance of the ventilation systems. The lessons learned from Zitron's extensive experience, coupled with the power of CFD tools, provide a valuable resource for engineers, researchers, and professionals in the field of underground infrastructure.

Keywords: Longitudinal ventilation, CFD simulation

1 INTRODUCTION

The design and implementation of longitudinal ventilation systems in tunnels present unique challenges that require careful consideration. This paper presents lessons learned from real-world tunnel ventilation scenarios and proposes innovative solutions using Computational Fluid Dynamics (CFD) tools to address these challenges.

The paper explores several key questions that arise during the design and installation of longitudinal ventilation systems. Firstly, it investigates the optimal spacing between jet fans in tunnels with wide cross-sectional areas. Secondly, it analyses the optimal placement of information panels in proximity to reversible jet fans, considering factors such as airflow distribution and speed. Additionally, it explores the ideal longitudinal distribution to optimize energy

*Corresponding author: anabelen@zitron.com

efficiency and maintain effective ventilation. Furthermore, this paper addresses the challenge of inadequate longitudinal ventilation in existing tunnels through a case study of a tunnel in the Netherlands, showcasing successful strategies for improving airflow distribution and enhancing safety.

The results emphasize the effectiveness of utilizing CFD-based tools in optimizing longitudinal ventilation designs, ensuring proper airflow distribution, and validating ventilation system performance.

2 TUNNEL WITH LARGE CROSS-SECTION

In this tunnel, reversible jet fans with a diameter of 1200 mm and a power rating of 45 kW are installed in pairs. The tunnel's cross-sectional area measures approximately 88.6 m² and is notably wide, as seen in Figure 1. Given the absence of placement restrictions, a Computational Fluid Dynamics (CFD) analysis was conducted to determine the optimal fan spacing for this section.

Figure 1. Tunnel cross-section.

Four CFD simulations were performed, varying the distances between fans at 1.8m, 2.4m, 3m, and 5m, aiming to identify which configuration yielded the highest airflow rate or average velocity within the tunnel. Figure 2 and 3 illustrates the results, presenting a plan view and cross-sectional profiles along the tunnel of the different simulations. The colour scale represents velocities ranging from 0 to 10 m/s.

Figure 2. Contours of velocity different simulations.

Figure 3. Cross sections of contours of velocity.

The graphical results reveal that greater fan spacing leads to a more favourable average velocity within the tunnel. Consequently, for this particular tunnel with a substantially wide cross-section, the optimal configuration involves placing the fans 5 meters apart. This configuration results in a 5.7% increase in velocity compared to a 1.8 meter spacing, while also there is enough separation for electrical installation trays, as demonstrated in Figure 4, consistent with practices in other tunnels.

Figure 4. Tunnels with significant jet fans spacing.

3 TUNNEL WITH INFORMATION PANELS

During the installation of reversible jet fans in a tunnel, technicians noticed that information panels would be located nearby. These raised questions about whether there would be a change in tunnel velocity and what the optimal distance would be to place the information panels in these circumstances. To address these concerns, Computational Fluid Dynamics (CFD) simulations were conducted. These simulations considered the geometry of the tunnel in question along

with the installed ventilation system, pairs of 1200 mm diameter, 30 kW jet fans, and information panels placed at different distances, ranging from 5 to 100 meters, to gain a broader understanding of what might occur.

In Figure 5, various velocity contours obtained from the CFD simulations are displayed. These contours illustrate scenarios where the information panel is positioned at different distances from the fan on the impulsion side. The colour scale represents velocity ranging from 0 to 10 m/s, with red indicating velocities of 9 m/s or higher. It is observed that in the absence of an information panel, the tunnel exhibits an average velocity of 4.67 m/s. However, when an information panel is placed on the impulsion side of the fans at varying distances, a collision occurs between the fan's jet and the information panel, resulting in a consequent reduction in the tunnel's average velocity. When the panel is positioned 5 meters away, the average velocity decreases by 36%. Conversely, if the panel is placed 100 meters away, there is a 4% reduction in comparison to the average velocity generated without any obstacles.

Figure 5. Contours of velocity with information panel on the impulsion side of jet fans.

In scenarios where the information panel is located in the aspiration zone of the jet fans at different distances, Figure 6 illustrates that the reduction in average tunnel velocity due to the obstructive nature of the information panel is much smaller. In fact, the reduction is only 2% less than the velocity without a panel when the panel is situated at 5 meters.

Figure 6. Contours of velocity with information panel on the aspiration side of jet fans.

Based on the results obtained from the simulations, the following solutions are proposed:

In unidirectional tunnels, it is recommended to position the information panels on the aspiration side of the jet fans if possible. This placement minimizes their impact on the tunnel's average velocity.

In bidirectional tunnels, a compromise solution should be sought. Information panels should be placed as far away as possible from the jet fans to minimize their impact on tunnel airflow.

4 TUNNEL AND FAN DISTRIBUTION

This tunnel boasts a length of 505 meters, a cross-sectional area of 166 m², and a 2% gradient. It is an unidirectional urban tunnel with high traffic density. A study conducted for this tunnel indicated the need for 6 jet fans with an inner diameter of 1000 mm and a power rating of 30 kW to fulfil ventilation requirements in both normal and emergency modes. To determine the optimal fan distribution in terms of the average airflow generated within the tunnel and the length of cable used in the installation, simulations using Computational Fluid Dynamics (CFD) were employed. It's essential to note that the electrical technical room was located at the tunnel's entrance.

Four different fan distributions within the tunnel were considered, and the graphical results are depicted in Figure 7. The colour scale represents velocity ranging from 0 to 15 m/s, with red indicating velocities equal to or exceeding 14 m/s.

Figure 7. Contours of velocity at fans level for different distributions.

In **Case 1**, the six required jet fans in this tunnel were divided into three banks, with a distance of 12 hydraulic diameters (140 m) from the entrance to the first bank and 10 hydraulic diameters (117 m) between banks, following CETU guidelines. With these conditions, the fans move 850 m³/s of air within the tunnel. Taking into account that the electrical technical room is located at the tunnel entrance, the minimum cable distance required with this distribution would be 1662 m, considering a cost of € 100 per meter (materials + labour), then incurring a final electrical cost of 166.200 euros.

In **Case 2A**, the distribution was modified to consist of two banks of three fans each. The first bank is located 12 hydraulic diameters (140 m) from the entrance, and the second bank is positioned 10 hydraulic diameters (117 m) from the first. This configuration yielded an airflow of 892 m³/s, a 4.7% improvement over the previous case. Additionally, the cable length required was reduced to 1311 m, resulting in a cost of 131.100 euros.

In **Case 2B**, there are still two banks of three fans each, but the position of the first bank has been changed to the vicinity of the tunnel entrance, with the next bank situated 12 hydraulic diameters (140 m) from the entrance. This arrangement guarantees an airflow of 905 m³/s (1.4% more than Case 2A) within the tunnel, with a reduced cable length of 540 m, incurring a cost of 54.000 euros.

Finally, in **Case 3**, all six fans were placed at the tunnel entrance. This configuration achieved 944 m³/s (4.1% more than Case 2B) and required approximately 62 m of cable. However, this option was discarded due to potential safety risks, especially in the event of a fire at the tunnel entrance that could damage most of the fans.

Therefore, the optimal fan distribution, considering the highest airflow achieved within the tunnel, the shortest cable length, and cost-effectiveness, is Case 2B.

However, when the results were presented for approval, it was discovered that the tunnel was not straight but had a pronounced curve, as shown in Figure 8.

Figure 8. Tunnel geometry.

It was uncertain whether the fluid behaviour would be the same in a curved tunnel, and to avoid assumptions, additional simulations were conducted with the corrected tunnel layout while maintaining the same distribution cases as before. The new graphical results, compared to the previous ones, can be seen in Figure 9.

In **Case 1**, in the curved tunnel with three banks of fans, the airflow when the fans were operational was 838 m³/s. In **Case 2A**, an airflow of 887 m³/s was achieved inside the tunnel. For **Case 2B**, an airflow of 884 m³/s was achieved, and for Case 3, it was 886 m³/s. Choosing **Case 3** is still ruled out as a risky option.

Figure 9. Comparison of velocity contours in straight and curved tunnels.

It is evident that in all cases, the airflow generated is lower than in the straight tunnel due to the reduced effectiveness of the fans' jets when directed toward the tunnel walls.

Although Case 2A in the curved tunnel is slightly better than Case 2B, the reduction in cable length required for Case 2B is considered significant. Therefore, Case 2B remains the best option for fan distribution in this tunnel.

5 TUNNEL WITH VENTILATION ISSUES

This tunnel, situated near an airport, spans a length of 536 meters with a cross-sectional area of 75 m². Inside, there are 19 jet fans equipped with deflectors, featuring a diameter of 700 mm and a power rating of 15 kW. These fans are not evenly distributed but are positioned on one side of the tunnel. Despite its relatively short length and numerous fans, ventilation issues have been observed within the tunnel. Strong winds (~5 m/s) blowing into the tunnel, opposing the ventilation, are a common occurrence. To identify the root of the problem, a Computational Fluid Dynamics (CFD) simulation was conducted to analyse airflow behaviour within the tunnel when ventilation was in operation and wind was acting against it.

In the graphical results obtained from the CFD simulation, as depicted in Figures 10 and 11, it is evident that the velocity distribution within the tunnel is non-uniform, with low velocities and even flow recirculation along the side opposite to the fans.

Figure 10. Contours of velocity in different cross-sections.

Figure 11. Path lines of velocity inside the tunnel.

Thus, under these conditions, it is confirmed that ventilation is not adequate in all areas of the tunnel, as initially suspected.

As a solution to counteract the wind effect within the tunnel and homogenize the velocity, various fan configurations were tested. The most effective result was achieved by adding two additional fans near the tunnel exit on the side opposite to the others.

Graphical results obtained from the CFD simulation with the added tunnel fans are presented in Figures 12 and 13.

Figure 12. Velocity contours in different cross-sections with two new jet fans.

Figure 13. Path lines of velocity inside the tunnel, including two new jet fans.

These images demonstrate that the installation of two new fans near the tunnel exit, on the opposite side wall from the existing fans, achieves equal or higher velocities exceeding 1.5 m/s in all tunnel sections, effectively eliminating the previous air

recirculation issues, even when strong winds at the tunnel portal blow into the tunnel.

6 CONCLUSIONS

The research conducted on tunnel ventilation and the proposed solutions through CFD simulations has yielded valuable insights into addressing specific ventilation challenges in different tunnel scenarios.

For tunnels with a large cross-section, the optimal solution involves placing fans at meters apart. The case study of this paper with 5m increases tunnel velocity by 5.7% compared to a 1.8-meter separation and also separates the fans from electrical installation trays.

In the case of tunnels with information panels, it has been determined that in unidirectional tunnels, placing information panels on the aspiration side of the fans is the optimal solution. This placement has a lesser impact on the tunnel's average velocity. However, in bidirectional tunnels, a compromise solution is needed, with information panels placed as far away as possible from the fans.

In relation to the distribution of fans in tunnels with significant traffic density, the optimal configuration consists of two banks of three fans each, with the first bank located at the portal and the second bank positioned 12 hydraulic diameters from the portal. This configuration maximizes tunnel velocity while minimizing the length of cable required for installation. The option of placing all six fans at the tunnel entrance is discouraged due to potential safety risks, especially in case of a tunnel fire.

In the case of curved tunnels, the effectiveness of jet fans is reduced compared to straight tunnels due to the diversion of air towards the tunnel walls. Despite slight variations, the configuration with two banks of three fans each, one in the portal, remains the most practical choice, particularly considering cable length requirements.

In tunnels experiencing ventilation issues due to strong winds blowing against the ventilation direction, adding two additional fans near the exit portal effectively counters the wind effect, achieving velocities of 1.5 m/s or higher in all tunnel sections and eliminating air recirculation, even with strong winds blowing into the tunnel.

In summary, no tunnels are the same and each one has its own challenges, but the use of CFD allows for faster and more reliable solutions. The research provides valuable recommendations for optimizing tunnel ventilation in various scenarios, taking into account factors such as fan placement, tunnel geometry, and safety considerations.

Italian guidelines for the risk classification, safety evaluation and monitoring of existing tunnels: An overview

Andrea Carigi* & Carmine Todaro
Politecnico di Torino, Turin, Italy

Giuseppe Silvestri
Consiglio Superiore dei Lavori Pubblici, Rome, Italy

ABSTRACT: The Italian transport network had a great expansion after World War II and a great number of tunnels were built. After 70 years, those tunnels are approaching their design lifetime. With more than 9000 tunnels extended for 2600 km of underground structures on the Italian national territory, the correct management of this asset is challenging, especially in the context of a complex road network.

To provide an integrated method to monitor and plan the maintenance actions for the different stakeholders on a national scale, a Guideline for the risk classification, safety evaluation and monitoring of existing tunnels has been implemented by the Italian Superior Council of Public Works and is now mandatory for roadways tunnels in Italy. The guidelines are structured in 5 levels with progressively increasing levels of knowledge requirements and detail of the investigation, where level 0 is dedicated to a census of all the available information about the tunnel, level 1 is dedicated to the inspections that have to be carried out with the help of a specifically designed defect catalogue. Then, accordingly to the data collected, in level 2 a classification to prioritize further investigations, standard maintenance procedures, or ad hoc designs is regulated through a series of logical operators to ensure that the same classification procedure is used for all the tunnels in the national territory. This last level is subdivided into 6 fields with regard to specific critical phenomena that may lead to a risk to the proper functioning of the tunnel. Then, levels 3 and 4 are respectively dedicated to preliminary and accurate safety evaluations, while the last level regulates the maintenance of tunnels of strategic interest for the nation.

In this paper, a detailed discussion of the structure of the guidelines and about their application is presented.

Keywords: Tunnel, Knowledge, Maintenance, Inspections, Guidelines

1 INTRODUCTION

In the aftermath of World War II, Italy embarked on a plan of infrastructure development, expanding its transport network to accommodate the demands of a growing nation. A crucial component of this expansion was the construction of an extensive network of road and highway tunnels that stretched beneath the complex Italian orography. These tunnels are now nearing the end of their designed lifetimes, having served the nation for over seven decades.

Italian subterranean infrastructure boasts an impressive count, with over 9,000 tunnels spanning an extensive 2,600 km (Pireddu & Bruzzone, 2021). However, the longevity of these critical conduits presents a unique challenge that demands careful consideration and comprehensive management.

As these tunnels have matured over the years, a pressing need has emerged for a holistic approach to their maintenance and safety assessment. The task of ensuring the continued functionality and safety of these subterranean assets has become increasingly complex. In response to this challenge, the Italian Superior Council of Public Works (Italian infrastructure ministry), recognizing the need for a standardized and integrated framework to manage tunnel maintenance, has introduced a Guideline for the Risk Classification, Safety Evaluation and Monitoring of Existing Tunnels (in Italian, “Linee Guida per la Classificazione e Gestione del Rischio, la Valutazione della Sicurezza ed il Monitoraggio delle Gallerie Esistenti”), hereinafter GL2022, adopted by means of the Ministry of sustainable infrastructure and mobility Decree 257/2022. This guideline offers

*Corresponding author: andrea.carigi@polito.it

a comprehensive methodology for safety evaluation and continuous monitoring of Italy's existing tunnels. This approach, now mandatory for all road tunnels in Italy, marks a pivotal moment in the nation's commitment to ensuring the enduring safety and efficiency of its underground infrastructures.

In the following pages, we delve into the structure of this guidelines, exploring its structure, fields of applicability and the base philosophy.

2 GUIDELINES 2022

2.1 Complementary normative

The GL2022 complement the legislative framework, including Legislative Decree 35/2011 and Legislative Decree 264/2006 which, respectively, address the road and fire safety standards for motorway tunnels. Furthermore, it's worth noting that the technical standards for construction introduced in 2018 (in Italian "Norme tecniche per le costruzioni – NTC2018") remain the primary legislative reference for all design criteria.

2.2 Field of applicability

The GL2022 must be implemented comprehensively for all motorway tunnels with a length exceeding 200 meters within the territory of Italy. However, the section pertaining to hydraulic aspects is required also for tunnels with a length less than 200 meters. This exception is primarily driven by the substantial number of underpasses that may be vulnerable to flooding during extreme meteorological events.

Additionally, it's important to note that the GL2022 does not automatically apply to transnational tunnels. The decision is entrusted to the international security committee to establish a consistent method for managing tunnels subject to the regulations of the two nations sharing the infrastructure. This collaborative approach ensures the harmonization of safety standards across international boundaries.

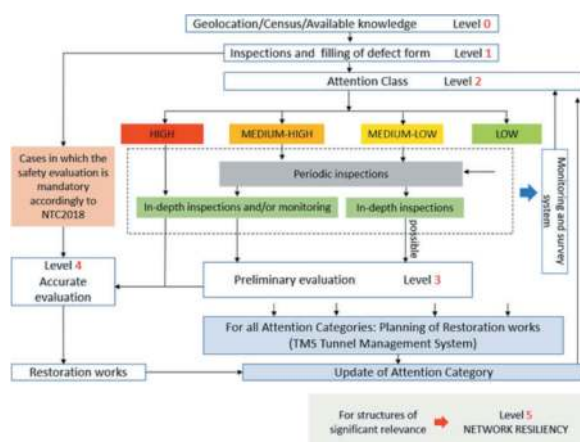

Figure 1. Overall structure of GL2022.

2.3 General structure

The articulated structure of LG2022 is summarized with the flux diagram given in Figure 1 and an in-depth analysis is provided in the following sections where are described the various steps (i.e. levels) to be developed.

2.4 Level 0 – Census

The acquisition of data for the tunnel census, that constitutes Level 0 of the multilevel approach, involves cataloguing all structures within the guideline's scope. The goal is to obtain detailed information about tunnel geometry, structural elements, and existing analyses to better understand their condition, the surrounding road network, and their location. Data collected by managing entities contribute to creating a national database of tunnels, which must be consistently updated in accordance with the guidelines. The census goes beyond a simple count and aims to achieve a comprehensive understanding of existing tunnels, including all available data related to their condition. Tunnel condition is not solely influenced by structural aging but also by various factors, including environmental conditions, initial design choices, construction methods, and maintenance interventions over time. This process helps prioritize initial visual inspections and initiate Level 1 activities. Moreover, the data collected and subsequent visual inspections allow for identifying cases requiring in-depth safety assessments beyond the Level 2 classification. The acquisition of data for the tunnel census is based on analysing available information and documentation. Retrieving technical and administrative documentation related to the tunnel is crucial to gather necessary information for subsequent preliminary risk assessment. Processing and summarizing these data represent a way to capitalize on resources used in previous studies and investigations during the tunnel's design, construction, and operation phases, and become part of the tunnel's technical documentation. It is essential to conduct thorough research of both technical documents (design, construction, subsequent interventions, etc.) and administrative and accounting documents that document the tunnel's evolution over time. Additionally, it is important to search for data documenting the tunnel's role in the transportation system and its socioeconomic implications, including the road or transportation networks the tunnel is part of, traffic volumes, and available alternatives in case of limitations or closures.

2.5 Level 1 – Inspections

Level 1 involves conducting initial inspections on all tunnels catalogued in Level 0 of the census. These inspections are tailored to the specific characteristics of each tunnel and the existing level of knowledge. The primary goal of these initial inspections is to check and to contextualize the data collected during Level 0, gather additional information about the tunnel's geometric and structural features, evaluate the structural

condition, especially for tunnels with limited available information and low knowledge levels. These inspections provide an objective assessment of the tunnel's conditions, including its interior and key structural elements, and require thorough visual examination, which may involve cleaning surfaces for effective assessment of any damages, defects, or infiltrations. The inspection also covers tunnel access areas and non-structural elements such as installations and vertical signage. Visual examinations, supported by portable instruments where necessary, aim to build upon the Level 0 findings and address initial concerns related to the tunnel's characteristics and natural conditions. The Tunnel Officer, with specialist support based on the tunnel's specific features and initial visual inspection findings, should assess whether further, more detailed experimental investigations are needed for defect reconstruction, planning their quantity and location, potentially leading to subsequent in-depth inspections. If specific conditions for the tunnel require additional investigations in terms of quantity and type, as outlined above, the Level 1 phase can still be completed, considering the knowledge gap as a factor that contributes to raising the attention class. This class may be re-evaluated based on the outcomes of subsequent investigations, aligning with the initial attention class priority. During the initial inspection, along with comprehensive photographic documentation and geometric measurements of key tunnel dimensions (where possible), the structural condition is assessed to identify, highlight, and report existing degradation phenomena and defects. Specialized forms or suitable data management systems are utilized for data collection and assessment. These records help identify specific degradation phenomena, their intensity, and extent, which are vital parameters in the Level 2 classification method.

2.6 Level 2 – Attention category classification

The classification of tunnels on a territorial scale involves estimating the “risk” factors associated with these structures. In this phase, the risk estimation is simplified and expedited, conducted by expert judgment (the decision-making process, generally multidisciplinary, coordinated by Tunnel Officer) on the basis of data collected in Level 0 and Level 1. The risk associated with tunnels is approximated using the “Attention Class” (CdA). It's important to note that this isn't a comprehensive risk analysis, which should require more complex investigations.

CdA is a tool for setting priorities for further investigations, verifications, controls, and maintenance planning.

The guidelines include four Attention Classes (CdA):

- High
- Medium-High
- Medium-Low
- Low

The CdA value is determined by evaluating hazard, exposure, and vulnerability, based on available knowledge and Level 1 inspections. The CdA cannot be lower than Low Attention Class or higher than High Attention Class.

Various risk types are considered relevant for tunnels, considering their characteristics and the contexts they're in. These risk types include:

- Global structural and geotechnical risks, such as tunnel and geological interactions.
- Local structural issues within the tunnel, including non-structural elements.
- Seismic risk.
- Road-related risk.
- Geological risk related to landslides.
- Hydraulic risk.

These risks independently and define a separate Attention Class for each are analysed. Each Attention Class is uniquely defined based on the three parameters: hazard, exposure, and vulnerability.

The methods for evaluating and classifying these different CdAs are based on logic flowcharts.

After determining the relevant CdAs, they are combined to obtain the overall CdA of the tunnel, which forms the basis for subsequent actions. The classification method is inspired by risk assessment principles.

Each of the primary and secondary parameters required to define the CdA are determined through expert judgment of the Tunnel Officer, considering both the data collected during knowledge gathering and Level 1 visual inspections. Depending on the primary parameter values a class – among Low, Medium-Low, Medium-High, and High – is assigned, with specific criteria for each parameter. Then, these classes are then adjusted based on secondary parameters, which may have two or more classes.

When hazard, vulnerability, and exposure classes are identified, the Attention Class is derived by combining them according to the general scheme shown in Figure 2, applicable to all risk aspects.

Figure 2. General scheme for the CdA determination.

The tunnel divided in stretches with length about 20m and for each of these segments the Attention Class is defined.

The tunnel's Attention Class corresponds to the most critical segments along the route and then a diffusion index (the percentage of tunnel length for each CdA) is added to further characterise the obtained CdA.

It has to be highlighted that a High Attention Class does not mean directly that there is a risk. Rather, it is a condition where additional investigations and

analysis have to be carried out to understand if a risk is present or not.

In Tables 1 to 6 the primary and secondary parameters used for the definition CdA for the different risk types are given.

The Global Structural and Geotechnical Attention Class concerns the possibility of a global collapse of the tunnel as a consequence of the interaction of the structure with the surrounding soil. It involves considering key parameters that influence the structural behaviour of the tunnel, especially concerning the final lining, at a global level, and its interaction with the surrounding rock mass or soil. This entails evaluating parameters related to the magnitude and variations of the applied loads compared to the design predictions for the final lining, as well as factors related to the structural characteristics of the tunnel linings and their level of defectiveness.

Furthermore, due to the global nature of a potential collapse, the potential exposed subjects have been considered, which include both the tunnel users and any structures and infrastructures above the tunnel that may be affected by ground movements.

Table 1. Parameters for the evaluation of Global structural and geotechnical CdA.

	Primary parameters	Secondary parameters
Hazard	Level of knowledge of geotechnical, hydrogeological, and hydraulic characteristics of the mass and reliability of the geomechanical model	Geomechanical characteristics of the rock mass and/or soil, external factors interacting with the tunnel structure.
Vulnerability	Level of defectiveness, type of tunnel, constituent materials, and construction issues	Rate of degradation, presence of circulating water or infiltration, and presence of the waterproofing layer
Exposure	Level of average daily traffic and tunnel length	Heavy vehicles (mass ≥ 3.5 tons), maximum design speed, alternative routes, interference with buildings and infrastructure

For the Local Structural Attention Class, the primary concern is the possibility of a portion of the lining or any non-structural component detaching and posing a danger to tunnel users. Unlike the previous Attention Class, which only considers local detachments without consequences for overall stability, this class focuses on conditions, including widespread ones, where portions of the lining may interact with the roadway but do not result in global structural instability.

Table 2. Parameters for the evaluation of Local structural CdA.

	Primary parameters	Secondary parameters
Hazard	Presence of water	Characteristic compressive strength of the lining
Vulnerability	Fracture condition, slab thickness (resulting from construction defects) or presence of internal discontinuities in the lining (such as cold joints, casting inhomogeneities)	Presence of reinforcement, lining history and existing deteriorations
Exposure	Level of average daily traffic and tunnel length.	Heavy vehicles (mass ≥ 3.5 tons), maximum design speed, alternative routes

The Seismic Attention Class assesses the potential risks associated with seismic activity on the tunnel, taking into consideration potential local amplification phenomena. In its definition, it was considered that an underground structure, except for portal areas and in case of interference with active faults, is not particularly sensitive to seismic phenomena. It's worth noting that has been included the strategic importance of the structure as an exposure parameter. This is because damage to the tunnel could also affect the emergency response capability for the surrounding area in the event of a seismic event.

Table 3. Parameters for the evaluation of Seismic CdA.

	Primary parameters	Secondary parameters
Hazard	Presence of active faults, susceptibility to landslides, unfavourable geological conditions, Seismic acceleration	Potential local amplification phenomena
Vulnerability	Morphological position, overburden	-
Exposure	Level of average daily traffic and tunnel length	Alternative routes, heavy traffic, strategic importance of the structure

The definition of the Road-related Attention Class considers the key parameters that influence the safety and functionality of the tunnel under normal operating conditions. These parameters encompass aspects related to the tunnel's geometric characteristics, the efficiency of the road surface, its degradation over time, and the volume and composition of

vehicular traffic. Additionally, it includes parameters associated with the operation and management of the road network to which the tunnel belongs.

Table 4. Parameters for the evaluation of Road-related CdA.

	Primary parameters	Secondary parameters
Hazard	Road accidents	Fires
Vulnerability	Road surface defectiveness level, pavement materials	Rate of degradation evolution, design standards
Exposure	Level of average daily traffic and tunnel length	Heavy vehicles (mass ≥ 3.5 tons), maximum design speed, alternative routes

The definition of the Geological Attention Class associated with landslide risk takes into consideration specific parameters indicating the level of the structure's involvement in potential landslide phenomena, both spatially and temporally. In general, artificial tunnels and underpasses in sub-flat areas are excluded from this classification. On the other hand, particular attention should be given to tunnels with low cover and portal areas.

Table 5. Parameters for the evaluation of Geological risk related to landslides CdA.

	Primary parameters	Secondary parameters
Hazard	Slope instability (magnitude, velocity, state of activity)	Mitigation measures or monitoring
Vulnerability	Relationships between the tunnel and morphological conditions: deep instability along the alignment or at the portals, model uncertainty/reliability of the assessment	-
Exposure	Level of average daily traffic and tunnel length	Heavy vehicles (mass ≥ 3.5 tons), maximum design speed, alternative routes, interference with buildings and infrastructure

The Hydraulic Attention Class considers the possibility of aquaplaning caused by flooding of the road, which can result from meteoric contributions and infiltrations from the lining. This class also considers control strategies, focusing on the reliability of capture systems and early alert systems for users. It analyses the causes and identifies the

parameters influencing potential flooding phenomena in the structure, defining flooding as any phenomenon that could compromise the functionality and safety of users.

Table 6. Parameters for the evaluation of Hydraulic CdA.

	Primary parameters	Secondary parameters
Hazard	Precipitation intensity, water table level	Contributing surface at access points, hydraulic conductivity of soils, waterproofing deficiency
Vulnerability	Capture system, conveyance system, gravity or lift return system	Capture system blockage, flammable/hazardous liquid collection system, automatic traffic signal system
Exposure	Level of average daily traffic	Transportation of flammable/hazardous liquids, maximum design speed, exposure reduction systems

After defining CdA values for each 20-meter segment of the tunnel, the various CdAs associated with different risk types are aggregated to calculate an overall CdA for each segment. Subsequently, the tunnel's Attention Class is determined by selecting the highest CdA value found (Figure3). A qualification index is then assigned based on the percentage of tunnel segments falling within this highest CdA category.

Figure 3. Example of representation of the CdAs along the tunnel.

Table 7. Qualification indexes.

Risk type	CdA	Qualification Index
Global structural and geotechnical	Medium-High	10%
Local structural	High	2.5%
Seismic	Medium-High	40%
Road-related	High	5%
Geological risk related to landslides	High	20%
Hydraulic	Medium-High	10%

2.7 Level 3 – Preliminary evaluation

Level 3 preliminary assessment primarily aims to verify the Attention Class assigned to the tunnel in Level 2. It involves a deeper examination of the information obtained in the previous levels, typically based on existing knowledge and data.

The results of the preliminary assessment can lead to two outcomes:

1. Confirmation of a significant risk for the specific context, as previously attributed to the tunnel. In this case, a detailed assessment is necessary.
2. Redefinition of the Attention Class.

If the level of knowledge and available data are deemed insufficient to arrive at a reliable estimate of safety margin, it will be necessary to proceed with an in-depth knowledge assessment and a Level 4 detailed assessment.

2.8 Level 4 – Deep evaluation

Level 4 detailed assessment aims to provide a reliable evaluation of the safety margin associated with specific portions of the tunnel or ancillary works, including portals. It also determines whether any mitigation measures are necessary for a specific risk. The reliability of these assessments must be ensured through an adequate level of knowledge. To achieve this, it will often be necessary to plan and carry out additional investigations and measurements, in addition to the data available from previous levels and from the monitoring systems that will be addressed in chapter 2.11.

2.9 Level 5 – Strategic infrastructures

Level 5 applies to tunnels considered of significant importance within the road network. For such structures, it is useful to conduct more sophisticated analyses, such as network resilience assessments, by evaluating their transport relevance, analysing the interaction between the structure and the road network to which it belongs, and assessing the consequences of a possible disruption of tunnel operations on the socio-economic context in which it is situated. Due to the importance and the specificity of each of these tunnels, the approach to be used is not specifically regulated by the GL2022 to not constrain the approach of the owner in the management of the infrastructure.

2.10 Regulatory compliance

Three main figures are identified in the GL2022: the Tunnel Manager, that is the Body that owns the road or the concession holder, the Tunnel Officer and the Inspector.

The Tunnel Manager must appoint a Tunnel Officer with specific expertise in tunnel management and maintenance. This Officer will oversee and coordinate activities based on the guidelines, under the Operator’s supervision.

The Tunnel Officer can oversee multiple tunnels but must have an adequately staffed and skilled operational structure. Also, has to plan activities per the guidelines and coordinate inspections, involving specialists from various disciplines. They must also provide data for the annual tunnel condition report.

Inspections come in different types, as described in Annex 4 of LG2022, and frequencies based on the assigned attention class to the tunnels as described in Table 7.

Table 8. Inspection frequencies.

Inspection	Low	Medium-Low	Medium-High	High
Initial	At the beginning of the Level 1			
Detailed	6 years	4 years	2 years	1 year
Regular periodic	1 year	6 months	3 months	2 months
Post-incident	After a relevant event			

Operators must document inspections with records listing participants and their evaluations. Inspections also cover tunnel-adjacent spaces and specific external zones. If the lining prevents visual inspection, temporary removal procedures should be adopted.

The inspection program considers maintenance and inspection needs from other regulations and aims to minimize impacts on traffic.

Inspections are carried out by competent technical personnel under the Tunnel Officer’s coordination. In the absence of in-house expertise, the Operator may engage external entities with competence.

2.11 Monitoring and investigations

Monitoring programs must be based on a comprehensive examination of existing information and should be tailored to the specific tunnel’s issues, utilizing both direct and indirect types of surveys. Indirect surveys offer the advantage of collecting widespread and non-specific information along the tunnel, usually with relatively quick field operations (high-performance surveys), which is significant for minimizing traffic disruptions.

Measuring indirect physical quantities to correlate with material characteristics and natural formations, as well as assessing their relationships, always requires recourse to direct calibration surveys. This considers the reliability of survey results, which is influenced by the data acquisition phase along with calibration and calibration of the acquisition system relative to the specific conditions and environments in which it operates. It also depends on the processing phase and the representativeness of the adopted reference models and the interpretation phase of the overall measurements, considering direct surveys.

Monitoring programs should also be prepared with specific reference to individual situations, graded, and deepened in relation to the nature and importance of the safety issues identified.

The preparation of investigation and monitoring programs will be coordinated by the Tunnel Officer, who will enlist the expertise of Inspectors and experts while justifying the choices made in relation to specific identified issues.

3 ANNEXES TO GUIDELINES 2022

3.1 *Annex A*

The Annex A contains a “Level 0 Census and Knowledge Sheet” to be compiled for each structure, serving as the initial phase in organizing documentation related to the tunnel. This sheet, signed by the tunnel’s manager, provides an assessment of the existing knowledge level and identifies initial indicators of potential hazards, especially those relevant to classifying attention levels. Additionally, the sheet suggests specific areas for in-depth examination during the tunnel’s ongoing development. While this document serves as a starting point for determining the initial Attention Class, it will be continuously updated over time to maximize understanding of the structure. To efficiently manage this information, employing a computerized data management system is recommended.

3.2 *Annex B*

The defect catalogue serves as a reference throughout various inspection phases for identifying consistent, comparable, and repeatable elements in tunnels, monitoring their evolution over time, and ensuring the objectivity of defect assessments.

The defect list is categorized into sections, including defects due to water presence, surrounding soil-related defects, deterioration in unreinforced sections, defects in lining materials (stone or masonry, concrete), defects in waterproofing, drainage, and surface water collection systems, defects related to structural elements and tunnel geometry, fire-related defects, defects due to inadequate maintenance, defects related to the road platform, defects in non-structural elements and installations.

The defect level should be evaluated by critically analysing inspection results alongside other available information, either documented or obtained through specialized investigations, using expert judgment. It’s crucial for the appointed inspector to gather the necessary elements, through data sheets, to assess the current state of the structure as accurately as possible.

Inspectors should refrain from assessing the causes of defects during inspections, as tunnel contexts often lack straightforward cause-and-effect relationships. Instead, a comprehensive evaluation considering

inspection findings and the overall knowledge base, with the inspector collaborating with specialists, should guide the assessment, especially when a single cause can lead to multiple correlated defects or a single defect can have multiple potential causes.

During inspections, inspectors must geographically reference each defect along the tunnel’s alignment. Geometrically referencing each defect is essential to clearly identify evolutions of the defects in time.

The assignment of defect severity (G), with possible values from 1 (not severe) to 4 (high-severity) is the responsibility of the Tunnel Officer, based on all inspection findings. Additionally, for each defect type, two parameters should be defined: extension (k1) and intensity (k2), which reflect the defect’s spatial spread and magnitude, respectively.

With this information, defect levels can be classified from High, for tunnels with defects that they may lead to the incipient failure or loss of functionality of the structure, to Low for defects that does not pose a significant risk to the structure’s overall stability.

3.3 *Annex C*

In Annex C inspection sheets are given. In the header of each inspection sheet, for each element, it is necessary to indicate:

- The tunnel’s location by providing toponymic information or the road’s name it serves, along with the kilometric progression.
- The identifier of the reference section subject to inspection.
- The date of inspection site visits and the technician who conducted them.

In case the defect is identified on the structure, it is essential to indicate its extent, following the quantitative indicators provided on the specific defect sheet given in Annex B. During the evaluation of the inspection results, these data will be examined to determine the values to be attributed to the defect’s extent using the variable coefficient k1 and the defect’s intensity using coefficient k2. The potential values for these two coefficients, based on the elements identified during the inspection, are outlined in the defect recording and evaluation sheets (Annex C).

Each defect is associated with a severity (G). The presence of high-severity defects, requiring thorough assessment, may indicate significant and/or immediate structural issues potentially endangering user and employee safety. Therefore, they have a considerable impact on determining the defect class level.

Furthermore, for defects of greater severity, there is the option to indicate whether the presence of such defects could jeopardize the structure’s stability and pose a significant risk (“PSg” for a defect affecting the “global” structural response of the structure, and “PSI” for a defect that, although widespread, may lead to local structural crises).

It should be noted that the field inspector should limit themselves to collecting relevant information

for the subsequent defect severity assessment, which will be performed by expert judgment in coordination with the Tunnel Officer.

If a defect listed on the sheet is not identified on the structure, to further characterise the reason why, it should be indicated as follows:

- Use the “NA” box if the defect does not apply to the type of structure and element under examination.
- Use the “NR” box if the defect cannot be detected through visual inspection (e.g., part of the structure is not accessible, etc.).
- Use the “NP” box if the defect is not actually present.

The photo of each defect should be attached to the inspection sheet and appropriately catalogued, numbered, and provided with captions indicating the type of defect, its location, and geometric references within the structural complex.

Finally, each sheet includes a dedicated space for any notes and observations. Emphasis is placed on acquiring as much data as possible during the inspection, so it’s important to note any additional relevant information, even if not explicitly indicated in the sheets. This aligns with the primary function of the inspection, which is to record anything potentially useful and meaningful for subsequent evaluations.

In addition to the defect recording sheets, for each tunnel, it is necessary to verify the data from the tunnel census sheet (Annex A) with the main characteristics of the structure identified during the visual inspection, such as structural type, type and material of structural elements, hydro-geomorphological characteristics of the area, rough geometric layouts, and so on. The information collected in this sheet is useful for verifying and confirming the reliability of the data gathered during the initial census and for enhancing the knowledge of the examined structure.

3.4 Annex D

Within this Safety Management System, various types of inspections are specified:

1. Initial Inspections
2. Detailed Inspections
3. Regular Periodic Inspections
4. Post-Incident Inspections

The frequency of these inspections is determined based on the infrastructure’s Attention Class and environmental conditions.

Authorities overseeing network Operators have the option to conduct their inspections, in addition to those performed by the Operators or other involved bodies.

All inspection findings and observations must be documented, including the use of predefined forms. Detailed inspection reports are required for comprehensive assessments.

Initial inspections are performed when the guidelines are first implemented, upon opening new tunnels, or after major renovations. For existing tunnels, they may also be carried out following significant upgrades or structural changes. These inspections use information gathered from previous activities to establish a baseline knowledge level.

Initial inspections aim to validate the accuracy of available documentation, assess the tunnel’s physical and structural characteristics, and evaluate its overall condition. The outcomes determine the tunnel’s initial Attention Class, which may lead to further assessments for tunnels with limited data or concerning findings.

Detailed inspections are conducted when specific issues or concerns arise during initial or regular periodic inspections, classifying the tunnel as high or medium-high attention, or as required for in-depth investigations. These inspections may involve the removal of non-structural tunnel linings for comprehensive examinations.

Comprehensive assessments encompass various specialized non-destructive and direct testing methods, including laboratory analysis, to investigate structural components. Advanced technologies like laser scanning, thermography, or ground-penetrating radar may be employed to detect hidden defects or anomalies.

Regular periodic inspections are routine assessments based on predefined schedules, adapted to the tunnel’s Attention Class. These inspections are vital to monitor the tunnel’s ongoing condition and ensure safety.

Post-incident inspections are initiated following significant events, such as accidents, fires, structural failures, or seismic activity, which could compromise the tunnel’s stability. These inspections help assess damage and plan necessary repairs or maintenance.

In summary, various inspection types are integral to maintaining the safety and integrity of road and highway tunnels. They involve a combination of visual assessments, non-destructive testing, and, if necessary, in-depth investigations. The data collected during these inspections inform safety evaluations, maintenance programs, and any required interventions, ensuring the ongoing reliability of tunnel infrastructure.

4 CONCLUSIONS

In conclusion, the introduction of Italy’s Guideline for the Risk Classification, Safety Evaluation, and Monitoring of Existing Tunnels (GL2022) represents a significant milestone in the nation’s commitment to the preservation and security of its large number of subterranean infrastructures. As we have summarised in this paper, GL2022 is a multifaceted framework, structured across six steps (levels), each with its specific role and purpose.

Level 0 serves as the information repository. Moving up to Level 1, we encounter the initial inspection phase, where the condition and basic characteristics of each tunnel are assessed. Level 2 takes a more nuanced approach, defining the class of attention for each tunnel, considering various parameters and ultimately providing a comprehensive overview of tunnel's status distinguishing across different possible risk sources. At Level 3, the focus shifts towards regular safety assessments, ensuring that these tunnels continue to meet the required safety standards. At the highest operational level, Level 4, in-depth safety evaluations are developed. Level 5 developed for to strategically significant tunnels.

In adopting GL2022, Italy has established a unified and systematic approach to tunnel management, ensuring that the challenges posed by aging infrastructure are met with a comprehensive and forward-thinking strategy.

Through the institution of an observatory for the application of GL2022, it is ensured an increasing level of knowledge also on the compliance practicality and a periodic review of this technical document

making this regulation a dynamic and evolving tool, able to adapt to the changing landscape of tunnel maintenance and safety.

ABSTRACT: This paper presents a method that enables a finite element (FE) model of shield tunnels to update the geometric changes caused by cracks, using computer vision (CV) techniques and geometric analyses. Currently, there is a shortage of research on the automatic utilization of tunnel damage detection information for updating FE models. Thus, the objective of this study is to automate the process from tunnel damage detection to numerical analyses in order to quickly evaluate the structural capacity. The Segment Anything Model (SAM) and CV techniques are employed to determine the shapes and dimensions of both tunnel components and damages. Geometric analyses are utilized to develop algorithms that automatically transform coordinates and select elements of FE models for updating the geometric changes. A tunnel segment test is conducted to verify the effectiveness of the proposed technique and algorithms.

Keywords: Shield tunnel, Tunnel cracks, Finite elements model, Computer vision techniques, Segment anything model, Geometric analyses

1 INTRODUCTION

Mass Rapid Transit (MRT) systems, an integral component of urban transportation networks worldwide, rely heavily on tunnel infrastructures (Ye and Liu, 2018). As these subterranean passages play host to countless commuters daily, their safety evaluation during operation becomes a subject of paramount academic and practical importance. As urban populations surged and the demand for efficient transportation grew, so did the complexity and length of these MRT tunnels (Yang et al., 2018). Meantime, over time, the material degradation and damages (i.e., cracks, spalling, and leakage) of tunnel structures can pose challenges in accurately assessing their state. Misjudgement of the structural health status of MRT tunnels could cause unexpected safety problems during operation, such as water intrusion, train derailment, and even geological disasters (Liu et al., 2022; Liu et al., 2021b). Therefore, an accurate assessment of the structural health status of MRT tunnels is essential for understanding the structural behaviour and interactions between the tunnels and their surroundings, as well as ensuring uninterrupted, safe transportation for the public.

Generally, convergence prediction can be carried out through data-driven analysis and numerical methods. Data-driven analysis directly evaluates the tunnel health status based on the measured data. Data analysis tools (i.e., empirical models, statistic models, and machine learning methods) can predict the structural responses, identify the tunnel damage, and detect data anomalies to acquire the overall condition of the tunnel (Chen et al., 2021; Ding et al., 2020; Xie et al., 2021; Zhu et al., 2020). However, the precision of analyses driven by data greatly relies on the quality and integrity of the input data. Inadequate, deficient, or antiquated data has the potential to yield misleading results. Many advanced data-driven models, such as deep learning algorithms, can act as “black boxes,” posing a challenge to comprehending the underlying rationale behind their predictions. Alternatively, numerical methods can be used to model the real components of a tunnel and its surrounding environment such as soil, track, and train. These methods solve mechanical equations to determine the tunnel responses, aiding in the evaluation of its safety. During tunnel operation, cracks, spalling, and leakage are the common issues that need to be considered for the assessment of the structural health status (Liu et al., 2021a; Wu et al.,

*Corresponding author: XIANGYU005@e.ntu.edu.sg

2020). It is imperative to ensure that the numerical model (NM) constructed using design files remains up-to-date throughout the duration of the operation period. Currently, a significant challenge for NMs is to model localized damages like cracks, concrete spalling, and leakage within the models. This is primarily because tunnels tend to sustain various forms of localized damages during their operational phase. Manually creating models of these damages is time-consuming, and a resolution that is too coarse may overlook intricate details, while an excessively fine resolution can be costly in terms of computational resources. Therefore, a more efficient approach is needed to accurately simulate local damage in shield tunnels.

In order to achieve automatic updates of the NM with damages, it is typically necessary to perform two primary steps. The first step is the identification of tunnel damages, while the second step entails updating the NM by utilizing the information obtained from the identified damage (Zhang and Lin, 2021). At present, the predominant focus of research lies on the first stage. The development of techniques for identifying structural damage has been enhanced for better accuracy and robustness using various strategies, such as computer vision (CV), structural responses, and natural modes (Ding et al., 2020; Liu et al., 2021b). It is evident that visual information of structures offers a higher level of intuitiveness. This is due to the fact that various structural behaviours, including displacement, damage, and deformation, can be readily identified from the visual data with a high degree of certainty (Chen et al., 2021). Through the utilization of CV algorithms, researchers have successfully devised numerous measurement methodologies within the domain of shield tunnels. For instance, U-Net is a type of convolutional neural network originally designed for image segmentation. It features a distinctive U-shaped architecture that consists of a contracting path to capture context and a symmetric expanding path that enables precise localization (Li et al., 2018). Zhao et al. (2023) developed a hybrid position-channel network by incorporating channel and position attention modules into U-Net to address the crack discontinuity problem in feature channel (i.e., characteristics of the image or feature map) and spatial dimensions. However, CV algorithms, especially deep learning models, require vast amounts of labeled data for training. Gathering and labeling this data is a resource-intensive task. If the training data is not representative of real-world diversity, the algorithm may perform poorly on unseen or underrepresented data, leading to biased outcomes. To overcome such issues, Kirillov et al. (2023) proposed the segment anything model (SAM), which is a deep learning model that has undergone pre-training. This model has the ability to adjust and accommodate various pre-existing and recently developed segmentation tasks by utilizing prompt engineering techniques. Thus, it may be more suitable for detecting the tunnel damages with distinct uncertainties and variability.

To evaluate the residual loading capacities of the tunnels, further developments (step two as mentioned)

are needed following the damage detection results. However, this idea is in its early stages as it requires work on damage identification, quantification, localization, alignment, meshing, and further development of modeling methods to solve engineering problems. As a start, some studies attempt to utilize CV techniques (e.g., images, videos, and 3D point cloud data) to update the finite element (FE) model with damages (Korumaz et al., 2017; Zhang et al., 2023). For example, Zhang and Lin (2021) presented a method that enables an FE model to remesh itself for updating the geometric changes caused by structural damages, using CV techniques and geometric analyses. The proposed method utilizes CV techniques to determine the shapes and dimensions of structural components and damages, and geometric analyses to develop algorithms for automatically deleting, generating, and splitting the elements of FE models. Ghahremani et al. (2018) proposed a method using two sets of point cloud data (before and after the damage occurs) to detect the structural damage, quantify the structural change, and generate a solid model of the damage. These results are encouraging since the method can update the geometry of the FE model to consider the structural damage. However, a tunnel segment has a specific cylinder shape resulting in distortion on the image, making it hard to match geometric information in the image with the FE tunnel model. Hence, the additional geometric analysis for both damage images and FE model is required to improve the model accuracy and make it possible to fully automate the procedure of estimating the remaining structural capacity.

In summary, the main contributions of this paper are two-fold. First, a structural damage method based on SAM is proposed to identify tunnel damages on the images. The presented method exhibits superior generalization capacities in multi-task segmentation systems and effectively detects tunnel damages on the image. To the best of the authors' knowledge, SAM has rarely been used in underground structures, and this is the first time to apply it for detecting tunnel damages. Second, an image unwrapping method for tunnel segments is proposed based on CV algorithms to solve segment distortion on the image. The feasibility of the proposed method is validated using the damaged tunnel segment image collected from a loading test. Results show that the proposed model exhibits high precision for updating the FE model based on the identified damages on the image.

2 METHODOLOGY

2.1 Overview of the method

The proposed method aims to accurately update the local geometric changes of an FE shield tunnel model caused by structural damages (i.e., crack) using CV techniques and geometric analyses (Figure 1). This approach necessitates two key components: (1) a segmented image that represents distinct elements within the tunnel, such as the tunnel segment,

damages, and the background, and (2) an FE model of the tunnel in its undamaged or original condition. The segmented image can be acquired through the utilization of deep learning models designed for image segmentation, such as U-Net (Li et al., 2018), SAM (Kirillov et al., 2023), or by employing labeling tools. The deletion algorithm employed in this method was introduced by Zhang and Lin (2021).

The pipeline of the proposed method can be summarized into four steps. First, the segmented images representing the tunnel damages are obtained by using SAM. Second, (1) the tunnel segment in the image is unwrapped using CV techniques and (2) the damage on the unwrapped image is also detected by SAM. Third, based on the meshing information (i.e., node list (NL) and element list (EL)) of the FE tunnel model, geometric information is also unwrapped, and the deletion algorithm is applied to calculate the elements and nodes that need to be deleted based on the damage on the unwrapped image. Finally, the updated FE tunnel model is obtained by deleting these corresponding elements.

2.2 CV algorithms

2.2.1 Image segmentation

SAM is a deep learning model that has undergone pre-training. The purpose of this model is to generate a valid segmentation mask in response to any given segmentation prompt. This model has the ability to adjust and accommodate various pre-existing and recently developed segmentation tasks by utilizing prompt engineering techniques. It is essential to acknowledge that this approach differs from prior research conducted on multi-task segmentation systems. An essential differentiation of this model lies in its capability to perform diverse tasks during inference time, owing to its training in promptable segmentation. In this paper, SAM is applied to extract the tunnel segment information and detect the damage information in the image. Detailed discussions on the SAM can be found in Kirillov et al. (2023), and only a brief introduction to SAM is provided here.

SAM consists of an image encoder, a flexible prompt encoder, and a fast mask decoder (Figure 2). Transformer vision models are utilized to achieve

real-time performance (Carion et al., 2020; Li et al., 2022). The components are explained as follows:

- (1) Image encoder. An image encoder is employed in order to address concerns regarding scalability and leverage the effectiveness of pretraining techniques. Specifically, a vision transformer (ViT) that has been pre-trained using mean absolute error is minimally modified to accommodate high-resolution inputs. This image encoder is executed once for each image and can be employed before initiating the model.
- (2) Prompt encoder. Two categories of prompts, namely sparse (points, boxes, text) and dense (masks), can be employed. Points and boxes are denoted by positional encodings combined with acquired embeddings for each type of prompt and unconstrained text using a pre-existing text encoder from CLIP (Radford et al., 2021). Convolutional operations are utilized to embed dense prompts (i.e., masks), which are then added element-wise to the image embedding.
- (3) Mask decoder. The mask decoder effectively corresponds to the embedding of the image, the embeddings of the prompts, and a token produced as output to a mask. This design utilizes a variation of a Transformer decoder block (Vaswani et al., 2017) and subsequently incorporates a dynamic mask prediction head. The altered decoder block employs self-attention and cross-attention in two orientations (from prompt to image embedding and vice versa) to revise all embeddings. After executing two blocks, the mask decoder enhances the image embedding and a multilayer perceptron links the resulting token to a dynamic linear classifier, which subsequently calculates the probability of the mask foreground at every image position.

The model will compute an average of multiple valid masks in the case of an ambiguous prompt. In order to deal with this issue, SAM is adjusted so that it can forecast multiple output masks for a single prompt (Figure 3). It has been discovered that a total of three mask outputs prove to be satisfactory in dealing with the majority of typical scenarios (nested masks tend to have a maximum depth of three: encompassing the whole, part, and subpart).

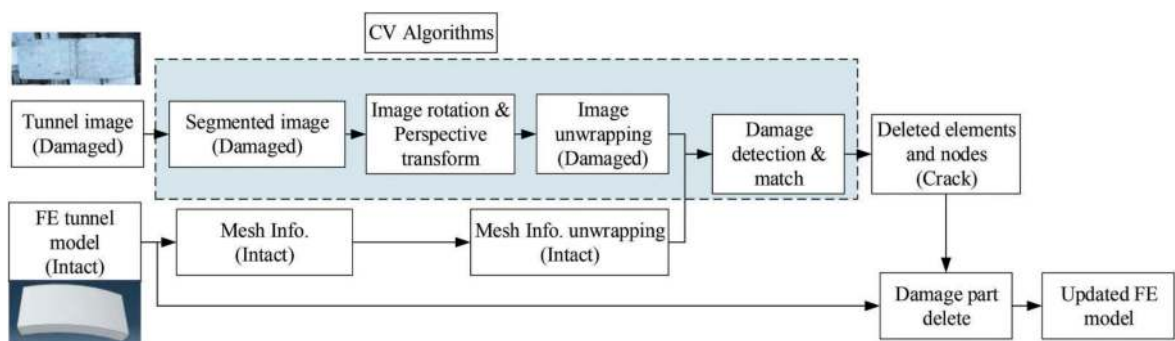

Figure 1. Research framework.

Figure 2. Segment anything model.

Figure 3. Each column shows 3 valid masks generated by SAM from a single ambiguous point prompt (green circle) (kirillov et al., 2023).

2.2.2 Image unwrapping and damage detection

A tunnel segment has a specific cylindrical shape resulting in distortion in the image (Figure 4). To precisely align the damage information from the image with the Finite Element (FE) model, the tunnel segment depicted in the image needs to be unwrapped into a rectangular shape. This adjustment allows for an accurate correspondence with the nodes and elements of the FE model, facilitating the acquisition of detailed damage information. In this paper, a six-point method is applied to fully unwrap a tunnel segment. More specifically, A vertical-align algorithm is used to rotate the tunnel segment mask to the standard position (Figure 4). The basic idea of the vertical-align algorithm is to maximize the number of fully black columns of the provided mask. Then, six points around the edges of the

segment are detected and positioned, where the corner points (A, C, D, and F) are searched by iterating with the diagonals of the image first (Figure 5).

Figure 4. Image rotation.

Figure 5. Positions and detection of six points.

The X coordinate for the point B is calculated by:

$$X_B = (X_A + X_C)/2 \quad (1)$$

where X_B is the X coordinate for point B. The column vector Y_{X_B} of the segment mask corresponding to X_B is selected and find the first non-zero value of the column vector from the top down as the Y coordinate of X_B (Figure 6).

Figure 6. Detection of Y coordinate.

The rationale is the same for the E point: the column vector in the middle of the D and F point first is found and this time the column vector iterates from bottom to top until it finds the first white pixel.

As shown in Figure 5, the tunnel segment consists of two curves ABC and DEF and two vertical lines AF and CD. Vertical lines AF and CD are defined by

the corresponding point coordinates. It is found that an ellipse is a fairly accurate approximation for these curves. Hence, a parametric form of the ellipse could be used to represent these curves:

$$x_e = a \times \cos(t) \quad (2)$$

$$y_e = b \times \sin(t) \quad (3)$$

where x_e and y_e are the coordinates of any point on the ellipse, a and b are the radius on the x and y axes respectively, t is the parameter, which ranges from 0 to 2π radians.

The next step is to unwrap the tunnel segment in the image based on the four edge functions (i.e., left line, right line, top ellipse, and bottom ellipse). Figure 7 shows the technical procedures. First, the lengths of vertical lines and ellipses are calculated using the corresponding point coordinates. Two grid meshes are then built covering cylinder and rectangle surfaces separately. Finally, the information from cylinder surfaces is remapped to the rectangle surfaces by performing the CV algorithms, and the crack in the unwrapping image is detected by SAM.

Figure 7. Technical procedures of image unwrapping and crack detection.

2.3 Geometric match and modelling updating

2.3.1 Node and element information unwrapping

In order to match with the unwrapped image, the coordinates of nodes in the FE tunnel model need to unwrap from 3D to 2D. A coordinate unwrapping method is proposed to obtain the converted 2D coordinates of nodes. Given that the centre of the tunnel segment is at the origin of the coordinates, the coordinate Z remain the same after the coordinate unwrapping. The coordinate X^* in the X^*-Z coordinate system (unwrapped rectangle surface) can be calculated based on the coordinates x and y in the $X-Y$ coordinate system. Figure 8 shows the process of the coordinate unwrapping method. The coordinate unwrapping method will be introduced in the following part.

As shown in Figure 8 (b), line EF is the unwrapped result of the arc BC . Point $D(x_d, y_d)$ is the midpoint of the lines BC and EF . The angle θ of point (x, y) can be given by:

Figure 8. The process of the coordinate unwrapping method.

$$\theta = \begin{cases} \theta_1 - \theta_0, & \theta_1 \geq \theta_0 \\ \theta_0 - \theta_1, & \text{else} \end{cases} \quad (4)$$

where $\theta_1 = \arctan(y/x)$ and $\theta_0 = \arctan(y_d/x_d)$. Then, d_3 is calculated by:

$$d_3 = \frac{\theta \cdot \pi R}{180} \quad (5)$$

where R is the radius of the tunnel segment. Finally, the X^* of the X^*-Z coordinate system can be obtained by:

$$X^* = \begin{cases} \frac{d_2}{2} - d_3, & \theta_1 \geq \theta_0 \\ \frac{d_2}{2} + d_3, & \text{else} \end{cases} \quad (6)$$

Therefore, the coordinates (x^*, z) of all nodes in the X^*-Z coordinate system are solved. It is ready to use the unwrapped damage image and nodes and elements information to update the geometry of the FE model.

2.3.2 Deletion algorithm of nodes and elements

The FE tunnel model is modelled by commercial FE software Abaqus. Manual deletion of nodes and elements in affected regions requires precise measurement of the damage dimensions to identify polygons of the damaged area (PDA). It involves recognizing the intersecting nodes and elements with the damage, followed by their removal. This process can be quite lengthy and labor-intensive. Therefore, a more efficient approach is to apply a deletion algorithm, as outlined in Algorithm 1 (Zhang and Lin, 2021).

Algorithm 1. The deletion algorithm of nodes and elements of FE models.

Require: PDA , the polygons of damaged areas

Require: EL , element list of the intact FE model

Require: NL , node list of the intact FE model

Require: DEL , empty list of saving the deleted elements

For element i in EL :

If $i \cap PDA \neq \emptyset$:

Add i to DEL

Delete i from EL

End for

For j in DEL :

For node k in j :

If k does not constitute any element in EL :

Delete k from NL

End for

End for

Return EL, NL, DEL ,

The geometric analyses are conducted through the utilization of the Shapely package, which is firmly grounded in the geographic information system field. In this paper, an FE model is considered akin to a map, allowing for the examination of the spatial connection between nodes and elements using Shapely.

2.3.3 Tunnel FE model updating

An FE model updating algorithm is proposed to assess and delete the damage elements on the intact FE tunnel model using its geometric information obtained in the previous section. Finally, the updated FE tunnel model can be obtained after deleting the damage elements.

3 CASE STUDY

To validate the proposed method for automatically updating the geometries of FE models, one lab loading test of a tunnel segment is used. The image should be taken under good lighting conditions. It must include all information from the damaged side of the tunnel segment (including the vertices of the segment and damages). Additionally, the image should be taken from the normal position of the middle surface of the segment to ensure the precision of the information in the image. All the proposed algorithms have been implemented and verified within the Python 3.10 environment. Figure 9 shows the set-up for the loading test. The segment is hinged at the ends and loaded by a vertical jack. The test result is shown in Figure 10. It can be found that a vertical crack is observed in the middle of the tunnel segment.

An FE model of the tunnel segment is established as shown in Figure 11. To demonstrate the updated results with clarity, the mesh employed in this model comprises 823, 143 nodes and 761, 000 elements.

Image segmentation is carried out to obtain the contour of the tunnel segment by specifying the foreground point based on SAM and the segment damage

Figure 9. The set-up for loading test.

Figure 11. The FE model and mesh of a tunnel segment.

image in Figure 10 (b). Figure 12 shows 3 mask outputs (i.e., whole, part, and subpart) of image segmentation. It is shown that even if there are many other objects around the tunnel segment, mask 2 (part) still provides a good result with a high identification precision of the tunnel segment. Hence, mask 2 will be selected as the mask of the tunnel segment.

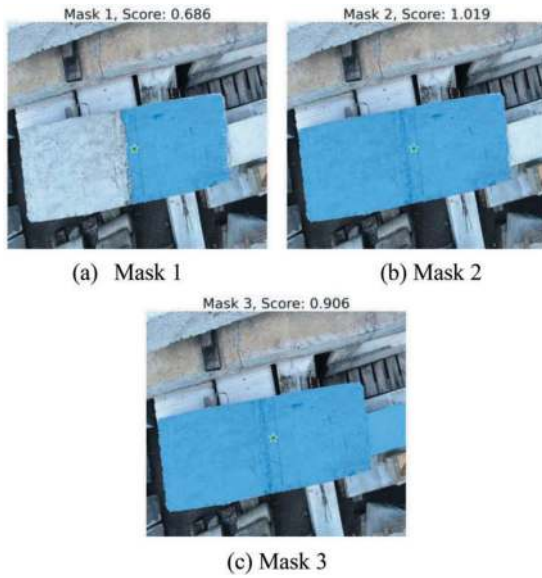

Figure 12. 3 mask outputs of image segmentation from SAM.

The output of each step for image unwrapping is demonstrated sequentially in Figure 13. The whole specimen is seriously damaged after the test, especially in the middle and edges. This will affect the accuracy of the image unwrapping results. However, in practice, cracks and segment edges generally need to be repaired when they are mildly damaged. Finally, Figure 14 shows the crack detection result by SAM in the unwrapped image. It is shown that SAM can detect the crack in the image by specifying proper foreground points.

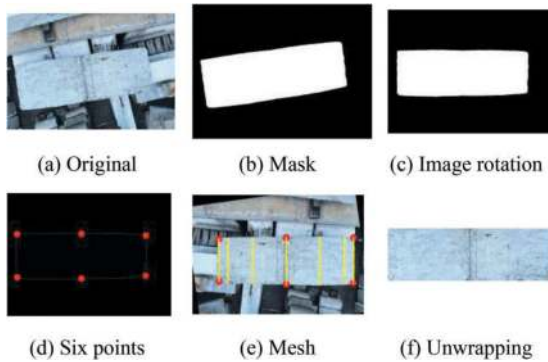

Figure 13. Procedure of image unwrapping processing.

Figure 14. The crack detection result by SAM on the unwrapped image.

Based on the nodes and elements lists of the FE model, the coordinates of nodes are unwrapped from 3D to 2D information. Table 1 shows a part of the

results of geometric information unwrapping. Based on the obtained mask of the crack as well as the NL and EL of the FE model, the deletion algorithm is applied to find the nodes and elements that need to be deleted. First, PDA can be generated by using the contour information obtained from the CV algorithms. By using the deletion algorithm, elements in the FE model that have intersections with PDA can be identified. Figure 15 shows the results of intersection elements with damage on the images. Finally, the intersection elements are removed and the FE model becomes in the state as shown in Figure 16.

Table 1. Results of geometric information unwrapping (unit: mm).

Element ID	Coordinates after geometric information unwrapping							
	Node1	Node2	Node3	Node4	Node5	Node6	Node7

4 CONCLUSIONS

In this paper, a computer-vision-based model strategy to update the finite element (FE) model of shield tunnels with cracks. The feasibility of the proposed method is validated through a test on a tunnel segment. The obtained findings are as follows:

- (1) The pre-trained segment anything model (SAM) is capable of accurately segmenting the tunnel segment and damages depicted in the image without the need for additional training.
- (2) The method of unwrapping an image can perform tasks such as image rotation, detection of six points, creation of a mesh, and mapping of information within the image.
- (3) The coordinates of the elements in the finite element model for the 3D coordinate system are converted into 2D coordinates in order to align with the unwrapped image. Subsequently, a deletion algorithm is employed to identify the elements that intersect with the damages on the image.
- (4) The proposed approach enables the automatic revision of the FE tunnel model based on damages found in the images using computer vision techniques and geometric analyses. This approach can be effectively employed to evaluate the state of shield tunnels.

ABSTRACT: Nowadays, the scale of new city construction and old city reconstruction in big cities is unprecedented. The load capacity and structural durability of shield tunnel are always influenced by exterior workings, especially for the situation of tunnel lining breakage or puncture. And then, the structural safety and normal operation of shield tunnel will be seriously influenced correspondingly. Based on the operating metro tunnel which was punctured by drilling machine accidentally, the stress characteristics of tunnel lining under normal earth pressure are firstly analyzed, then the relevant tension and compression regions of tunnel lining are deeply analyzed and made clear. The specific influences on lining capacity with little range of damage are explained, the advantages and disadvantages of lining repair methods in common use are made clear, and the basic principles of lining repair are also put forward. As for large range of lining damage, the newly built shaft for structure repair is put forward, and the stress characteristics and corresponding safety situation evolution of lining during the whole stage are made clear, from lining damage, to shaft excavation, to structure repair, and to shaft backfilling. The load conversion structure with sharp top and archlike bottom is adopted which can obviously reduce all earth pressure while shaft backfilling. And the working shaft based on the combination of transverse passage and conventional shaft is also proposed to adapt environment requirements. This paper can lead a reference for similar project in future.

1 INTRODUCTION

By the end of 2022, the nationwide operational mileage of urban rail transit has exceeded 10,000 kilometers. The investment intense and construction speed of rail transit in major cities have reached new level once and once again. The protection situation of operational rail transit is becoming more and more seriously while the operation miles are becoming longer and longer. Kinds of structural safety hazards are arising constantly during metro operation, although specific protection regulations are issued by local government.

Researches on punctured tunnel and corresponding repair methods are relatively few based on literature. According to the investigation of punctured metro tunnels in different situations, the classification of

punctured tunnel and its influences on lining structures are made clear. The common repair methods for damaged lining structures are summarized. The advantages and disadvantages of interior repair method are made clear, and the corresponding selection principle are put forward. And then, key technologies for steel plate reinforcement inside tunnel are made clear. At last, the repair method with outside shaft for large area of tunnel damage is deeply studied. The transverse passage combined with traditional shaft is proposed for tunnel repair as for complex external environment. The lining reinforcement method with cap structure and the load conversion structure with archlike shape are put forward, and the vertical earth pressure can be converted into horizontal load. And then, the force stabilization and long-term durability of lining structure can be ensured.

2 CLASSIFICATION AND SAFETY ANALYSIS OF PUNCTURED SHIELD TUNNEL IN RAIL TRANSIT

There have been cases of rail transit tunnels under construction or in operation punctured by external workings in big cities. Statistics of typical cases are shown in the following table.

Table 1. Statistics of punctured rail transit tunnels and relevant structural repair methods (incomplete statistics).

Region & line	lining puncture	Repair methods
Line 1 in Nanning	Tunnel lining was punctured Train collided with drill bit	Grouting sealing & steel plate reinforcement inside tunnel
Line 11 in Shenzhen	Tunnel lining was punctured by pre-stressed pipe pile at 1 o'clock	Grouting sealing & steel plate reinforcement inside tunnel
Line 10 in Shenyang	Segment joint of lining was punctured	Grouting sealing & aramid fabric cloth reinforcement inside tunnel
Line 1 in Chongqing	Lining of mined tunnel was punctured	Grouting sealing & rebar reconnection inside tunnel
Line 1 in Hangzhou	Segment joint of lining was punctured	Grouting sealing & steel plate reinforcement inside tunnel
Line 7 in Chengdu	Standard segment of line 7 was punctured, 10.4m depth	Shaft & rebar reconnection outside tunnel
Line 8 in Chengdu	Key segment of line 8 was punctured, 11.2m depth	Shaft & rebar reconnection outside tunnel
Line 17 in Chengdu	Key segment of line 17 was punctured, 17.5m depth	Shaft & rebar reconnection outside tunnel
Line 18 in Chengdu	Connecting segment of line 18 was damaged by drilling, 16cm depth of damage was found outside tunnel	Shaft & rebar reconnection outside tunnel

From the table above, as for the punctured tunnel lining by outer workings, shaft and lining repair outside tunnel are always adopted for the relatively better formation in Chengdu, Chongqing and so on. The lining repair methods inside tunnel are adopted in other areas. Rebar reconnection is adopted for the repair of little range, structural repair and steel plate reinforcement inside tunnel are adopted for the repair of large range or segment joint.

2.1 Classification of punctured shield tunnel

Tunnel lining is a typical reinforced concrete member which mainly bears bending moment and axial force. According to the distribution of bending moment

inside tunnel, the upper half of tunnel can be divided into three regions, namely the tension region, the compression region, and the transition region of tension and compression. As shown in Figure 1.

Figure 1. Sketch map of region division for upper half of tunnel based on bending moment distribution inside tunnel.

As for the upper half of shield tunnel, the tension region inside tunnel is distributed within 30 degrees around tunnel vault, namely region I. The compression region is distributed within 40 degrees above tunnel haunch, namely region III. The transition region of tension and compression is distributed within 30 to 50 degrees on both sides of tunnel vault, namely region II. Most of the lining damage and puncture are focused in tension region and the transition region. Based on the statistics, the probability of lining puncture in the tension region is at the highest lever, and the maximum safety influences will be resulted correspondingly.

2.2 Safety analysis of punctured tunnel lining

If damaged region is under control after lining puncture, the self-stability of tunnel in short term can be ensured. However, the potential hazards of structure safety are becoming more and more seriously in long term.

2.2.1 Safety analysis in short term

The operation of metro line should be recovered as soon as possible after lining puncture. The self-stability of formation and the safety margin of lining structure will be well utilized in this situation. The self-stability of formation above tunnel is mainly depended on the collapse arch which has not been completely destroyed in short term. As for little area of damage, metro tunnel and surrounding formation form a force balanced state, and tunnel safety is still under control in short term.

If large area of lining damage or broken segment joint is encountered, the self-stability of segment can not be ensured especially for the adoption of bent bolt situation. Then, the continuous collapse of shield segment and large area of settlement and deformation of stratum may be resulted.

2.2.2 Safety analysis in long term

Lining cracks and fragmentation will develop, and the self-stability of stratum above tunnel will decrease due

to train vibration and redistribution of lining stress, if the repair of punctured tunnel can not be carried out in time. The overall earth column pressure will be resulted if collapse arch reaches ground surface, and tunnel safety will be influenced correspondingly.

1) Influence analysis of crack propagation

Structure capacity and durability of tunnel lining will be influenced in some extent by structural cracks due to exterior action.

As for structure capacity, in the range of crack depth, the binding force between steel bar and concrete will be reduced, and even the function of concrete in crack depth will end. As for structure durability, the thickness of the protective layer of steel bar will be reduced, infiltration process of oxide and carbonate will be accelerated, steel corrosion and expansion cracking will be resulted. As shown in Figure 2.

Figure 2. Sketch of durability influences on concrete by corrosive medium with different thickness of protection layer.

2) Influence analysis of the change of earth pressure

The depth of metro tunnel is always more than 10m, the earth pressure of collapse arch above tunnel should be considered correspondingly. One certain tunnel runs mainly in weathered sandstone stratum, and gravel soil and miscellaneous fill lays above. The ground water lever is 3.1m to 5.2m under ground table. The physical and mechanical parameters are shown in Table 2.

Buried depth of one certain tunnel vault is more than double of its diameter, and the earth pressure based on collapse arch should be considered. Lining thickness is 0.35m, reinforced concrete is C50. According to the equivalent calculation

Table 2. Physical and mechanical parameters of stratum.

stratum	γ kN/ m ³	E_0 MPa	K_0	Poisson's ratio	coefficient of subgrade reaction MPa/m	
					K_v	K_x
Miscellaneous fill	19.0	5	0.65	0.39	10	8
Gravel soil	23.0	55	0.19	0.16	115	90
Decomposed sandstone	20.5	40	0.30	0.23	115	105

model of flexural rigidity, namely $E_1 I_1 = 0.8EI$, then, $h' = \sqrt[3]{0.8h} = 0.325m$.

According to Terzaghi collapse arch theory, the loose earth pressure can be calculated, namely $p_e = 121.31kPa$. Relevant lateral earth pressure can also be obtained:

$$e_1 = \lambda \cdot (p_e + 20) = 42.4kPa$$

$$e_2 = \lambda \cdot (p_e + 20 + \sum^n D) = 78.8kPa$$

And the reaction force at tunnel invert is 148.8kPa. Water pressure at tunnel vault is 72kPa, and 134kPa at tunnel invert.

If the earth pressure of all earth column above tunnel is considered, earth pressure is 274.1kPa at tunnel vault. And relevant lateral pressure is 88.23kPa at tunnel vault and 125.4kPa at tunnel invert, and the reaction force at tunnel invert is 297.6kPa.

From Table 3, stress in tunnel vault is relatively small under collapse arch load mode, and tunnel structure is under the state of small eccentric compression. Structure crack can meet requirement without the need of checking calculation. Stress in tunnel vault nearly doubles under all earth column load mode, and structure crack reaches 0.15mm. It can be obviously seen that structure stress and crack width will increase caused by the change of earth pressure mode due to exterior working, especially for large buried depth of tunnel.

From the analysis above, it can be seen that the damage range of tunnel lining is relatively small for

Table 3. Stress and rebar reinforcement at tunnel vault based on loose earth pressure and all earth column pressure.

Operation conditions	Action mode of vertical load	Vertical load	Vault stress/standard combination		rebar mm ²	crack width /mm
			M	N		
Undisturbed formation	h_0 height of collapse arch	P_e	63.1	-564.9	1527	Satisfied
Tunnel puncture	h all earth column	P_1	132.1	-789.7	1527	0.15

exterior working such as geology drilling, the stability of tunnel can be ensured in short term based on the overall capacity of tunnel lining and the constraint of surrounding formation. However, structure durability will severely decrease in long term, and tunnel stresses and crack widths will sharply increase due to the change of earth pressure mode, especially for relatively large buried depth. The repair of damaged tunnel lining should be carried out as soon as possible.

3 REPAIR SCHEME OF TUNNEL LINING IN COMMON AND ITS BASIC PRINCIPLE

3.1 Feature analysis of repair scheme

3.1.1 Classification of common repair scheme

As for the common repair circumstances of shield lining, based on the repair site, it can be divided into three modes, namely repair inside tunnel, repair from ground, and combined repair. As for structure reinforcement, it can be divided into two types, namely structure self-reinforcement, and structure reinforcement combined with steel plate. Steel plate can also be replaced by aramid fabric cloth or composite cavity.

Figure 3. Steel plate bonded with lining inside tunnel.

Figure 4. Composite cavity bonded with lining inside tunnel.

3.1.2 Advantages and disadvantages analysis of common repair schemes

Steel plate is always adopted in structure reinforcement inside tunnel, the composite cavity is a new reinforcement method. Compared with steel plate, composite cavity is more than 40mm in thickness, and it will result in the risk of equipment and safety operation due to relatively limited space in metro tunnel. And the width of composite cavity is less than 160mm in common, the bonding strength between tunnel and composite cavity is relatively weak. And the bonded surface will open relatively easy in tunnel deformation experiment, and its application is influenced correspondingly.

The steel plate, which is bonded with lining inside tunnel, is corrosive when time goes by. Steel plate should be avoided when obvious corrosive environment inside tunnel is encountered or structure self-reinforcement can meet the requirements. As for the assembly of steel plate inside tunnel, the dedicated device should be adopted in assistance due to its big self-weight, and complex procedure and long construction period will be resulted correspondingly.

The repair measures outside tunnel based on shaft or foundation pit are relatively reliable while the damaged region of lining structure is completely revealed. And little influences will be resulted on metro operation correspondingly. However, excavation period of shaft or foundation pit is relatively long, the earth pressure mode above shield tunnel can be changed due to backfilled soil, the soil arch effect above tunnel will disappear, and the lining safety will be influenced correspondingly.

3.2 Basic principles of lining repair

Tunnel repair should be based on the basic principle of lining safety and its durability in the long term. Then, the working time and influences on safety operation of metro tunnel should be reduced to the maximum extent. At last, repair cost and implementation complexity should also be taken into account.

3.2.1 Principles of lining repair and reinforcement inside tunnel

Lining repair and reinforcement should be carried out inside tunnel while surrounding stratum has a good self-stabilization and little range of lining damage is found. Meanwhile, steel plate or aramid fabric may also be adopted for overall lining reinforcement in addition. Nowadays, standards of steel plate reinforcement inside tunnel are not inconsistent. However, crack width, damaged area ratio, change of tunnel diameter or ellipticity are the indexes should be considered in general. The relevant indexes are listed in following table, and steel plate reinforcement can be implemented as any index in the following table is reached.

Table 4. Principles and indexes of steel plate reinforcement inside tunnel.

Sequence number	Stratum	Corrosiveness of ground water and soil	Diameter change/mm	Crack width/mm	Segment misalignment /mm	Damage region
1	Stratum with good self-stability such as hard plastic clay, medium dense and dense pebble soil, medium weathered rock	Microcorrosion	≥ 120 or ellipticity is more than 20%		≥ 30	
		Moderate and above	≥ 70		≥ 20	
2	Stratum with poor self-stability such as soft soil, weathered and strong weathered rock, loose and denser pebble soil, fine sand and sand soil, saturated soft loess	Microcorrosion	≥ 100	V type crack width ≥ 0.4 mm or penetrated crack width ≥ 0.2 mm. Grouting sealing should be implemented firstly for other cracks	≥ 25	Rectangle side length or diameter of damaged area is larger than steel bar spacing, namely two steel bar will be cut at least
		Moderate and above	≥ 70		≥ 20	
3	Specific stratum such as collapsible loess, fault fracture zone, and soft and hard composite soil.	Microcorrosion	Transverse change ≥ 80 , vertical change ≥ 100		≥ 25	
		Moderate and above	≥ 70		≥ 20	

3.2.2 Principles of lining repair and reinforcement outside tunnel

If tunnel damaged area is relative large or earth pressure mode is obviously changed from collapse arch to all earth column pressure, structure safety and stability can not be ensured by repair method inside tunnel. Then, shaft or foundation pit can be implemented for lining repair. Special structure can be superposed on the damaged lining, and the all earth column pressure can be reduced in other ways.

4 LINING REPAIR SCHEME BASED ON STRUCTURE REINFORCEMENT INSIDE TUNNEL

4.1 Scheme introduction

Lining repair and reinforcement inside tunnel can be divided into two types, namely structure self-reinforcement, and steel plate or aramid fabric reinforcement combined with structure self-reinforcement.

If the damage range of tunnel lining is relatively small and little influences on lining safety are found, then structure self-reinforcement inside tunnel can be implemented, and steel bar reconnection and slightly expanded epoxy mortar can be implemented correspondingly. If the damaged range is relatively large, steel plate or aramid fabric reinforcement should be adopted inside tunnel.

4.2 Key technologies

Key technologies for structure reinforcement inside tunnel are described as follows.

- 1) Steel bar reconnection in damaged area should meet the requirement of equal rebar strengthen. And concrete with micro expanded epoxy mortar should be casted in the damaged region.
- 2) Relocation of trackside facilities or pipeline equipment should be avoided if steel plate is reinforced inside tunnel. The whole lining ring should be bonded with steel plate, and the bull leg should be installed near the track bed, in order to ensure the stability of the whole lining ring.
- 3) Epoxy slurry should be grouted into the interface of steel plate and lining, and a brand new circle force structure is formed. Aramid fabric can be bonded in damaged area as temporary reinforcement for emergency treatment, in order to restrain further deformation of lining as soon as possible. And steel plate can be bonded as permanent reinforcement.
- 4) Durability of tunnel lining largely depends on its water resistance. And multi-layer waterproofs can be realized by slurry grouted into surrounding strata inside tunnel and epoxy slurry grouted into segment joints.

5 LINING REPAIR SCHEME BASED ON STRUCTURE REINFORCEMENT OUTSIDE TUNNEL

Shaft or foundation pit is always adopted for structure reinforcement outside tunnel, then the circumstances of damaged tunnel exterior will be totally revealed, and the suitable repair scheme can be confirmed based on the damaged situations of tunnel lining correspondingly.

If exterior environment is relatively complex, and shaft or foundation pit can not be implemented right above the damaged tunnel, then transverse passage and traditional shaft can be combined for lining repair.

5.1 Repair scheme outside tunnel based on the combination of transverse passage and shaft

If ground condition is complex and shaft or foundation pit can not be directly implemented right above the damaged tunnel, as for tunnel is beneath operated road or near important buildings in big cities. Then, the ground location of shaft or foundation pit can be led to places with relatively good environment conditions based on the adoption of transverse passage. The conventional shaft is divided into two

parts correspondingly, which are connected by transverse passage, and lining repair can be implemented from ground surface.

5.2 Repair scheme outside tunnel based on ground shaft or foundation pit

Shaft or foundation pit can be implemented right above the damaged tunnel if ground condition is permitted. And different types of shaft or foundation pit can be adopted according to the site and size of damaged lining.

(1) Repair scheme for little damaged lining

If only little damaged region of tunnel is found, such as one penetrated crack or lining fragmentation, then small shaft can be adopted for lining repair. The bottom of shaft can be directly set on tunnel lining. The stress converting structure with sharp top and archlike bottom can be set in a certain distance from tunnel vault, and wing angle member is placed at the end of stress transferring structure. Then, the vertical earth pressure resulted from backfilled soil in shaft can be largely converted into horizontal pressure. Lightweight concrete can be taken as backfilling material and the mattress layer which is more than 300mm in thickness can be set beneath the stress converting structure. As shown in Figure 6-a.

The broken steel bar is firstly reconnected in shaft, and micro expanded epoxy mortar is adopted for concrete cast. In order to enhance the effect of structure reinforcement, the superimposed component can be cast in site together with the recovery of damaged lining, namely the cap shaped structure. As shown in Figure 6. Tunnel lining is a typical compression-flexure member, the height of lining compression zone can be enlarged by the cap shaped structure, and the bearing capacity of external loads will be enhanced correspondingly.

(2) Repair scheme for large damaged lining

If large damaged region of tunnel is found, such as several penetrated cracks or punctured area, then larger shaft or foundation pit should be adopted for lining repair. The bottom of retaining pile of shaft or foundation pit can be set more than 3m deeper than tunnel invert. Meanwhile, the load converting structure with sharp top and archlike bottom above tunnel vault can be connected to retaining pile by planted rebar. And the earth pressure based on backfilled soil can be transmitted to deeper stratum. As shown in Figure 6-b.

5.3 Typical case analysis

Based on the project case described in Section 2.2, numerical analysis is carried out on the repair of tunnel vault in shaft. MIDAS/GTS is adopted correspondingly, then formation-structure calculation model is established, the displacement boundary condition and the modified Moore-Coulomb constitutive model are adopted. Shaft side-wall, lightweight concrete which is used as backfilled material,

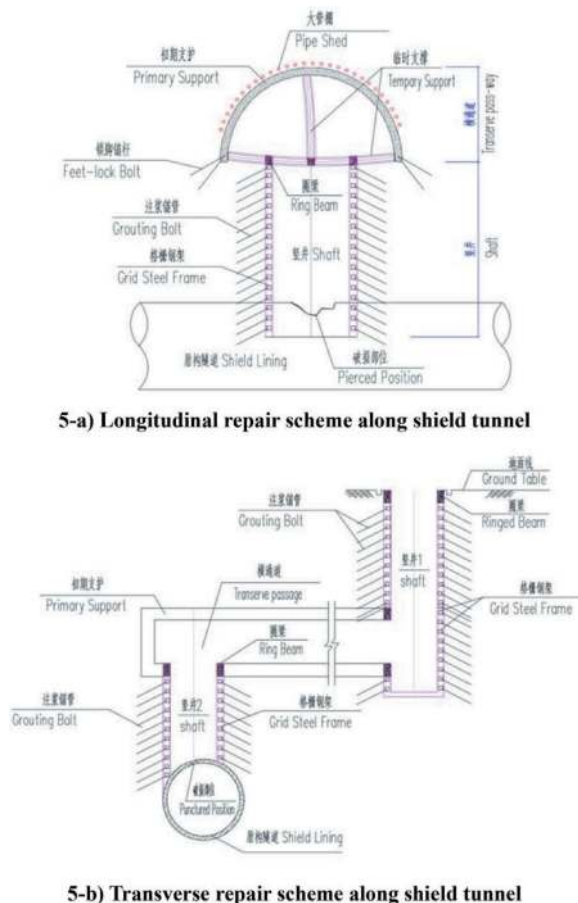

Figure 5. Diagram of lining repair scheme based on the combination of transverse passage and shaft.

6-a) Shaft or foundation pit for little damage

6-b) Shaft or foundation pit for large damage

Figure 6. Lining repair scheme based on the combination of shaft or foundation pit.

Figure 7. Cap component scheme based on lining reinforcement.

and load converting structure with sharp top and archlike bottom and so on are simulated as solid elements. Tunnel lining is simulated as beam element. Contact element is set between shaft side-wall

and backfilled soil. There are 1566 units and 1232 nodes in the numerical model. And the horizontal distance from tunnel haunch to model border is more than the triple of tunnel diameter.

5.3.1 Stress analysis of tunnel lining

Stress analysis of tunnel vault is carried out in different construction stages. As shown in Figure 8 and Table 5.

As shown in upper table and figure, the maximum bending moment in tunnel vault reduces due to partially structural fragmentation. Namely the maximum bending moment reduces from 77.5kN.m to 44.3kN.m, and the bending moment in damaged region sharply reduces to 10kN.m. Bending moment of lining near shaft side-wall obviously increases while shaft excavation goes on. And the relevant maximum bending moment reaches 130kN.m when

8-a) tunnel excavation completed

8-b) shaft excavation completed

8-c) Construction of load converting structure

8-d) shaft backfilling completed

Figure 8. Bending moment diagram of tunnel lining in different construction stage (units: KN.m).

Table 5. Lining stress in tunnel vault in different stage.

Working conditions	Maximum of bending moment		Axial force N/kN
	Value M/kN.m	Location	
tunnel excavation completed	77.5	Tunnel vault	-388.3
Tunnel lining damaged	44.3		-372.9
shaft excavation completed	130.5		-248.3
Cap component construction	130.4	Left side of tunnel vault	-250.8
Load converting structure	139.2		-250.7
shaft backfilling completed	169.2		-264.7

shaft excavation completes and cap component reinforcement begins, the increasing rate is 67.7% correspondingly. However, bending moment in damaged region is still around 10kN.m throughout all stages. With the reinforcement of cap component, bending moment in tunnel vault reaches 169kN.m in shaft backfilling stage. And the correspondingly increasing rate is 30% from shaft excavation to shaft backfilling, and the increasing value of bending moment is 39kN.m. This indicates that partially damage of lining can lead the bending moment transferring from the damaged region to its near sides. As a result, the potential safety hazard of lining near shaft side-wall increases correspondingly due to the increase of bending moment.

Figure 9. Equivalent stress of load converting structure while shaft backfill completed (units: kPa).

As seen from the change of axial force in tunnel vault, the decreasing rate of axial force reaches 36% from tunnel excavation to lining damage stage, and the value change of axial force is less than 30kN from shaft excavation to shaft backfilling stage.

5.3.2 Stress analysis of load converting structure

In order to deeply analyze the function of load converting structure with sharp top and archlike bottom, the stress flow of equivalent stress and maximum principle stress in load converting structure are analyzed during shaft backfilling stage.

As seen from the equivalent stress figure above, the equivalent stress in the middle part of load

Figure 10. Maximum principle stress of load converting structure while shaft backfill completed (units: kPa).

converting structure is only 226.3kPa, which is nearly equal to vertical earth pressure in the same formation depth. However, the maximum equivalent stress in the wing angle, at the end of load converting structure, reaches 1221.1kPa, namely 5.4 times as in the middle part, even though all parts of the load converting structure nearly lay in the same formation depth. It indicates that the ideal load bearing and converting effect can be ensured based on the load converting structure during shaft backfilling stage.

As seen in the stress flow of maximum principle stress in load converting structure after shaft backfill, the direction of principle stress in wing angle, at the end of load converting structure, rotates. The direction of maximum principle stress in left wing angle shifts from vertical direction to 30 degrees above horizontal direction, and the direction of principle stress in right wing shifts from vertical direction to nearly horizontal direction. It is indicated that vertical earth pressure caused by backfilled soil can be efficiently transferred into horizontal load by the wing angle of load converting structure.

6 CONCLUSIONS

According to the frequent occurrence of damaged lining or punctured tunnel by exterior workings in big cities, this paper made the deep analysis of structure safety caused by lining fragmentation, and the applicability of lining repair and reinforcement methods. Main conclusions can be obtained as follows.

- (1) According to stress distribution in top half of tunnel section, the region classification of lining fragmentation is carried out. It is made clear that the region in 30 degrees around tunnel vault belongs to inner tensile area, the relevant punctured rate is highest, and the influence on tunnel safety is biggest.
- (2) If small range of lining damage occurs, self stability of tunnel can be maintained in short term based on the overall capacity of lining and the constraint of surrounding stratum. The earth arch will disappear and the earth pressure mode above tunnel will be influenced when time goes by, and tunnel stresses and lining cracks will sharply increase correspondingly. Structure repair and reinforcement of damaged region should be carried out as soon as possible.

- (3) The advantages and disadvantages, and reinforcement principles for lining repair inside tunnel and outside tunnel in common use are summarized. It is made clear that lining repair and reinforcement inside tunnel should be carried out for little damage, such as only one penetrated crack.
- (4) As for large area of lining fragmentation, the combination of transverse passage and shaft or foundation pit for lining repair outside tunnel is put forward. The load converting structure with sharp top and archlike bottom, which can obviously make vertical backfilled earth pressure transferred into horizontal load, is put forward. And the influences of all column earth pressure caused by shaft backfilling on operating tunnel will be successfully reduced correspondingly.
- (5) As for lining repair in shaft or foundation pit outside tunnel, bending moment of tunnel vault increases and axial force decreases from lining damage stage to shaft excavation stage, and this stress transfer process is very harmful to lining safety. The bending moment in lining repaired region may turn over due to backfilled earth pressure, the stress state of tunnel vault will change from inner tensile to outer tensile, and segment cracks may be enlarged correspondingly.

ACKNOWLEDGMENTS

The approach to lining repair summarized in this paper evolved over a long period in the rehabilitation of several metro tunnels in Chengdu. The authors acknowledge the contribution of colleagues involved in the remedial construction work and the subsequent collaboration of numerous construction practitioners. The authors also acknowledge support from the innovation team for key technology research of Xi'an Metro (2016KCT-07) and scientific research project from FSDI (19-52).

Smart tunnel in industry 5.0: Improving road tunnel resilience by dynamic risk analysis

Alessandro Focaracci*

Prometeoengineering.it Srl, Rome, Italy

Luigi Martirano & Francesca Zacchei

Università di Roma – La Sapienza, Rome, Italy

ABSTRACT: After the accidents occurred in Mont Blanc, Tauern and St. Gotthard tunnels, safety started to be contemplated as a holistic approach. These events have become a critical issue for politicians and for public, pushing the European Commission to establish the Directive 2004/54/EC, which tackles road tunnels safety and aims to guarantee a minimum safety level to the tunnel users. Technological innovations have led to the tunnel concept evolution from civil works to technological infrastructure, where technology overcomes the geometric-functional limits, increasing its operating capacity. This paper aims to illustrate the fundamental principles of SCADRA (Supervisory Control Acquisition & Dynamic Risk Analysis) system, developed and implemented thanks to EURAM (EUropean Risk Analysis Method) methodology, which assessed the risk of over 600 Italian road tunnel tubes according to the Legislative Decree 264/06, focusing on Industry 5.0 perspective: users and managers' needs (Human-centricity), usage of new green technologies and application of an energy saving strategy (Sustainability), and improvement of tunnels resilience (Resilience).

SCADRA was installed in 3 Italian road tunnels, executing over 130,000 instantaneous risk analyses and this report illustrates the main outcomes and an evaluation for a correct tunnel management during normal operation and emergency situations. SCADRA continuously monitors the tunnel state by gathering the influence variables for tunnel safety and performing a dynamic risk analysis, quantitative and probabilistic, at regular intervals or due to sudden change in the data.

This paper presents the most significant results obtained and identifies possible future developments, in terms of tunnels' safety improvement and conservation, and tunnels' maintenance and management. SCADRA system is therefore a supplementary prevention and safety measure for tunnels management, both during normal operation and in emergency conditions, capable of guaranteeing a real-time monitoring of tunnel risk level.

Keywords: Resilience, Tunnelling, Real Time Risk

1 INTRODUCTION

Italy has an extraordinary formation of its terrain varying from mountains to plains. In order to have an accessible land connection throughout the country that will facilitate the flow of people and goods, the importance of tunnels in road transportation network enters the scene.

After the accidents occurred between 1999 and 2001 in Mont Blanc, Tauern and St. Gotthard tunnels, safety in tunnels started to be contemplated as a holistic approach. These events have become a critical issue for politicians and for public, pushing the European Commission to establish the Directive 2004/54/EC, which specifically tackles the safety in TERN road tunnels (Trans-European Road

Network) and aims to guarantee a minimum level of safety to the tunnel users.

In Italy, the European Directive was implemented through the Legislative Decree n.264 of the 5th October 2006, with the purpose of guaranteeing a minimum and sufficient safety level for users in all TERN tunnels, defining a series of minimum safety requirements to be implemented in all tunnels longer than 500 m.

The complexity of an underground structure – environment, planning and construction, safety design, operation and management procedures, etc. – and the fast technological advancement have led to the concept of the “tunnel system”.

Due to the accidental events, the European political response and the engineering technique, safety in tunnels has become a central and complex issue involving:

*Corresponding author: alessandro.focaracci@prometeoengineering.it

- Users’ behaviour in emergency situations;
- Infrastructure characteristics (construction typology, escape routes, portals, etc.);
- Operational characteristics, such as type and functioning of the equipment installed, including safety measures (fire prevention, ventilation, lighting, etc.).

Technological innovations have led to the tunnel concept evolution from civil works to technological infrastructure, where the installed technology overcomes the geometric-functional limits, increasing its operating capacity.

The purpose of this paper is to illustrate the fundamental principles of SCADRA (Supervisory Control Acquisition and Dynamic Risk Analysis) system, developed and implemented thanks to EURAM methodology and software [1], which assessed the risk of over 600 Italian road tunnel tubes according to the Legislative Decree 264/06, to present and comment the most significant results obtained and to identify possible future developments, in terms of tunnels’ safety improvement and conservation and tunnels’ maintenance and management.

2 SMART TUNNEL

Smart Tunnel idea [2] comes from the achievement of Industry 4.0, in which there is a strong industrial automation that integrates the most innovative technologies (integrated memories, wireless sensors, integrated actuators and intelligent software), in order to improve the operating and safety conditions and increase the equipment productivity and quality.

Smart Tunnels allow optimal tunnel management during operation and in emergency situations thanks to the installation of traditional and technological sensors and the real-time assessment of tunnels’ safety level, as a function of climatic conditions, traffic data and equipment state, in accordance with the Legislative Decree 264/06. Smart Tunnel together with SCADRA system (Figure 1) allow controlling the systems in the tunnel and improving the effectiveness of the operational and integrative measures increasing the safety of the users and producing also other advantages like energy savings and the improved scheduling of maintenance.

Figure 1. Smart tunnel with SCADRA.

SCADRA system was installed in three Italian road tunnels, executing over 130,000 instantaneous risk analyses in real situations and this report illustrates the main results and the considerations that can be drawn for a correct tunnel management during normal operation and emergency situations (Table 1).

Table 1. SCADRA analyses report.

Tunnel	N. of instantaneous risk analyses executed	Hours of analysis [h]
TUNNEL 1	8.640	2.160
TUNNEL 2	92.160	23.040
TUNNEL 3*	28.608	7.152

*Data analysed from 15/10/21 to 10/11/22.

From the results of the first installations, the Supervisory Control Acquisition Dynamic Risk Analysis (SCADRA system) is proving to be a powerful prevention tool that significantly increases the resilience of road tunnels. Since 2019, the system is installed in tunnels with different structural and technological characteristics and with different environmental and traffic characteristics, and the results are clear and consistent with each other, as shown by the analysis of the data of the first plants.

3 SCADRA SYSTEM

The Supervisory Control Acquisition and Dynamic Risk Analysis (SCADRA) is a system that continuously monitors the tunnel state by collecting the variables that can influence the tunnel safety conditions (equipment and structures state, traffic data and environmental parameters) and performing a dynamic risk analysis, quantitative and probabilistic, at regular intervals or due to sudden change in the gathered data [3]. If the risk level grows towards the unacceptability threshold or in case of anomalous situations (traffic flows increase, equipment deterioration, etc.), SCADRA activates or signals the necessary safety measures in order to restore the required safety level. Instead, if the risk level is low for a certain amount of time, SCADRA suggests energy saving strategies to perform energy management for the lighting and ventilation equipment [4].

SCADRA configuration sets alongside the traditional SCADA, a system of acquisition of all the parameters, that can influence the tunnel management (collecting dated related not only to systems fault and malfunctions, but also on traffic type and intensity, dangerous goods and vehicles presence, air quality, visibility, wind speed, etc.) in order to get information on safety systems operating status, on environmental conditions and on traffic status within the tunnel, necessary for the subsequent dynamic risk analysis. Through the elaboration and analysis of all parameters, obtained from sensors and system,

a continuous safety level monitoring of the tunnel is carried out, performing the Dynamic Risk Analysis at regular pre-established intervals, under normal operating conditions and in emergency case. The equipment installed elaborates an analysis on a series of external input data. These external input data have been divided into 2 macro categories:

- Fixed inputs are the input data related to the tunnel structure, which are not variable over time, unless the structure characteristics or the tunnel systems changes;
- Variable inputs are the input data that may vary over time, such as the weather situation, the vehicular flow data and the actual tunnel systems efficiency (lighting, ventilation, etc.).

SCADRA subsystem acquires, as dynamic inputs, the input data and the parameters necessary for its processing, directly from the SCADA tunnel. The information provided by the sensors and the historical data recorded are processed by the SCADRA through a specific software in order to execute a risk assessment in real time and to determine if the risk is tolerable or if it is necessary to implement further safety measures (Figure 2).

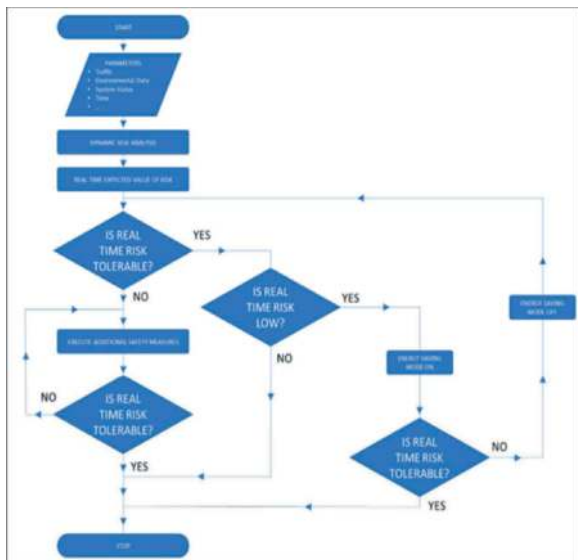

Figure 2. SCADRA flow diagram.

According to the expected level of risk, SCADRA provides a safety management (Figure 3) that can be used for:

- Planning preventive measures, like reducing speed limits, minimum distance among vehicles and prohibition of overtaking for HGV;
- Executing protective measures, such as sending communications to users, fire brigade alert, interruption of the systems energy saving mode.

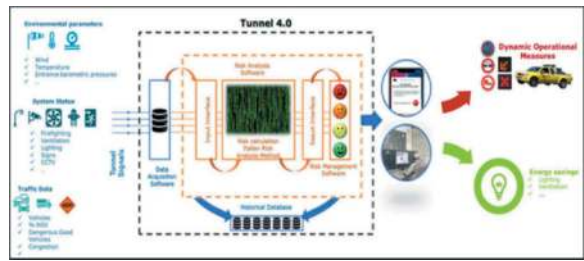

Figure 3. SCADRA system layout.

4 DYNAMIC RISK ANALYSIS (DRA)

SCADRA is based on the Dynamic Risk Analysis (DRA): the data are acquired by technical systems and specific sensors. Afterwards, a processor installed in the server performs the DRA and manages the residual risk (Figure 4).

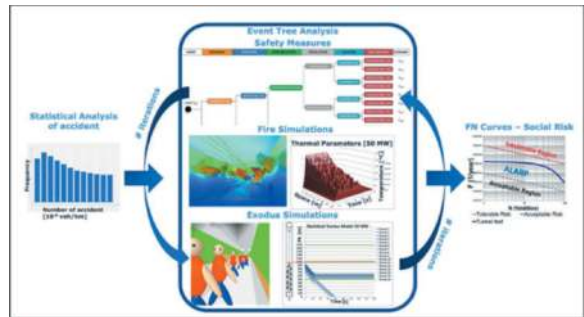

Figure 4. DRA method.

The DRA results are processed in order to classify the value of the risk according to pre-established levels that allow to undertake the appropriate actions associated with them and envisaged in the risk management plan, and it is normally implemented every 10 to 15 minutes, during the operation period, and in case of sudden changes of traffic or environmental conditions and operating level of safety systems.

The risk value is obtained by executing the quantitative probabilistic analysis, according to the method defined by the Italian Law (Italian Risk Analysis Method - IRAM), and the results are represented by the Live Expected Value of Damage (LEVD) and the F-N Curve, which defines the social risk.

The tolerability and acceptability criteria are settled by evaluating the risk level in real time (Live Expected Value of Damage - LEVD) and by comparing it with the reference value, assessed during the tunnel design and approved by the Administrative Authority. If the real time risk becomes relevant, SCADRA starts to manage the technical systems and to introduce effective safety operational measures that can reduce it (Figure 5).

The risk level, calculated as Live Expected Value of Damage (LEVD), has been classified according to 4 categories of instantaneous risk:

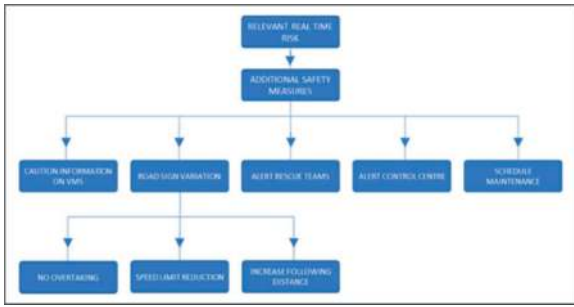

Figure 5. Relevant real time risk.

- Level 1: Low risk level (LEVD continuously below the reference value), which corresponds to optimal safety conditions, where the energy saving mode can also be permitted;
- Level 2: Normal risk level (LEVD close to reference value), which corresponds to standard safety conditions;
- Level 3: Pre - alert level (LEVD is equal to the reference value);
- Level 4: Alert level (LEVD exceeds the acceptable risk level).

The risk levels are represented by a graphical interface, which shows different coloured emoticons according to the real time risk level (Figure 6).

Figure 6. Risk levels.

The graphical interface shows the LEVD trend related to the surveys taken in the last 24 hours and it highlights the significant deviations of the input parameters (Figure 7).

A browser-based graphical user interface was developed in order to be user-friendly to facilitate the control centre operator in the real time risk level monitoring and to easily understand the causes behind the risk level increase and to quickly decide on the necessary safety interventions.

5 SCADRA AND ROAD TUNNEL RESILIENCE

Tunnel resilience has been defined, by PIARC Technical Committee 4.4 “Tunnel”, as “The ability to prepare and plan, resist/absorb, recover or adapt more successfully (promptly and efficiently) to the actual or potential negative effects of events or developments affecting the use of a tunnel. In this context, an acceptable level of safety is an essential constraint

Figure 7. SCADRA interface.

for the availability of the tunnel”. SCADRA system installation perfectly fits within improving road tunnel resilience, since it is always possible to know in real time what happens inside the tunnel, the environmental conditions, the traffic data and the system status. Therefore, SCADRA allows to monitor continuously the tunnel risk level (Figure 8) and, if needed, to apply operational measures with the purpose of ensuring the required safety.

Consequently, the system supports the increasing of the road tunnel resilience by preventing and planning safety measure according to every critical situation that might occur. Among all possible applications, it is possible to:

Figure 8. Data collected analysed by SCADRA.

- Pre-alarm the entities involved in the emergency;
- Interrupt of the energy saving mode;
- Identify critical solutions in real time;
- Alert users in critical situations;
- Reduce the evacuation and rescue time;
- Restore the acceptable risk level by intervening on the technical systems or through management operations;
- Plan optimal maintenance, focusing on users' safety;
- Reduce maintenance operating costs and interventions time.

SCADRA system can also represent an effective optimization for the firefighters' management, in order to reduce the instantaneous residual risk in critical conditions, such as congested traffic in a tunnel with longitudinal ventilation. Furthermore, through the continuous acquisition and processing of data, it is also possible to have preventive maintenance focused on user safety, with the aim of reducing interventions, operating costs, intervention times, MTTR (Mean Time To Repair), and system(s) unavailability.

Therefore, SCADRA system allows to operate and manage technical systems improving the effectiveness of operational and integrative measures, by enhancing the maintenance design and planning and considering the users' safety.

6 INSTALLATION RESULTS

SCADRA implementation is quite simple: an industrial PC is installed in the main technical room and connected with the SCADA system and all the necessary sensors. The software installed in the SCADRA allows the DRA execution.

SCADRA cost is compatible with a SCADA system cost, but the obtainable benefits from SCADRA are remarkable as described in the previous paragraphs. In fact, SCADRA has already been successfully installed in unidirectional road tunnels in operation.

The system has been installed in tunnels with different structural and technological characteristics and diverse environmental and traffic characteristics. The main significant data obtained from the tunnels analysis and the main characteristics are summarised in Table 2.

Figure 9 Shows the trend of the LEVD calculated by the SCADRA system in real time for the three tunnels for a period of four days.

It is interesting to observe the excellent consistency of all the data and the risk trend in the different situations which for each tunnel are absolutely different from each other both in terms of type and intensity/severity.

7 CONCLUSIONS AND FUTURE CHALLENGES

Increasing tunnel resilience is mainly achieved through the search for a continuous improvement in safety during the tunnel operation, by applying the dynamic monitoring of the risk conditions in the tunnel through SCADRA, and targeted maintenance which takes into account the ageing of construction materials and the interaction with the environment, which can endanger infrastructure stability and functionality, as well as the users' safety.

The current technical and technological progress in the field has enabled the safety achievement, for this reason the SCADRA system can be considered a powerful prevention tool that should be integrated in all types of tunnels to increase their resilience. From the applications examined, it has been seen that this system is also suitable for existing tunnels by exploiting innovative low-cost technologies and improving safety in old tunnels thanks to operational measures integrating the systems and, if necessary, replace the lack of requirements.

Italy is the European country with the largest number of tunnels with about 650 km of tunnels in operation on TERN and, worldwide, Italy is second only to Japan for tunnel equipment. Over 600 tunnels

Table 2. SCADRA analyses report.

Distance between emergency exits [m]	460 m	400 m	300 m

Figure 9. LEVD calculated by SCADRA system.

many of which were built before the 90s and immersed in often very poor soils. This particular feature requires special attention to the theme of resilience of underground works. Therefore, the topics of safety in operation, of a correct structural and plant maintenance and the monitoring of a tunnel play a fundamental role to increase its ability to react or adapt more successfully to the negative effects of events, actual or potential, which affect the tunnel usage.

SCADRA demonstrated to be a supplementary prevention and safety measure for the tunnels management, both during normal operation and in

emergency conditions, capable of guaranteeing real-time monitoring of the tunnel risk level. Future developments foresee that the SCADRA will also be able to monitor the structural state of the tunnels and any other structures, such as bridges, viaducts, as well as the presence of any landslides in the surrounding environments (Figure 10).

Tunnel asset management: Risk analysis through the MIRET approach

Federico Foria*, Gabriele Miceli & Mario Calicchio

ETS Srl, Rome, Italy

ABSTRACT: A high percentage of existing tunnels on heritage infrastructures is currently approaching or already exceeding the expected lifespan, and therefore require periodic and thorough inspections. Tunnel asset management becomes fundamental in order to guarantee the structure's safety and functionality. However, inspections could be problematic due to the danger and difficulty of operating on-site. Proper asset management would require an organized and systematic approach to evaluate and analyze all acquired information and data.

New technologies and methodologies, largely based on the use of mobile technologies and artificial intelligence, make it possible to create a complete digital representation of the infrastructure with reduced impact on traffic. The digital twin and the digital transformation of the processes allow an optimised workflow for the evaluation of the risks, that can be efficiently estimated, identified and mitigated.

Categorizing defects and using artificial intelligence to analyze them, make it possible to obtain a digital representation of the tunnel's state of the art, which allows for timely and effective maintenance intervention planning. Therefore, a new integrated approach, based on logical and coordinated decisions in a digital and multidisciplinary environment, is required. The MIRET (Management and Identification of the Risk for Existing Tunnels) approach allows the digital transformation of asset management, ensuring that existing tunnels meet modern safety standards, preserving their integrity through time and enabling the coexistence of environmental sustainability and technological growth.

By integrating and use efficiently these technologies and methodologies, engineers and professionals can effectively manage ageing infrastructure, improve safety, and ensure the long-term sustainability of critical assets.

Keywords: MIRET, Digital strategies, Survey, Inspection, Planning, Maintenance

1 INTRODUCTION

Infrastructures are crucial and strategic value in a country for both social and economic reasons. Its possibility to create connections and to ensure the movement of people and goods is a key for the development. Ensure the safety and the reliability of the risk management of them is therefore of a high importance and under focus of authorities.

Nowadays the environmental sustainability, together with the social sustainability, is becoming always more and more of a great relevance, and a lot of methodologies, beside the analysis of the safety take in consideration also the impact of the carbon emissions, their mitigation and adaptation to design new processes and products.

As reported also by a paper from Shanghai University (Sun, 2020) there is the need to analyze, integrate and implement tunnel management processes with

new, sustainable and reliable tools, in order to ensure safety of operators and the entire society.

Use of digital technologies is one of the most important tools in the hands of people who have the responsibility to manage tunnel maintenance, as reported by a paper of University of Science and Technology of Nanjing (Qihu Qian, 2016).

Working on the management system for the maintenance of existing tunnels is one of the path to reach the goal of a safe, sustainable and even more strategic infrastructure, and it is also the topic we present on this paper.

2 TUNNEL MANAGEMENT AND MAINTENANCE

The planning of resources, environments and the management of existing tunnels are central

*Corresponding author: federico.foria@etsingegneria.it

challenges for industrialized countries. The positive outcome of this challenge, which focuses on coexistence and collaboration environmental sustainability and an exponential technology growth, depends significantly whether objectives are successfully articulated in an understandable, visible, and comprehensive way, and based on clear, repeatable and objective data. This general framework is essential to be able to implement a strategy aimed at the management of existing assets by all the actors involved in the entire cycle of life of the work. A fundamental step forward will be to attribute, especially in the operation phase, a fundamental role to the user, as a single person, a group of people, companies that use and manage the infrastructure, and the environment in which it is deployed and interacts. The user fulfils a socio-economic role that requires greater transparency and possible involvement in the decision-making table. This is possible only with understandable and objective processes. However, a careful and effective management of tunnels that includes all the actors and all the activities related to inspection, planning, design, construction and maintenance is not yet usual. Therefore, proper management would require an organized and systematic approach to evaluate and analyze all the information acquired. ETS srl is moving in this direction, with a new approach based on logical and coordinated decisions in a digital and multidisciplinary environment. The creation of such a scenario requires a dense network of actors and a high concentration of economic, intellectual and technological resources. The summary point of this complex mechanism is MIRET (Management and Identification of the Risk for Existing Tunnels). MIRET is a methodology, a process and a technology for digitalisation, planning and digital and integrated management of existing tunnels. But MIRET is above all a new philosophy “of building”, which has conquered the trust of international experts in geo-technical engineering who have awarded its value with the title of best digital innovation at the Ground Engineering Awards 2020 (Digital Innovation), becoming a natural extension in the approach to different projects and flows, from hydrogeological instability to flood risk. The process combines innovative multidimensional mobile mapping survey systems, geotechnical and structural analyses, artificial intelligence and risk, in a common workspace at the service of technical and management table, to aim for a transparent, smart and sustainable system for the planning, design and maintenance of tunnels. The general approach is focused on an integrated workflow capable of linking and manipulating survey-inspection data over time, standardizing processes and languages. This is where the MIRET journey begins, from the surveys, investigations and inspections.

Figure 1. MIRET puzzle chart. Flow of information and their correlation used for the asset management platform starting from survey and inspection and arriving at the Works for Maintenance.

2.1 *Survey and Inspection (SI)*

The current tunnel surveillance system is based on visual inspections, usually conducted on foot or on a trolley with partial or total disruption of traffic. On the one hand, this implies greater attention to the work, on the other hand it creates a situation of discomfort, for users who are excluded from using the infrastructure, for the operators, with a high risk for their own safety, and finally for the managers, who have to face a high resource expenditure. The latest technologies enable survey and inspection of tunnels and infrastructures with Mobile Mapping. These systems can operate at different speeds, depending on the precision and accuracy to be obtained and based on the engineering and management purposes. Mobile Mapping can count on great advantages in terms of speed, efficiency and safety, reducing downtime on the line and moving the activity back office. In this scenario, ETS srl has developed a proprietary Mobile Mapping system: ARCHITA (Foria F. et al., 2019), which in a single pass acquires georeferenced data from several sensors installed on a moving vehicle, and, through the use of appropriate post-processing techniques, allows to obtain a consistent number of information representative of the actual state of the works.

Figure 2. ARCHITA configuration for rail inspection, equipped with tunnel scan, lights, georadar, thermal imaging cameras.

ARCHITA is a multidimensional system, ideal for the survey of linear infrastructures, which allows to acquire simultaneous and integrated information with the use of different technologies, such as: laser scanners, georadar, thermal imaging cameras and high-definition photographs.

Figure 3. ARCHITA example of data acquisition (from left to right) by: laser scanner, thermal imager, high definition photograph from tunnel scanner.

Data acquisition takes place with limited disruption of traffic flow, as the system allows to survey the entire tunnel at sustained speeds (i.e. 15-30 km/h) with a single pass. The reconstruction of geometry and state of consistency of the tunnel takes place with more objective, clear and repeatable data. These assumptions are essential for the survey and inspection phase, often at the top of the MIRET process, as it can be repeated cyclically, or in post operam phase, to collect and analyze data at different instants of time. This is the only way the inspection can become a tool for monitoring the actual state of the work in order to carry out a predictive and objective analysis.

2.2 Defect Analysis (DA)

The thermal-photographic acquisition system installed on ARCHITA, consisting of 3 high resolution linear cameras with 16 LED lights system and 1 thermal camera, allows to obtain a high-resolution photographic reconstruction of the tunnel lining and carry out a detailed defects analysis retrospectively. Key tools of this process are defects catalogues and the relative algorithm for combining the parameters considered, in order to obtain synthetic indices representative of the actual state of the work. Nowadays there is a great variety of catalogues and methods among the clients. There are many differences in the decision-making choices and more generally in the infrastructure management and planning system. MIRET considers the same key tools, but different catalogues and methodologies adopted by the clients are unified in a single standard, which acts as an order system, rather than as a further tool in addition to those available. Subsequently, defects are digitized through a specific software environment in order to

obtain output in standard digital formats, ready to be integrated in the following stages.

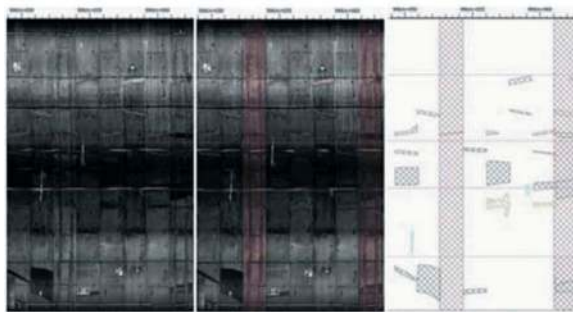

Figure 4. Defect analysis and graphic outputs.

The digitized data can be integrated with data acquired with punctual tests and traditional inspections. Defects are statistically processed and combined in order to obtain easy-to-read indexes, both for the entire tunnel and for sectors of the same. The acquisition of actual state and the digital mapping of defects are part of the standardized, repeatable and objective workflow in the MIRET process which allows a time comparison. Such comparisons also make it possible to generate models on which predictive maintenance is based. Predictive maintenance is fundamental in terms of resource planning and management. The diagnostic process thus becomes repeatable and automatable. ETS srl has chosen to invest in the development of Artificial Intelligence (AI) algorithms for the defect detection (Foria F. et al., 2021a). To date, this algorithm is capable of detecting and segmenting defects related to the presence of water, cracks and detachments, for masonry and concrete. Development starts from the Crack SegNet implementation (Ren, Y. et al., 2020), with a Convolutional Neural Network (CNN) able to automatically detect and segment some defects starting from the analysis of the images. The implementation was done in Python and C++ using Google's Tensorflow software library which, among the available libraries, had the best processing times. Algorithm training was performed on a dataset of 100-1,000 images. Validation and tests carried out on images not used in the training phase show a slight overestimation of defects by AI (10% more on average) than manual detection. Such overestimation has been deliberately calibrated to get ratings that, for the benefit of safety, don't underestimate the problems of the tunnel. Big data therefore becomes smart data, which is then validated by specialized operators. The result is that ETS proprietary software MIRET-Tunnel AI allows line disruption times to be reduced from day/km to h/km.

Figure 5. Manual detection vs AI detection. A slight over-estimation of defects by AI (10% more on average) than manual detection can be observed.

2.3 Digitization (DI)

Digitization (DI) means all those processes which, starting from the Survey & Inspection phase, lead to the creation of a digital model of the work in question. Through the combination of laser scanner and ground penetrating radar of ARCHITA, it is possible to create a 3D model of the tunnel and associate the related information to set up the digital twin in BIM, with the physical and functional characteristics of the work (Foria, F. et al., 2020). In this way, a close relationship can be established between the graphic representation of the model and the technical information that the model is able to store and report with various scales of definition and information. The geometric reconstruction is used as a support tool for the milestones of the MIRET methodology, but also as a check tool in its own right (i.e. transitivity checks for limit gauges in the railway sector).

2.4 Planning and Design (PD)

Available data and/or milestones (Defect Analysis, Digitalization and Work & Maintenance) underlie the crucial phase of Planning and Design (PD). In this phase, decision-making and design strategies are updated for the purposes of maintenance or management by the clients in a computerized environment (Foria, F. et al., 2020). Even in this case, each line manager makes use of its own flow which identifies the priorities of intervention according to technical and economic considerations. In MIRET, data coming from the mapping of the defects are processed statistically and combined with further parameters (e.g. geological context) which provide descriptive and analytical information on the boundary conditions in which the work is located. These categories are combined with each other through a Spatial Multicriteria Analysis (SMCA). The use of the SMCA is essential in order to have a general picture of the conditions of the tunnel with a structured and repeatable index that takes into account the danger of the phenomena and the vulnerability of the structures (Priority Index), to make comparisons over time and between different works (Foria, F. et al., 2021b). This assessment aims at the management and

identification of the risk for existing tunnels (MIRET) for the strategic management of resources and infrastructure assets. To do this, the following categories are taken into consideration: Seismic, Surface Geology, Deep Geology, Cracks and Water. In order to have a detailed and comparable analysis of the different areas, it was decided to divide the gallery into homogeneous sectors. The analysis described takes place according to the Italian guidelines (cslp.mit.gov.it). The ultimate goal is the management and identification of the risk for existing tunnels (MIRET).

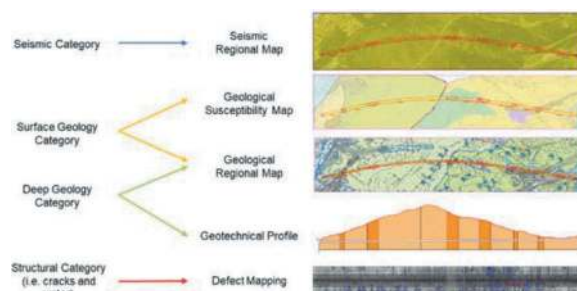

Figure 6. Considered Categories for the identification of risks (Sismic, Surface Geology, Deep Geology and Structural categories).

2.5 Work and maintenance

Any cycle of maintenance or intervention on the work passes through the Works and Maintenance phase, where the specific choices determined by the Planning & Design phase are implemented. From the realization of structural interventions to the simple sealing of cracks, this phase contains all the tunnel intervention solutions.

The intervention contributes to the tunnel system, reducing its risk and defining a further moment of analysis of its history. In fact, this gives us a new point of analysis from which to resume the phases of Survey & Inspection, Defect Analysis and heuristically bring together the phase of Planning & Design.

2.6 Monitoring (MO)

An effective Monitoring (MO) system provides a continuous source of data allowing a constant input through the different phases. Monitoring allows continuous evaluation, moving the analysis system towards a dynamic structure for asset management by the client and the choices to be made in the Planning & Design phase. This milestone makes it possible to update the parameters taken into consideration for risk calculation over time and to implement a predictive analysis model (Planning & Design phase) and predictive maintenance (Planning & Design, Work & Maintenance phase).

2.7 Asset management

The 'MIRETS Platform' asset management project is part of a digital transition context.

Figure 7. MIRETS Platform example of geolocalized and digitalized information for the management of tunnels in Italy.

It is aimed at creating a product that represents a digital service for analysing data relating to the infrastructure and assessing the risk and context of the same.

A systematic and forward-looking research and innovation strategy is essential to optimize resources in a sustainable way, both in a context of high-level management of infrastructure assets and as a data archiving system.

2.8 Sustainability of MIRET

For MIRET process, ETS specialists performed an environmental sustainability analysis to investigate the impact in terms of carbon footprint and social impact of the innovation.

To evaluate the decarbonization of the entire process, MIRET emissions of carbon dioxide were computed, analysed quantitatively and compared with two baselines which represent the most common way to inspect tunnels nowadays, one for rail tunnels and one for highways tunnels, both studied regarding carbon dioxide emissions.

The investigation followed the LCA (Life Cycle Assessment) approach, considering the entire lifetime of the process (the so-called "from cradle to grave"): it considered all the emissions involved from the on-site inspection to the final reporting.

Results show that there is a very interesting save in terms of CO₂ equivalent using the MIRET method, up to 90%, for some types of inspection and their management, thanks to ARCHITA digitalized process and the MIRET data elaboration process. Improvement in terms of safety for workers is also another achieved target for MIRET.

It is registered in risk analysis a reduction on both risk quantity (from 17 to 13 relevant risks) and risk entity (from an average of level 5 risk to an average of level 3,4). This is a great achievement in terms of social sustainability.

ETS researchers are also working not only on CO₂ equivalent reduction, as a Climate Change

effect mitigation, but also on climate change adaptation, by implementation of a tool, named C2Risk, able to identify and help reliable risk analysis for climate change on infrastructure as railways.

Figure 8. Example of C2RISK tool giving information about vulnerability to climate change of an Italian railway line, in terms of risk for infrastructures.

3 CONCLUSIONS

MIRET's milestones are varied and complex, as well as the connections between its elements. Experience, technique, multidisciplinary, innovation and, above all, balance are required. MIRET's systemic-relational approach draws solutions from cutting-edge technologies, IT structures and processes, linking them to a unified approach of clients, the actual and necessary leaders of resilient change. MIRET is not the answer to the balance question, but one of the main means of conveying it. Deep knowledge and conscious use of resources can make the difference in the impact of a work or its maintenance. Tunnels, bridges, support works, hydrogeological instability and infrastructures are just some of the elements in which engineering and technical value must be the balancer between grey and greenery, applying flexible solutions that aim at the resilience of the work and its perfect integration with the surrounding environment for the duration of the cycle of life (and beyond).

ACKNOWLEDGMENTS

The authors thank the Geotechnics, Geology and Hydraulics Department and the Research and Development Department of ETS for the experience shared which was fundamental in the methodology.

Tunnel renewal strategy – The evaluation of the advantages through LCA

Sara Frisiani*, Matteo Pierani, Francesca Magnelli, Lapo Baccolini & Andrea Poli
Tecne Gruppo Autostrade per l'Italia S.p.A., Roma, Italy

ABSTRACT: The assessment of the environmental impact of all the phases of a production process, whether related or independent within the entire production cycle, is booming within the world of large road infrastructures and civil engineering.

Considering the relevant environmental impact of construction materials, due both to their production process and to the enormous volumes used, the introduction of the concept of ‘Life Cycle Thinking’ within the preliminary assessments of a large infrastructure is nowadays strategic and opportune.

The environmental performance of the infrastructure, assessed by Life Cycle Analysis (LCA) methodology, can become a tool for designing and choosing between engineering solutions, as is already the case for technical and economic aspects.

This paper will illustrate the results of an LCA applied to the works to fully relining an existing tunnel, originally built in the 1960s and located in the Tuscan section of the main Italian motorway (A1), managed by the concessionaire Autostrade per l'Italia (ASPI).

The study is focused on the comparison between a traditional solution using standard reinforced concrete and an innovative solution using a special fibre-reinforced concrete, which guarantees better environmental performance and speeds up the maturation of the concrete, guaranteeing, for the same activity, a shorter duration of the construction works.

Keywords: Road tunnels assessment, Re-lining works, Innovative concrete, Construction site, LCA, Environmental impact

1 INTRODUCTION

In 2020 ASPI has launched an extraordinary Tunnel assessment plan, performed on 365 km of motorway tunnels belonging to the Italian highway network, mainly built in the 1960s and 1970s by systematic inspections and testing combined with reactive maintenance works.

Within the 3 years (2020-2023) experience the Concessionaire ASPI together with its design agency TECNE has developed the so-called Tunnel Renewal Strategy (Alessio et al., 2022) which provides a new approach to Tunnel Rehabilitation.

Based on the results of detailed inspections and analyzing the development of defects and degradation of the tunnel final lining the effect of water as well as the natural degradation of the concrete and masonry linings, the effect of water has been found as the main driver of deterioration. For this reason, the TRS approach is aimed, not only to the extension of tunnel linings’ life cycle of at least additional 50 years, through the construction of new inner shell, able to

replace the structural function of the existing one but to integrate an additional waterproofing layer capable to collect mountain water and to insulate the new inner lining from the effect of water.

In order to allow rapid construction site start-up and dismantling and overall construction period thus mitigating the impact on motorway traffic, the TRS has required innovative technical and technological solutions like use of high performance materials, automation and mechanization of operations, the maximization of flexibility in terms of sites and logistics.

The selected case study (Ragnaia II tunnel) is part of a broader plan for the structural renewal of existing tunnels along the Tuscan section of the A1 highway. The Ragnaia II Tunnel, which is approximately 130 m long.

The study presented in this paper aims to analyse the environmental impacts associated with two methods for carrying out the tunnel renewal. Specifically, (1) through the Life Cycle Assessment (LCA) methodology, the impact on various environmental

*Corresponding author: sara.frisiani@tecneautostrade.it

issues will be estimated, with particular reference to climate change, associated with two different design solutions that, with the same structural performance, refer to the use of different materials: a traditional reinforced concrete and a particular fibre-reinforced concrete. Then, the elements related to site logistics are analysed, with particular attention to the sustainability (2) of a solution that, thanks to a greater speed of execution of the work, allows for the minimisation of traffic impacts and road congestion.

2 THE RAGNAIA II TUNNEL

The Ragnaia II Tunnel is a twin bore tunnel located between the ch. 272+428 and the ch. 272+556 of A1 highway. It has a straight alignment and an upward profile toward the North. The relining concerns the right-hand bore.

The tunnel is excavated through conventional method. The tunnel also has two artificial tunnel sections of approximately 7,5 m and 29,8 m in length, respectively, at the Bologna-side and Florence-side entrances. Furthermore, it was built in the 1960s and is characterized by an unreinforced concrete final lining.

2.1 Solutions compared

Table 1 shows the technical specifications of the concretes used in the two different design solutions.

Table 1. Technical specifications of the concretes used in the two different design solutions.

Technical specifications	Reinforced Concrete Lining	Fiber-Reinforced Concrete Lining
Concrete strength class	C45/55	C50/60
Concrete exposure class	XD1 XF2 (Tab.4.1.III NTC2018)	XD1 XF2(Tab.4.1.III NTC2018)
Concrete slump class	S5 (UNI EN 206)	S5 (UNI EN 206)
Incidence steel bars	174 kg/m ³	-
Incidence steel fibers	-	40 kg/m ³

In addition to the differences summarised in the table, a further point of divergence between the two concretes concerns the maturation speed. The innovative binder used in the production of fibre-reinforced concrete, in fact, guarantees shorter maturation times of the concrete mix compared to traditional concrete made with CEM IV 42.5R. It is estimated that the time required to cast the innovative concrete is halved (22 days) compared to the time required to lay traditional concrete (44 days).

3 MATERIALS AND METHODS

The quantification and comparison of the sustainability of the two operational methodologies is carried out by implementing a life cycle assessment (LCA). Based on the current ISO standard reference standards (UNI EN ISO 14040 and UNI EN ISO 14040), an LCA study consists of the steps listed below.

1. Goal and scope definition: preliminary phase in which the purpose of the study, the functional unit, the system boundaries studied and the assumptions are defined;
2. inventory analysis: quantification of input and output flows for all the processes analysed;
3. impact assessment: aggregation of the inventory results, using scientific models, into potential environmental impacts;
4. interpretation: analysis of the results obtained.

The four steps of a life cycle assessment are inter-related, making the entire process iterative (Figure 1). In fact, each step is based on the results obtained in the previous step. This promotes the completeness and consistency of the study and any changes made at previous steps are carried over to subsequent levels of the analysis

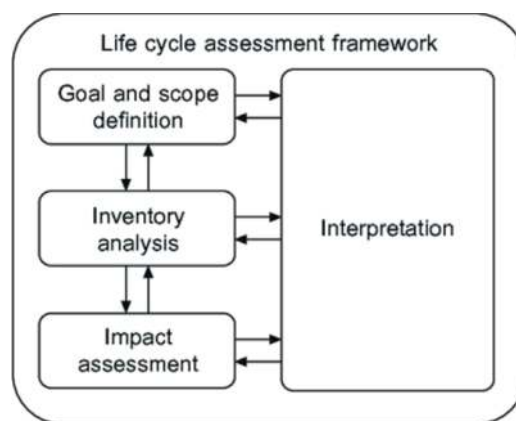

Figure 1. LCA framework - ISO 14040/14044.

3.1 Goal and scope definition

This study analyses the environmental implications of two different methodologies used for the lining of the right tube of the Ragnaia II Tunnel. Two different concrete solutions, listed below, were identified for the relining of the structure.

1. Classic solution: traditional reinforced concrete;
2. Innovative solution: concrete with innovative binder and steel fibres.

3.2 Functional unit

The term “functional unit” means the reference for the implementation of a life cycle assessment. The functional unit is represented by the portion of the

tunnel affected by the lining, equal to 128 m. The different solutions guarantee the same structural performance and are subject to maintenance at a similar frequency. A unit length was not taken as a reference due to the presence of fixed impacts independent of the linear development of the site.

3.3 System boundaries

The system boundaries, where the LCA is carried out, include the production and the construction phase of the material required to provide the lining of the tunnel. The decision not to consider the maintenance and disposal phases was determined by the desire, at this level of the analysis, to give more attention to the construction phase of the lining to compare the environmental sustainability of the construction materials. Specifically, phases of the production of two types of concrete, the production of steel and the production of all elements used in the tunnel lining were included; the site operating equipment, which differed in type and time of use according to the two concrete solutions used, was taken into account; the transport of construction materials to the site was also counted. Figure 2 summarises the system boundaries.

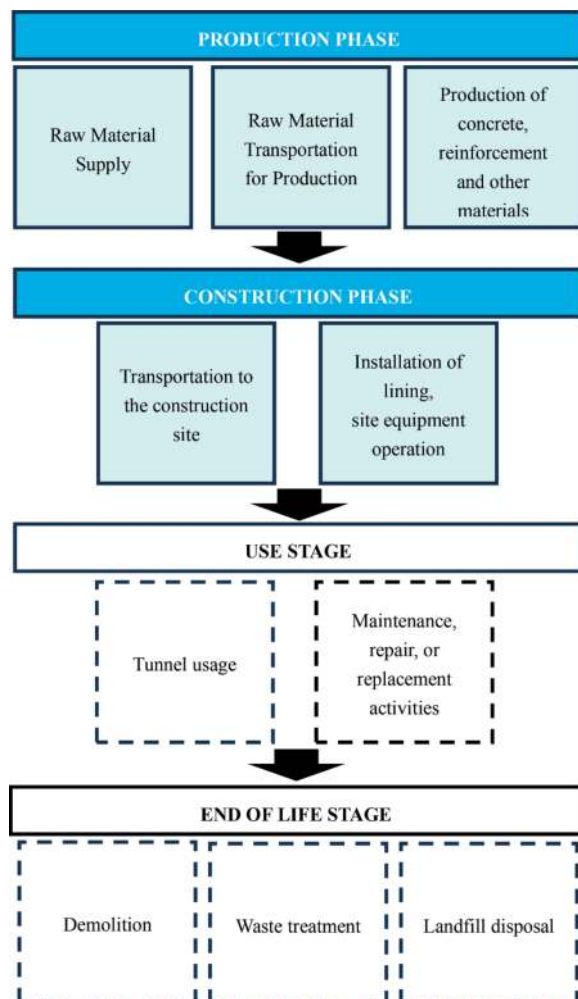

Figure 2. System boundaries. The not colored boxes represent the life cycle phases that are not considered.

3.4 Inventory analysis

In this step of the LCA, all input and output material and energy flows are considered for each life cycle phase studied, related to the functional unit. The sum of the emissions of the materials used and the processes implemented, within the system boundaries, constitutes the overall emissions of the tunnel lining process, which are transformed into environmental impacts at a later stage of the analysis. The collection of all emissions, at the selected life cycle stages, constitutes the inventory. In this study, the emissions associated with the different materials and production processes were obtained from the specific production plant or from databases. Listed below is information on how the materials needed to construct the inventory were sourced:

- Concrete with a traditional binder and fibre-reinforced concrete with an innovative binder: the specific production plant directly provided the emissions per cubic metre of the two types of concrete, without allocating the impact between the different constituent materials. Although based on only two individual products, for the purposes of this study, it is considered correct to use the data provided. In fact, it is assumed that they are manufactured at the same production site, and in this way, all variables associated with different production plants, for example the fuels used, the geographical production context or the raw material procurement method, have been eliminated;
- Reinforcing steel bars: the impact of reinforcing steel was quantified using the emissions associated with 1 kg of a generic steel in the ecoinvent v3.6 database (www.ecoinvent.org). This database details the raw materials and energy consumption required to make one unit of material. In the case of steel, its composition was modified to conform to a reinforcing steel produced in Italy in an electric furnace with a recycled steel percentage of 75%, as imposed by the Minimum Environmental Criteria for construction which, although not directly applicable to infrastructures, were taken as a reference for modelling the steel used in the classical solution. Varying the composition of the material changes its emissions.
- Paints, mortars, PVC sheets and geotextile sheets: similar to steel, the impact of these materials is derived from generic elements in the ecoinvent database;
- Transport: Emissions associated with the transport of materials depend on means of transport used, distance travelled and quantity of material transported. The ecoinvent database offers a wide variety of selectable vehicles but, due to focus is mainly on the impact of construction elements, a common vehicle was selected for all materials transported from the different production plants to the construction site. The database expresses

the emissions of the means of transport in terms of “kg·km”. This because the emissions of a vehicle increase as the load transported increases and, of course, as the distance travelled. 250 km from the reinforcing steel production plant to the construction site was considered; this value is an average of the distances of two plants that would likely supply the construction site. The impact of concrete transport is quantified not in terms of distance but in terms of the amount of fuel and compressed air consumed by the concrete mixer on the way to the construction site. The quantities of fuel and compressed air are estimated from similar construction sites;

- Fuels: in order to quantify the impact related to the installation of materials and the operation of site equipment, which ensure the correct execution of activities, the quantities of diesel, petrol, electricity, lubricant and compressed air used were estimated from similar construction sites. The emissions reported by the ecoinvent database were associated with these quantities. Also included in this category are the fuels consumed to transport all materials other than steel from the production plant to the construction site: paints, mortars and sheets, as well as concrete. Table 2 summarises the estimated construction site equipment with relative consumption of diesel and lubricants.

Table 2. Construction site equipment consumption.

Equipment type	Diesel [lt/h]	Lubricants [lt/h]
Generator set	3,5	0,49
Aerial platform	15	1,5
Truck 4-6 tons	12	1,2
Truck 1,6-4 tons	8	0,8
Compressor for concrete pump, 65 kW	13	0,14
Spritz pump(concrete mixer)	18	1,8
Tanker >18 tons	18	1,8

Table 3 summarises the materials and the relative environmental information collected during the inventory. The emissions of all materials, with the exception of concrete, were taken from average data, modified if necessary, in ecoinvent. The original string by which they are identified in the database is shown.

3.5 Impact assessment

Impact assessment is the stage in which the emissions collected during the inventory are translated into potential impacts affecting specific environmental components called ‘impact categories’. The LCA methodology involves the division of the

Table 3. Summary of materials analysed.

Construction materials	Ecoinvent string
Concrete classic solution	Emissions Modeled from a Specific Manufacturing Plant
Concrete innovative solution	Emissions Modeled from a Specific Manufacturing Plant
Reinforcing steel	<i>Steel, low-alloyed {RER} steel production, electric, low-alloyed Cut-off, U</i>
Polyurethane paint	<i>Alkyd paint, white, without water, in 60% solution state {RER} market for alkyd paint, white, without water, in 60% solution state Cut-off, U</i>
Epoxy paint	<i>Acrylic varnish, without water, in 87.5% solution state {RER} market for acrylic varnish, without water, in 87.5% solution state Cut-off, U</i>
Two-component background painting	<i>Acrylic varnish, without water, in 87.5% solution state {RER} market for acrylic varnish, without water, in 87.5% solution state Cut-off, U</i>
Anti-sale siloxane primer	<i>Polydimethylsiloxane {GLO} market for polydimethylsiloxane Cut-off, U</i>
Mortar	<i>Cement mortar {RoW} market for cement mortar Cut-off, U</i>
Epoxy filler	<i>Stucco {GLO} market for Cut-off, U</i>
PVC sheets (2 mm thickness)	<i>Polyvinylchloride, bulk polymerised {GLO} market for Cut-off, U + Extrusion of plastic sheets and thermoforming, inline {GLO} market for Cut-off, U</i>
Water	<i>Tap water {Europe without Switzerland} market for Cut-off, U</i>
Lubricant	<i>Lubricating oil {RER} market for lubricating oil Cut-off, U</i>
Compressed air	<i>Compressed air, 1000 kPa gauge {RER} market for compressed air, 1000 kPa gauge Cut-off, U</i>
Diesel	<i>Diesel, burned in building machine {GLO} market for Cut-off, U</i>
Petrol	<i>Petrol, unleaded, burned in machinery {GLO} market for petrol, unleaded, burned in machinery Cut-off, U</i>
Electricity	<i>Electricity, medium voltage {IT} market for Cut-off, U</i>

‘environmental system’ into a limited number of categories that are impacted, according to different environmental mechanisms, by the emissions generated in the considered life cycle phases. In this study, the environmental results are expressed according to the impact categories referred to the EN 15804 standard, except for the “climate change” category for which, for the simplicity of communication, the environmental results will be expressed in the aggregate form “GWP”.

Each emission collected during the inventory phase is associated with one or more impact categories. Each emission is multiplied by equivalence factors (FE) that express the contribution relative to a reference emission, whose FE is equal to 1 by definition. After the application of the equivalence factors, each impact category will be expressed with a specific unit of measurement.

The association of emissions with specific impact categories, the application of equivalence factors and the sum of emissions within each impact category are performed using the LCA software SimaPro v9.5. This program quantifies the environmental impact by applying the “EN 15804+A2 Method v1.00” calculation method, which expresses the results in accordance with the EN 15804 standard.

3.6 Interpretation

The environmental impacts of the two tunnel renewal methods are shown in tabular and graphic form (Table 4 and 5, Figures 3 and 4). The items expressed in the header of the tables include production, transport to the site and installation of the material. The exception is the item “site equipment” which only describes the energy consumption of the vehicles and machinery used during construction, without counting the impact associated with their production and transport to the construction site.

Table 4. Environmental impacts, classic solution - EN 15804+A2 Method v1.00.

Impact category (unit)	Steel	Concrete	Site equipment	Other	Total
GWP (kg CO ₂ eq)	1,56E+05	4,17E+05	1,02E+05	7,37E+04	7,49E+05

Figure 4. Environmental impacts, innovative solution - EN 15804+A2 Method v1.00.

For almost all categories, most of the impact depends on the production and installation of the concrete, in the innovative scenario, or the production and installation of the concrete and steel in the traditional scenario. It is therefore evident that technological improvement strategies need to be implemented for these two construction materials in order to limit environmental externalities. Globally, it is estimated that around 8% of total CO₂ emissions are due to the cement industry (Supino et al., 2023).

Table 6 compares the aggregate environmental impacts in the different impact categories of the two tunnel renewal solutions. The last column represents the percentage variation of the environmental impact of the innovative solution compared to the traditional solution.

WDP	m ³ depriv.	1,03E+05	1,02E+05	-1%

allow the application of weights to prioritise impact categories; therefore, it is not possible to discriminate which of the two solutions is more environmentally impactful in absolute terms. However, following the international sustainability goals that aim to achieve climate neutrality by 2050, as mandated by the Paris Agreement, it is appropriate to focus primarily on the “climate change (GWP)” category, which represents the effects of climate-changing emissions. The reference unit is the CO₂ equivalent (CO₂ eq).

Figure 5 shows that the relining performed with innovative concrete has a reduction in CO₂ eq impact of 12% compared to the operation performed with traditional concrete.

Figure 5. GWP tunnel renewal, comparison - EN 15804 +A2 Method.

Still focusing on the most highly-prioritised impact category, the climate-changing emissions associated with the production and installation of construction materials are presented in Table 7 and Figure 6, Table 8 and Figure 7, on the other hand, express the impact on climate change generated by the use of construction equipment.

Table 7. GWP production and installation of construction materials, comparison - EN 15804+A2 Method.

Impact category	Unit	Traditional solution	Innovative solution
GWP	kg CO ₂ eq	6,50E+05	6,23E+05
GWP compared to traditional solution	%	100%	96%

Figure 6. GWP production and installation of construction materials, comparison - EN 15804+A2 Method.

Table 8. GWP construction equipment, comparison - EN 15804+A2 Method.

Impact category	Unit	Traditional solution	Innovative solution
GWP	kg CO ₂ eq	9,94E+04	3,51E+04
GWP compared to traditional solution	%	100%	35%

Figure 7. GWP construction equipment, comparison - EN 15804+A2 Method.

The results show that the impact of the construction site is decisive for the quantification of overall climate-changing emissions.

4 SITE LOGISTICS

Environmental impact is not the only element to be analysed to define the sustainability of the intervention under study. In fact, it must also include assessments concerning the social and economic spheres of the sustainability. The parameter used to assess the overall sustainability is time.

The duration of the maintenance work in the two solutions varies depending on the concrete casting speed and the time required to assemble the prefabricated steel reinforcements cage: in the classic configuration, the steel reinforcement is used for the entire covering, while in the innovative solution, only the sidewalls will be reinforced, with a significant reduction in time. The solution using traditional concrete requires an average concrete casting speed of 3 m/day, while the fibre-reinforced concrete casting is at twice the speed of approx. 6 m/day, thanks to the higher maturation speed of the concrete mix, which ensures that the formwork will advance in less time.

Relating the length of the tunnel (128 m) to the concrete casting speed, the paving of traditional concrete takes around 44 days compared to 22 days for fibre-reinforced concrete. Considering also all the other intervention phases and counting a shorter time required for the assembly of the prefabricated steel reinforcements cage in the innovative solution, the relining carried out using fibre-reinforced concrete guarantees an estimated time saving of approximately 50 days compared to the intervention using traditional concrete.

The shorter construction time can be translated into lower environmental, social and economic impacts. In fact, although difficult to quantify in numerical terms, a longer construction phase creates the restriction of the road network with a consequent increase in travel time on the road section. This results in greater emissions for each vehicle that travels on the road interfered with by the construction site (environmental impacts); a reduction in road safety and an increase in noise pollution and stress (social impacts); last but not least, damage to local businesses based on the transport of goods and employees (economic impacts).

5 CONCLUSIONS

This study analyses the environmental impacts of two different ways to carry out the relining works of the right tube of the Ragnaia II Tunnel on the Tuscan section of the A1 motorway, which differ in terms of the type of concrete used: reinforced with steel in the 'traditional' scenario or with an innovative, fibre-reinforced bond in the 'innovative' scenario. The analysis was based on a life cycle assessment (LCA) from the production of the construction materials to the execution of the tunnel renewal.

The study showed that the intervention using fibre-reinforced concrete leads to a reduction in

climate change impacts compared to the solution using traditional concrete. This reduction depends not only on the different concrete mix used and the absence or presence of steel reinforcement, but also on the different number and timing of construction equipment used.

However, it cannot be said that the ‘innovative’ solution is less impactful in absolute terms due to the absence of standardized weight coefficients to determine the greater severity of the different impact categories. On the other hand, the high casting speed of fibre-reinforced concrete, thanks to the shorter maturation times required, means that relining according to the innovative method guarantees a shorter site duration, with consequent advantages in terms of environmental, economic and social sustainability.

The increase in traffic and road congestion caused by the longer duration of the construction site, although not quantified through LCA analysis in this study, presents objective problems that contribute to making the traditional solution less efficient.

ABSTRACT: Urban railroad tunnels located in seaside areas or near rivers at low tide where affected by leakage water containing chloride ions originated from seawater have been deteriorated particularly in rebar corrosion, while the restriction of repairing work time slot for the railroad structures in the Tokyo metropolitan area due to the quite limited construction time and narrow construction space makes repairing difficult. In addition, conventional patch repair method using polymer cement mortar with nitrite-based admixture has another issue such as slower repairing speed, less sprayable thickness and adhesion performance. Authors have suggested in this paper a newly developed "two-material shot repairing system" with polymer cement fiber mortar to overcome these subjects, by utilizing calcium aluminate powder that performs accelerator as well as chloride ion immobilizer and a liquid accelerator that is to be mixed up just before the spray nozzle. As a result, it was found that the construction cost can be reduced around 30% with keeping fairly same chloride proofing and with obtaining better workability and adhesion performance compared with the conventional patch repairing method.

Keywords: urban railroads, chloride induced corrosion, polymer cement fiber mortar, calcium aluminate admixtures, liquid accelerator, patch repair method

1 INTRODUCTION

In recent years, the proportion of aged infrastructure has tended to increase rapidly. Railroad owners always have the responsibility to supply safe and stable transportation while ensure the structure in proper condition to keep safety, serviceability, and ease of repair work. In addition, there is a demand for more efficient inspection and repair methods in the maintenance and management of railroad structures due to a decrease in the number of employees, lack of well-experienced engineers, increase in the number and frequency of survey points, and

reduction of the maintenance and management costs. Tunnels and shafts located on the waterfront of urban railroads and near rivers at low tide are subject to salt damage, and it is necessary to inspect, repair, and improve structures deteriorated by salt damage within the limited working slot and narrow working spaces. Repair methods that can extend the service life of existing structures at a low cost without causing re-degradation of repaired areas are required. Therefore, in this study, the authors decided to develop a new patch repair method using spray mortar for tunnel concrete structures deteriorated by salt damage in commercial urban railroad lines,

*Corresponding author: kose@jreast.co.jp

taking into account the to overcome several issues the above.

2 PREVIOUS STUDIES

Since generally the tunnel structures are unlikely affected by airborne salt and de-icing agents sprayed on roads, there have been quite limited reports on salt damage e.g. in the slab of Shinkansen tunnels and floor slabs of road tunnels by 1990s. Since 2000, intensive investigations have begun however mainly conducted in urban tunnels constructed by open-cut, submerged tunneling, and shield tunneling methods, such as subway, expressway, and power transmission line tunnels, and there are still few reports about repair and reinforcement work in these tunnels. These reports indicate that the salt damage in tunnels often occurs locally in the vicinity of water leakage and at locations where cover thickness for reinforcing bars is thin. Therefore, the patch repair method is effective among many kinds of repairing methods for salt damage of urban railroad tunnels.

Also, constraints in commercial rail line construction include short construction time and small construction space.

Figure 1. Example of work time for commercial railways construction.

As shown in Figure 1, the work time is limited to approximately 90 minutes. In addition, as shown in Figure 2, railway construction limit is set so as not to interfere with train operations, and construction facilities, including temporary facilities, must be located outside the railway construction limit. The time between the completion of the repair work and the start of train operation is short, and the repair method must be easy to apply, exhibit sufficient strength at an early stage, and have sufficient adhesion strength between the repair material and base concrete to stand the wind pressure and vibration caused by passing trains.

After considering these factors, authors concluded that the spraying method is the most superior for our targeted structures. The conventional spraying method

Figure 2. Margins of the construction limit on a commercial railways.

is to use a pre-blended type of polymer cement fiber mortar with chloride proof properties. As shown in Figure 3, This is a method to prevent salt affected using a polymer cement mortar with a mechanism to adsorb chloride ions (Cl^-) and release it with nitrite ions (NO_2^-) by blending a Ca-Al complex hydroxide called nitrite-type hydrocalumite. At present, the effectiveness of this method in terms of durability has been confirmed as shown by Ueda et al.(2012).

On the other hand, it was confirmed that there was room for performance improvement in terms of workability and adhesion under the constraints of this study. Therefore, it was decided to develop a new sprayed mortar utilizing cement mortar, polymers, short fibers, and calcium aluminate admixtures such as rapid hardener and salt fixing material. In this development, a two-material shot method is adopted where the liquid accelerator is added before the spray nozzle. Table 1 shows the performance of the conventional method and the required performance of the newly developed method. The target performance values for workability and adhesion were set based on the construction conditions of the target repair area, while those for durability were set with reference to the performance of the conventional products.

Figure 3. Mechanism of salt adsorption of salt adsorption.

Table 1. Comparison of performance requirements between conventional method and developed method.

Test Items	Conventional method	Developed method
【Construction performance】		
• Flow value (JIS R 5201)	147mm	160mm or more
• Set start time	48 minutes	More than 15 minutes
• Set end time	55 minutes	45 minutes or less
• Spraying speed	0.2~0.3m ³ /hour	0.6~0.7m ³ /hour
【Adhesion performance】		
• Spraying thickness (Upward· Sideways)	20mm· 40mm	100mm· 100mm
• Adhesion strength (Age of material 1 hour)	0.2N/mm ²	0.2~0.5N/mm ²
【Durability】		
• Chloride Ion Penetration Depth	1.8mm	1.8mm
• Apparent diffusion coefficient of chloride ions	0.37cm ² /year	0.37cm ² /year

3 DEVELOPMENT OF PATCH REPAIR METHOD

3.1 Spraying equipment

In developing the method, development of materials was started based on the concept of two-material shot method. In the two-material shot method, mortar and liquid accelerator are pumped in two separated systems, and the mortar is mixed with the accelerator before the spraying nozzle. Compared to the conventional one-material shot method in which the mortar is generally sprayed in one system of pre-blended type mortar, the two-material shot method can maintain mortar fluidity for longer time with having superior pumping performance, and can obtain superior workability. The addition of liquid accelerator instantly solidifies the mortar into a plastic state is the additional feature.

3.2 Preliminary tests

In developing the materials, a cement mortar named as “Control” whose concept was shown by Hirama et al. (2016) containing the rapid hardening material shown in Table 2 was used as the basis for testing. Three improved materials were provided such as Improvement 1 with the addition of a polymer for

cement, Improvement 2 with the addition of a salt fixing material, and Improvement 3 with both. Ordinary Portland cement, vinylon fiber, and lime-crushed sand were used for all these mortars. Poly-acrylic ester, one of the re-dispersible powder resins, was used as the polymer for cementation. Two calcium aluminate admixtures were used: a rapid hardener, a mixture of 12CaO-7Al₂O₃ and anhydrite, and a salt-fixing material (hereafter referred to as CA₂) consisting mainly of CaO-2Al₂O₃. Liquid accelerator were also used, mainly composed of aluminum sulfate.

3.2.1 Test method

In order to select the best performance mortar, tests were conducted using the following method to compare properties, using the amount of polymer and CA₂ as parameters.

(1) Fresh mortar property

Flow tests were conducted in accordance with JIS R 5201 "Test Methods for Cement physical" to confirm that the required flowability as a wet shotcrete material could be obtained.

(2) Setting time

In order to confirm the rapid hardening properties that ensure a short construction time and surface troweling time, setting time tests were conducted for

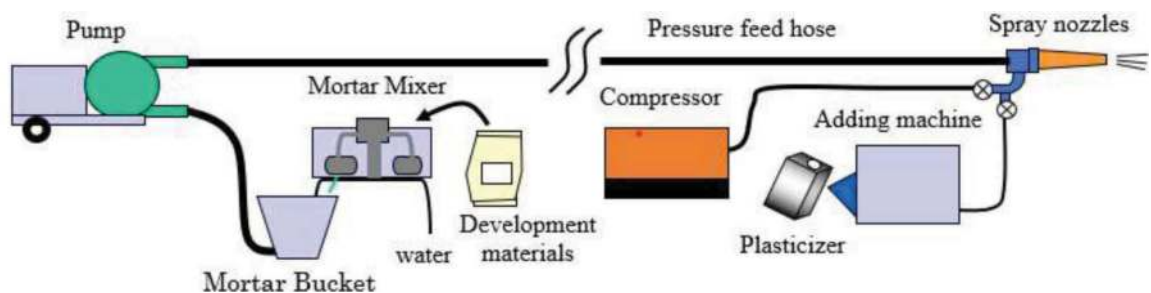

Figure 4. Spraying equipment (2-material shot).

Table 2. Material mix in preliminary test.

No	Product name	density (kg/m ³)			water-cement ratio W/C(%)	water-reducing admixture (%)	short fiber (%)	redispersible polymer powder (%)	calcium aluminate admixtures		liquid plasticizer/material ratio (%)
		water	cement	sand					quick hardening (%)	fixed chloride ion (%)	
1	Control	271	621	1293	44	C×0.05	C×1.6	—	C×10	—	1.1
2	Improvement 1	265	607	1191	44	C×0.06	C×1.6	C×12	C×10	—	1.1
3	Improvement 2	271	621	1229	44	C×0.05	C×1.6	—	C×10	C×10	1.1
4	Improvement 3	263	601	1117	44	C×0.06	C×1.6	C×12	C×10	C×10	1.1

each material in accordance with JSCE-D 102, "Draft Quality Standard for Rapid Setting Agents for Shotcrete (Mortar) and JIS A 1147, "Concrete setting time test.

(3) Length change

Since the initial expansion and drying shrinkage of the materials were considered to have an effect on debonding and cracking, the test for restraint condition was conducted in accordance with JIS A 6202 "Restraint expansion and shrinkage test of expanded concrete". A specimen was taken by spraying the material downward onto a 40 mm x 40 mm x 160 mm formwork in which a restraint device was installed, and finishing with a surface trowel. The specimens were demolded at 1 hour of age, and after that cured in air-dried condition, and the rate of length change was measured with a dial gauge at 1, 3, 6 hours, 1, 3, 7, 14, 21, and 28 days of age.

3.2.2 Preliminary test results and discussion

The following are the test results and discussion.

(1) Fresh mortar property

Table 3 shows the results of air temperature, water temperature, mixing temperature, and flow at the time of testing. All of the mixing patterns satisfied the development performance target of a flow value of 160 mm or more.

(2) Setting time

Figure 5 Shows the results of tests using a proctor penetration resistance tester. Table 4 shows the initial and final setting time.

The polymer-added Improvement 1 and Improvement 3 showed open time of more than 15 minutes, which comply with the development performance target. This is thought to be due to retarding effect by the increased amount of water reducing agent in response to the reduced flowability caused by the addition of polymer. The results for the setting end time showed that Improvement 1 and Improvement 3 satisfied the development performance target.

(3) Length change

Figure 6 Shows the results of the length change test. All of the mix showed expansion behavior until around 1 day of age, which is considered to be caused by the hydration reaction of the hardened

Figure 5. Results of the coagulation test.

Table 3. Test temperature and flow.

Product name	outside temperature (C)	water temperature (C)	material temperature (C)	flow value (mm)
Control	14.6	18.2	18.8	186
Improvement 1	15.4	17.5	17.9	185
Improvement 2	15.7	17.9	18.8	176
Improvement 3	14.8	17.6	18.9	178

Table 4. Starting and ending time.

Product name	time (min)	
	Set start	Set end
Control	8	12
Improvement 1	18	27
Improvement 2	13	20
Improvement 3	22	34

material. The smaller expansion of Improvement 2 and 3 with the addition of salt fixative at 1 day of age is considered to be due to the suppression of ettringite expansion by hydration shrinkage during hydrocalumite formation from the reaction between CA_2 , the main component of the salt fixative, and cement hydrates as shown by Fukudome.(2014).

Figure 6. Length change (restraint, air-dry curing).

3.3 Performance tests

3.3.1 Materials to be used

Since the preliminary test results indicated that Improvement 3 was the material that met the performance requirements, the material used in the performance test was a polymer cement fiber mortar with a calcium aluminate admixture of rapid hardener and salt fixing material.

3.3.2 Test methods

To confirm the workability, adhesion, and durability of the developed product, tests were conducted using the following methods to evaluate its performance.

(1) Thickness of the sprayed material

Figure 7 Adhesion test (1 to 24 hours).

By increasing the maximum spraying thickness at the time of construction, it is possible to reduce the

construction time and cost. To confirm the maximum thickness of the splayed material, a mortar plate (commercial product with dimensions of 70 mm x 70 mm x 20 mm) with a jig for adhesion test and a wooden frame with a $\phi 60$ mm opening shown in Figure 7 is installed on the ceiling surface. The test specimens were prepared by spraying the material upward and then pressing the surface with a trowel to measure the adhesion thickness and adhesion strength for each age of the material. The parameters were 60 mm/layer, 90 mm/layer, and 120 mm/layer, and three specimens were prepared at 1, 2, and 3 hours of age, respectively, to measure the adhesion strength. The curing condition before the measurement was air-drying.

Figure 7. Adhesion test (1 to 24 hours of age).

(2) Workability

Cycle time and spraying volume per hour were measured to confirm the spraying speed, pump frequency, and discharge rate during installation. The sprayed area was 6.4 m^2 (3.2 m high x 2.0 m wide) and the thickness of splayed material was 120 mm. The first layer was 90 mm, the second layer was 30 mm, and the test was divided into two blocks, upper and lower, using a single pipe scaffold.

(3) Chloride penetration resistance

To evaluate the durability of the test specimens against chloride ions after construction, the material was sprayed downward onto a 40 mm x 40 mm x 160 mm formwork, and the surface was trowel-finished. The specimens were then cured in air-dried condition, and at 28 days of age, the specimens were immersed in seawater and the split sections were sprayed with a coloring reagent (0.1 mol/l silver nitrate solution). The depth of chloride ion penetration was measured at 7 locations each at 28, 56 and 91 days after immersion at 5 mm intervals on one side and the average value was used to evaluate the resistance to salt penetration.

(4) Apparent diffusion coefficient of chloride ion

Figure 8 Adhesion thickness test (sprayed thickness: 60, 90, 120 mm)

To evaluate the durability against chloride ions after construction, specimens were prepared as in the salt penetration resistance test and immersed in seawater after age of 28 days for 10 months. The concentration of chloride ions in the depth direction was measured by EPMA for the immersed specimens,

and the apparent diffusion coefficient was determined to evaluate the long-term durability.

3.3.3 Performance test results and discussion

Test results and discussion are shown below.

(1) Thickness of the sprayed material

Only the developed product was tested. Table 5 shows the fresh properties of the product at the time of testing, and Figure 8 shows the test results. The developed product showed high adhesion strength of more than 0.5 N/mm² under all conditions of the thickness of sprayed material of 60, 90 and 120 mm and ages of 1, 2 and 3 hours.

The developed product can be sprayed upward with a maximum thickness of 120 mm and shows adhesion strength of 0.5 N/mm² or higher at an age of 1 hour, ensuring sufficient adhesion strength at the start of train operation on commercial lines.

Table 5. Fresh properties of developed products.

outside temperature (°C)	water temperature (°C)	temperature of mixed mortar (°C)	flow (JIS A 1171) (mm)	slump (mm)
11.3	15.8	16.1	169	115

Figure 8. Adhesion thickness test (sprayed thickness: 60, 90, 120 mm).

(2) Workability

Only the developed product was tested. Table 6 shows the fresh properties during the test, Table 7 shows the test results, and Table 8 shows the cycle time. By setting the mixing temperature of the material at 15 to 20°C, the targeted spraying speed of 0.6 to 0.7 m³/hour and the sprayed volume of 0.77 m³ within

the assumed working time of 90 minutes were confirmed. Figures 9 and 10 show the finished surface after the test, and a certain degree of smoothness was confirmed.

Under the restrictions of only 90 minutes of work time in the commercial railway construction, the developed product can secure a maximum spraying volume of 0.7 m³/hour and a maximum spraying thickness of 120 mm, which is two to three times greater than the conventional product, enabling 70% reduction in the process related to conventional spraying work. As shown in Figure-11, the construction cost is expected to be reduced by approximately 30%. Specifically, the spraying process for two repair sites with a repair area of 18 m² (repair volume of 2.1 m³) can be shortened from 21 days to 6 days. In addition, since there will be almost no material loss due to rebounding, there will be almost no impact such as scattering on the railways and overhead wires.

Table 6. Freshness of the developed.

(3) Chloride penetration resistance

Table 9 shows the mix of concrete used as a comparison sample (28 days of age, The curing condition before the measurement was air-drying) and both conventional and developed products were tested, and the test results are shown in Figure 12. After 91 days of immersion in seawater, the depth of chloride ion penetration of the concrete was 13.4 mm, while that of the conventional product was 1.8 mm and that of the developed product was 1.9 mm. When the chloride ion penetration depth of concrete is considered to be 100%, both the conventional and developed products reduced the penetration of chloride ions by 86%. The developed product showed the same resistance to chloride penetration as the conventional product due to its ability to immobilize soluble chloride ions, as Friedel's salt by the reaction of CA₂, the main component of the salt fixative, with cement hydrate.

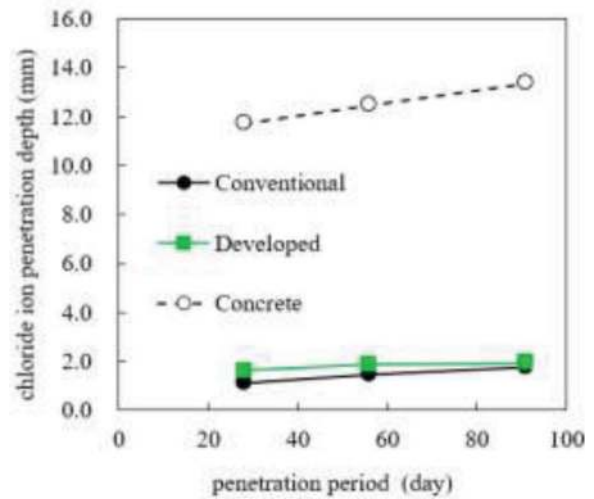

Figure 12. Chloride Ion Penetration Depth Test Results.

(4) Apparent diffusion coefficient of chloride ion

Figures 13 and 14 show the results of EPMA measurements of the chloride ion concentration in the depth direction for the conventional and developed products, and Table 9 shows the analysis results. The developed product showed almost the same performance as the conventional product.

In general, the apparent diffusion coefficient of chloride ions is said to be 5.8 cm²/year for concrete

Figure 13. Chloride ion content in depth direction by EPMA (Conventional product).

	Apparent diffusion coefficient of chloride ions
Conventional	0.37cm ² /year
Developed	0.36cm ² /year

using ordinary cement and 1.4 cm²/year for concrete using blast furnace slag as shown by Japan Cement Association.(2008). The measured values are low, ranging from 0.36 to 0.37 cm²/year for both conventional and developed products, showing high salt barrier properties. The measured values are low at 0.36 to 0.37 cm²/year for both the conventional and developed products.

4 CONCLUSIONS

Table 11 shows the performance of the conventional method and the required performance of the newly developed method as well as the actual performance. A new patch repair method was developed for concrete tunnels deteriorated by salt damage in commercial urban railroad tunnels by taking into consideration construction constraints and the service environment after repair. As a result, the following findings were obtained.

1) A new two-material shot method was developed, in which a reinforced polymer cement fiber mortar is mixed with a calcium aluminate admixture, a rapid hardener and a salt fixative, and a liquid accelerator is added before the nozzle of the shot-concrete equipment.

2) Tests were conducted on the workability of the sprayed polymer mortar, and it was confirmed that workability has been improved and construction costs significantly reduced by adjusting fresh properties such as mortar flow and mixing temperature, the amount of plasticizer added, spraying speed, and discharge rate.

3) Adhesion tests of the sprayed polymer mortar were conducted, and it was confirmed that the adhesion strength of the sprayed material and the sprayed thickness at a young age qualified the required performance by optimizing polymer and calcium aluminate admixtures amount in the mortar, amount of liquid accelerator and the spraying speed and discharge rate of the spraying equipment.

Table 11. Comparison of performance between conventional method and developed method.

Test Items	Conventional method	Developed method	
		Performance Requirements	Actual Performance
【Construction performance】			
· Flow value (JIS R 5201)	147mm	160mm or more	178mm
· Set start time	48 min	More than 15 min	22min
· Set end time	55 min	45 min or less	34min
· Spraying speed	0.2~0.3m ³ /hour	0.6~0.7m ³ /hour	0.7m ³ /hour
【Adhesion performance】			
· Spraying thickness (Upward· Sideways)	20mm· 40mm	100mm·100mm	120mm·120mm
· Adhesion strength (Age of material 1hour,)	0.2N/mm ²	0.2~0.5N/mm ²	0.5N/mm ²
【Durability】			
· Chloride Ion Penetration Depth	1.8mm	1.8mm	1.9mm
· Apparent diffusion coefficient of chloride ions	0.37cm ² /year	0.37cm ² /year	0.36cm ² /year

4) Tests were conducted on the durability of the sprayed polymer mortar, and the depth of chloride ion penetration and the apparent diffusion coefficient of chloride ions were evaluated, and it was confirmed that the performance of the developed product was equivalent to that of the conventional product with high salt barrier performance.

Ventilation for a long underground road tunnel system from a modern perspective

Tsz Kin Lam*

COWI A/S, Kongens Lyngby, Denmark

Ertan Hataysal

COWI UK, London, UK

ABSTRACT: Long road tunnels are becoming a preferred option for the cities to expand the public realm. Therefore, an increasing number of long underground road tunnel systems have been planned and constructed in recent years, with some spanning a length of 10km or more. Such lengths was an issue for the tunnel ventilation system in the past due to the excessive requirements. Nevertheless, the modern vehicle fleet structure includes cleaner engines and electric vehicles which have reshaped the situation recently. This paper discussed the trend of ventilation in long road tunnels from a modern perspective. It covered the transition of ventilation strategy from old to new long road tunnels. It addressed the fundamental principle of ventilating long road tunnels for normal and fire operations and how the tunnel ventilation system has switched from a pollutant driven system to a smoke driven one. The discussion was exemplified on a 10 km long underground road tunnel system for which is a live project in Scandinavia. It included design considerations in pollutant and smoke control; also presented technical challenges in handling airflow in approach ramps.

Keywords: Long tunnels, Tunnel ventilation, Pollutant control, Smoke control

1 INTRODUCTION

For decades, it has been well understood that ventilating a long road tunnel is challenging. Ventilation plays a crucial role in the design of tunnels, requiring a special focus. It affects the tunnel's cross section as it consumes space for air ducts and equipment. It can even affect the profile by incorporating ventilation shafts throughout the tunnel. Therefore, the cost of a tunnel ventilation system is far more than the cost of the mechanical and electrical equipment alone. In reality, it is a huge add-on on top of the cost of the tunnel structure. Nevertheless, the tunnel ventilation system must remain in place to maintain the operational safety and perform during critical incidents.

The main challenge of ventilating long road tunnels was to remove pollutants effectively. The pollutant concentration increases along the tunnel, and it peaks towards the exit portal. This stimulates an increase in the design velocity during normal operation. Which means larger equipment, technical spaces even larger tunnel cross-section.

Today, the vehicle engines are getting cleaner, even there is a trend in replacing the internal combustion engine (ICE) vehicles by the electric ones. It relieves the pressure from the tunnel ventilation system by diluting the in-tunnel pollutants. Some long-span road tunnels which may have seemed impossible in the past have now become more practical and feasible. Now, there are some live road tunnel projects in Scandinavia with overall length of over 10km.

This paper will start with the traditional approach on ventilating long road tunnels. It will discuss how pollutants drive the ventilation system by starting from the basic principles, the characteristics of the predominant ventilation systems and the transition to the modern approaches.

This paper will then provide the details of the transition by the help of quantitative figures on vehicle emissions, and address the consequences on the tunnel ventilation system.

Finally, a future 10km long road tunnel system in Scandinavia will be used as an example to demonstrate the ventilation design in a modern urban example. The challenges about smoke management within this complex tunnel will also be covered.

2 PAST PERSPECTIVE

2.1 Pollutant driven ventilation systems

A tunnel ventilation system in a road tunnel primarily serves for two purposes, smoke control and pollutant dilution.

In controlling the smoke, the system is basically dictated by the fire size in the tunnel. The fire size is constant regardless of the length of the tunnel. In a long tunnel, the travel distance of the smoke is also an important issue to be considered.

During daily operation, the vehicle generated pollutants build up in the tunnel. The level of pollutant concentration is directly proportional to both the number of vehicles present in the tunnel and the overall length of the tunnel. Despite the pollutant generation rate varying with changing gradients along the tunnel, the relationship between the pollutant levels can still be simplified and represented by a linear correlation, Figure 1. As the acceptable pollutant level is constant along the tunnel, it becomes more challenging to keep that below the threshold for longer tunnels, especially towards the end.

In the past, the vehicle engine exhausts were worse, which are presented with a steeper line in Figure 1. This was a limiting factor for the tunnel length. Although the distance could extend the length, it would come at a cost such as an interim shaft (if possible) and/or a large ventilation duct.

The smoke control in a fire event was easier to resolve comparing to the dilution of pollutants. Therefore, the ventilation designs were mainly pollutant driven.

Figure 1. Pollutant levels along a road tunnel.

2.2 Predominant ventilation strategies

The vehicle movement in a tunnel generates piston effect and this effect will draw in ambient air from tunnel portals and/or ventilation shafts which helps to dilute the pollutants. If the amount of ambient air drawn is sufficient to dilute the pollutants, the tunnel is self-ventilated.

At the time when the vehicle emissions were high in pollutant concentration, this ideal situation was happening rarely. Therefore, a mechanical ventilation system was required to constantly supply

supplementary fresh air from the ambient to lower the in-tunnel pollutant concentration levels. This was comprising a large portion of the operation cost of a road tunnel.

Longitudinal ventilation which only draws ambient air in from tunnel inlet portals was also not feasible for most of the long road tunnels in urban areas. The pollutant concentrations increase linearly towards the exit portal and could easily exceed the threshold value. Therefore, it was required to utilize other ventilation schemes such as fully transverse and semi-transverse as illustrated in Figure 2. These schemes enable introducing fresh air into the system more effectively, as well as reducing the pollution concentrations along the tunnel simultaneously by removing the polluted air from the system.

Figure 2. Schematic of fully-transverse (top) and semi-transverse (bottom) tunnel ventilation systems (ASHRAE, 2007).

These schemes require additional ventilation shafts and equipment. It is not always possible to put the ventilation shafts right to the point where the fresh air is supplied from. It depends on geological conditions and other factors. Surely it is easier to place a shaft on land instead of the seabed. Having a ventilation shaft in the middle of the sea can still be achievable; e.g., Hugh L. Carey Tunnel and Tokyo Aqua Line Tunnel. However, it comes at a significant cost.

The air ducts can take up a decent amount of space in a road tunnel. They practically require at least an additional 20% of the tunnel cross section. For long tunnels, the air duct can be even bigger to compensate the huge pressure loss along the ducts due to the long travel distance for the air.

In some tunnels, air purification systems can also be utilized as a pollutant management system alongside with the tunnel ventilation system. The air purification system can also serve as a control measure on the pollutants discharged to the ambient from a tunnel, but this approach involves significant equipment and infrastructure investment.

3 MODERN PERSPECTIVE

3.1 Cleaner vehicles

Today, road vehicles are progressively getting cleaner. The European Union (EU) started regulating the vehicle emissions in 1992 by setting up the European emission standards. The standards are staged as legal frameworks applied to all new selling vehicles in EU and they are categorized from EURO 1 to EURO 6. Many countries have already harmonised their legislations in accordance with the EU regulations.

Recently, EU has targeted to ban all new selling ICE vehicles by 2035 and it has been seconded by many countries including the United States and China.

These changes are favourable for longer road tunnels. Improving the vehicle pollutant discharge reduces the emission rates in the tunnels significantly as shown in Figure 1. This enables extending the physical length of a tunnel without exceeding the pollutant concentration threshold.

3.2 Pollutant emission

The pollutant emissions from new vehicles are much lower compared to the ones manufactured 20 years ago. World Road Association (PIARC) have a series of publications (PIARC, 1995, 2004, 2012 & 2019) which document a methodology and database to calculate the pollutant levels in road tunnels. Figure 3 shows the trend of the pollutant generation rate from EURO 1 to EURO 6 engines.

Electric vehicles can further lower the emission figures in the tunnels. Even though these vehicles are often considered as zero emission vehicles, non-exhaust pollutants such as particular matter (PM) are still generated by these vehicles. Therefore, ventilation is still required to control this type of pollutants in tunnels.

Figure 3. Reduction of NO_x generation rate of gasoline passenger cars from EURO 1 to EURO 6 engines at zero gradient (PIARC, 2019).

3.3 Fire driven ventilation systems

The introduction of cleaner vehicles has significantly reduced the levels of pollutants in tunnels. As a result, the ventilation systems in long road tunnels

have undergone a transformation and moved away from being a primarily pollutant-driven system.

The changes have shifted the focus on pollutant control and the interventions during a fire incident have become predominant in defining the characteristics of a tunnel ventilation system. The fire incident, being a localized event, is independent from the length of the tunnel; therefore, this removed the key challenges in ventilating the long tunnel sections.

4 CASE: A NEW SCANDINAVIAN ROAD TUNNEL SYSTEM

In recent years, there are a number of long road tunnels planned in Scandinavia. The most significant one is the 18km long Fehmarnbelt tunnel connecting Denmark and Germany. A new road tunnel system has also planned to route the traffic around the city centre in one of the Scandinavian capitals. The tunnel system consists of a 10km long main tunnel and associated ramps along the main tunnel. The overview of the system is presented in Figure 4. This system will be used as a current example case to show how the ventilation system design shifted due to the change in the vehicle fleet.

Figure 4. Overview of the new Scandinavian road tunnel system.

4.1 Baseline ventilation scheme

The baseline ventilation scheme is longitudinal ventilation using jet fans. It is in general the most cost-effective scheme as it eliminates the ventilation shafts, headhouses and air ducts. In the conceptual design stage, this scheme has been proven to be a robust scheme without any major issues.

4.2 Pollutant control

The pollutant analysis in the tunnel reaffirmed the fact that the pollutant control is a lower tier concern in road tunnels nowadays even for long tunnels. By the design year 2035, 46% of passenger cars will be electric and the removal of old ICEs has pushed the in-tunnel pollutant levels far below the threshold.

Nevertheless, the intervention from the tunnel ventilation system is still required in congested traffic scenarios. The critical pollutant has switched from NO₂ to PM which is driven by the cleaner vehicles, as shown in Figure 7. The lowest self-ventilation traffic speed has been reduced from 30km/h to 10km/h in this Scandinavian tunnel.

Figure 5. Estimated traffic fleet for the Scandinavian tunnel.

Figure 6. Estimated NO₂ pollutant level in the tunnel at 60km/h.

Figure 7. Fresh air requirement to dilute NO₂ and PM in the tunnel at different traffic speeds.

4.3 Smoke management

For this tunnel, the ventilation system is completely fire driven. The number of jet fans required to ventilate a tunnel fire is up to three times of that required to ventilate the pollutants generated during normal operation. These figures are given for a critical tunnel section.

The average air velocity is maintained above the critical velocity during a fire incident and it is used as the strategy of smoke management in this Scandinavian tunnel. The tunnel is not a straight single tube, but it is a complex underground tunnel network due to the presence of several ramps spread along the main tunnel. This creates some challenges in applying the longitudinal ventilation scheme in particular in the vicinity of the ramps.

4.3.1 Short-circuit and recirculation through ramps

The ramps are approximately 200m in length and the shortest main tunnel section is 2.5km. It is inevitable that some percentage of the air will move in and out of the tunnel network through the ramps rather than following the main air stream within the tunnel. This way the tunnel main airflow short-circuits through the ramps.

In normal operation, the impact of the short-circuit is minimal. Firstly, the fresh air requirements to dilute pollutants is low due to the cleaner vehicles. Secondly, the tunnel air movement is driven by the piston effect from the vehicles. Most of the traffic is in the main tunnel and sufficient air can be maintained to dilute the pollutants. The problem only occurs when the traffic speed reduces and so as the piston effect. The portal winds start to dominate the airflow in the ramps.

Figure 8. Short-circuit (top) and recirculation (bottom) through ramps and their air path are illustrated in orange arrows.

The airflow short-circuit has a more significant impact on the smoke control within the tunnel. In contrast to a conventional longitudinally ventilated tunnel where smoke is discharged solely through the tunnel portal, the ventilation design in this tunnel should consider whether the smoke goes through the main tunnel or ramps (or both).

The close proximity of the ramps presents an issue where the smoke discharged from one ramp may recirculate back into the tunnel through an adjacent ramp. This creates a potential challenge in maintaining robust smoke ventilation within the tunnel.

4.3.2 Spatial constraints

The junction points are located where a two-lane wide main tunnel tube and a one-lane wide ramp connection come together. These junctions facilitate connections to the main tunnel traffic flow. The most challenging part for emergency ventilation is at the transition sections, which are the tunnel stretches located between two junctions. There are a number of these transitions along the main tunnel and they are relatively short in length.

During a fire at a transition section, the short-circuit in ramps is an important issue, since significant amount of the airflow is leaked through the ramps. This results in poor ventilation performance in these sections.

The ventilation scheme in these sections is designed in two steps to overcome the short-circuit issue and remove the smoke in a controlled way.

The first step is to utilise the jet fans in the main tunnel and the ramp sections. This is to adjust the balance between different sections, as shown in Figure 9.

Figure 9. Ventilation scheme to compensate the short-circuit in ramps.

The second step is to optimize the number of jet fans in the transition sections and ramps. This will help boosting the airflow in the transition section. Further, it will improve the system resilience against portal winds in ramps. However, due to spatial constraints only limited number of jet fans can be installed at a certain transition section.

The spatial constraints can be expressed in two dimensions, the tunnel longitudinal span and the tunnel width.

There is a minimum separation between jet fans along the tunnel. The efficiency of jet fan banks will be reduced if they are placed too close to each other. At the transition sections, the distance between jet fans has been lowered to 70m to fit more jet fans whilst keeping the system efficiency at a similar level.

The tunnel width dictates the number of jet fans that can be installed at each location. This dimension is fixed as it is determined by the number of traffic lanes and emergency walkways. The space for jet fans is especially limited in ramps as these only have one-lane traffic. The whole width of the cross section must be occupied to install jet fans at the same location to achieve the necessary thrust. It is also not possible to install more jet fans longitudinally as the ramps are short and there is a need to account for redundancy during a fire event.

Figure 10. Spatial constraint of jet fans in a single lane tunnel cross section.

4.3.3 Asset protection

Depending on the ventilation operation, the smoke can occupy the entirety of the downstream of the fire. Alternatively, it can be discharged through the nearest ramp(s) and the rest of the tunnel can be kept smoke free. These are both shown in Figure 11.

Figure 11. Schematics of two different ventilation approaches and tunnel sections occupied by smoke are coloured in grey.

From an asset protection perspective, it is beneficial to discharge smoke out of the tunnel as soon as possible. In this Scandinavian tunnel, the ramps can be used as a shortcut for smoke discharge and prevent transporting smoke all the way down to the tunnel exit portal. Even though tunnel installations and equipment are fire-rated, insurance and warranty coverage may still be triggered if these equipment have been exposed to fire and smoke. For a long tunnel, this has a serious cost implications considering the amount of equipment.

5 OTHER VENTILATION DESIGN ASPECTS

5.1 Heat

Heat build-up can also be an issue in long tunnels, which can be caused by various factors such as vehicles, equipment, metrological and geological conditions. Therefore, it should be looked at and considered in the design of these systems. For example, Yamate Tunnel in Tokyo utilizes a water mist system to bring down the temperature during normal operation.

5.2 Traffic fleet

Modern tunnel ventilation designs increasingly align with the progressive agenda of replacing ICE vehicles, particularly in long tunnels. However, some countries already stepping back from their plans.

Electric, hydrogen, and other alternative-powered vehicles are still an emerging research field, making it difficult to predict future issues that may currently go unnoticed. These systems will evolve alongside the changing fleet structure and adapt to ensure a comfortable and safe experience for users.

Therefore, it is important to take into account the recent updates in the traffic fleet and update the emerging risks accordingly.

6 CONCLUSIONS

Due to recent advancements in vehicle technology, the tunnel ventilation systems in long road tunnels have transitioned from a pollutant-driven system to a fire-driven system. This shift is primarily attributed to the widespread use of cleaner vehicles in recent years.

The smoke ventilation is still challenging though; especially, in the long and complex urban road

tunnel setup. These tunnels can include networks of ramps connecting to other road systems. In order to create an efficient smoke ventilation system, several key factors need to be taken into consideration such as flow short-circuiting, spatial constraints and heat build-up. It is also key to develop strategies which consider the protection of the assets in long tunnels.

Finally, it is important to ensure that the tunnel ventilation system kept up to date in parallel with the evolving traffic fleet composition. This proactive approach can help alleviate the strain on the systems, leading to safer and more efficient operations.

Study on fire smoke exhaust strategy in daliangshan no.1 super-long expressway tunnel*

Fuan Lan, Haiyun Zou & Lingshen Wu
Sichuan Lexi Expressway Co., Ltd, Leshan, China

Yong Wang & Yandan Deng
China Railway Academy Co., Ltd., Chengdu, China

ABSTRACT: Based on the control project of Leshan-Xichang Expressway in Sichuan Province, this paper focuses on the study of the fire smoke exhaust strategy for the Daliangshan No. 1 Tunnel. To address the issues caused by long smoke exhaust distances and inadequate smoke exhaust efficiency at both ends of a single inclined shaft tunnel, such as the rapid spread of smoke and a wide range of hazards, a new fire smoke exhaust mode was studied and designed. Based on this new mode, a civil engineering model for fire smoke exhaust in tunnels was developed, and the smoke exhaust efficiency of this model was predicted and analyzed. Different fire scenarios at various locations within the tunnel were considered, and a one-dimensional analysis approach was used to predict and compare the smoke exhaust efficiency under different strategies. The prediction results of the fire smoke exhaust model efficiency indicate the following: In the original model, certain fire scenarios could not be effectively controlled due to insufficient upstream air flow velocity and downstream smoke exhaust capacity. Smoke stratification and backflow could affect vehicles and personnel upstream of the fire. For fire incidents near the inclined shaft, the original model allowed smoke exhaust through the inclined shaft, which proved to be more efficient compared to using the nearest vehicle cross passage for smoke exhaust. After optimization, the civil smoke exhaust duct featured a cross-sectional area of 9.9 m². The smoke exhaust capacity from the smoke outlet above of individual vehicle cross passages was increased, ensuring that any single vehicle cross passage could meet the requirements for fire smoke exhaust. By utilizing the smoke exhaust route downstream, which was closest to the fire location, along with longitudinal smoke induction, it was possible to effectively exhaust all smoke and prevent its diffusion from affecting vehicles upstream and downstream of the fire.

Keywords: fire smoke exhaust strategy, extra-long highway tunnel, single inclined shaft, parallel adit, prediction and analysis

1 INTRODUCTION

In recent years, there has been a rapid development in the construction of extra-long highway tunnels, with increasing scale, providing significant transportation convenience. However, due to the structural characteristics of these tunnels, which resemble narrow and elongated pipes, the risks and safety concerns associated with tunnel fires have become more prominent. To ensure the safety of personnel inside tunnels and to safeguard the socioeconomic aspects, the fire smoke exhaust system has been recognized as a vital component of extra-long highway tunnels. Extensive research has been conducted and the

resulting findings have been actively implemented in practice.

In the existing extra-long highway tunnels in China, various ventilation and smoke exhaust schemes are implemented based on factors such as topography, geology, meteorology, and natural environment. The main modes adopted for ventilation and smoke exhaust are longitudinal smoke exhaust, transverse and semi-transverse smoke exhaust, as well as centralized smoke exhaust. Domestic and international scholars have conducted extensive research on different ventilation and smoke exhaust modes. For example, based on the Qinling Zhongnanshan Tunnel, Yu Li, Wang

*Corresponding author: 1294647485qq.com

Mingnian, et al(2009). employed a three-shaft segmented longitudinal ventilation mode. In addition, in the context of a twin-tube unidirectional tunnel, they established, for the first time, ventilation control strategies for tunnels with cross passages in the event of a fire. They also proposed ventilation control benchmarks at different fire locations for tunnels with multiple shafts. Based on the Erlangshan Tunnel, Liu Tong, et al(2006). proposed, for the first time, the use of parallel adits for semi-transverse air supply in a single-tube bi-directional tunnel. This approach was introduced to achieve network ventilation in situations where it is challenging to implement smoke exhaust solely through longitudinal ventilation due to the absence of inclined shafts. Based on the Yunshan Tunnel, Jia Jilin et al(2014). analyzed energy consumption under different angles between the inclined shaft and the main tunnel. They obtained the relationship between ventilation resistance along the tunnel and the inclination angle of the inclined shaft. Zhang Jinglong et al(2012). studied the impact of the angle of ventilation cross passages on the twin-tube complementary ventilation system. Xia Fengyong et al(2014). proposed ventilation modes that can be used in uphill tunnels with varying traffic volumes. Academician Wang Mengshu(2015) also proposed that tunnels with a length of less than 6 km do not necessarily require ventilation shafts or inclined shafts. Based on the Huangjiaoping Tunnel, Xu Baiyang, Liang Shicheng, et al.(2021), developed three smoke exhaust schemes and corresponding smoke exhaust duct structures for extra-long highway tunnels. They analyzed the impact of different smoke exhaust schemes and exhaust duct structures on smoke exhaust efficiency. Ingason et al.(2011) conducted research on single-point and two-point vacuum ventilation systems as well as their effectiveness in controlling tunnel fires and smoke flow. Xu Haozhuo et al., using an orthogonal experimental design, studied the impact of the spacing between smoke outlets and the smoke exhaust rate on the smoke exhaust efficiency of centralized smoke exhaust.

The aforementioned research work demonstrates that investigating suitable smoke exhaust schemes and exhaust duct structures for different extra-long highway tunnels is not only a challenging task but also a crucial aspect of successful tunnel construction and operation.

Based on the engineering project of the Daliangshan No. 1 Tunnel, which is an extra-long highway tunnel with a total length of 15.3 km, and with reference to the ventilation shaft setting as described in Section 4.1.5 of Guidelines for Design of Ventilation of Highway Tunnels (JTGT-D70-2-02-2014), it is typically recommended to have 2 or 3 ventilation shafts for tunnels with lengths between 12000 m and 16000 m. However, due to the unique geographical location of this project, only one combined air supply and exhaust inclined shaft can be

accommodated. After analyzing various fire smoke exhaust modes, it was found that the commonly used modes cannot meet the requirements of this project. In response to the challenge of smoke exhaust in the extra-long highway tunnel where only one ventilation shaft can be accommodated, a new smoke exhaust mode was studied and designed in this paper. Based on this fire smoke exhaust mode, smoke exhaust efficiency prediction and comparative analysis of various fire smoke exhaust strategies were conducted. This enables the identification of the optimal tunnel fire smoke exhaust strategy and provides auxiliary references for evacuation rescue and automatic control system schemes.

2 PROJECT OVERVIEW

2.1 *Project scale and overall layout*

The Daliangshan No. 1 Tunnel, a control project of the Leshan-Xichang Expressway in Sichuan Province, features a main tunnel length of approximately 15.3 km. The cross-sectional area of the tunnel for each direction is 68 m². The tunnel is designed according to the standards of a twin-tube, single-direction, four-lane highway, with a design speed of 80 km/h. The tunnel is located within the Mamize Provincial Nature Reserve and can only accommodate one combined air supply and exhaust inclined shaft. It is divided into two sections, with lengths of “9+6.3” kilometers, forming a ventilation tunnel. To address the issues caused by long smoke exhaust distances and inadequate smoke exhaust efficiency at both ends of a single inclined shaft tunnel, such as the rapid spread of smoke and a wide range of hazards, it is proposed to adopt a section layout of “left main tunnel - run-through parallel adit - right main tunnel” based on the new fire smoke exhaust mode and design the main model for tunnel ventilation and smoke exhaust accordingly.

Figure 1 shows the main model of the tunnel designed based on the new smoke exhaust mode. The tunnel model includes a run-through parallel adit, the left main tunnel, and the right main tunnel. Between the run-through parallel adit and the main tunnels, there are a total of 16 vehicle cross passages and two multi-functional traffic transition zones (approximately 800 m spacing between adjacent passages, the distance between the vehicle cross passages and the multi-functional traffic transition zones is also 800 meters). Besides, there are 4 cross passages for fresh air supply (with an area of 27 m²). The space above the run-through parallel adit and the vehicle cross passages is allocated for the tunnel fire smoke exhaust ducts (with an area of 7.1 m²). The smoke exhaust ducts above the run-through parallel adit and the single inclined shaft are interconnected. Ventilator rooms and related ventilation equipment are installed at the entrances and exits of both ends of the inclined shaft and the parallel adit to ensure effective

ventilation and smoke exhaust in the tunnel. Additionally, two multi-functional traffic transition zones are dividing the tunnel into three sections (“4687 m + 5050 m + 5543 m”). In the event of an accident or maintenance work in one section, it is possible to maintain the traffic capacity of the remaining sections by diverting vehicles through alternative routes.

Figure 1. Tunnel plan.

2.2 Tunnel ventilation system

The new smoke exhaust mode is based on a combined fire smoke extraction strategy, which combines longitudinal induced smoke exhaust and single-point concentrated smoke exhaust. It aims to control the stratification and diffusion of smoke while efficiently directing the smoke generated by the fire through 1 to 2 designated smoke exhaust ducts for centralized removal. This helps to prevent the impact of fire smoke on vehicles upstream and downstream of the fire.

There are three main smoke exhaust strategies used in the tunnel, including:

- 1) Utilizing jet fans in the main tunnel to longitudinally induce smoke exhaust and to prevent smoke layer re-circulation and spread.
- 2) Utilizing the inclined shaft and its associated ventilation equipment to exhaust the smoke generated by tunnel fires to the outside.
- 3) Utilizing the run-through parallel adit, inclined shaft, and smoke exhaust ducts above the vehicle cross passages, as well as their related ventilation equipment to centralize smoke exhaust and direct the smoke generated by tunnel fire to the outside.

The specific strategy is depicted in Figure 2.

Figure 2. Smoke exhaust path.

Figure 3. Cross section of parallel pilot tunnel.

Figure 4. Cross section of vehicular cross passage.

Considering the elongated nature of extra-long highway tunnels, to achieve effective smoke exhaust in the event of tunnel fires, a combined fire smoke exhaust strategy of “inclined shaft + run-through parallel adit” was adopted for fires occurring at different locations within the tunnel. Prediction and analysis were conducted specifically for this strategy.

3 PREDICTION METHOD AND RESULT ANALYSIS

3.1 Prediction and analysis of fire smoke exhaust efficiency

This paper is based on the structural model of the Daliangshan No.1 Tunnel. A one-dimensional analysis method, along with the continuity equation, momentum equation (Navier-Stokes equation), and energy equation, was applied to predict and compare

the smoke exhaust efficiency under different fire smoke exhaust strategies for fire scenarios at different locations within the tunnel.

Continuity Equation:

$$\frac{\partial \rho}{\partial t} + \frac{\partial(\rho u)}{\partial x} + \frac{\partial(\rho v)}{\partial y} + \frac{\partial(\rho w)}{\partial z} = 0 \quad (1)$$

Momentum Equation:

$$\frac{\partial(\rho v_i)}{\partial t} + \text{div}(\rho v_i v) = \rho \left(\frac{\partial v_i}{\partial t} + v_i \cdot \text{grad} v_i \right) \quad (2)$$

Energy Equation:

$$\lambda \frac{\partial^2 T}{\partial x^2} + \lambda \frac{\partial^2 T}{\partial y^2} + \lambda \frac{\partial^2 T}{\partial z^2} = c_p \rho \left[\frac{\partial \rho}{\partial t} + \frac{\partial(uT)}{\partial x} + \frac{\partial(vT)}{\partial y} + \frac{\partial(wT)}{\partial z} \right] \quad (3)$$

According to Guidelines for Design of Ventilation of Highway Tunnels (JTGT-D70-2-02-2014), the fire scale was assumed to have a heat release rate of 30 MW. It was assumed that the smoke exhaust equipment at both ends of the parallel adit and that in the inclined shaft would be activated simultaneously to maximize the smoke exhaust capacity. Additional fire prediction scenarios are outlined in Table 1.

Table 1. Predicted fire smoke exhaust scenarios.

	Upstream air velocity (m/s)	Smoke exhaust capacity(m ³ /s)	Fire location
Case1	2	136	Far from inclined shaft (upstream location)
Case2	3	204	Near inclined shaft
Case3	2	136	Far from inclined shaft (downstream location)

Figure 5 depicts the predicted smoke exhaust efficiency for fire scenarios at different locations, and the results indicate the following: (1) In case of a fire occurring far from the inclined shaft (upstream location), there is an air-crossing section bottleneck in the smoke exhaust ducts above the run-through parallel adit and the vehicle cross passages, which requires smoke exhaust through the smoke exhaust ducts above two adjacent vehicle cross passage. However, this may result in smoke affecting personnel and vehicles located between the two vehicle cross passages downstream of the fire. If the smoke is adequately controlled in the longitudinal direction, the further downstream spread will be prevented. (2) In case of a fire occurring near the inclined shaft, it is possible to solely rely on the inclined shaft for smoke

exhaust. Additionally, the smoke exhaust capacity of the inclined shaft is superior to that of the smoke exhaust ducts above the run-through parallel adit and vehicle cross passages. (3) In case of a fire occurring far from the inclined shaft (downstream location), the smoke exhaust capacity of the smoke exhaust ducts above the run-through parallel adit and vehicle cross passages is insufficient. In this case, the remaining smoke inside the tunnel needs to be extracted from the tunnel portals. (4) When the upstream air velocity is less than 3 m/s, it is not sufficient to control the smoke backflow, which may result in the smoke affecting personnel and vehicles upstream of the fire.

Figure 5. Predicted Smoke Exhaust Efficiency for Different Fire Scenarios at Various Locations (Area of Smoke Exhaust Duct A = 7.1 m²).

3.2 Prediction and analysis of optimized fire smoke exhaust efficiency

Considering the insufficient smoke exhaust capacity of the smoke exhaust ducts above the run-through parallel adit and vehicle cross passages, to meet the smoke exhaust requirements in the event of a fire in the Daliangshan No. 1 Tunnel, which is an extra-long highway tunnel, and to minimize the harm to vehicles and personnel, further optimization research and smoke exhaust efficiency prediction of these smoke exhaust ducts were conducted in this study. The specific fire prediction scenarios are shown in Table 2.

Table 2. Predicted fire smoke exhaust scenarios after optimization.

	Upstream air velocity (m/s)	Smoke exhaust capacity(m ³ /s)	Fire location
Case4	3	272	Far from inclined shaft (upstream location)
Case5	3	272	Near inclined shaft
Case6	3	272	Far from inclined shaft (downstream location)

To prevent further downstream spread of the smoke, it is necessary to ensure a critical air velocity of 3 m/s upstream of the fire. Additionally, an air velocity of -1 m/s should be set downstream of the fire to achieve a longitudinal induced smoke exhaust effect.

Figure 6 shows that by increasing the smoke exhaust duct area to 9.9 m², the optimized smoke exhaust duct exhibits a stronger smoke exhaust capacity. In the event of a fire occurring far from the inclined shaft, the smoke generated at the fire location can be completely extracted and expelled through the smoke exhaust outlet and air duct above a single

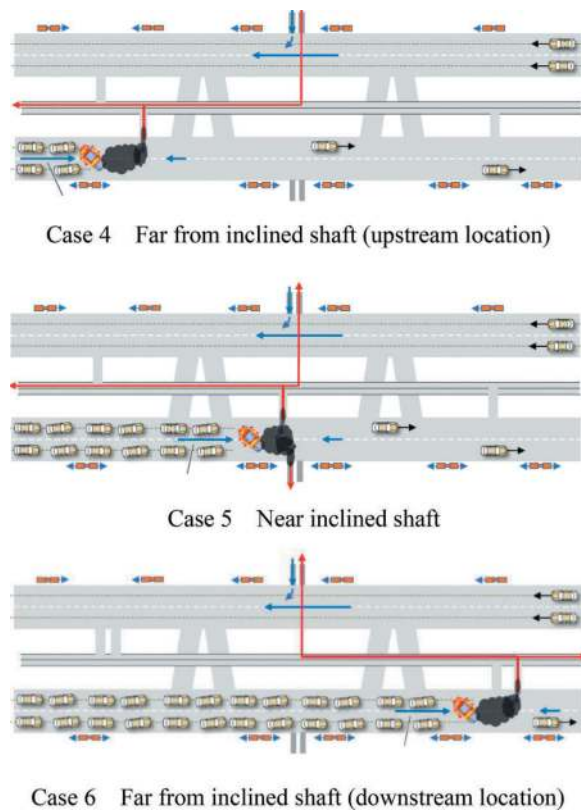

Figure 6. Prediction of smoke exhausting effect in different fire conditions (as the area of smoke-extraction duct is 9.9 m²).

vehicle cross passage near the fire source, preventing the smoke from spreading downstream. This reduces the distance of smoke dispersion inside the tunnel, resulting in improved smoke extraction efficiency during tunnel fire incidents.

3.3 Alternate route of fire exhaust smoke

To ensure effective smoke exhaust in the tunnel during the activation of alternate routes under special conditions, prediction and analysis were conducted for various fire scenarios under the activated alternate route condition. The fire prediction scenarios are outlined in Table 3.

For fires at bidirectional traffic, according to the Austrian design guideline, the jet fans shall be regulated for lower air velocities of approximately 1.0 to 1.5 m/s, with the aim to keep the stratification of the smoke layer intact, and to give people on both side of the fire more time to evacuate. In this study, according to the amount of smoke from the fire, a representative air velocity of 1.2 m/s was assumed.

Table 3. Predicted fire smoke exhaust scenarios for alternate route.

	Upstream air velocity (m/s)	Smoke exhaust capacity(m ³ /s)	Traffic conditions
Case7	1.2	81.6	Full closure of single-track tunnel
Case8	1.2	81.6	Closure of top section of single-track tunnel
Case9	1.2	81.6	Closure of both ends of single-track tunnel

Figure 7 shows the predicted smoke exhaust efficiency under different traffic conditions. The results indicate that: (1) To exhaust a large amount of smoke in the two vehicle cross passages downstream of the fire, the inclined shaft and the parallel adit exit can be used at the same time for smoke exhaust while controlling the longitudinal flow of smoke so that the smoke will not continue to spread downstream. (2) When the upstream air velocity is 1.2 m/s, this speed is insufficient to prevent smoke stratification and the occurrence of smoke backflow. This may result in the personnel and vehicles located upstream of the fire being affected by the smoke.

3.4 Fire smoke exhaust prediction for optimized alternate route

In light of the predicted results of fire smoke exhaust for the alternate route described in section 3.3, prediction and analysis were conducted for the

Figure 7. Predicted Smoke Exhaust Efficiency for Different Fire Scenarios at Various Locations on the Alternate Route (Area of Smoke Exhaust Duct $A = 7.1 \text{ m}^2$).

optimized alternate route to meet the fire smoke exhaust requirements for the Daliangshan No. 1 Tunnel, minimize potential harm to traffic and personnel, and prevent non-fire areas and closed areas from being affected by smoke. The fire prediction scenarios are outlined in Table 4.

Figure 8 shows the predicted smoke exhaust efficiency under different traffic conditions. The results indicate that: (1) When the single-track tunnel is fully closed, vehicles may be present upstream and downstream of the fire. With the upstream air velocity set at 1.2 m/s, the air velocity is insufficient to control smoke stratification and back-layering, and upstream vehicles may be affected by smoke, but the smoke exhaust capacity is sufficient to discharge all the smoke through the nearest smoke outlet downstream of the fire source, thereby avoiding the impact of smoke on downstream vehicles. This wind speed is only suitable for two-way traffic, whether it is using a smoke outlet or shaft to exhaust smoke, the longitudinal wind speed is 1.2m/s. (2) When the fire occurs on a unidirectional traffic section, setting the upstream air velocity at the critical air velocity can prevent smoke stratification and ensure sufficient smoke exhaust capacity.

Table 4. Predicted fire smoke exhaust scenarios for optimized alternate route.

	Upstream air velocity(m/s)	Smoke exhaust capacity(m^3/s)	Traffic conditions
Case10	1.2	81.6	Full closure of single-track tunnel
	Upstream air velocity(m/s)	Smoke exhaust capacity(m^3/s)	Traffic conditions
Case11	v_{crit}	—	Closure of top section of single-track tunnel
Case12	v_{crit}	—	Closure of both ends of single-track tunnel

Figure 8. Prediction of smoke exhausting effect in different fire conditions of alternate route (as the area of smoke-extraction duct is 9.9 m^2).

All smoke can be exhausted through a single smoke exhaust outlet, allowing all smoke to be discharged through a single smoke outlet, thus avoiding the impact of smoke on downstream vehicles and personnel.

4 CONCLUSIONS

Relying on the control project of Leshan-Xichang Expressway in Sichuan Province, this paper studied and designed a new fire smoke exhaust mode. A new fire smoke exhaust model was constructed based on this mode, employing a one-dimensional analysis method to predict and compare the smoke exhaust efficiency under various fire scenarios and smoke exhaust conditions at different locations within the tunnel. Major findings were summarized as follows:

- (1) The fire smoke exhaust model before optimization cannot provide sufficient smoke exhaust due to the insufficient cross-sectional area of the smoke exhaust duct. Under fire conditions where the fire occurred far from the inclined shaft, the smoke cannot be controlled effectively by sufficient upstream air velocity, leading to stratification and backflow of smoke, which might affect vehicles and personnel upstream of the fire;
- (2) For fire incidents near the inclined shaft, the original model allowed smoke exhaust through the inclined shaft, which proved to be more efficient compared to using the nearest vehicle cross passage for smoke exhaust.
- (3) For the optimized fire smoke exhaust model, the cross-sectional area of the smoke exhaust duct is increased from 7.1 m^2 to 9.9 m^2 . The smoke exhaust capacity from the smoke outlet above of individual vehicle cross passages was increased, ensuring that any single vehicle cross passage could meet the requirements for fire smoke exhaust. By utilizing the smoke exhaust route downstream, which was closest to the fire location, along with longitudinal smoke induction, it was possible to effectively exhaust all smoke and prevent its diffusion from affecting vehicles upstream and downstream of the fire.

Based on the comprehensive analysis and predictions, it is concluded that the proposed new fire smoke exhaust mode is feasible. Through the prediction and analysis of the fire smoke exhaust efficiency, it is proven that the tunnel fire smoke exhaust model developed based on this new smoke exhaust mode exhibits excellent smoke exhaust performance. Furthermore, it can serve as a valuable reference for similar engineering projects.

Positioning and autonomous control of intelligent hydrodemolition robot

Wei Liang*

China Railway Construction Heavy Industry Corporation Limited, Changsha, China

ABSTRACT: In order to alleviate the unexpected damages and environmental pollution during the mechanical demolition process of underground spaces, we developed a hydrodemolition robot based on the design of end-effector with ultra-high pressure water jet. Aiming at the environment of tunnels, we built the kinematic model of the manipulator and end-effector, the typical operation positions and orientations in the tunnel are simulated and analysed, which can further be used to verify and optimize the mechanical and control parameters. In combination with the trajectory planning of the manipulator and the RTK positioning control of the crawler chassis, the working space and accuracy of the robot in complex tunnel environment are improved. Manual setting and autonomous navigation functions for moving paths and working areas are developed, which can further ensure the operation efficiency and safety of the robot.

Keywords: robot, high-pressure water jet, concrete demolition, kinematic modeling, RTK positioning, autonomous navigation

1 INTRODUCTION

Hydrodemolition, also known as water jet demolition, is a technology using high-pressure water jets to impact the concrete surface at very high speed and forming a water wedge effect and water hammer effect, so as to peel off the damaged, aged or loose concrete particles [Montero, R., et al., 2015, Momber, A., 2011]. During the maintenance of a tunnel, it is often necessary to demolish the damaged concrete or structures in the tunnel at fixed points, so as to ensure the overall safety and durability. In comparison with traditional mechanical methods, this hydrodemolition technology is featured by many advantages: 1) with water jet demolition technology, the jet direction, target distance, strength and flow rate can be changed to achieve accurate demolition of damaged and deteriorated concrete; 2) the pressure and flow of hydrodemolition are controllable, and the risk of damage to reinforcement and other internal structures is controllable; 3) irregular surfaces can be effectively created with the hydrodemolition technology, contributing to the adhesion of subsequent coating or repair materials; 4) by water jet demolition, the vibration, noise and dust generated in the process of construction will be reduced, making the whole process more environmentally friendly.

The water jet system is combined with the robot operating system to form hydro-demolition robot system. By the water jet system, high-pressure water is

transported to the jet mechanism installed at the end of the robot working device through a high-pressure hose to form a high-speed water jet beam, generating strong shooting energy. By the robot operating system, the end spray mechanism is positioned to the demolition point based on the calibrated position information, so as to accurately complete the demolition working task.

Conjet in Sweden has launched a series of products including Robot324, Robot365 and Robot432D, of which Robot 432D is a large-scale concrete removal robot in horizontal working planes [Fang, X.W., 2019]. The high-pressure water jet robots produced by Aqua-Jet in Sweden include various models such as 410 and 710, which can realize the operations in horizontal and vertical working planes in narrow spaces to remove concrete from bridges and pavements [Yang, W.J., 2016]. NLB in the United States is also one of the R&D manufacturers of high-pressure water jet robots, such as NLB6600 concrete hydraulic crusher, which can achieve different effects according to the specific engineering requirements. For example, where the pressure is lower than 150MPa, only a layer of concrete in about 25mm thick on the surface will be removed to avoid the exposure of reinforcement; its water pressure can be risen up to 280MPa, making it possible to penetrate the concrete layer to completely expose reinforcement [Xing, J.Z., 2015]. CITIC Heavy Industries and Giant Hydraulic Tech in China have also launched their own crawler-type high-pressure water jet robots, which are applied to the renovation,

*Corresponding author: liangwei2.zg@crcc.cn

reconstruction and reinforcement of the concrete structures of important buildings such as bridges, dams, tunnels, wharves, airports and power stations [Cai, S. *et.al.*, 2019].

At present, most of the hydro-demolition robot technologies integrate various sensors such as advanced 3D scanner and camera, with the function of real-time construction environment feedback; the function of remote operations is also developed to ensure the safety of operators. However, the development of water jet demolition robots is still being confronted with some constraints. For example, the maneuverability of robot in a narrow space is limited, and the robot arm is difficult to extend with increased the risk of collision, causing difficulty to ensure construction safety; secondly, most robots are still manually manipulated for working, with poor vision in tunnels and differences in accuracy and consistency of demolition, causing difficulty to ensure the construction quality and efficiency; in addition, there are safety risks in the short-distance operations of water jet, and it is inadvisable for construction personnel and operators to make close observation and control.

Therefore, it is necessary to accurately model the kinematics of robots to achieve precise operations in narrow or complex spaces, reduce working errors and waste in materials, and improve the construction quality and efficiency; meanwhile, it is necessary to increase the autonomous navigation and autonomous operation functions of robots, which are conducive to enlarging the robots' working range, automatic obstacle avoidance and working area identification, adapting to the diversified tasks and environments, lowering the participation degree of operators, reducing the labor workload and improving the construction safety.

In this paper, the hydro-demolition robot developed by China Railway Construction Heavy Industry Corporation Limited (CRCHI) is introduced, and the modeling of manipulator motions and the planning of working paths are carried out for the robot. In the second part below, the method of modeling each component of the robot is introduced, while in the third part, the motion effect is introduced, and a summary of robot development in the fourth part.

2 MODELING

The hydro-demolition robot SPC-1340A (Figure 1) developed by CRCHI consists of crawler chassis, control module, hydraulic actuator, manipulator and end-effector. Of them, the robot manipulator has four degrees of freedom, and can assist the end-effector to reach different positions and postures around the construction plane circumference; the end-effector has three degrees of freedom, and can realize a variable-angle demolition path with a maximum width of 2 meters on the basis of manipulator positioning; the crawler chassis is

strong in comprehensive motion performance, suitable for unstructured construction environment, and able to move to the set working point by itself; the hydraulic actuator powers each of the above-mentioned actuating subsystems.

2.1 Modeling of manipulator

The motion of manipulator is of great significance to tunnel maintenance: 1) ensure the accurate removal of concrete; 2) adapt to complex structures and avoid existing obstacles; and 3) improve the construction efficiency. Therefore, the motion of manipulator in the internal space of a tunnel requires precise positioning and trajectory planning, all of which require modeling the kinematics for the manipulator.

As shown in Figure 2, the manipulator has 4 links (Link 1 ~ Link 4), of which Link 4 is connected to the end-effector (Link 5). In the process of manipulator modeling, a fixed coordinate system $\{0\}$ is set at the proximal end of Link 1 as the base coordinate system; coordinate systems $\{1\} \sim \{4\}$ represent each motion joint of the manipulator. It should be noted that joint $\{2\}$ is a moving subjoint while others are rotating subjoints. Therefore, the DH parameters required for kinematic modeling can be extracted according to the origin and attitude of each coordinate system in Figure 2 and the size of each link (Table 1).

Figure 1. Hydro-demolition robot SPC-1340A designed by CRCHI.

Figure 2. Coordinates of manipulator joints.

Table 1. DH parameters of manipulator and end-effector.

Joint i	α_{i-1} (rad)	a_{i-1} (m)	d_i (m)	θ_i (rad)
1	0	a_1	d_1	θ_1
2	$\pi/2$	0	d_2	0
3	$-\pi/2$	0	d_3	θ_3
4	0	a_4	d_4	θ_4
5	$-\pi/2$	a_5	d_5	0
6	0	a_6	d_6	0
7	$\pi/2$	0	d_7	θ_7
8	$\pi/2$	0	d_8	θ_8

Note: In the table, α_i means: z_i in coordinate system $\{i\}$ is rotated around x_i by α_i and coincides with z_{i+1} in coordinate system $\{i+1\}$; a_i means: the distance between z_i in coordinate system $\{i\}$ and z_{i+1} in coordinate system $\{i+1\}$ along the direction x_i ; d_i means: the distance of x_i in coordinate system $\{i\}$ along the direction z_i relative to x_{i-1} in coordinate system $\{i-1\}$, where d_2 , d_5 , and d_6 are variable; θ_i means: the angle of rotation around z_i in coordinate system $\{i\}$.

According to the DH parameters, a homogeneous transformation matrix ${}^{i-1}T$ between adjacent joint coordinate systems can be established:

$${}^{i-1}T = Rot_{x_{i-1}}(\alpha_{i-1})Trans_{x_{i-1}}(a_{i-1})Rot_{z_i}(\theta_i)Trans_{z_i}(d_i)$$

$$= \begin{bmatrix} \cos \theta_i & -\sin \theta_i & 0 & a_{i-1} \\ \sin \theta_i \cos \alpha_{i-1} & \cos \theta_i \cos \alpha_{i-1} & -\sin \alpha_{i-1} & -d_i \sin \alpha_{i-1} \\ \sin \theta_i \sin \alpha_{i-1} & \cos \theta_i \sin \alpha_{i-1} & \cos \alpha_{i-1} & d_i \cos \alpha_{i-1} \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (1)$$

Further, the homogeneous transformation matrix 0_4T of the end connecting joint $\{4\}$ relative to the fixed coordinate system $\{0\}$ can be obtained by multiplying each adjacent transformation matrix:

$${}^0_4T = {}^0_1T \cdot {}^1_2T \cdot {}^2_3T \cdot {}^3_4T \quad (2)$$

According to the homogeneous transformation matrix, the position and posture of the end-effector relative to the base coordinate system can be solved by changing the angle of each joint; on the contrary, the rotation angle or moving distance of each joint can also be calculated according to the posture of the end coordinate system as required in construction.

2.2 Modeling of end-effector

The pressurized water passes through the nozzle to form a single beam of high-pressure water jet impacting on the deteriorated concrete, and the range of demolition with the nozzle alone is quite limited. Therefore, on the basis of positioning completed by the manipulator, a horizontal reciprocating motion mechanism and an equidistant reversing mechanism are added to the end-effector of the hydro-demolition

robot, to expand the working width of the water jet nozzle and improve the uniformity and stability of the operation.

As shown in Figure 3, the whole end-effector is connected to the manipulator end through joint 4, wherein the sliding frame realizes overall left-right translation based on the moving subjoint $\{5\}$, increasing the actual working width; meanwhile, through the moving subjoint $\{6\}$, the sliding bracket realizes translational motion relative to the sliding frame in the process of demolition; the nozzle is installed on the sliding support, and two hydraulic motors respectively realize equidistant reversing rotation around axis z_7 and continuous working swing around axis z_8 .

Figure 3. Coordinates of end-effector.

Similarly, the homogeneous transformation matrix 4_8T of the nozzle relative to joint 4 and the homogeneous transformation matrix 0_8T of the nozzle relative to base coordinate $\{0\}$ can be obtained according to formula (1) and formula (2) and in combination with Figure 3 and the DH parameters in Table 1. The position and posture of nozzle relative to the base coordinate system has a definite solution relationship, providing a kinematics basis for the positioning of robot for accurate construction in the later stage.

As shown in Figure 4, an eccentrically connected linkage (around axis z_7) is driven by a hydraulic motor to realize equidistant reversing of the nozzle. Stop blocks are added on the left and right sides of the nozzle respectively to effectively fix the demolition angle of the nozzle. The mechanism can ensure that the distance from the nozzle to concrete surface are remained unchanged during the reversing, so as to ensure the consistency of demolition effect; meanwhile, it can prevent the nozzle from being damaged due to collision with the ground and ensure reliable operation of the nozzle.

2.3 Modeling of crawler chassis

The forward and backward motion of the crawler chassis can be realized by the motion of crawlers on the left and right sides at a same speed. However, the modeling of crawler chassis steering motion is complex. As shown in Figure 5a, the coordinate system of the chassis in a plane is established with the center of gravity (COM) of the chassis as the origin, the direction of forward motion as the x-axis, and the direction on left side as the y-axis. Points A and B are set at the front and rear ends of the left crawler respectively, and Point D is set at the front end of the right crawler. At this time, if the crawler needs to make steering motion around the instantaneous center of rotation (ICR), the following conditions shall be met:

$$\begin{cases} v_A \neq v_B \\ v_{Ax} = v_{Bx} \end{cases} \quad (3)$$

$$v_{Ay} = v_{Dy} \quad (4)$$

According to Formula (3) and Formula (4), the longitudinal component velocities of all points on the crawler on same side are required to be the same; in addition, the transverse component velocities of two symmetrical points about x-axis on the left and right crawler are required to be the same.

Further, by simplifying the model of crawler motion to a virtual two-wheel differential model as shown in Figure 5b, the following relationship can be obtained:

$$r_c = \frac{v_c}{w_c} = \frac{(v_l + v_r)d_{LR}}{2(v_r - v_l)} \quad (5)$$

Where r_c denotes a radius of rotation (m) at point COM, v_c denotes a linear velocity at point COM, w_c denotes an angular velocity (rad/s) at point COM, d_{LR} denotes a virtual wheel spacing (m), and v_l and v_r denote respectively the virtual left and right wheel linear velocities (m/s, equal to the left and right crawler linear velocities).

Figure 4. Equal distance switching system.

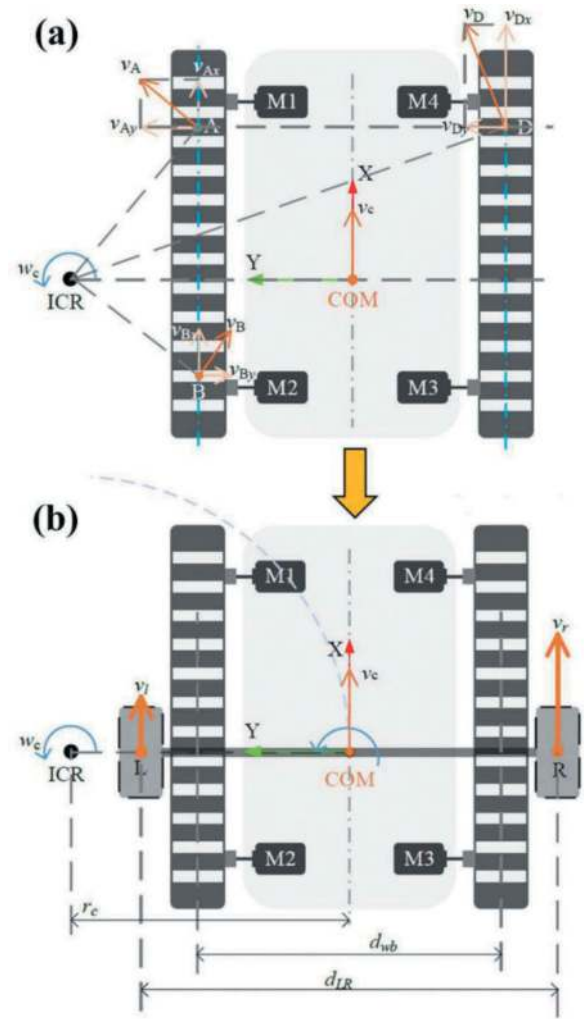

Figure 5. Crawler chassis model, (a) crawler wheel model analysis; (b) equivalent virtual two-wheels model.

Virtual wheel spacing is a complex parameter related to load, friction coefficient, turning radius and center-of-mass position. It is generally obtained through tests:

$$d_{LR} = \gamma d_{wb} \quad (6)$$

Where γ is the dimensionless empirical parameter and d_{wb} is the actual wheel spacing of the robot (m). At this time, the forward kinematic model of the crawler chassis can be obtained as follows:

$$\begin{bmatrix} v_c \\ w_c \end{bmatrix} = \begin{bmatrix} 1/2 & 1/2 \\ 1/(\gamma d_{wb}) & -1/(\gamma d_{wb}) \end{bmatrix} \begin{bmatrix} v_r \\ v_l \end{bmatrix} \quad (7)$$

The inverse kinematic model is:

$$\begin{bmatrix} v_r \\ v_l \end{bmatrix} = \begin{bmatrix} 1 & \frac{\gamma d_{wb}}{2} \\ 1 & -\frac{\gamma d_{wb}}{2} \end{bmatrix} \begin{bmatrix} v_c \\ w_c \end{bmatrix} \quad (8)$$

2.4 GNSS-based RTK navigation modeling

A GPS-based GNSS (Global Navigation Satellite System) navigation system is adopted for Robot

SPC-1340A. The ranging principle of GNSS is to obtain the distance between the marked point and the satellite by multiplying the velocity of electromagnetic wave and the time of signal transmission, where time is the key to measurement accuracy. GNSS positioning is based on the principle of distance resection, that is, a spherical surface is established with the satellite as the center and the measured distance as the radius; two points are obtained by intersecting three spherical surfaces formed by three satellites, and the positioning is completed after unreasonable points are excluded geographically.

Since the measuring point has four unknown quantities that are the three coordinates (x, y, z) of the position and the clock difference t , it is necessary to introduce the fourth satellite to form 4 equations for solving them, so as to obtain the longitude, latitude and altitude of the measuring point.

$$p_i = (x_i - x)^2 + (y_i - y)^2 + (z_i - z)^2 + t \quad (9)$$

Where $i=1\sim 4$; p_i denotes the relative position of the observation point measured by the i th satellite; x_i, y_i and z_i denote the relative coordinates of the observation point measured by the i th satellite respectively; t denotes the clock difference (s).

In order to carry out the demolition construction more accurately, it is necessary to further improve the positioning accuracy to centimeter level; and according to the dynamic action process of the robot, the robot should be positioned in real time. Therefore, RTK (Real-Time Kinematic) positioning technology is adopted.

RTK is a relative, dynamic and real-time measurement technology which is realized based on carrier phase. First, the calculation equation based on the observations of carrier phase is as follows:

$$P_{s,m}^i = \rho_m^i + c(dt_m - dt^i) + \mu_s \cdot I_m^i + T_m^s + \beta_{s,m} - \beta_s^i + d_m^i + \varepsilon_{s,m,\rho}^i \quad (10)$$

$$\lambda_s \varphi_{s,m}^i = \rho_m^i + c(dt_k - dt^i) - \mu_s \cdot I_m^i + T_m^i + \lambda_s (\delta_{s,m} + \delta_s^i + N_{s,m}^i) + d_m^i + \varepsilon_{s,m}^i \quad (11)$$

Where i is expressed as the satellite number, s and m are expressed as the frequency of the satellite and the receiver of the user; $P_{s,k}^i$ is the original observed value of the pseudorange; $\varphi_{s,k}^i$ is the observed value of carrier phase; ρ_m^i is the distance from the satellite to earth (m); c is the velocity of light in vacuum (m/s); dt_k, dt^i is the receiver clock difference and the satellite clock difference (s); I_m^i is the delay of ionosphere at frequency f_l (m); μ_s is the ionospheric amplification factor between frequencies f_i and f_l ; T_m^i is the delay of troposphere on inclined path (m); $\beta_{s,m}$ is the pseudorange delay of the user receiver end at frequency s (m); β_s^i is the pseudorange delay of satellite end at frequency s (m); λ_s is

the wavelength (m); $\delta_{s,m}, \delta_s^i$ is the phase delay of satellite and user end at frequency s ; $N_{s,m}^i$ is the ambiguity (weeks); d_k^i is other errors unrelated to frequency; $\varepsilon_{s,m,\rho}^i, \varepsilon_{s,m,\varphi}^i$ is the measured noise at the same frequency (m).

Based on Formula (10) and Formula (11), for Robot SPC-1340A, 2 stations are used for real-time carrier positioning (Figure 6), in order to achieve the high-precision positioning in centimeter level. The differencing between the observation equations of two different stations is called single difference between stations, and the pseudorange and carrier phase equations for the differencing between two stations m and n through common observation satellite i are as follows:

$$\Delta P_{s,m,n}^i = \Delta \rho_{s,m,n}^i + c \cdot \Delta dt_{mn} + \mu_s \cdot \Delta I_{mn}^i + \Delta \beta_{s,mn} + \Delta d_m^i + \Delta \varepsilon_{s,mn,\rho}^i \quad (12)$$

$$\lambda_i \Delta \varphi_{s,m,n}^i = \Delta \rho_{mn}^i + c \cdot \Delta dt_{mn} - \mu_s \cdot \Delta I_{mn}^i + \Delta T_{mn}^i + \lambda_i (\Delta \delta_{s,mn} + \Delta N_{s,mn}^i) + \Delta d_m^i + \Delta \varepsilon_{s,mn,\rho}^i \quad (13)$$

Figure 6. Single differential RTK model between stations.

3 RESULTS

3.1 Manipulator and end-effector

By modeling the DH parameters of the manipulator joints and solving the homogeneous transformation matrix of the end connecting joints, Robot SPC-1340A is capable of completing the motions in three degrees of freedom in the plane of workspace. As shown in Figure 7, the manipulator end can complete the motions in three degrees of freedom: horizontal motion, vertical motion and rotation in end posture around axis z_4 .

According to the motion of the manipulator position and posture, the posture of end-effector in the working plane is further calculated. As shown in Figure 8, Robot SPC-1340A can adapt to the configuration of various walls in tunnels with a diameter not more than 6 meters, realize the end positioning and complete the demolition operations.

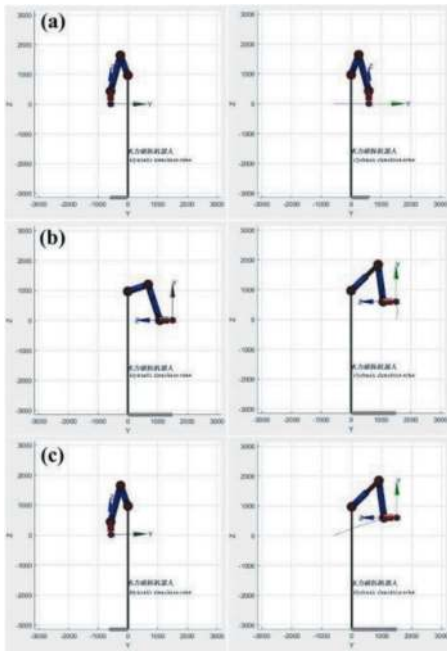

Figure 7. Motions of manipulators, (a) horizontal motion; (b) vertical motion; (c) rotating motion.

Figure 8. Orientations and Positions of end-effector in the working plane.

3.2 Robot positioning and automatic operations

Robot SPC-1340A can automatically complete the positioning, navigation and demolition operations (Figure 9), with the implementation process as follows: 1) complete the robot's own positioning through GNSS system; 2) identify the relative position of a working area to the robot through four marking points; 3) calculate the walking path, working position and actuator posture of the robot based on the kinematic model of the crawler chassis, manipulator and end-effector; 4) carry out the operations based on the GNSS system and planned path.

The human-machine interaction interface on the control panel is shown as Figure 10, where the green line is the robot's walking path, and the yellow line is the demolition + walking route of the robot.

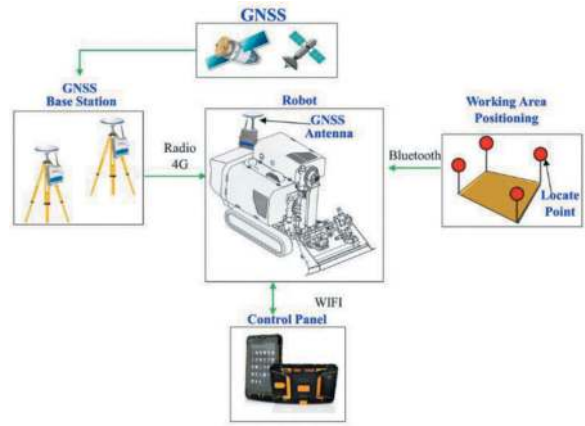

Figure 9. The robot positioning and working area identification.

Figure 10. Orientations and positions of end-effector in the working plane.

3.3 Demolition capability of the robot

Robot SPC-1340A has been subject to the in-plant hydrodemolition test (Figure 11) and the verification of demolition effect on tunnel maintenance site (Figure 12).

In the process of the in-plant test, under the conditions of water pressure of 160 MPa, flow rate of about 30 L/min, water nozzle aperture of 2.2 mm and frequency of 35 Hz, the demolition finally produced a deep groove in 110 cm long, 21 cm wide and 6 cm deep through three effective travels of the crawler (Figure 11b). The volume of concrete demolished per unit time is about 0.014 m³/h. Although the test block is nominally a C10 concrete test block, it is poured concrete with more pebbles and higher actual strength.

The industrial field verification was carried out at a tunnel construction site of China Railway 22nd Bureau Group. The track laying of the

construction tunnel was completed. Within about 5.3 m*2.46 m left to and 3.12 m*2.75 m right to the position of lining arch crown and about 100 m from the portal, some defective reinforced concrete needed to be demolished by a depth of 0.5 m and then poured again (Figure 12b). The target concrete strength grade was C50; the concrete specification was 2 m*1.6 m*0.2 m. Under the conditions of water pressure of 160 MPa and flow rate of about 30 L/min, the demolition depth was between 30 ~ 40 cm, and the C50 concrete volume of demolition per unit time was about 0.014 m³/h (Figure 12c). Meanwhile, Robot SPC-1340A was also verified for its functions of outdoor high-precision positioning in RTK centimeter level, with the functions such as real-time position monitoring, setting and automatic planning of motion route, setting and automatic planning of working area assisting the intelligent operations of hydro-demolition robot.

Figure 11. In-plant hydrodemolition test, (a) robot displayed in-plant; (b) demolition area of one swept of nozzle.

4 CONCLUSION

In the field of tunnel maintenance and construction, CRCHI has integrated the traditional water jet technology with advanced robot control technology, developed hydro-demolition robot and related algorithms for intelligent construction operations, and redefined the construction method for removing the deteriorated concrete through the synergistic effect among kinematic modeling, end-effector design, crawler chassis integration and navigation system,

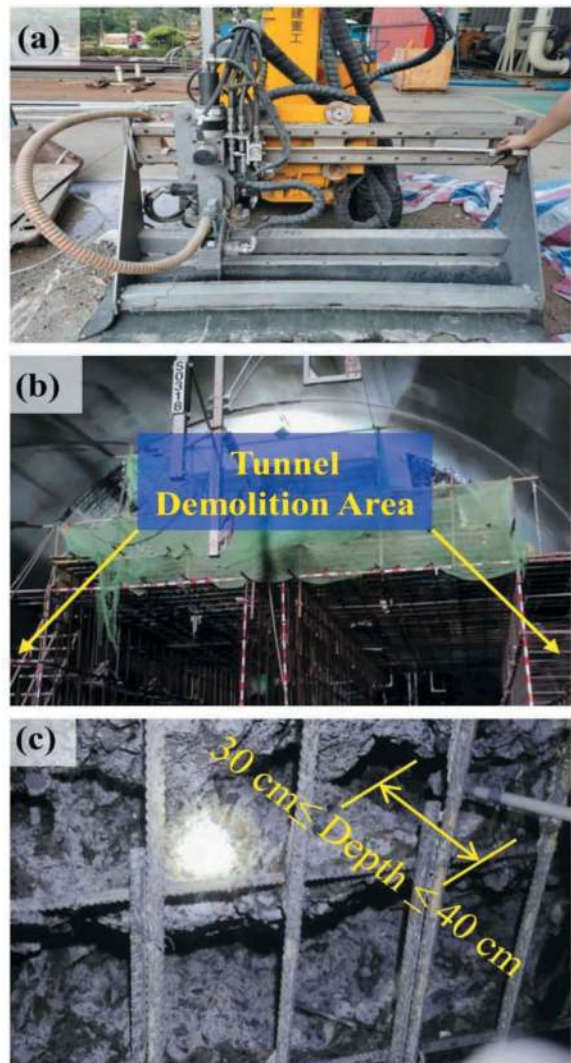

Figure 12. On-site hydrodemolition test, (a) robot displayed tunnel maintenance site; (b) demolition area of tunnel; (c) demolition result of the robot.

thus improving the efficiency, accuracy and safety of construction.

The kinematic modeling of manipulator and end-effector enables the robot to achieve flexible working positions and postures in tunnel spaces. In the process of maintenance, the robot can selectively demolish the damaged parts while retaining structural integrity, which not only adapts to different collective surfaces, but also improves the accuracy and quality of the demolition process, laying a foundation for efficient and accurate restoration of various structures.

The modeling of crawler chassis and the integration of RTK positioning technology bring high maneuverability to the robot in various terrains. It has the ability to autonomously plan paths, avoid obstacles and optimize trajectories. This level of intelligence not only enhances the safety, but also minimizes the human intervention, minimizing the

risk of performing tasks in hazardous or remote environments.

In summary, the collaboration among hydro-demolition robot SPC-1340A, kinematic modeling of robot arm, end-effector design, crawler chassis modeling and navigation system integration can effectively improve the construction efficiency, reduce the waste in materials, enhance the construction safety and protect the critical structures.

ABSTRACT: The existing tunnel lighting standards are mainly based on physical evaluation indicators, such as luminance and luminance uniformity in photopic vision, which do not fully consider the actual changes of the visual environment when driving in the tunnel, and do not fully reflect the psychological and physiological perception and the behavioral response of drivers. This paper made a systematic study on the information and perception in the tunnel lighting environment, revealed the change rule and relationship between physical information and physiological perception, and proposed a series of evaluation methods of tunnel lighting environment based on information perception, and then verified by numerous static and dynamic information perception experiments. The results show that the tunnel lighting environment is composed of material information and the characteristics of the tunnel lighting environment are represented by physical information. As a coupled human-vehicle-road environment, information perception involves not only the physical information of the tunnel lighting environment, but also the subjective response (i.e. physiological perception) of the driver. Through the comprehensive analysis of the specific relationship between physical information and physiological perception, the information perception mechanism is formed, and the tunnel lighting environment evaluation method based on information perception is further constructed. It provides basis and reference for tunnel lighting environment design.

Keywords: Tunnel lighting environment, Physical information, Physiological perception, Information perception mechanism, Evaluation method

1 INTRODUCTION

At present, China's economy has changed from the stage of rapid growth to the stage of high-quality development of "satisfying people's yearning for a better life". Tunnels play an important role in ensuring smooth traffic and promoting economic prosperity. By the end of 2022, there are 24850 highway tunnels in China, with a total length of 26.7843 million meters (Ministry of Transport of the people's Republic of China, 2022). However, as a kind of semi-closed tubular space structure, the "black hole, white hole" effect of vehicles entering and leaving will cause visual oscillation to the driver (Liang et al., 2020). Drivers obtain information from the outside world through vision, hearing, and smell, of which more than 80% of the outside information perception is obtained through visual perception during tunnel driving (Mehri et al., 2019). A large sample survey of traffic accident

causes shows that the proportion of traffic accident causes as the dominant human factor is as high as 92.6% (Shi et al., 2022). Therefore, in the process of driving in the tunnel, how to obtain and correctly perceive the information and make a correct response to the constituent information, especially the lighting environment, is directly related to the safety and comfort of tunnel operation.

Drivers' perception of information involves not only physical information, but also people's subjective reaction, namely physiological perception (Liang et al., 2023). Among them, physiological perception refers to the physiological and psychological response indicators of drivers under tunnel lighting environment, which can also be called biological indicators (Hamedani et al., 2019). Including electrocardiogram (ECG), electromyography (EMG), electroencephalogram (EEG), reaction time, perceived contrast and visual efficacy of a series of indicators (such as pupil

*Corresponding author: ja_niu@163.com

diameter and change rate, fixation, saccade frequency) and so on (Niu et al., 2024). Physical information refers to the definite indicator used to measure material properties and describe matter in different motion states under tunnel lighting environment, which can also be called physical indicator (Niu et al., 2022). Including luminance, luminance uniformity, illuminance, space size, color, traffic flow, speed, visibility and so on. Moreover, the way drivers perceive the lighting environment can be divided into static perception and dynamic perception. The static perception of tunnel lighting environment is the perception mode of tunnel lighting environment under static conditions (Pigliautile et al., 2020). At present, the research on drivers' perceptual characteristics under static conditions is more mature, such as human visual search features, human depth perception features and so on. Dynamic perception in tunnel lighting environment is the way of perception under driving conditions (Zhang et al., 2022). There are two main research methods for dynamic perception: one is dynamic perception in virtual scene, and the other is dynamic perception in real traffic environment.

At present, the design and research of tunnel lighting at home and abroad are mostly focused on the value and evaluation of the physical indicator of lighting environment, without fully considering the driver's physiological perception under the condition of human-vehicle-tunnel lighting environment, and its impact on driving behavior and traffic safety (Qin et al., 2023). The research work and results of tunnel lighting environment are seldom carried out from the point of view of information representation and information perception (Bellazzi et al., 2022), and the dynamic perception mechanism and experimental research are seldom carried out from many aspects, such as driving simulation experiment and real vehicle test. There is no tunnel lighting environment evaluation method considering both physical information and physiological perception (Chihara et al., 2020).

Against the above background, this paper studies the relationship between the physical information of tunnel lighting environment and the physiological perception from the point of view of ensuring safety and comfort, and clarifies the information perception mechanism of drivers in different motion states. A tunnel lighting environment evaluation method based on dynamic perception of biological visual indicator is proposed to provide theoretical basis and evaluation indicator for tunnel operation environment safety, quality improvement and future intelligent lighting.

2 COMPOSITION AND CHARACTERIZATION OF TUNNEL LIGHTING ENVIRONMENT INFORMATION

2.1 Analysis on the composition of tunnel lighting environment information

The tunnel lighting environment information is composed as shown in Figure 1.

Figure 1. Sketch of tunnel lighting environment information composition.

2.1.1 Direct influencing factors

- 1) Light source. The light source in the tunnel is one of the important components of the tunnel lighting environment. In addition to the inherent properties such as luminance and light color, the layout of lamps and lanterns is also an important factor affecting the composition of the tunnel lighting environment.
- 2) Sidewall material. With the improvement of driving safety and comfort requirements in the tunnel, a single concrete sidewall material has been unable to meet the requirements. At present, tunnel sidewall materials can be classified into seven categories: concrete, enamel steel plate, ceramic tile, composite aluminum plate, fireproof material, fiber reinforced concrete board and energy-storage and self-luminous material (Shen et al., 2022).
- 3) Tunnel vault. As an important part of the tunnel lighting environment, the color of the vault will affect the driver's identification of the tunnel lighting environment and driving comfort.
- 4) Road surface. As a driving carrier, the road surface is an important part of the tunnel lighting environment. When motor vehicle drivers drive, they feel the road surface luminance visually. Therefore, the lighting design of highway tunnel should meet the requirements of average luminance, total luminance uniformity, longitudinal uniformity, flicker and inducement of pavement centerline.

2.1.2 Indirect influencing factors

- 1) Traffic safety signs. Traffic safety sign setting system includes color, shape, text, graphics, layout, location, structure and materials and other elements, the accuracy and completeness of these information is directly related to the effectiveness of traffic signs.
- 2) Vehicle characteristics. In addition to the main structure of the tunnel, the composition of the lighting environment also includes the vehicle characteristics such as the size, color, light and

siren of the vehicles in the tunnel. Vehicle color can provide some safety warning information while driving, and whether the lights are normal or not directly affects the driving safety.

- 3) Guidance signs. The driver is the main factor in driving in the tunnel, improving the visual guidance environment inside the tunnel, keeping the driver within a reasonable range of environmental information, and enabling the driver's visual perception ability to process the driving environment information inside the tunnel, thereby improving the safety of driving.

2.2 Indicators for characterizing tunnel lighting environment information

2.2.1 Physical information

Describing the physical information of tunnel lighting environment and putting forward the evaluation indicator is not only the key basis for the formulation of tunnel lighting design standards, but also an important basis for tunnel lighting theoretical research.

In the aspect of driving safety, luminance is a physical information that indicates the luminous (or reflective) surface of the luminous body (or reflector). It is the subjective feeling of the light intensity, which determines whether the human eye can see the basic information of the object. Disability glare refers to the occurrence of excessive luminance or excessive luminance change before and after a certain part of the field of vision, which seriously affects the judgment and working ability of drivers in the process of driving, thus leading to safety accidents. Visibility refers to the maximum distance that a person with normal vision can identify the target from the background, which determines whether the driver can clearly identify the outline characteristics of the target from a 20-degree perspective, which is an important factor for safe driving.

In terms of driving comfort, luminance uniformity is an indicator to ensure the visibility and visual comfort of drivers. When the environmental luminance reaches a certain value, the human eye is in an environment with large luminance contrast, so it will be easier to adapt to the environment and identify objects. Uncomfortable glare refers to the repeated high luminance changes in the driving field of vision, which is one of the important causes of visual fatigue, which can lead to the decrease of image clarity and contrast. Color temperature is a general term that indicates that light contains color components. Reasonable color temperature distribution in tunnel lighting environment can shorten the reaction time of drivers and improve driving safety and comfort.

Therefore, as a tunnel lighting environment at a certain speed, the driver's visual perception and judgment of physical information in the process of vehicle driving is obviously different from that in the static state.

2.2.2 Physiological perception

When the driver passes through the tunnel, due to the change of the lighting environment and speed in different tunnel lighting areas, the driver's physiological perception changes accordingly, which affects the driver's real perception of the tunnel lighting environment information, and even lead to traffic safety accidents.

Under different light conditions, the changes of ECG can reflect the degree of emotional tension of drivers. The level of skin conductance can show the muscle fatigue accumulated by the driver during driving. EEG signals can record the changes of electric waves during brain activity and indicate the degree of consciousness of the driver. Visual efficacy can describe the influence of the change of tunnel environment luminance on drivers' fatigue and tension, and the degree of difficulty for drivers to obtain tunnel lighting environment information. The reaction time is the time it takes for the driver to identify obstacles and complete braking in the tunnel lighting environment. The perceived contrast can characterize the effects of windshield, atmospheric dispersion, range and luminance of human eye field on drivers' information perception.

Under different speed conditions, the visual spectral sensitivity curve of the driver moves to the short wave direction in advance during dark adaptation, which leads to a change in the dynamic perception state of the visual field luminance of the driver, which in turn affects the driver's driving behavior. The real car test shows that increasing the ambient luminance of the driver in the 20 ° field of view angle in the tunnel can alleviate the driver's tension. As the driving speed increases, the driving task becomes more difficult, the visual task becomes more difficult, and the driver will pay less attention to the road ahead.

3 MECHANISM AND EXPERIMENTAL RESEARCH ON PERCEPTION OF TUNNEL LIGHTING ENVIRONMENT INFORMATION

3.1 Experimental study on static perception of tunnel lighting environment information

3.1.1 Construction of static information perception simulation testing platform

To test the reaction time of human eyes to random targets on the background under the same lighting luminance (luminance uniformity) and different lighting environments (such as changing background luminance, target contrast, eccentric angle, sidewall material, etc.), an information perception analysis model under static conditions is proposed. The reaction time was selected as the evaluation indicator to study the influence of different lighting environment on the visual efficacy of the subjects. Reaction time directly evaluates the tester's ability to perform visual tasks under different lighting conditions,

which is similar to the completion of visual tasks in the actual visual working environment. Therefore, the visual model based on reaction time can be used to evaluate the information perception ability of highway tunnel lighting environment.

The information perception simulation testing platform under static conditions is shown in Figure 2. It is composed of the target generation of the highway tunnel lighting environment scale model by the photosensitive reaction time measuring device used in the tunnel lighting environment simulation test and the reaction time data acquisition and integrated processing system linked with the reaction time measuring device. The purpose of this paper is to provide the experimental basis for determining the reaction time of the people tested under different sidewall materials.

Based on the information perception simulation testing platform under static conditions, the project team carried out a series of experimental studies, including target perception response time, small target visibility (STV), spectral distribution of tunnel lighting assisted by different materials and so on.

Figure 2. Information perception model under static condition and simulation testing platform.

3.1.2 Response time test of target perception

The tunnel lighting uses LED energy-saving light source, and its luminance range can be adjusted (1-15 cd/m^2) to simulate the lighting level of the middle section of the highway tunnel, and the lighting environment of the tunnel can be adjusted according to the two dependent variables of contrast and luminance. According to the position of the target spot, the eccentricity angles of 0° , 10° and 20° are randomly distributed, and the reaction time of target discovery is recorded by timer to simulate the different conditions of middle axis and non-middle axis.

When the contrast C is 0.5 and the background luminance L is $10 \text{ cd}/\text{m}^2$, the reaction time of the three test materials with the deflection angle of the sight mark is shown in Table 1. Among them, the reflectivity of cement mortar is the lowest, the energy-storage and self-luminous material is the highest, and the ceramic tile is in the middle. It can be seen from Table 1 that at the same eccentricity angle, the reaction time decreases with the increase of the reflectivity of the sidewall material, and for the same material, the reaction time increases with the increase of the eccentricity angle. The experimental data show that the effect of

the increase of the reflectivity of the sidewall material on the reduction of reaction time is more obvious than that of the background luminance.

Table 1. Contrast eccentricity and reaction time when C is 0.5 and L is $10 \text{ cd}/\text{m}^2$.

Contrast eccentricity/ $(^\circ)$	Reaction time/ms			
	Cement mortar	Ceramic tile	Energy-storage and self-luminous material	Total reduction of reaction time/ms
0	292.11	262.54	256.37	35.74
10	296.93	275.67	262.81	34.12
20	303.81	292.26	277.48	26.33
Total added value	11.70	29.72	21.11	

3.1.3 Small target visibility information perception test

In this paper, cement mortar, ceramic tile and energy-storage and self-luminous material are selected as the sidewall materials of the tunnel. In the tunnel model shown in Figure 2, the composition of the lighting environment such as luminance and color temperature in the tunnel is changed by adjusting the lighting luminance in the model, so as to change the composition information of the lighting environment. Then send out small targets with different information (such as size, position, luminance, etc.) through the small target generator, and take the time needed for the human eye to capture the small target as the experimental data. In this experiment, the laboratory test of small target visibility was carried out by correlation luminance uniformity and discovery time. The visibility curve of small targets under different sidewall materials is shown in Figure 3.

Figure 3. Relationship curves between average luminance and small target visibility (STV).

It can be seen from Figure 3 that the STV value of small target visibility increases with the increase of small target size, and the growth range of small target visibility (STV) is further increased with the increase of small target size. It also further confirms the common sense that larger obstacles are more conducive to identification in reality.

3.2 Experimental study on dynamic perception of tunnel lighting environment information

3.2.1 Construction and experimental research of a dynamic information perception simulation testing platform

Based on virtual simulation technology, we have independently developed a simulation testing platform for dynamic information perception (Figure 4). We use a dynamic environment simulation output device to achieve a realistic restoration of the tunnel driving environment in the laboratory, which can be used to conduct indoor research on the safety and comfort of driving environments in different tunnel visual environments.

Figure 4. Dynamic information perception simulation testing platform.

The team conducted a series of experiments on driving dynamic information perception in tunnels based on the dynamic information perception mechanism and the reaction time indicators in visual efficacy theory, and relying on the developed dynamic information perception simulation testing platform.

By recording high-definition videos of 6 extra long highway tunnels at speeds of 60, 70, and 80 km/h, and using a dynamic information perception simulation testing platform, the indoor driving environment was realistically restored to obtain the response time characteristics of the driving process. The reaction time is to simulate the target object with a spot emitter and randomly project it onto different positions in front of the photographic recording road surface. By pressing the brake or pressing the timer, a computer mini program is used to automatically record the time when the driver discovers the spot. The average reaction time of drivers at different distances from the tunnel entrance is shown in Figure 5.

The main experimental conclusions are as follows: 1) Overall, the reaction time shows a process of decreasing first and then slowly increasing; 2) The reaction time at the entrance of the tunnel is relatively long, then rapidly decreases, and the

Figure 5. Average response time of drivers at different entrance distances from tunnel.

reaction time is the shortest at around 750 meters; 3) The driver's reaction time increases with the increase of tunnel length and driving time, and there are significant fluctuations in physiological and psychological changes during this period; 4) As the vehicle speed gradually increases, the refresh rate of traffic information in the driver's field of view accelerates, the level of danger during driving increases, the driver's attention and vigilance significantly increase, and the reaction time gradually decreases.

3.2.2 Research on dynamic information perception in real vehicle testing

Based on the Lushan Tunnel, Yeyatang No.1 and No.3 Tunnels in Yunnan, Maoba No.2 Tunnel in Shaanxi, Zhujiadu Tunnel and Shizizhai Tunnel in Sichuan, as well as 13 highway tunnels in Chongqing, including Xianghuang Tunnel, Changchong Tunnel, Nanshan Tunnel, Zhenwushan Tunnel, Cimushan No.1 Tunnel, Bayi Tunnel, and Hengkou Tunnel, a total of 316.24 km of eye movement and physiological indicators were tested for a total of 2004 participants. The study on the eye movement characteristics of drivers based on visual efficacy is to test the eye movement characteristics of drivers driving under different tunnel lighting environments (different lamps, lamp layout methods, etc.) and the same driving conditions during day and night. By analyzing the eye movement characteristics, the changes in eye movement parameters of drivers under different tunnel lighting environments are obtained, The on-site experiment is shown in Figure 6.

Figure 6. Schematic diagram of field test car and pupil area data collection.

1) Analysis of the changing trend of pupil parameters of drivers

To more intuitively characterize the visual load of drivers at the entrance and exit of the tunnel and evaluate the safety of the entrance of the tunnel, on the basis of the widely accepted definition of the visual oscillation time indicator of drivers, and based on the pupil diameter change ratio $PDCR$, the visual oscillation indicator of drivers is modified, and the visual oscillation duration indicator T_{PDCR} is proposed. The entrance section is selected as the research object. at a certain time, the pupil diameter of the driver is d_{i+1} , and the pupil diameter of the previous moment is d_i . The average pupil diameter of the driver during this period is M , and the pupil diameter change ratio $PDCR$ is:

$$PDCR = \frac{d_{i+1} - d_i}{M} \quad (1)$$

$$T_{PDCR} = T_e - T_s \quad (2)$$

When the $PDCR$ value of a driver at a certain point is compared with the two points before and after, and the fluctuation of the two points is outside the range of $\pm 5\%$ of the pupil diameter change rate and the difference between the two points is more than 10%, the phenomenon of visual oscillation will occur. The first point T_s outside the range of $\pm 5\%$ of the pupil diameter change rate was used as the start of the oscillation for the duration of the visual oscillation, and the first point T_e within the range of $\pm 5\%$ of the pupil diameter change rate was used as the end of the oscillation for the duration of the visual oscillation, as shown in Figure 7.

Figure 7 shows that the ratio of changes in pupil diameter at the inlet and outlet during each time period can be observed. At 9:30 am and 5:30 pm, when the illuminance changes are relatively small, the maximum $PDCR$ values at the inlet and outlet are significantly smaller compared to other time periods. Among them, the maximum $PDCR$ values at 9:30 am and 17:30 am are only 11.34% and 11.45%, respectively. On the other hand, the maximum ($PDCR$) of the import and export segments in other time periods is generally greater than 20%, and is basically distributed between 20% and 40%; At 13:30, the maximum ($PDCR$) of the entrance section even reached 51.9%. During this period, the maximum value of the illuminance change rate I_c in the entrance section was 3127.637 lux/s, which is the maximum value of the illuminance change rate in the entrance and exit section of the whole day working condition. It can be seen that excessive illuminance change rate has a significant impact on the driver's visual characteristics.

Moreover, drivers at the entrance and exit of the tunnel have different degrees of visual oscillation, but due to the change of illuminance, the duration of visual oscillation T_{PDCR} is different. When the illuminance change is relatively low, for example, the T_{PDCR} of the driver's visual oscillation at the

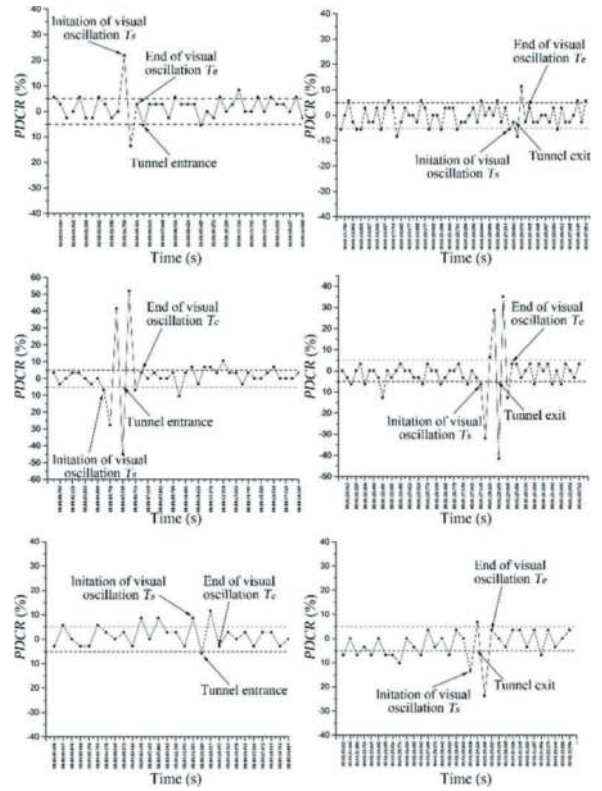

Figure 7. Changing trend of $PDCR$ value at the entrance and exit of the tunnel: (a) 9:30 Entrance, (b) 9:30 Exit, (c) 13:30 Entrance, (d) 13:30 Exit, (e) 17:30 Entrance, (f) 17:30 Exit.

entrance and exit at 9:30 and the exit at 17:30 are 1.22s, 1.68s and 1.28s, respectively, while at the entrance and exit at 10:30, 11:30, 13:30 and 15:30 where the illuminance changes greatly, and at 17:30, the visual oscillation duration T_{PDCR} is more than 2s. At 11:30, the visual oscillation duration T_{PDCR} of the driver in the exit section is as high as 2.4s. It can be found that the more severe the illuminance difference is, the longer the visual oscillation duration of the driver is, the shorter the visual oscillation duration of the mild illuminance change is, and even there is no visual oscillation phenomenon; it is considered that within a certain range, there is a certain positive correlation between the illuminance difference at the entrance and exit of the tunnel and the visual oscillation duration of the driver.

2) Analysis of drivers' saccade behavior.

The saccade parameters include saccade amplitude and saccade speed, which is the breadth of visual range acquisition by human eyes in a period of time, and the saccade speed reflects the speed of visual range acquisition.

$$V_s = \frac{A}{T} \quad (3)$$

Where, V_s is the saccade speed, $^\circ \cdot s^{-1}$; A is the saccade amplitude, $^\circ$; T is the time of a saccade event, s.

After organizing the analysis of driver's saccade amplitude, it was found that the saccade amplitude of the driver on the entire road section changed slightly at any time, and the overall trend of change was basically consistent. Therefore, a graph of the change in driver's saccade amplitude at 11:30 was drawn as shown in Figure 8:

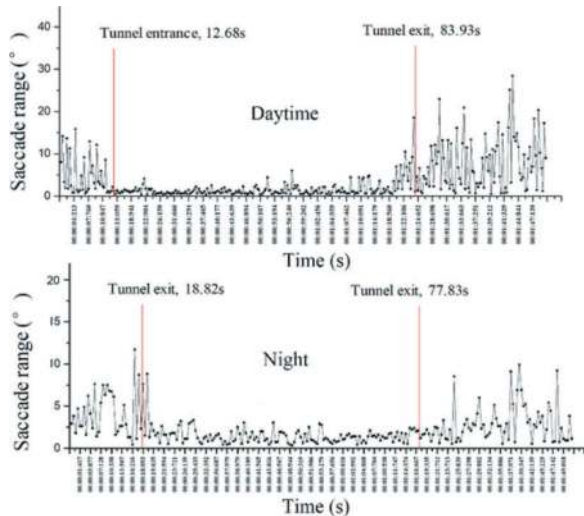

Figure 8. Change in saccade amplitude of the driver.

According to the analysis in Figure 8, it is found that the saccade range of the driver while driving outside the tunnel is basically maintained at 0-30°. At a distance of 1-2 seconds before the tunnel entrance (i.e. 20-30m from the entrance), the saccade amplitude suddenly decreases, and the saccade amplitude of the driving in the tunnel remains basically at 0-3°, indicating a small saccade behavior; When approaching the exit of the tunnel, the saccade amplitude increases until it reaches the level of saccade amplitude of the driver in the driving environment outside the tunnel.

The saccade behavior in which the saccade speed is less than 30°/s is regarded as fixation behavior, so the average saccade speed of drivers in the middle section of the tunnel under daytime conditions is calculated, and the distribution of different saccade speed ranges is drawn as shown in Figure 9. It can be seen from the Figure 9 that 80% of the drivers' eye movement behavior in the middle section of the four tunnels is fixation behavior. The analysis shows that for

Figure 9. Analysis of saccade behavior of drivers.

the driving environment in the tunnel, because the tunnel is a special semi-closed tubular structure. There is less traffic reference information in the hole, and the saccade speed of the driver is greatly reduced.

4 RESEARCH ON EVALUATION METHOD OF TUNNEL LIGHTING ENVIRONMENT BASED ON INFORMATION PERCEPTION

4.1 Selection of evaluation indicators and construction of evaluation models

In this paper, according to the changes of lighting environment in the process of driving through the tunnel, the tunnel section is divided into:

- 1) Dark adaptation section (scotopic vision): During the day, the driver drives from outside the tunnel to inside the tunnel; The process of driving from the inside of the tunnel to the outside of the tunnel by night drivers;
- 2) Bright adaptation section (photopic vision): During the day, the driver drives from inside the tunnel to outside the tunnel; The process of driving at night from outside the tunnel into the tunnel;
- 3) Middle section: The middle section of the tunnel where the luminance remains unchanged in the design of tunnel lighting.

Divide the tunnel driving section into dark adaptation section, bright adaptation section, and middle section. The lighting environment physical indicators for the dark and bright adaptation sections are selected based on the change in illuminance value, while the driver's biological indicators are selected based on the driver's visual oscillation duration indicator (safety evaluation indicator) and saccade speed indicator (comfort evaluation indicator). The selection of physical indicators for the middle section of the tunnel is based on the visibility and illuminance values inside the tunnel. The biological indicators of drivers selected are reaction time (safety evaluation indicator) and saccade speed (comfort evaluation indicator), combined with probability theory 3σ calculate the threshold and evaluation level of each evaluation indicator in principle, and then obtain the safety and comfort rating table for each road section. Based on the functional relationship between various physical indicators of the lighting environment and the biological indicators of the driver, a tunnel lighting safety and comfort evaluation model is constructed to achieve the evaluation of lighting safety and comfort for different sections of the tunnel at different time periods.

4.2 Research on tunnel lighting environment evaluation based on dynamic perception of biological visual indicators

Based on the previous test and analysis of the lighting environment physical information and drivers'

physiological perception of the tunnel, the tunnel section is divided into dark adaptation section, bright adaptation section and tunnel middle section according to the changing trend of illuminance, and the safety and comfort evaluation model of each lighting section of the tunnel is constructed.

1) Lighting safety and comfort evaluation model for dark adaptation section of tunnel.

$$\begin{cases} T_{PDCR} = 3.59 * \exp\{-1117.4/(E_c - 397.65)\} \\ V_S = \exp(5.12 + 1.81e^{-4}E_c - 6.5e^{-7}E_c^2) \\ x_{vs} = \ln V_S \end{cases} \quad (4)$$

Where, T_{PDCR} is visual oscillation duration (ms); E_c is illuminance change value (lux); V_S is saccade speed; x_{vs} is saccade speed.

Table 2. Safety and comfort evaluation table of tunnel lighting (dark adaptation section).

T_{PDCR} x_{vs}	[0.2,0.7 4s)	[0.74,1.1 3s)	[1.13,1.9 1s)	[1.91,1.2. 3s)	[2.3,2.6 9]
[4.29,4. 55]	A	B	C	D	E
[4.03,4. 29)	B	C	D	E	F
[3.51,4. 03)	C	D	E	F	G
[3.25,3. 51)	D	E	F	G	H
[2.99,3. 25)	E	F	G	H	I

(The evaluation level in the evaluation table is divided into 9 levels, A-I, among which A-level has the best driving safety and comfort, followed by B-I evaluation levels where driving safety and comfort gradually deteriorate, and I-level is the worst. The following evaluation criteria are the same.)

2) Lighting safety and comfort evaluation model for bright adaptation section of tunnel.

$$\begin{cases} T_{PDCR} = 3.59 * \exp\{-1117.4/(E_c - 397.65)\} \\ V_S = \exp(3.72 + 7.05e^{-4}E_c - 9.48e^{-8}E_c^2) \\ x_{vs} = \ln V_S \end{cases} \quad (5)$$

Table 3. Safety and comfort evaluation table of tunnel lighting (bright adaptation section)

T_{PDCR} x_{vs}	[0.2,0.7 4s)	[0.74,1.1 3s)	[1.13,1.9 1s)	[1.91,1.2. 3s)	[2.3,2.6 9]

5 CONCLUSION

- 1) This study elucidates the main factors and transmission methods of highway tunnel lighting environment information representation, comprehensively summarizes the information composition and information characteristics of tunnel lighting environment, and deeply analyzes the direct and indirect influencing factors of information composition. The indicators for characterizing tunnel lighting environment information are summarized from two aspects of physical information and physiological perception.
- 2) Through indoor static and dynamic information perception simulation testing platforms, combined with a large number of actual vehicle experiments, a series of physiological perception reactions of drivers during tunnel static and dynamic driving processes were analyzed, including reaction time, small target visibility, visual oscillation, and saccade behavior. Further revealed the changing trend and interaction relationship between the physical information of tunnel lighting environment and physiological perception during driving, comprehensively studied and elucidated the information perception mechanism of drivers under different motion states.
- 3) From the perspective of drivers' perception of tunnel lighting environment information, taking

into account both the physical information of tunnel lighting environment and the driver's physiological perception, a tunnel lighting safety and comfort rating table is proposed. Combining the functional relationship between physical and biological indicators of lighting environment, a dynamic evaluation model for tunnel lighting environment based on biological visual indicators is established.

ABSTRACT: Traditional lighting technology is not reasonable enough to improve the quality of tunnel lighting environment. Therefore, it is necessary to further solve the bottleneck problems of energy saving, safety, maintenance under the coupling effect of human-vehicle-tunnel lighting environment. Based on the “non-equivalent characteristics of lighting environment load and visual perception effect” and “the mechanism of equivalent lighting environment affecting driving safety and comfort”, this study proposes the theoretical path of equivalent lighting environment combining the effect of multiple light sources and natural light. Through the static and dynamic visual efficacy test, the evaluation method of driver information perception state under the equivalent lighting environment of tunnel is established. By analyzing the change of lighting environment for tunnel under the condition of multiple factors, the specific application method of equivalent lighting environment of tunnel is proposed. The results can providing theoretical and technical references for the realization of safe and energy saving of lighting system for road tunnel, and making positive contributions to the national energy conservation and emission reduction strategy.

Keywords: Road tunnel, Lighting environment, Equivalent lighting theory, Visual perception, Evaluation method

1 INTRODUCTION

As a highly restricted space environment with long depth and strong closure, tunnel must rely on artificial lighting to meet the necessary lighting environment for tunnel traffic (Liang, et al., 2020, Wang, et al., 2016). When drivers pass through the tunnel, they experience the process of alternating cycle mutation of lighting environment and rapid transformation of visual adaptation to light and dark, which is easy to cause visual impairment and lead to traffic accidents (Ma, et al., 2015). Therefore, how to provide a safe and energy-saving lighting environment that meets the visual needs of drivers has become the focus of scholars (Liang, et al., 2019).

The existing lighting specifications for tunnel are based on physical quantity indicators (illuminance, luminance, luminance uniformity) to develop lighting quality evaluation indicators, which is the practice of following lighting specifications for road

(JTG/TD70/2-01-2014, CIE88:2004), and does not fully consider the influence of biological quantity (eye movement parameters, physiological parameters, brain electrical parameters) under the tunnel lighting environment. Therefore, the coupling mechanism of human-vehicle-tunnel in operation lighting environment for tunnel is ignored (Yang, et al., 2016, Yan et al., 2022).

Existing studies believe that it is a feasible scheme to achieve traffic safety to improve the lighting power and meet the required physical quantity under the most unfavorable lighting conditions for tunnel (Shi, 2020, Chen, et al., 2006). However, there is a great non-equivalence between the environmental load of lighting and the effect of visual perception for tunnel lighting environment. Although the physical quantity reaches or even exceeds the standard requirements, the overall visual effect of lighting environment is not ideal (Ye, et al., 2022, Liu, et al., 2019).

Many scholars also believe that the degradation of the lighting quality of lighting environment for

*Corresponding author: qinc714@163.com

tunnel is mainly caused by the light decay of lamps. Therefore, the replacement of lamps is often used as the main means to improve the quality, and the influence of the pollution situation and the reflection brightening effect during the operation stage of tunnel sidewalls is not considered (Mehri, et al., 2022, Liang, et al., 2015).

In this study, the theoretical path of equivalent lighting environment combining the combination of multiple light sources and natural light was proposed based on “non-equivalent characteristics of lighting environment load and visual perception effect” and “the mechanism of equivalent lighting environment affecting driving safety and comfort”. Moreover, the evaluation method of driver information perception state in equivalent lighting environment for tunnels was established through the static and dynamic visual efficacy test. Finally, based on the analysis of the changes of lighting environment under multi-factor conditions, the realization of equivalent lighting environment for tunnels was built.

2 TUNNEL EQUIVALENT LIGHTING ENVIRONMENT TEST

2.1 Test device

According to the common size of existing tunnels, a simulated tunnel with a ratio of 1:10 to the actual tunnel was designed and manufactured. The simulated model is a wooden structure, consisting of tunnel ceiling, movable sidewall panel, road surface plate, lamp support and circuit system. Based on 1:1 physical tunnel, the rule of change of physical evaluation indicators (illuminance, luminance, luminance uniformity) is analyzed from the perspective of tunnel light distribution, spacing of lamps, sidewall material, and type of light source. The simulation tunnel and physical tunnel are shown in Figure 1.

In order to realize the indoor simulation of lighting environment for road tunnel under the coupling condition of multiple lighting factors and the visual efficacy evaluation based on reaction time, combined with the characteristics of visual environment, visual efficacy theory and the reaction time principle of the driver’s actual driving condition, the tunnel lighting quality evaluation device and simulation test platform were proposed, which is depicted in Figure 2.

In this experiment, real-car test of biological quantity with a total of 2004 person-times was conducted in 316.24 km of 13 highway tunnels, including Lushan Tunnel, Xianghuang Tunnel, Changchong Tunnel. The biological quantity of drivers driving in tunnels with different materials sprayed on the sidewalls were tested by eye movement instruments, electroencephalographs and

Figure 1. Simulation tunnel and physical tunnel.

Figure 2. Tunnel lighting quality evaluation device and simulation test platform.

physiological instruments, respectively. The collection device and acquisition process is show in Figure 3.

Figure 3. Collection device and acquisition process.

2.2 Physical quantities test

Based on 1:10 simulation tunnel and 1:1 physical tunnel, considering the reflection coefficient, lamp layout spacing, lamp installation angle, test voltage, sidewall material, light source type, the physical quantity was explored. The Schematic diagram of lamp layout and sidewall materials is shown in Figures 4 and 5.

2.3 Static and dynamic visual efficacy test

In static indoor simulation test, the driving environment of tunnel is simulated by the simulation test platform, and the reaction time is carried out. In the test, the diameter of the red circular spot is 25mm, the background luminance is 2 cd/m², the spot appears in the position of the optical eccentricity angle is 0°, 10°, 20° random distribution, the target spot luminance is 6 cd/m², 7.2 cd/m², 9 cd/m².

In dynamic indoor simulation test, in order to study the influence of the lighting environment on the driver's driving, the Nanshan, Zhenwu Mountain and Cimushan in Chongqing was selected, and the driving video of the vehicle passing through the tunnel at a relatively stable speed is recorded from 10:00 to 17:00. Using the tunnel lighting simulation test platform and the reaction time test program, the experimenter interacts was conducting.

Figure 4. Schematic diagram of different sidewall materials.

Figure 5. Schematic diagram of lamp layout.

3 THEORETICAL PATH OF EQUIVALENT LIGHTING ENVIRONMENT

3.1 Reduction methods of lighting environmental load

In Figure 6, the sidewall reflectivity is linear with the illumination uniformity of road surface and wall. For every 10cm increase in lamp spacing, the road surface uniformity decreases by about 0.022. For every 1 increase in lamp angle, the road surface uniformity increases by 0.0016, and for every 1° decrease, the road surface uniformity decreases by 0.0036.

As shown in Figures 7 and 8, under the same lighting conditions, the road surface illumination, luminance and uniformity increase with the increase of sidewall reflectivity. It can be concluded that improving the sidewall reflectivity can improve the lighting environment in tunnels. From the perspective of energy saving, the reflectivity of sidewall materials can be improved to increase the reflected illumination, and then reduce the lighting power of lamps, which is also to meet the original lighting needs. It means that the

reflective increment of sidewall coating materials can be used as auxiliary lighting, so as to reduce the lighting environment load and achieve the purpose of lighting energy saving.

3.2 Visual efficacy analysis in lighting environment

In Figure 9, the driver's reaction time decreases first and then increases, and the minimum reaction time occurs at the middle measuring point (3 or 4). Because when drivers approach the tunnel, they realize the black hole effect at the tunnel entrance, their attention is enhanced, they are more sensitive to the traffic information around the vehicle, and their reaction time is reduced.

It is revealed in Figures 9 and 10, with the increase of reflectivity increment, the visibility of small targets also increases. It can be concluded that to improve the visibility of small targets can be achieved by improving the reflectivity of sidewall materials. If the number of lamps is reduced or the energy consumption of lamps is reduced, the sidewall materials with higher reflectivity can be used for auxiliary lighting to ensure the visibility of small targets in the tunnel lighting environment.

3.3 Biological quantity characteristics of drivers

Figure 11 shows that the heart rate and respiratory rate of different drivers are quite different. After entering the tunnel, the drivers have a higher degree of psychological tension, and the corresponding heart rate and respiratory rate will rise. Moreover, compared with No. 1 tunnel, the heart rate and respiratory rate of drivers driving in No. 3 tunnel are lower, indicating that drivers are more comfortable when driving in No. 3 tunnel sprayed with reflective materials.

It is found from Figure 12 that when drivers drive into the tunnel, due to the narrowing of visual field, the tunnel lighting environment begins to darken, and the proportion of fixation time and pupil area rise sharply, while the saccade range decreases rapidly. When entering the interior zone, due to the relatively dark lighting environment, the proportion of fixation time and saccade range rise slowly, and the pupil area rises to the maximum value. While in the exit zone, the overall luminance of the tunnel increases, and the proportion of fixation time, pupil area and saccade range all show a downward trend. Compared with the daytime, the proportion of fixation time, saccade range and pupil area change less when drivers go from the approach zone to the threshold zone.

It can also be seen from Figure 12 that, in daytime or night, the biological quantity of each zone when drivers drive in No. 3 tunnel are better than those in No. 1 tunnel, which indicates that the lighting environment of No. 3 tunnel is improved after spraying reflective materials, making drivers more relaxed and focused in the driving process, which is conducive to safe driving.

Figure 11. Average heart rate and respiratory rate of drivers during daytime and night.

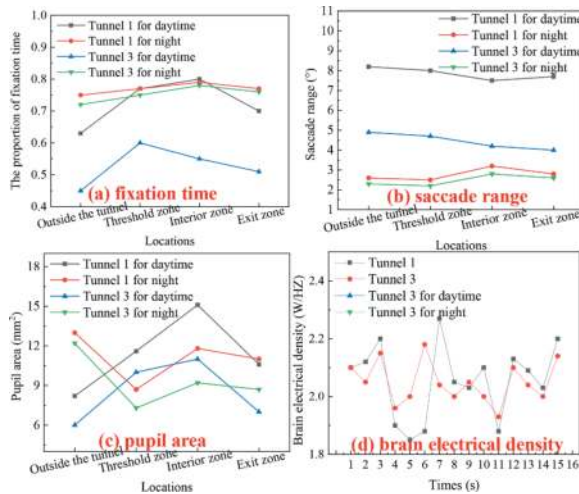

Figure 12. The proportion of fixation time, saccade range, pupil area and brain electrical characteristics of drivers during daytime and night.

3.4 Realization theoretical path of equivalent lighting environment

Based on the “non-equivalent characteristics of lighting environment load and visual perception effect” and “the mechanism of equivalent lighting environment affecting driving safety and comfort”, the equivalent theory of lighting environment based on the combination of multiple light sources and natural light is proposed. This means that the quality of lighting environment is improved and the lighting environment load is reduced through reasonable matching of lighting environment.

Based on the above research results, one can conclude that the realization of equivalent energy-saving lighting system of tunnel can be realized by adopting measures to improve the quality of the lighting and to reduce the power or energy consumption of the lighting to save energy. Therefore, the methods for realizing equivalent energy-saving lighting are discussed from different perspectives.

(1) Through certain technical methods, the sunlight can replace part of the light source in the tunnel, so as to reduce the energy consumption of tunnel lighting and realize the equivalent lighting of road tunnel. For example, by using solar power generation and photovoltaic technology, the generated

electric energy can be directly used as the electric energy of tunnel lighting. Besides, according to the longitude and latitude, orientation and solar altitude of tunnel, the degree and range of the influence of the sunlight on the tunnel can be determined, and then the lamps can be guided to choose a reasonable power for lighting.

- (2) Relevant studies have found that under the intermediate visual conditions, the light source spectrum has a great impact on the correct recognition rate of small color targets. For example, the road luminance provided by LED lamp is lower than that provided by HPSL (HPSL), but the correct recognition rate of small targets at each viewing distance is higher than that of HPSL. This shows that compared with HPSL, even if the road luminance is properly reduced, the LED lamp with high color rendition will not affect the correct recognition rate of small color targets, realizing the energy-saving lighting of tunnel.
- (3) Tunnel is a semi-closed tubular structure composed of tunnel sidewall and road surface. The sidewall will reflect the light to the road surface once or more, so as to improve the luminance of the road surface. If the sidewall coating material with high reflectivity is used, the light intensity reflected to the ground can be increased, and the increased light intensity can be offset by increasing the spacing of lamps or reducing the number of lamps. Therefore, the number of lamps can be reduced under the condition of maintaining the original lamp design demand unchanged, so as to achieve the purpose of saving tunnel lighting energy consumption.

4 EVALUATION METHOD OF EQUIVALENT LIGHTING ENVIRONMENT

4.1 Optimization of evaluation indicator

To ensure that the human eye can better adapt to the changes in the surrounding environment, the pupil needs to adjust the amount of light entering the eye by increasing and decreasing the diameter of the pupil. If the driver’s pupil diameter changes too drastically, it will cause it to be unable to see the road conditions ahead. The saccade is an eye movement process that connects two successive fixation behaviors, which can indicate the acquisition width of the human eye to the visual range. The saccade range and saccade speed are the acquisition width and speed of the human eye to the visual range, respectively. Therefore, the pupil and the saccade are used as the evaluation indicator of the equivalent lighting environment in tunnels.

In order to more intuitively characterize the visual load of the driver and the pros and cons of the lighting environment in tunnels, the pupil diameter change ratio (*PDCR*) is proposed.

$$PDCR = \frac{d_{i+1} - d_i}{M} \quad (1)$$

In the equation (1), the pupil diameter of driver at a certain moment is d_{i+1} , the pupil diameter of the previous moment is d_i , and the average pupil diameter at this time is M .

4.2 Establishment of evaluation method

4.2.1 Analysis of pupil diameter

Figure 13 shows that the pupil diameter of drivers during the daytime driving through the tunnel shows an overall trend of first increasing and then fluctuating slightly, and then decreasing to the value outside the tunnel. When vehicles pass through the entrance and exit of the tunnel at high speed, due to the sharp transition from light to dark, the pupil area of driver changes rapidly, and the rate of change of pupil area increases rapidly.

Figure 13 also shows that the initial pupil diameter of drivers is large at night due to the dark driving environment outside the tunnel, the pupil diameter of drivers shows an overall trend of first decreasing and then increasing, with a small fluctuation in the interior zone. The pupil diameter decreases in the exit zone and gradually increases to the average pupil diameter of drivers outside the tunnel.

Figure 13. The pupil diameter of the driver in daytime and night.

4.2.2 Analysis of visual shock phenomenon

Figure 14 shows that compared with the daytime, visual shock phenomenon still occurs at night, but the degree of visual shock is low and the duration is short. It shows that the driving also causes visual adaptation discomfort under the low illumination outside the tunnel at night.

4.2.3 Analysis of saccade parameters

In Figure 15, the drivers' saccade range when driving outside the tunnel during the daytime is basically maintained at 0~30°. In 1~2s before the tunnel entrance, the saccade range suddenly decreases, and

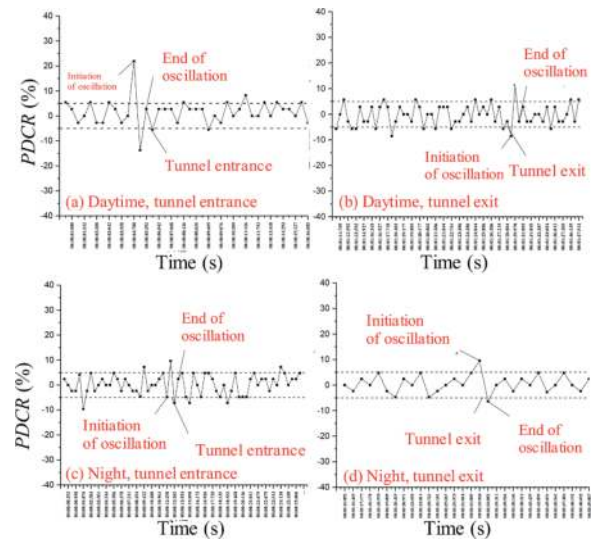

Figure 14. PDCR values of the entrance and exit zone of the tunnel in daytime and night.

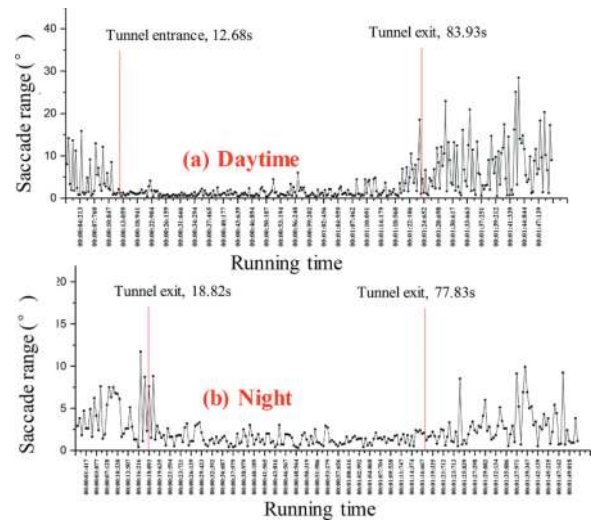

Figure 15. The drivers' saccade range during the day and night.

the saccade range of driving in the tunnel basically stays at 0~3° small amplitude scanning behavior; when approaching the tunnel exit, the scanning amplitude increases until it reaches the level of the scanning amplitude of the driver outside the tunnel environment.

As can be seen from Figure 15, compared with the drivers' saccade range outside the tunnel during the daytime, the drivers' saccade range at night is overall reduced, and the maximum saccade range value of the driver is about 12°, without a large abnormal value of the saccade range.

4.2.4 Analysis of saccade behavior in the interior zone

It is illustrated in Figure 16(a), 82.6% of the drivers' eye movement behavior in the interior zone of the

tunnel is fixation behavior. The analysis shows that, because the tunnel is a special semi-closed tubular structure, there is less traffic reference information in the tunnel, and the saccade speed is greatly reduced.

As depicted in Figure 16(b), the overall distribution of the driver's saccade speed is smaller and the average saccade speed is smaller during the 10:00~12:00 when the traffic flow is large and the visibility is low. Moreover, the overall saccade speed is the highest and the average saccade speed is the highest during the 20:00~22:00 when the traffic flow is large and the visibility is best in the tunnel. The distribution of drivers' saccades during other periods with smaller changes in visibility in the tunnel was similar.

Figure 16. Distribution of saccade speed: (a) frequency, (b) time.

5 REALIZATION APPROACH OF EQUIVALENT LIGHTING ENVIRONMENT

5.1 Control principle of luminance difference in threshold zone

5.1.1 Layout of reflective materials in threshold zone

Combined with reflectivity, lighting layout and sky factors, the simulation analysis of the layout height of

reflective materials in the threshold zone is carried out. Based on the previous research results and the lighting specifications, the three-dimensional simulation is formulated to lay reflective materials in the range of 2m, 2.5m, 3m and 3.5m on both sides of the road. The lighting effect of reflective materials in the entrance in complex lighting environment is comprehensively analysed. The results are shown in Figure 17.

As can be seen from Figure 17, when the reflectivity is fixed, the improvement of reflective materials on road surface illumination and illumination uniformity on sunny days is much greater than that on cloudy and mixed days. With the same sky type and lighting layout, the average road surface illumination and illumination uniformity at the entrance are positively correlated with the reflectivity of reflective materials. The larger the reflectivity of reflective materials is, the larger the average road surface illumination is and the better the illumination uniformity is.

Therefore, the sidewall layout of high reflective materials is conducive to improving lighting quality and achieving the purpose of energy-saving lighting. With the same sky type and reflective material reflectivity, the higher the height of reflective materials layout is, the larger the average road surface illumination and illumination uniformity value of the tunnel threshold zone is. The reflective material reflectivity is fixed. From the perspective of lighting quality and safety, staggered lighting in the tunnel entrance can greatly improve the uniformity of road surface illumination, which is more conducive to driving.

5.1.2 Optimization of luminance curve in threshold zone

According to the measurement data of the physical tunnel, the actual luminance peak in different seasons and under different skies and the luminance of threshold zone in a day are obtained. The results are shown in Figures 18 and 19.

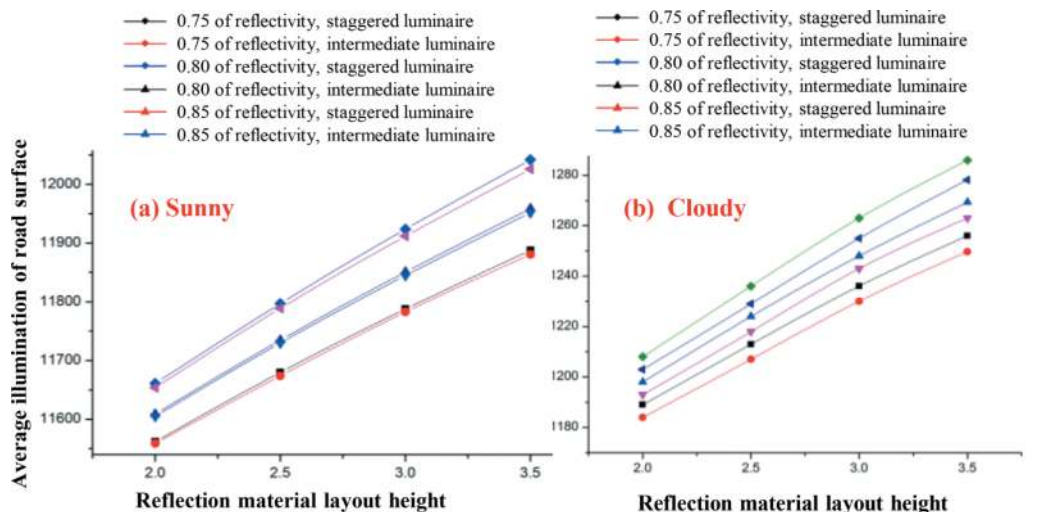

Figure 17. Road surface illumination in south and north directions: (a) sunny day, (b) sunny day.

In Figures 18 and 19, there are great differences in the luminance L_{th1} in threshold zone at noon every day throughout the year. From high to low, it is sunny in summer, sunny in autumn, sunny in spring, cloudy in summer, sunny in winter, cloudy in autumn, cloudy in spring, cloudy in winter, cloudy in summer, cloudy in spring, cloudy in autumn, and cloudy in winter. The luminance peak in cloudy seasons is 0.51-0.63 times of that in sunny seasons.

Based on the above research, it is proposed to set shading vegetation in threshold zone (TH_1) to replace the original artificial lighting and then combined with the grading dimming in threshold zone (TH_2) in the tunnel. It can realize the gradient reduction of natural light lighting in the decrease zone and the smooth transition of lighting luminance inside and outside the tunnel.

Figure 18. Changes of luminance peak of the entrance in different seasons and under different skies.

Figure 19. Luminance changes of the tunnel entrance in a day.

5.2 Reasonable arrangement of equivalent lighting environment

5.2.1 Matching analysis of reflective materials and lighting lamps

As shown in Figure 20, under any lamp spacing condition, the road surface illumination under the condition of reflective materials is greater than that of

reflective paint and cement mortar. The increase ratio of road surface illumination under different lamps is MHL, LED and HPSL from large to small. However, when the lamp spacing is 3m, the increase ratio of HPSL is greater than that of LED.

Figure 20. Road surface illumination under different sidewall materials (a) and (b) lamps.

5.2.2 Matching analysis of vehicle lamps and lighting lamps

In order to further study the influence of vehicle lamps on the lighting environment with the sidewall material, three types of vehicles (small car, large truck and passenger car) were selected for experimental study, and the lamp spacing was set at 3m. The test results are shown in Figure 21.

As shown in Figure 21, the illumination under vehicle lamp irradiation generally shows a trend of gentle, rapid increase, rapid decrease and gentle, and the rapid change interval is about 5m-15m. For various types of vehicles, the maximum illumination of the lane centerline under the illumination of the vehicle lights is from large to small: bus, car, truck. Moreover, the maximum illumination of the lane sideline under the illumination of the vehicle lights is from large to small: bus, truck, car.

5.2.3 Comparison analysis of lighting schemes

As shown in Figure 22, under LED lamp, HPSL and MHP, to achieve the same standard value of road surface illumination, the lamp spacing required by reflective paint and reflective material is greater than the cement mortar. It indicates that the reflective materials was set on the sidewall can increase the lamp spacing on the premise of ensuring the quality of lighting, thus reducing the number of lamps and realizing energy saving of lighting.

Based on the above research results, one can conclude that, under the same road surface illumination value of the three test light sources, the lamp spacing required by reflective material is greater than that required by reflective paint. It shows that the reflective material has a reflectivity 0.2 higher than that of reflective paint, which makes it able to reflect more light energy from the sidewall onto the surface, thus further increasing the lamp spacing.

Besides, under the conditions of 3m~7m lamp spacing, the ratio of lamps reduced by LED with high reflective material is greater than that of HPSL

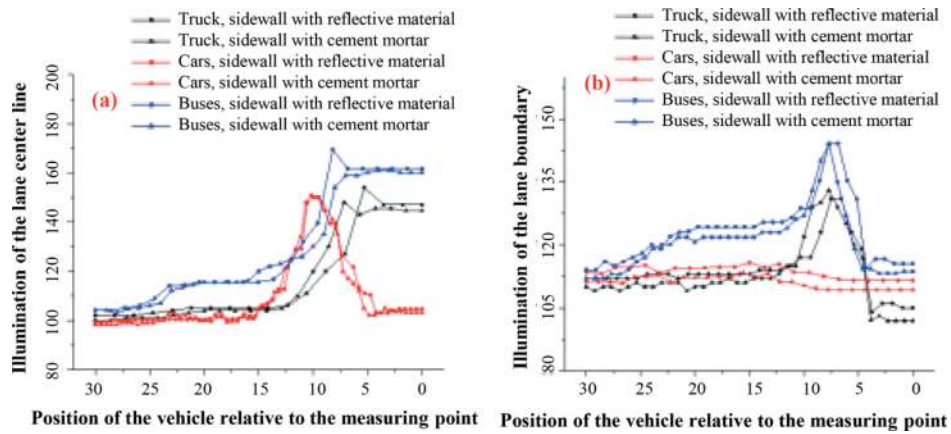

Figure 21. Illumination changes of (a) lane centreline and (b) sideline under vehicle lamp irradiation.

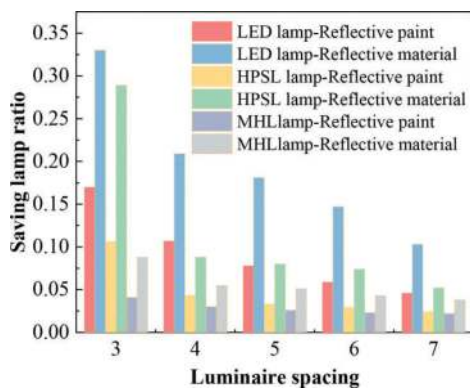

Figure 22. The ratio of saving lamps under different sidewall materials and lamps.

light source with reflective material and MHP with reflective material, indicating that the reflective material has better compatibility with LED light source, which can release more energy-saving space.

6 CONCLUSION

- (1) Based on the non-equivalent characteristics of lighting environmental load and visual perception, the quality of lighting environment is improved by reasonable matching of lighting, which reduces the lighting environment load. While meeting the lighting standards to ensure the quality of lighting, the equivalent lighting environment of tunnel based on safety and energy saving is constructed, and the theoretical path of equivalent lighting environment of tunnel based on safety and energy saving is proposed.
- (2) Through the simulation tunnel and physical tunnel, static and dynamic lighting environment visual efficacy test, combined with indoor

simulation and real vehicle test, from the perspective of the lighting environment load and the equivalent visual perception for tunnel, the evaluation method of driver information perception state is established.

- (3) Based on the principle of luminance difference control in the threshold zone, the change of lighting environment under the condition of multiple factors is analyzed, and the specific realization method of equivalent lighting environment in the tunnel is proposed. Besides, the optimization research on the configuration of lighting environment for tunnel is carried out based on the compatibility of lighting lamp, sidewall materials and vehicle lamps.

A numerical investigation on the long-term stability of tunnels excavated in the upper stratum of expansive layer

SuJian Ma* & Ying Cui

Graduate School of Urban Innovation, Yokohama National University, Yokohama, Japan

ABSTRACT: Nowadays, the deformation of tunnels during the service period, which occurs after several years or decades of construction, has been reported. The majority of these tunnels were constructed in rock formations with the potential for swelling or weathering. This research focuses on expansive rock as the target type to investigate the long-term stability of tunnels. A long-term seepage model experiment was conducted to study the deformation characteristics of the surrounding soil and tunnel stress response. This experiment aimed to simulate the long-term infiltration of water into the surrounding ground. The experimental results indicate that water infiltration induces swelling of the expansive soil, leading to the deformation of the surrounding ground. When an expansive layer exists beneath the tunnel, differential displacement occurs between the tunnel base and the surrounding ground, developing a significant vertical shear band around the tunnel edge. Initially, deformation occurs at the junction between the surrounding ground and expansive soil. As saturation progresses, deformation accumulates near the top of the tunnel, particularly when it reaches nearly full saturation. The stress distribution on the invert, wall, and crown was investigated. It was found that considerable stress is concentrated at the bottom of the tunnel due to boundary constraints, and a passive pressure acts on the invert at the bottom, causing the incremental pressure acting on the invert to be larger than the expansive pressure of the material. This can be one of the main reasons for invert heave. Furthermore, a corresponding finite element analysis was conducted, incorporating constitutive models capable of simulating the swelling behaviour of the ground. Specifically, the swelling rock model (Wittke-Gattermann & Wittke, 2004) was adapted in Plaxis to replicate the model experiment, aiming to verify the applicability of this model and expand its usage in more complex projects involving swelling strata.

Keywords: Expansive soil, Tunnel, Model test, Simulation, Swelling rock model

1 INTRODUCTION

The rapid development across the globe intensifies the swift progress in the transportation industry, with tunnels serving as pivotal means for interregional connectivity in various modes of land and water transportation. Tunnel construction assumes a pivotal role in the progression of urbanization and facilitation of human connectivity (Asakura, 2003). Tunnel construction plays a crucial role in urbanization and human communication. Despite advancements in the field over the years, it still encounters significant challenges. Tunnels experience structural changes during their service life due to evolving geological conditions, including rock disturbances from excavation and environmental erosion (Zheng et al., 2017). One of the primary factors contributing to tunnel erosion and alterations in the surrounding geology is the ingress of water, which is accompanied by complex stress processes in both saturated and unsaturated geological zones. Research by

Usman et al. (2011), Roatesi et al. (2013), and Gschwandtner et al. (2011) has focused on the construction and support of tunnels in complex stress regions. Furthermore, time-dependent deformations, such as creep and swelling, may result in substantial tunnel deformations, potentially leading to instability. Expansive soils, widely distributed in nature, exhibit notable expansion and contraction characteristics, with their high hydrophilic properties making them highly sensitive to changes in water content. Infiltration of water significantly increases their deformations while concurrently reducing their strength. As our understanding of the mechanisms of deterioration remains limited, maintenance of tunnels passing through expansive soil layers primarily relies on safety considerations, prompting the implementation of various reinforcement measures.

Numerous researchers have undertaken extensive investigations into the influence of expansive soils on tunnels through direct means such as field observations

*Corresponding author: sai-ei-mx@ynu.ac.jp; ma-sujian-ft@ynu.jp

and model experiments. Wang et al. (2014), based on field trials and theoretical analyses, elucidated the response patterns of soil pressures around tunnels during the expansive soil swelling process. They proposed a beam-spring model for the pressure load induced by swelling in shield tunnels. Wu et al. (2021), on the other hand, established an indoor experimental model to simulate typical dry-wet cycling conditions. This approach allowed them to study ground failure and instability under tunnel excavation and support conditions in expansive soil environments.

The study of expansive soil constitutive behaviour constitutes a significant portion of theoretical research. A constitutive model for unsaturated soil swelling proposed by Alonso (1990) is widely acknowledged by the majority of researchers. Subsequently, a constitutive theory considering the combination of micro and macro aspects of expansive soil has been detailed (Alonso, 1999), although due to the multitude of parameters and the necessity to consider macro-micro integration, its theoretical rigor is higher than its practical application.

Led by Professor Thomas from NTNU, the swelling rock model exhibits great predictive capabilities regarding the swelling process of expansive rock and soil. Derived from previously established expansive soil theories, this model can simulate the time-dependent anisotropic expansion of rock and soil. A plethora of scholars have employed the swelling rock model to conduct research on expansive soil. For instance, Ammering (2013) proposed an anchor support model under the influence of expansive soil to study the stability of tunnel structures. Hakro (2022) combined laboratory testing with simulations to investigate the impact of in-situ swelling of expansive soil on upper concrete structures. El-Shamy (2019) utilized the swelling rock model to discuss the advantages and disadvantages of different pressure methods and the Huder-Amberg method for testing expansive soil characteristics through pressure consolidation experiments (Huder, 1970). Furthermore, Al-Maamori (2018) employed finite element analysis to examine the effects of time-dependent deformation (TDD) on tunnels constructed using micro-tunnelling technology in the Quaternary shale (QS).

As previously elucidated, several notable studies have been conducted to gain theoretical insights and employ numerical analyses to understand the role of the surrounding ground in tunnel failure mechanisms. Nevertheless, the discussion regarding the extent of the influence of the depth of expansive soils on tunnels has been relatively scarce. Considering this, the present study seeks to investigate the impact of different depths of expansive soil layers on tunnels using the swelling rock model. Building on the research findings of Saqib from 2021 (Ashraf & Cui, 2021), the swelling rock model is employed to examine the effects of varying depths of expansive soil layers on tunnels. The rationality of the modelled approach using the same experimental parameters is validated, and subsequently, the influence of expansive soils at different depths is evaluated.

2 SWELLING ROCK MODEL AND CALCULATION OF PARAMETERS

2.1 Outline of swelling rock model

The swelling rock model, originally formulated by Professor Thomas Benz and subsequently expanded upon by Bert Schädlich, is rooted in prior investigations conducted by Wittke-Gattermann & Wittke (2004), Anagnostou (1993), and Heidkamp & Katz (2002). This comprehensive model comprises five fundamental attributes. Significantly, the model can be assumed isotropy within the soil material, requiring the definition of 5 crucial parameters. The constitutive relationship adheres to the Mohr-column (M-C) model with the elastic-perfectly plastic framework.

In addition to its fundamental principles, the computational algorithm utilized in this model derives from three distinct theoretical frameworks: the Wittke model, the Anagnostou model, and a hybrid amalgamation of the two. It is noteworthy that all these theories can be traced back to Grob swelling law, thus furnishing a robust theoretical underpinning for the model computations and prognostications. Grob swelling law is characterized by a logarithmic relationship between the swelling pressure in a loading state and the swelling strain in a one-dimensional (1D) state, as depicted in Figure 1 and Equation 1. Moreover, in order to prevent unbounded expansion of this model, when the loading pressure falls below a specified minimum threshold, the swelling strain is held constant. Within this model, the minimum threshold for σ (stress) is set at -10kPa.

Figure 1. Grob semi-logarithmic swelling law (Grob, 1972).

$$\varepsilon_i^{q(t=\infty)} = \begin{cases} -k_{qi} \cdot \log\left(\frac{\sigma_c}{\sigma_{q0i}}\right) & , \sigma_i \geq \sigma_c \\ -k_{qi} \cdot \log\left(\frac{\sigma_i}{\sigma_{q0i}}\right) & , \sigma_{q0i} \leq \sigma_i \leq \sigma_c \\ 0 & , \sigma_i \leq \sigma_{q0i} \end{cases} \quad (1)$$

(El-Shamy, 2019)

The most direct method for formulating this law entails conducting a series of oedometer tests, where $\varepsilon_i^{q(t=\infty)}$ represents the ultimate swelling strain along

the swelling direction under the given stress, k_{qi} is the parameter associated with swelling and is equivalent to the slope of the swelling curve, σ_i signifies the axial stress aligned with the swelling direction, and σ_{q0i} denotes the maximum swelling stress within the same direction.

2.2 Parameter determination for swelling rock model

In this model, where considerations of coupling effects and water infiltration are omitted in favour of an emphasis on isotropic behaviour, the adaptation of the Wittle model (swell ID=1) is prominent. A total of 5 mechanical parameters and 3 swelling parameters are integral to the model. All these parameters, except for swelling parameter A_0 , can be rigorously determined through laboratory experiments.

The 5 mechanical parameters align with the M-C model, encompassing the friction angle (ϕ), cohesion (c), tensile strength (assumed as 0.001kPa to meet interpolation requirements for simulation results, Young's modulus and Poisson ratio. Following calculations based on similar principles, a simulated mixture of bentonite and Toyoura sand is employed for the expansive soil, comprising 75% sand and 25% bentonite. Laboratory experiments, specifically uniaxial compression and direct shear experiments, have yielded a comprehensive presentation of these five mechanical parameters, as shown in Table 1.

Parameters associated with soil swelling encompass the following key aspects: the maximum swelling pressure (σ_{qp} & σ_{qt}), the time-dependent swelling parameter (A_0), and the swelling potential parameters (k_{qp} & k_{qt}). The soil is presumed to demonstrate isotropic behaviour, implying that the values of these parameters in the normal direction are equivalent to those in the tangential direction. The determination of swelling pressure closely follows the methodology outlined in ASTM standard D4546-14 (ASTM, 2013), as depicted in Figure 2. This figure provides a visual representation of the procedural steps employed in the testing method.

Table 1. Model mechanical parameters.

Parameter	Symbol	Unit	Value
Friction angle	ϕ	°	42
Cohesion	c	kPa	0
Tensile strength	σ_{tens}	kPa	0.001
Young's modulus	E	kPa	4716
Poisson ratio	ν	-	0.3

The employed method entails subjecting a saturated soil sample, which has completed its expansion, to a gradual loading process. The ultimate pressure, referred to as the swelling pressure, is determined when the swelling strain has fully recovered to zero. Figure 3 illustrates the results obtained from an oedometer test conducted on an expansive soil sample consisting of 75% sand and

Figure 2. Oedometer test for swelling parameters.

25% bentonite. Notably, the final swelling pressure recorded in this test is measured at 161.72kPa.

Similarly, another critical parameter can be derived through a series of loading and unloading tests using the oedometer test setup. The Huder-Amberg method (Huder, 1970) is specifically employed to measure the swelling potential parameter. As illustrated in Figure 4, swelling potential (k_{qp}) can be calculated based on the results obtained from the loading and unloading recycling tests (set 3 in particular). Equation 2, as depicted, serves as the mathematical expression to determine the swelling potential.

$$k_{qp} = \frac{\varepsilon_i - \varepsilon_u}{\log(\sigma_i) - \log(\sigma_u)} \quad (2)$$

(El-Shamy, 2019)

Where, ε_i and σ_i represent the initial strain and stress before unloading, respectively. And ε_u and σ_u represent the final strain and stress when unloading is completed. Theoretical k_{qp} is calculated to be 0.162, and the final parameter is determined into 0.1 after revision. The swelling parameter A_0 cannot be accurately determined through experimental methods due to the complex and multifaceted influence of various factors. Consequently, it can only be established through a series of iterative trials conducted using the Plaxis model test.

Figure 3. Measurement for swelling pressure.

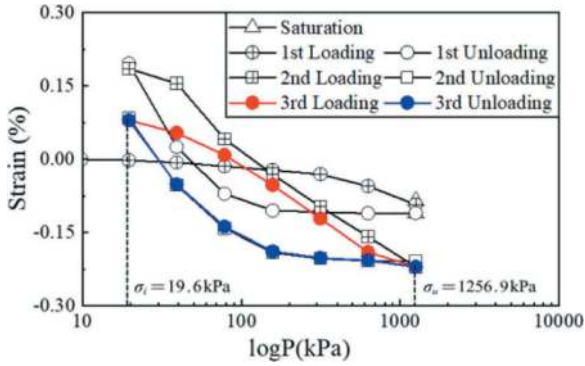

Figure 4. Oedometer test results for loading and unloading recycle.

2.3 Determination of final swelling parameters

The validation of the expansive soil model involves initially detecting its properties through soil testing in Plaxis, which includes determining the swelling parameter A_0 . However, the ultimate model is established based on physical reality, so verifying the correctness of the swelling model solely through soil tests in Plaxis is not sufficient. Therefore, it is essential to construct a physical model for a more rigorous verification process.

As depicted in Figure 5, the final swelling potential in the laboratory experiment is approximately 22%. When the ultimate parameters are set with $A_0 = 1$, the other two curves nearly coincide. Furthermore, the simulation results exhibit only fractional errors when compared to the actual results. Consequently, the definitive swelling parameters are summarized in Table 2.

Figure 5. Comparison of time-dependent swell potential between experiment and simulation.

Table 2. Swelling parameters.

Parameter	Symbol	Unit	Value
Time swelling parameter	A_0	1/day	1
Swelling potential	k_{qp}	kPa	0.1
Max swelling stress	σ_{qp} & σ_{qt}	kPa	161.72

3 MODEL TEST AND SIMULATION VERIFICATION

3.1 Outline of model test and simulation

The model test was conducted within a chamber constructed from steel and acrylic plates with 600mm in length and height and 200mm in width, as illustrated in Figure 6. To simulate an actual tunnel, a small-scale tunnel, shaped like a horseshoe and constructed from aluminium, was employed. Within this model test, the primary indicators of interest were the pressure exerted on the tunnel lining and the displacement of the surrounding soil. Figure 7 demonstrates the position of load cells (Tokyo Measurement Instruments Lab) at various locations within the tunnel. These load cells were strategically placed around the tunnel lining, crown, invert, wall, shoulder, and spring line. Furthermore, for each of these positions, corresponding symmetric placements were made, denoted as “l” for left, “r” for right, and “c” for centre.

Figure 6. Layout of model test.

In the simulation, the model consists of 3 main components: expansive soil, surrounding soil, and the tunnel. The properties of the expansive soil have been detailed in the second section of this paper. In this experiments, #6 silica sand was utilized, and to maintain consistency, the same parameters as those from the actual experiments were employed.

Figure 7. The position of the load cells on tunnel lining.

In this research, the surrounding sand was modelled using the Mohr-Coulomb model. After laboratory testing, the parameters for the sand are presented in Table 3.

Table 3. Material parameters for surrounding sand.

Parameter	Symbol	Unit	value
Friction angle	ϕ	$^{\circ}$	42
Cohesion	C	kPa	0
Young's Modulus	E	kPa	2070

To facilitate the validation process and further research regarding depth, the model has been simplified to a two-dimensional (2D) square configuration. This configuration operates as a plane strain model with dimensions measuring 600mm in both length and height, serving to simplify the model for validation purposes and to facilitate research regarding depth, as illustrated in Figure 8.

Figure 8. Schematic diagram of the analytical model.

3.2 Verification of analytical model

Considering the experimental results, the verification process primarily focuses on two essential aspects: the pressure distribution along the tunnel circumference and the displacements observed in the surrounding soil. To initiate this verification, an initial 0D model, mirroring the conditions of the experiment, is constructed. This model is subsequently subjected to analysis, particularly in assessing the tunnel pressure distribution and the displacements in the surrounding soil.

Given the absence of water throughout the entire process and considering that the soil's swelling process concludes at 100 hours, the calculation period is limited to this timeframe. Figure 9 presents the time-dependent displacements observed in the surrounding soil. Similar to the actual experiments (Figure 10), it is observed that swelling is an ongoing process that depends on time. As time progresses, the displacements on both sides of the model gradually accumulate, with the maximum displacement predominantly concentrated at the surrounding soil edges, ultimately reaching 2.60mm. Similarly, the region surrounding the tunnel remains constrained, and the upper portion of the tunnel remains stationary despite the continuous swelling.

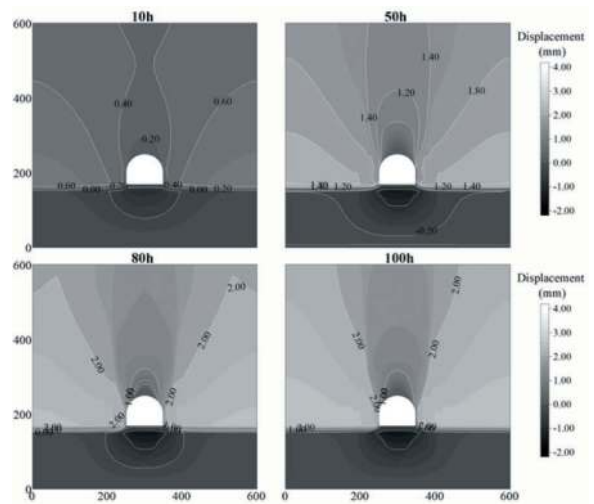

Figure 9. Time-dependent displacement contour around tunnel.

Figure 10. Time-dependent displacement contour of experiment.

Figure 11 illustrates ground movement at a 1D distance from the tunnel crown and displays the ultimate moisture content of the expansive soil upon completion of the process in the experiment. It is significant to note that the displacement of the upper soil is not zero, and this is primarily attributed to the compression exerted by the surrounding soil. The lateral soil compresses the middle soil, and its maximum displacement is 2.83mm, resulting in an increased state of density. As the swelling process continues, the middle soil gradually moves upward.

Upon completion of the test and subsequent measurement of the degree of saturation, it was observed that both sides of the expansive soil had reached full saturation. In contrast, the middle section exhibited a lower degree of saturation, approximately around 80%. Moisture content serves as a demonstration of the variation in swelling potential over time. Similarly, both sides of the model experience completion in terms of swelling; however, the middle section, constrained by the presence of the tunnel, impedes the infiltration of water, resulting in lower displacement compared to the other sections.

Figure 12 represents a comparison of the pressure response within the tunnel during the swelling of the expansive soil between the simulation and the actual experiment. It is evident that the invert, the lower part of the tunnel, is significantly affected by the

Figure 11. Time-dependent swelling comparison (a) Line cross section Y-direction displacement in simulation (b) Line cross section saturation degree in experiment.

Figure 12. Time-dependent pressure at different sections of tunnel.

swelling process, and it responds to swelling pressure quite rapidly.

However, notable differences exist in the pressure values at the three positions. Specifically, the pressure on the two sides of the invert is similar due to the tunnel symmetrical properties, but the middle part registers lower pressures. The pressure at the edge of the invert initially rises to about 50kPa in the first 20 hours and then steadily increases to reach a final peak of 81.44kPa. This final peak represents 50.58% of the swelling pressure measured by oedometer tests. Conversely, the middle part exhibits an initial increase to 56kPa, followed by a decrease to 46kPa upon nearing completion. This phenomenon appears to be associated with the heave (swelling) of the middle part.

As the swelling progresses, the stress variations between the left and right sides of the invert are relatively large, amounting to 75.6kPa, which corresponds to approximately 46.74% of the swelling pressure, where the error is only 3.84%. In contrast, the middle section of the invert registers a lower stress of 40.32kPa. When compared with the actual experimental results for the invert, these differences between simulation and experiment appear acceptable.

The comparison and analysis conducted in terms of the 0D model between the experiment and the simulation demonstrate that the simulation results, along with the selected parameters, meet the requirements for replication. Further research on different depths will be conducted using simulations with the same parameters.

4 INFLUENCE OF THE DEPTHS OF EXPANSIVE SOIL LAYER

4.1 Displacement of the surrounding ground

Figure 13 represents displacement contours for both the 0.5D and 1D cases at four different stages (10h,

50h, 80h, 100h). In both cases, it is evident that the displacement of the surrounding soil continuously increases at the edges of the model. The maximum displacement observed is approximately 2.56mm for the 0.5D case and 2mm for the 1D case, respectively. The final maximum cumulative displacement is concentrated at the left and right edges, consistent with the 0D case. Throughout this entire process, the swelling potential exhibits a time-dependent relationship. Due to the increased thickness of the model, the ultimate strain experiences a slight reduction from the 0D case to the 1D case (2.83mm → 2.56mm → 2.00mm).

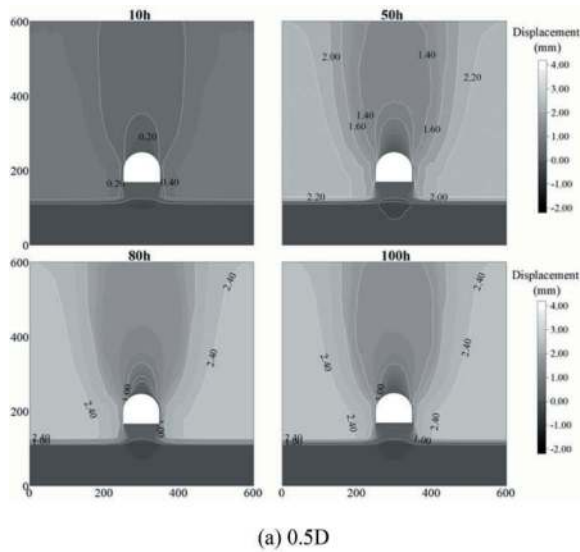

Figure 13. Time-dependent vertical displacement contour around tunnel for (a) 0.5D and (b) 1D.

Figure 14 illustrates the Y-direction displacement distribution of line cross section at a 1D distance from the crown for all three cases. The final maximum cumulative displacement is concentrated at the edge of the model, consistent across all cases. Over the course of the swelling process, the stiffness of the soil located at the tunnel bottom strengthens, leading to an increase in compression stress in this area. When combining this analysis with Figure 13, it becomes evident that the increasing compression stress leads to compression deformation with a negative value in the surrounding soil at the bottom of the expansive soil. Similarly, the movement trend of the surrounding soil shows that the upper soil, located at the crown of the tunnel, undergoes compression due to the movement of the edge soil and then moved by swelling, and the influence range of this behaviour is about 1D (-10~10 cm).

4.2 Shear deformation of the surrounding ground

Figure 15 compares deviatoric strain evolution over time between the 0.5D and 1D cases. In the 0D case, where there is no space between the tunnel and the expansive soil, no shear deformation occurs in the surrounding soil.

In the cases of 0.5D and 1D, the shear zone becomes prominently concentrated within the bottom soil adjacent to the tunnel sides. Notably, both the scale and magnitude of shear deformation

(a) 0.5D

(b) 1D

Figure 14. Line cross section Y-direction displacement distant 1D above the crown.

exhibit a progressive increase over time. This behaviour can be attributed to the constraints imposed by the tunnel invert, which limit the movement of the bottom soil. In contrast, the soil on both sides of the tunnel remains relatively free to move. Consequently, this non-uniformity in soil movement results in the occurrence of shear deformation along the two sides of the tunnel.

After approximately 10 hours of swelling, the shear zone is initially distributed vertically along the sides of the tunnel. As time progresses, the impact zone expands to cover a wider area. Notably, the shear belt is not a fixed entity; by the 50-hour mark, it stabilizes into a certain width, exhibiting around 20%. Over subsequent time intervals, the shear range experiences minimal variation, and the maximum shear strain value increases only by 1%. Additionally, minor shear strains emerge in the upper surrounding soil starting from the 50th hour, and as time progresses, these strains extend further into the upper soil.

(a) 0.5D

(b) 1D

Figure 15. Time-dependent shear development around tunnel for (a) 0.5D and (b) 1D.

In the 1D case, when compared to 0.5D, the shear zone initially appears exclusively at the base of the tunnel. However, as time progresses to 50 hours, the shear zone begins to connect with the expansive soil, creating a continuous shearing of 17%. Additionally, the increased thickness of the middle soil layer beneath the tunnel prevents shear damage from occurring in the upper surrounding soil. Consequently, the shear area mainly concentrates in the vicinity of the tunnel crown.

4.3 Time-dependent pressure acting on tunnel lining

Figure 16 illustrates the variation in tunnel pressure at different points over time. In the initial accelerating stage of 0.5D case, the pressure at edge reaches 121kPa within the first 20 hours and remains steady at 120kPa until completion. The middle part of the invert responds to pressure inferiorly compared to the sides, showing a trend of increasing pressure up to 100kPa at completion. The other points of the

tunnel remain relatively undisturbed, with a maximum pressure of 20kPa.

In the 1D case, pressure at the invert is most intense, with the left and right sides reaching 124kPa within the first 20 hours. The middle invert pressure reaches 100kPa and continues to rise with the swelling process, while the pressure at the tunnel edge shows a slight decrease. At the completion of swelling, the ultimate pressure at these two points reaches 119kPa and 106kPa, respectively. It is evident that the other points of the tunnel remain inactive and sustain a pressure no greater than 20kPa.

Figure 16. Time-dependent pressure on the tunnel.

When the bottom soil thickness is zero (0D), the maximum pressure registers at approximately 75.6kPa. In contrast, for the cases of 0.5D and 1.0D, the maximum pressures escalate to approximately 121kPa and 124kPa, respectively.

As the depth of the bottom soil increases, it leads to a corresponding rise in soil pressure, as there is an increase in the frictional forces between the bottom soil and the surrounding ground on both sides. This progressive intensification of frictional forces is consistent with the swelling pressure and consequently results in an augmented pressure exerted on the bottom of invert. Consequently, the maximum tunnel pressure experiences a continuous increase, particularly noticeable along both sides of the tunnel.

Likewise, in the context of shear deformation, the predominant shear deformation is concentrated primarily on the two sides of the invert. This phenomenon is another consequence of the augmentation of frictional forces with increasing depth.

5 CONCLUSIONS

- (1) Swelling effects induce movement constraints in the surrounding ground at approximately a distance equivalent to one tunnel diameter from both the left and right sides of the tunnel. The maximum displacement occurs at the two sides of the model, and this value decreases as the depth of the expansive soil increases, measuring 2.83mm (0D), 2.56mm (0.5D), and 2.00mm (1D), respectively.”
- (2) The tunnel constrains the soil beneath it, while the surrounding ground and soil elsewhere tend to freely move upward due to swelling pressure.

This leads to noticeable shear phenomena beneath both sides of the tunnel invert, forming a continuous shear zone. As the depth of the expansive soil increases, the shear deformation extends downward, while the shear deformation of the soil in the upper part of the tunnel disappears.

- (3) Compared to the pressure at the invert, pressures in other positions are notably lower. As the depth of the expansive soil layer increases, it intensifies frictional forces between the lower soil and surrounding ground on both sides, thereby steadily increasing the bottom pressure from 74.8kPa (0D) → 121kPa (0.5D) → 124kPa (1D).
- (4) The expansion deformation of expansive soil is exponentially distributed with time. As the increment of time, the swelling of expansive soil will further strengthen. At a certain stage, there is a substantial surge in the pressure applied to the tunnel. This surge corresponds with an escalation in the movement of the surrounding rock and shear deformation, consequently exacerbating the damage to the tunnel.

Subway ventilation system design and the importance of predicting the long-term wall surface temperature

Ibrahima Khalil Mbaye*

EUR ING, ing., PEng, Tunnel Ventilation Specialist, Parsons Corporation, Doha, Qatar

ABSTRACT: When designing tunnel ventilation system (TVS) for subway projects, consideration of the tunnel wall surface temperature is very important in quantifying the tunnel air temperature, in order to guarantee adequate and optimal operational conditions for tunnel equipment, thus ensuring their continued performance through their intended lifecycle.

The thermal load within the subway due to the trains' operation plays a key role in the long-term behaviour of the tunnel wall surface temperature. Typical Subway revenue hours period is about 20 hours a day, giving only few hours of rest for the subway without extensive thermal solicitation. The heat accumulated along the revenue hours is absorbed by the tunnel wall and its surrounding soil, preventing the heating of the tunnel environment. In the long term, the surrounding soil will reach its optimum geothermal heat absorption capacity. Consequently, during revenue hours, the heat not being absorbed by the tunnel wall surface temperature, will increase the tunnel air temperature, impacting the equipment operation condition.

The purpose of this paper is to describe the methodology to predict the long-term tunnel wall surface temperature based on the trains operation timetable, by means of unidimensional (1D) numerical simulation, in order to identify the potential appropriate measures such as additional mechanical or passive means of cooling the subway and more stringent specifications on the exposed equipment regarding their operating environment.

Keywords: Tunnel Ventilation Design, Subway, Heat sink, Tunnel wall surface temperature, Long-term simulations, Environment control

1 INTRODUCTION

Below ground level structures, such as caves, refuges, catacombs are generally controlled environment where the air temperature is steady along years. The explanation behind is that there are no major internal heat sources and there is minimal influence of the ambient environment as there is minimal air exchange between the ambient and the underground structures. Subway underground structure is different. There are major heat sources due to dissipating onboard train equipment, besides the fact that trains movement is dragging ambient air from the portals, the natural ventilation shafts and even the entrance when there are no platform screen doors. Other heat sources are related to the lighting, rail technologies, any other potential dissipating equipment installed in the tunnels. These heat sources influence the subway air temperature if the subway tunnel is an uncontrolled environment. This would affect the performance of the equipment installed in tunnel, hence their lifecycle. This paper provides an overview of the influence of these various heat sources on the tunnel wall

surface temperature in the long term, hence the tunnel air temperature taking into consideration the associated thermodynamics phenomena. The thermal load induced by the various heat sources is distributed to the tunnels wall surface which then distributed this thermal load to the surrounding soil. The wall and surrounding soil thermodynamic properties along with the depth of the tunnel influence the thermal behaviour of the tunnel air temperature. For the subway, the daily thermal solicitation during revenue service induces heat exchange between the tunnel air, the tunnel wall surface temperature, and the surrounding soil temperature. The surrounding soil heat capacity, also understood as its heat sink represents its budget consumed along the daily revenue service. This paper gives an overview of the consumption of the heat sink under the influence of various factors like the surrounding soil thermodynamic properties, the climate and ambient temperature, the train service daily timetable and its impact on the long-term tunnel wall surface temperature, hence the tunnel air temperature, using common simulation tool Subway Environment Simulation (SES).

2 ABOUT THE PHYSICS BEHIND

The subway is generally of a cylindrical shape structure with a layer of concrete, at a certain depth below ground surrounded by soil.

On the one hand, longitudinal air movement due to train movement along with heat dissipation due to the presence of several heat sources occur. The longitudinal air induced by trains movement leads to heat convection thermodynamic phenomenon between the tunnel air and the tunnel wall surface.

On the other hand, the tunnel wall surface exchanges the heat received from the tunnel air along its layer of concrete radially and subsequently within the surrounding soil. The surrounding soil environment is mostly influenced by the ambient temperature.

These thermodynamic phenomena are more elaborated in the following sections.

2.1 Heat convection phenomenon by forced ventilation

Convective heat transfer by forced convection occurs when a fluid is forced to flow over a surface by an internal source. In the case of a subway, the fluid is the air dragged by the train piston effect and exchanging heat with the tunnel wall surface. In such situations, thermal balance in a control volume control Sdx requires the amount of convective heat transfer between the air and the tunnel wall surface to be equal to the amount of internal energy change in the control volume. The thermal balance equation is given by the following equation:

$$\rho VS(\partial T_{\text{tunnel}}(x)/\partial x)dx = hP(T_w - T_{\text{tunnel}}(x))dx + Qdx \quad (1)$$

With the following parameters definitions:

T_w = Wall Surface Dry Bulb Temperature ($^{\circ}\text{C}$)

- ρ = Air density (kg/m^3)
- V = Airflow velocity (m/s)
- S = Tunnel Cross Section (m^2)
- cp = Specific Heat Coefficient ($\text{J}/(\text{kg}\cdot\text{K})$)
- h = Heat Transfer Coefficient ($\text{w}/\text{m}^2/\text{k}$)
- p = Tunnel perimeter (m)
- Q = Heat source in tunnel (w/m^3)

With the following relationships:

$$h = \text{Nu} \cdot \lambda / Dh; \text{Nu} = f(\text{Re}; \text{Pr})$$

$$\text{Re} = \rho \cdot V \cdot Dh / \mu$$

$$\text{Pr} = \mu \cdot Cp / \lambda$$

$$\mu = \text{Air Dynamic Viscosity } (\text{N} \cdot \text{s} / \text{m}^2)$$

$$\lambda = \text{Air Thermal Conductivity } (\text{W} / (\text{m} \cdot \text{K}))$$

$$Dh = 2 \cdot R = \text{Hydraulic Diameter of the tunnel cross section}$$

$$R = \text{Equivalent radius of the tunnel}$$

2.2 Heat conduction phenomenon

Conduction heat transfer occurs within an object due to the difference of temperature between its opposite ends. In the case of a subway, heat conduction occurs within the tunnel wall surface and the surrounding soil. Heat conduction occurs along the tunnel lining, generally in concrete, on the one hand, and on the other hand it occurs along the surrounding soil. The pace of the heat transfer by conduction is driven by the concrete and the surrounding soil respective thermal diffusivity noted $\alpha = \lambda / (\rho Cp)$, inm^2/s .

One dimensional heat conduction along the tunnel lining and the surrounding soil differential equations in polar coordinates can be written as:

$$\partial T(r) / \partial t = \alpha (1/r \cdot \partial T(r) / \partial r + (\partial^2 T(r)) / \partial r^2) \quad (2)$$

The initial temperature in any location of the lining or the surrounding soil is the deep sink temperature. The deep sink temperature is the surrounding soil temperature influenced by the yearly average ambient temperature, the surrounding soil thermodynamic properties and its depth. In a subway, before revenue service starts, the surrounding soil is assumed to be stable as well as the tunnel wall surface temperature.

Figure 1. Schematic description of heat conduction phenomenon.

$$T_w(t = 0s) = \text{Deep sink temperature}$$

$$T_{\text{soil \& lining}}(t = 0s, \forall r > R) = \text{Deepsink temperature}$$

Figure 2. Schematic description of the heat convection phenomenon.

Once revenue service starts, under the influence of the daily thermal solicitation due to numerous trains movement in the tunnel, the temperature at the tunnel wall surface $T_w(t)$, varies due to the heat transfer by convection, hence the soil temperature in the vicinity of the tunnel $T_{soil}(t)$. Boundary conditions can be defined as:

$$\begin{aligned} h(T_w - T_{tunnel}(x)) &= \lambda_{lining} (\partial T_{lining}(r)/\partial r) \\ T_{lining, ext}(t) &= T_{soil, int}(t) \\ \lambda_{lining} (\partial T_{lining, ext}/\partial r) &= \lambda_{soil} (\partial T_{soil, int}(r)/\partial r) \\ T_{soil, r \rightarrow \infty}(t) &= \text{Deep sink temperature} \end{aligned}$$

The following section describes the mathematical model of the heat convection and heat conduction phenomena computed within the Subway Environment Simulation (SES) software.

3 THE 1D ONE-DIMENSIONAL SOFTWARE SES

The Subway Environment Simulation (SES) software latest version 4.1 has been issued in 2002.

The SES computer model provides a dynamic simulation of the bi-directional operation of multiple trains in a multi-track subway and permits continuous reading of the air velocity, temperature, and humidity throughout any arrangement of stations, tunnels, ventilation shafts, and fan shafts.

The SES program comprises four interdependent computation sequences: a train performance subprogram, an aerodynamic subprogram, a temperature/humidity subprogram (thermodynamic subprogram), and a heat sink/environmental control subprogram.

Although all the subprograms are interdependent, the focus of this paper is on the temperature/humidity and the heat/sink environmental control subprograms.

The temperature and humidity of the air throughout a subway system reflect the heat added or removed by underground equipment, trains, and patrons, as well as by the rate of heat exchange across the system walls and by mixing with external ambient air.

The heat sink/environmental control subprogram purpose is to evaluate the interdependent influence of the heat conduction via the surrounding soil and the subway air temperatures.

3.1 SES Temperature/humidity subprogram

The thermodynamic subprogram requires input from the train performance subprogram and the aerodynamic subprogram. The thermodynamic subprogram computes several parameters such as the airflow, the average convective heat transfer coefficient for the tunnel wall surface, the rate of sensible and latent heat load due to trains and other heat sources to predict the temperature and humidity in the one-dimensional numerical model. The heat sink

being more related to the sensible heat load, the humidity is not elaborated in this paper.

The equation computed by the SES thermodynamic subprogram in a tunnel section/subsegment (i) having its front end defined as (f) and its back end (b) is the following:

$$\begin{aligned} \partial(MCpT_i)/\partial t &= M_{f,i-1}CpT_{i-1} + M_{b,i+1}CpT_{i+1} \\ &- (M_{f,i} + M_{b,i})CpT_i + q_i - h_{w,i}S_{w,i}(T_i - T_{w,i}) \end{aligned} \quad (3)$$

Depending on the flow direction in subsegment (i), the mass flow $M_{f,i}$ is either positive or null, same as $M_{b,i}$.

It is noticeable that there is a similarity between equations (1) and (3). The subsegment (i) air temperature rate of change is then based upon known parameters.

3.2 SES heat sink and air conditioning models subprogram

The heat sink subprogram uses the output from the aerodynamic and thermodynamic subprogram. The heat sink subprogram carries on an iterative procedure to resolve the tunnel air temperature and the wall surface temperature. The interdependence between the tunnel air temperature and the wall surface temperature drives the requirement for an iterative process. The wall surface temperature is a function of the tunnel air temperature, and the tunnel air temperature is dependent on the wall surface temperature. The iterative process stops when consistent and stable values of the wall surface temperature and the tunnel air temperature are obtained.

The heat sink computation predicts the tunnel wall surface temperature corresponding to the specified month of the year, considering the annual external ambient temperature range (annual amplitude).

The SES heat sink mathematical model, area of concern can focus on the dynamic thermal response matrix (DTRM) and the heat conduction model.

3.2.1 DTRM model

The DTRM is based upon 2 levels of derivation, the subsegment derivation which is about the tunnel air temperature prediction in a tunnel section and the node derivation which is about the air temperature at a node. A node is a location along the modelled geometry where 2 or more subsegments meet each other.

Regarding the subsegment derivation model, equation (3) above is considered. An integration of this equation to a Δt corresponding to a period where the tunnel air fluctuates around a mean value, gives the following equation:

$$\begin{aligned} \int_t^{t+\Delta t} \partial \frac{MCpT_i}{\partial t} * dt &= \int_t^{t+\Delta t} M_{f,i-1}CpT_{i-1} * dt + \int_t^{t+\Delta t} M_{b,i+1}CpT_{i+1} * dt \\ &- \int_t^{t+\Delta t} (M_{f,i} + M_{b,i})CpT_i * dt + \int_t^{t+\Delta t} q_i * dt \\ &- \int_t^{t+\Delta t} h_{w,i}S_{w,i}(T_i - T_{w,i}) * dt \end{aligned}$$

By considering the system is returning to an original state after a period of Δt , the following assumption has been made: $\int_t^{t+\Delta t} \partial \frac{MCpTi}{\partial t} * dt = 0$, hence

$$0 = \int_t^{t+\Delta t} M_{f,i-1} Cp T_{i-1} * dt + \int_t^{t+\Delta t} M_{b,i+1} Cp T_{i+1} * dt - \int_t^{t+\Delta t} (M_{f,i} + M_{b,i}) Cp T_i * dt + \int_t^{t+\Delta t} q_i * dt - \int_t^{t+\Delta t} h_{w,i} S_{w,i} (T_i - T_{w,i}) * dt$$

This equation reflects the balance between the energy flow in tunnel section (i) and the energy flow from upstream and downstream tunnel sections (i-1) and (i+1) as well as the energy absorbed by the tunnel section (i) wall surface and the energy due to steady and transient heat sources. The portion of energy absorbed by the tunnel wall surface and transmitted to the surrounding soil quantifies the heat sink.

Regarding the node derivation model, it is more about the air temperature by predicting the amount of energy leaving a node considering the thermal energy conservation equation.

3.2.2 Heat conduction model

The heat conduction model considered by SES heat sink subprogram is similar to the phenomenon described in section 2.2 Heat conduction phenomenon.

The subprogram assumes the tunnel wall surface temperature to be a function of the annual tunnel air average temperature plus the annual thermal amplitude, plus the diurnal thermal amplitude.

Equation (2), already provided above, is applied to each of the 2 regions considered by the subprogram, meaning the lining region and the surrounding soil region.

The initial and boundary conditions are the same as those described in section 2.2 Heat conduction phenomenon.

To resolve the equations and quantify the temperature distribution in both regions, the subprogram divides the temperature into 3 components: a transient component, a yearly component and a diurnal component.

The transient component, which is the major component, is calculated for each of the lining and the surrounding soil layers.

Regarding the lining layer, the transient component $T_{trans}(r,t)$, for $R < r < r_{soil,int}$ is a function of the tunnel wall surface temperature, the deep sink temperature and the unitless parameter $\tau_{lining} = \alpha_{lining} t / R^2$.

The unitless parameter τ allows to derive a coefficient $f(\tau)$ given by Jaeger and Chamalaun (1966). This coefficient is considered in the computation of the transient component of the tunnel wall surface temperature. SES derives the corresponding coefficient for a 30-year period of diffusivity.

The tunnel wall surface temperature is dependent upon the annual average tunnel air temperature which is calculated based on the DTRM model and the annual thermal amplitude.

$$T_{wall} = \frac{T_{annual,average} + T_{deep\ sink} \lambda_{lining} * f(\tau_{lining}) / (h R \ln 10)}{1 + \lambda_{lining} * f(\tau_{lining}) / (h R \ln 10)}$$

Finally, the transient component of the temperature in the lining is given by the following equation:

$$T_{trans}(r,t) = K_1(t) \ln r + K_2(t), R < r < r_{soil,int}$$

The transient component in the surrounding soil layer is also dependent on the deep sink temperature, the temperature at the boundary between the lining and the surrounding soil as well as the unitless parameter $\tau_{soil} = \alpha_{soil} t / (r_{soil,int})^2$.

$$(T_{trans}(r,t) - T_{deepsink}) (1 - f(\tau_{soil}) \ln(r_{soil,int}/r)) + T_{deepsink} = K_1 \ln r_{soil,int} + K_2, r \geq r_{soil,int}$$

Details about the mathematical model of the above as well as the annual and diurnal components of the tunnel wall surface temperature can be found in the SES programmers' manual (1975).

4 QUANTIFICATION OF LONG-TERM WALL SURFACE TEMPERATURE AND HEAT SINK

This is about a case study of a one bore bi-directional subway of 9 km circa. with 4 side platform stations fit out with full height platform screen doors and 4 mid tunnel ventilation shafts. The tunnel cross section is about 47 m². Each of the tunnel portal is connected to the atmosphere.

The metro tunnel ventilation is comprised of station trackway exhaust system and pressure relief shafts at each station end. The mid tunnel ventilation shafts are also operating as pressure relief shaft.

The metro service starts at 5:30 am and finishes at 1:30 am the day after. The peak and off-peak headways are 150 seconds and 300 seconds respectively.

There are 293 trips in each direction with the train fully loaded. The trains are equipped with AC condensers that dissipate heat in the tunnel.

The objective is to quantify the long-term wall surface temperature as well as the heat sink for various types of environment.

The adopted approach is to quantify the long-term wall surface temperature and the heat sink based on the yearly average temperature in these various regions. To do so, it is assessed the acceptability to consider the yearly average temperature instead of the month after month temperature.

As a reminder, the SES heat sink computation predicts the tunnel wall surface temperature for the corresponding month of the year, considering the annual outside temperature range (annual amplitude).

Consequently, the approach is to quantify, for a typical region, the long-term wall surface temperature for the colder month, usually January and the hotter month, usually July, having the same annual amplitude. In conjunction with the latter, the long-term wall surface temperature is quantified using the equivalent yearly average temperature with an annual amplitude equal to 0.

This scenario has been carried out for the Middle East region and the thermal properties of the lining and the soil are described in the following table:

Table 1. Tunnel lining and surrounding soil thermodynamic properties

	Tunnel Lining with a xx mm thickness	Surrounding Dry Soil
Thermal conductivity (W/m/K)	0.8	0.35
Thermal diffusivity (m ² /s)	$7.5 \cdot 10^{-6}$	$2.219 \cdot 10^{-7}$

The obtained results regarding the January, July, and the yearly average tunnel long-term wall surface temperatures are compared.

Looking at the ratio between the average of January and July obtained long term wall surface temperature and the yearly average one, it can be observed that it is in average 0.97.

Figure 3. Long-term tunnel wall surface temperature for January, July and yearly average ambient temperatures.

Based on the above, the approach of using the yearly average ambient temperature is acceptable to compare the long-term wall surface temperature of various regions.

4.1 Average long-term tunnel wall surface temperature based on the region

For the case study, it has been considered North America, South America, Europe, Africa, Middle East, Oceania, Asia regions.

Figure 4. Ratio of the average long term tunnel wall surface temperature obtained based on January and July ambient temperatures by the obtained one based on the yearly average ambient temperature.

The average yearly ambient temperature, in these regions, is given by ASHRAE climatic design conditions (2021) for the following locations:

Table 2. Yearly average ambient temperature in various regions across the world

	Lincoln (Nebraska, US)	Lima (Peru)	Anney (France)	Dakar (Senegal)	Auckland (New Zealand)	Abu Dhabi (UAE)	Gulin (Guangzhou, China)
Yearly Average Dry Bulb Temperature (°C)	11.2	20.1	11.0	25.1	15.6	28.7	19.8

The average yearly temperature is generally corresponding to the deep sink temperature considering the subway depth below ground.

SES simulations have been carried out accordingly assuming the soil thermodynamic properties to be the same for all these locations.

The obtained long term tunnel wall surface temperature is plotted on the following curve:

Figure 5. Long term tunnel wall surface temperatures in various regions across the world.

The maximum predicted long term tunnel wall surface temperatures vary between 33°C in region like Lincoln in the US or Anney in France to more than 55°C in region like the Middle East. The impacted tunnel region is less under influence of outside atmosphere. Where the tunnel is under influence of outside atmosphere, the tunnel wall surface temperature increase is less.

The results, also show that there is a minimum increase of 5°C in the tunnel according to the yearly average temperature and a maximum increase of around 30°C. The equipment installed in tunnel are generally able to operate in a degraded mode at 55°C. The maximum acceptable operating temperature for electrical devices is around 40°C.

This implies that subways for regions like the Middle East, South America, Africa and Asia, are required to be provided means to control the tunnel environment, after a certain period. For region like Oceania, the means to control the tunnel may not be mandatory, but it shall be foreseen a sensitive increase of the temperature in the tunnel after a certain period. While in region like North America and Europe, it is not mandatory to have means to control the environment. It may be a sensitive feeling of temperature increase in tunnel during the summer.

It is important to highlight that the trains are supposed to be equipped with AC, which might not be the case in all these regions and the tunnel is bidirectional. These observations shall be considered in the context of this assumption.

The means to control the environment, when mandatory can be operational from day 1 of the revenue service or after a certain period. In the latter case, this implies the design to account for such means to control the environment. The design shall be carried out not only in terms of operation, power supply and control system, but also in terms of space proofing for the future equipment delivery, installation, and maintenance.

Adequate monitoring devices such as linear heat detector cables laid along the tunnel wall surface at different locations could help to monitor the tunnel wall surface temperature. A threshold could be defined to alert the subway Operator about the necessity to plan for the procurement of the designed means of controlling the tunnel environment.

Besides the tunnel wall surface temperature, the overall heat sink along the alignment gives an indication of the heat sink budget consumption after years of operation.

4.2 Long term heat sink budget consumption based on the region

The heat sink magnitudes are among the output provided by SES.

The following curve is providing the heat sink budget consumption along the alignment for a typical revenue operation day, at the beginning of the service with the initial tunnel wall surface temperature:

It can be observed that, at the beginning of the revenue service, the heat sink is much less for region like the Middle East. The reason could be the that the difference between the tunnel air temperature and the wall surface temperature is much less than in the other regions.

One may wonder what the heat sink in these regions would be, when the tunnel wall surface temperature increases.

Figure 6. Heat sink with initial tunnel wall surface temperature in various regions across the world.

Simulations have been carried out accordingly to quantify the heat sink when the tunnel wall surface temperature increases for South America region and similar. The analysed tunnel wall surface temperature magnitudes are 26°C and 39°C. The deep sink temperature is still considered same as the average yearly ambient temperature.

The following curve corresponds to the heat sink obtained at the beginning of the revenue service, i.e., the tunnel wall surface temperature initially is equal to the deep sink temperature and the heat sink obtained after the wall surface temperature increases to a magnitude of 26°C and 39°C.

It is observed a decrease in the heat sink due to the increase of the tunnel wall surface temperature. It is important to highlight that when the heat sink is null on this curve, it means, in fact, that the wall is not absorbing heat but rather releasing heat warming up the tunnel air.

Figure 7. Heat sink with various tunnel wall surface temperatures.

5 IMPORTANCE OF THE SOIL THERMODYNAMIC PROPERTIES

The question which is considered here is whether the soil thermodynamic properties have an impact on the long-term wall temperature or whether it is the tunnel lining thermodynamic properties.

For South America region, comparative analysis has been carried out by increasing the soil thermodynamic properties on the one hand and the tunnel lining thermodynamic properties on the other hand.

The curve below represents the obtained long term tunnel wall surface temperature:

Figure 8. Long term tunnel wall surface temperature with increased lining and soil thermodynamic properties.

The results show that the soil thermodynamic properties have a major influence on the long-term tunnel wall surface temperature. A very conductive soil would consume less heat sink.

The tunnel lining thermodynamic properties do not affect the subway environment thermal behaviour.

6 SUMMARY

After explaining the physical phenomenon occurring in a subway regarding its environment thermal behaviour, after describing the mathematical equations driving the subway environment thermal behaviour and after presenting the equivalent mathematical models computed by SES software, a number of simulations have been carried out to showcase the subway environment thermal behaviour in the long term for various regions across the world.

The analysis show that the daily thermal solicitation due to the trains operation along with the tunnel ventilation configuration and the external ambient conditions drive the subway environment thermal behaviour. The key parameters involved in the subway environment thermal behaviour are the tunnel wall surface temperature and the tunnel lining as well as the surrounding soil thermodynamic properties.

Depending on the region, the long-term tunnel wall surface temperature may require accounting for means of controlling the environment. These means can be operational from day 1 of revenue service or they can be designed to be procured at a later stage. The means can be mechanical equipment such as axial fan, air handling unit. They can also be passive by circulating chilled water pipes along the tunnel wall surface, for instance.

The specifications of the equipment exposed to the tunnel environment could also account for the predicted long-term tunnel air environment.

The study also describes the heat sink magnitudes based on the tunnel wall surface temperature. While the tunnel wall surface temperature increases, the

heat sink decreases, and the tunnel is likely to act as heat source warming up the tunnel air.

The study finally shows that the surrounding soil thermodynamic properties have a considerable impact on the subway environment thermal behaviour. The higher its conductivity and diffusivity, the less the heat sink consumption along years of operation, hence the lower the long-term tunnel wall surface temperature.

7 CONCLUSIONS

This paper is about the importance of the subway long-term wall surface temperature and its inter-dependence with the surrounding soil heat sink.

Depending on the region, means to control the subway thermal environment may be required not to degrade the performance of the equipment installed in tunnel, hence reducing their lifecycle. These means of controlling the subway thermal environment can be either by mechanical cooling or by passive cooling. The increase of the long-term wall surface temperature may have an impact in case of human exposure whether it is about passengers when it comes to train evacuation via the tunnel or is about operators carrying out maintenance activities in tunnel. This subject has not been treated in this paper.

The surrounding soil thermodynamic properties play an important role in the subway long term thermal behaviour. The higher its conductivity and diffusivity, the lower the impact on the subway long term thermal behaviour. This may give perspective for geologist and geotechnical colleagues when it comes to survey the surrounding soil for a subway alignment study.

ABSTRACT: The Brussels North-South Railway Tunnel connects the northern railway station Brussels-North with the southern station Brussels-South as largest Belgian station. The tunnel is a large culvert construction and consists of an integral tunnel structure with 3 parts of two tracks with inner concrete columns making the tunnel a vulnerable part of the Belgium railway network. Although the tunnel of 1946 is a critical spot in the railway network, it does not comply with the current interoperability requirements in safety evacuation and structural fire resistance. A performance-based design approach is adequate to justify an acceptable level of higher structural fire resistance. The rectangular three shaft reinforced concrete tunnel model is setup in Siemens NX 12. Concrete is designed as a non-linear, isotropic, elastic material and the reinforcement is designed as a plastic, isotropic material, both materials follow the law of Von Mises. Two calculation environments are used within the Nastran solver namely, a transient thermal (sol 159) and a linear structural environment (sol 101). Different TT zones are constructed based on the computational fluid dynamics simulation results of a burning M6 train carriage of 600 m tunnel model. This approach results in a more specific and realistic thermal calculation model than those currently described in standards which use oversized benchmark fire curves. The tunnel stability is checked using the structural model based on the data results retrieved from the thermal calculation, leading to identifying zones of concrete damage. Additionally, a manual discretisation method is done to understand better the spalling behaviour during an M6 train carriage fire. An overview of the applied workflow is represented, added with possible extra implementations and improvements that can be done in further research. The paper is a result of a master thesis at the civil Engineering Department of Ghent University.

Keywords: 3D FEM tunnel, thermal calculation, stability check, Siemens NX 12

1 INTRODUCTION

The North-South Railway Tunnel (NSRT) connection has a total length of 1928 meter and exists of sixty-eight tunnel segments. The length of the tunnel segments varies depending on its location. As stated before, in this master thesis, the focus is on the straight tunnel segments sections S1 till S15. These tunnel segments are assumed to have an average length of 21 meters with cross-sections consisting of three tunnel shafts. The tunnel sections S1-S15 and an overview plan of the tunnel with segments is visible in Figure 1. It shows that each shaft has two railway tracks used to travel in both directions, separated by column rows. As a fire source can easily spread from one railway track to another, the space in between the columns was bricked up.

Phase 1 with tunnel segments S1 till S15 of the NSRT-connection, which was constructed between 1936 and 1938, is the subject of the investigation regarding its structural integrity in the event of a fire caused by an M6 train carriage. The M6 train carriage is a type of double-deck passenger train used in Belgium. It is part of the M6 series trains that were introduced in the early 2000s as part of a modernization program for the Belgian railway system and they are designed to be compatible with other types of trains used in Belgium, allowing for greater flexibility in the rail network. The M6 train carriage is given in Figure 2.

The HRR curve of the standard train carriage M6 is used to analyse the impact of the fire on the structural stability. The HRR curve considers the following fire spread scenario. It is assumed that a fire occurs in the lower compartment due to the ignition of a single seat. The fire spread within the M6 train

Figure 1. Overview and cross-section plan of the North-South railway connection in Brussels S1-S15.

Figure 2. The M6 train carriage - geometry and dimensions.

carriage is limited by the vents and an intermediate door that is opened during an evacuation attempt. Also, half of the total windows in the lower compartment, i.e. 8 out of 16, break. As a result of the broken windows, the fire spreads to the upper compartment of the train carriage, leading to breaking 11 out of 16 windows. The curve consists of two parts. The first part, up to 20 MW, represents the total heat released in the lower compartment, while the second part, from 20 MW up to 35 MW, represents the total heat released by the top compartment after which the fire ramps up to a maximum heat release rate at 37 minutes and later remains constant. The HRR curve is given in Figure 3.

The HRR curve is incorporated into the CFD model to understand the temperature development along the longitudinal direction of the tunnel's concrete surface. Siemens, a finite element software package, is employed to analyse both the thermal and structural behaviour of the tunnel. However, it should be noted that the modelled reinforced concrete material does not account for cracking or spalling behaviour. In the absence of comprehensive data, literature-based criteria are used as assumptions to guide the analysis.

The investigation begins with the creation of a simplified start-up model, which serves as an initial assessment. Subsequently, a longer and computationally demanding 21-meter model (general tunnel model) is developed to better understand the structural response on the fire.

The fire source (M6 train carriage) in the railway tunnel is designed to have a maximum HRR of 35

Figure 3. HRR in function of time due to combustion of the M6 train carriage.

Figure 4. RABT time temperature curves done by design office FESG.

MW as stated above. To consider the increase of temperature in the tunnel, the TT curve is designed based on the "Risk analysis and better targeting (RABT) train" fire curve, visualized in Figure 4. The RABT curve is used for the fire safety design in railway tunnels. It is a risk-based approach that considers the fire load, ventilation conditions and geometry of the tunnel. The RABT curve is the basis for the developing of the M6 curve done by the design office Fire Engineered Solutions Ghent (FESG). Following thorough the study of FESG, the maximum temperature (1200°C) described by the RABT curve can be considered as too conservative for the case study of the NSRT connection. Therefore, the maximum temperature is recalculated to 800°C, based on the results obtained from CFD simulations performed by FESG.

2 ANALYSIS PROCEDURE

The Siemens software, possesses a powerful environment to calculate and analyse heat transport and structural stability through the concrete lining of a three-

dimensional finite element tunnel model. The analysis procedure is represented in Figure 5. The Nastran SOL159 non-linear transient heat transfer analysis type is used to obtain the 3D temperature distribution in the reinforced concrete lining of the tunnel structure. The transition from the thermal analysis to the structural analysis is achieved through a coupled thermal-structural technique. This technique ensures the integration of thermal and structural responses, allowing for an assessment of the tunnel's behaviour under varying temperature conditions. By utilizing this approach, a representation of the tunnel's thermal and structural performance is achieved.

Figure 5. Analysis procedure in Siemens.

3 MODEL BUILD-UP

3.1 Geometry

Figure 6. Cross-section of the tunnel model.

To begin, a simplified start-up model is executed consisting of three straight adjacent tunnel shafts, with an inner length of 8 m by 5.2 m and longitudinal length of 1 m. The dimensions and denomination of the different structural parts are displayed in Figure 6. The successful finishing of the start-up model facilitates the base to extend the tunnel with 21 m in longitudinal direction. Three tunnel segments of 21 m are referred to as the general tunnel model. Calculation of the general model requires more powerful computing equipment (32 GB RAM) due to the increase of mesh points.

3.2 Modelling properties

Siliceous concrete in the tunnel is represented using hexahedral 8-node volume elements to ensure an optimal fit with the rectangular geometry of the tunnel. The concrete material is assumed to exhibit isotropic, linear elastic behaviour with a compressive strength of C20/25.

The mesh sizes of the concrete shafts vary based on the modelling requirements. An appropriate mesh size accomplishes a balance between calculation accuracy and computational efficiency, aiming to minimize resource utilization and excessive computation time.

Figure 7. Meshing tunnel model.

In the fire scenario, S1 corresponds to the shaft exposed to the burning M6 train carriage and is modelled using a mesh size of 50 mm. On the other hand, S2 and S3 are equipped with larger 100 mm volume elements, as thermal calculations require less accuracy in those areas. The different mesh sizes are interconnected using 100 mm hexagonal (8-node) volume elements, as depicted in Figure 7. The reinforcement within the model is represented as one-dimensional CBAR elements, which corresponds to a truss behaviour. To optimize computational efficiency, reinforcement is only included in the left shaft. The reinforcement material exhibit linear elastic, isotropic behaviour with a yield strength of 400 MPa and a diameter of 20 mm. Both the concrete and reinforcement materials adhere to the von Mises yield criterion. Temperature-dependent parameters, including mass density, E-modulus, Poisson's ratio, yield strength, ultimate tensile strength, thermal expansion, thermal conductivity, and specific heat, are implemented for both materials.

3.3 Boundary conditions and soil representation

To accurately capture the stiff and enclosed behaviour of each segment under investigation, a single boundary condition is applied to the tunnel lining. This boundary condition restricts longitudinal movement at the front and back faces of the entire cross-section. In the model, the surrounding soil is represented as an embedded spring system. A zero-dimensional mesh is created along the outer circumference of W1, W2, and the floor.

The calculation of the spring stiffness depends on the number of mesh nodes and the area affected by the corresponding springs. Based on the mesh modelling described in Section B "Modelling properties", five distinct zones of springs are identified, resulting in five springs, each with normal and shear components. CBUSH-grounded spring elements are utilized to model these springs, with a virtual node assigned with both normal (bi-linear) and shear (linear) stiffness at each mesh node. When a structural component displaces inwards, no resistance from the soil is considered as it cannot generate

Figure 8. Spring behaviour W1.

Figure 9. Spring behaviour W2.

tensile forces. However, for outward displacement, the soil provides counteracting forces proportionate to the magnitude of the displacement. The spring behaviour and variations in spring stiffness, as explained above, are depicted in Figure 8 and Figure 9, respectively, for walls W1 and W2.

3.4 Loading

Multiple static loads are employed to represent the acting forces on the tunnel and as accurately as possible simulate the interaction behaviour of the tunnel with its surrounding. The implemented forces are self-weight, water pressure and soil pressure. The temperature load data is statically implemented in the structural calculation environment as a three-dimensional temperature distribution through the reinforced concrete, obtained out of the thermal analysis.

4 GENERAL TUNNEL MODEL

The general tunnel model has the attributes as described in paragraph 2. The methodology for the assessment of the structural fire resistance follows three steps: (A) determining the fire scenario with a CFD simulation, (B) performing thermal analysis and (C) performing the structural analysis that considers the thermal load at a certain point in time.

4.1 Fire scenario and CFD simulation

Figure 10. Fire scenario.

The burning M6 train carriage is assumed to be stopped in the middle of tunnel segment 2 and close to the right sidewalk. Furthermore, only one shaft is exposed to a burning train carriage, in particular, the left shaft (Figure 10).

The CFD simulation based on the HRR of the M6 train carriage provides the ability to segregate the roof and walls in temperature zones. The floor is disregarded for analysis purposes. Each zone has a specific TT curve assigned. A total tunnel length of 63 meter, 3 tunnel segments, are investigated on its structural stability. An extended tunnel length analysis is unnecessary due to large decrease in temperatures at greater distance from the centre of the train carriage. The generated TT curves are based on the provided TT curve on the concrete lining by FESG. Figure 11 shows the maximum and minimum TT curves of the roof and walls implemented in segment 2. The fire duration is 170 min (10200 s) and the

maximum temperature is reached after 5 min and is detained for 55 min.

Figure 11. TT-curves of the roof (R), W1 and K1.

4.2 Heat transfer analysis

In order to gain a more comprehensive understanding of the three-dimensional heat distribution and its evolution over time, the thermal non-linear calculation method is employed. This computational technique is applied across twelve discrete time increments, which yield valuable data for investigating the time-dependent development of temperature within the reinforced concrete.

4.3 Structural analysis

To assess the tunnel's structural stability in ultimate limit state the accidental load combination is applied. The first step in this analysis involves determining the time increment at which the combined internal forces of the concrete and reinforcement are at their maximum. The point in time at which the maximum temperature of the reinforcement occurs and subsequently generates the highest levels of reinforcement internal forces, is at 6000 seconds. The highest internal forces in the concrete are reached at 3600 s. From this, the time increment in which the most severe heat loading of the tunnel is found to occur at 4800 seconds (Figure 12).

In order to assess the structural integrity of the tunnel, the three segments are divided into distinct zones (Figure 13). For the roof and wall structural components W1 and K1, the bending moment lines are compared with their ultimate moment capacity as determined by the NBN EN 1992-1-2 (2005) standard. In cases a part of the bending moment line within such a zone exceeds its ultimate moment capacity then, the part is defined as damaged reinforced concrete and no longer contributes to the local structural stability of the segment. This may result in a potential local collapse of the affected tunnel zone (Figure 14).

The roof zones with 100 % loss of structural capacity are identified as zones 4 to 8, corresponding to a tunnel length of 15 meters. Beyond these zones, it

Figure 12. Maximum internal forces in time for the 3 segments.

Figure 13. Division of the tunnel into zones in longitudinal direction.

Figure 14. Percentage of concrete damage for each zone.

is noticeable that the percentage of damaged volume of concrete decreases further from the train carriage fire. The maximum volume of damaged reinforced concrete in the walls is 54 %. The damage to the walls is lower because, the fire affects the upper parts more due to the rising hot smoke gases. Interestingly, the wall (K1) closest to the burning train carriage does not exhibit the highest percentage of damaged volume of concrete in every zone. A reason for this is that K1 has a lower stiffness and is connected with two other structural elements. Overall, segment 2 is in the worst condition, while segments 1 and 3 remain mostly intact.

5 SPALLING CONSIDERATIONS

Spalling, the loss of concrete mass during the event of a fire, can compromise the structural stability of the tunnel by reducing the concrete cross-section. Thereby, it allows the elevated temperatures to penetrate deeper into the structure. This induces augmented stresses for both concrete and reinforcement. Unfortunately, implementing spalling directly in Siemens is not possible.

Table 1. Results investigated spalling D300.

Max temperature [°C]	D300 [mm]	Damage Stage	Repairability
456	26	DS3	Clean surface
536	38	DS3	and replace
628	46	DS3	damaged
735	54	DS3	concrete

Figure 15. Investigation four spalling scenarios.

To estimate spalling, a manual discretization method based on a conservative temperature criteria of 380 °C is used to evaluate different scenarios. Thereafter, the resulting spalling depths are compared. Although using only a temperature criteria is not sufficient to fully describe this complex phenomenon, it can provide insight in its impact. The TT curve, as well as the specific scenario, have a significant impact on the spalling evolution and resulting spalling depth, observed in Figure 15. An alternative approach to measure spalling depth is the D300 method, which assesses the extent of damage based on the depth of penetration of a temperature of 300°C into the concrete, when subjected to a TT curve. Table 1 presents the reparability of concrete for each TT curve. For every TT curve the reparability result is “clean surface and replace damaged concrete. Figure 16 illustrates a technique depicting the implementation of spalling. The process involves obtaining the depths of spalling

in various TT zones, followed by the construction of a reduced model to assess the structural stability of the tunnel. In the general tunnel model spalling is incorporated by assuming the occurrence of scenario 2, where spalling continues until the reinforcement axis. The tensile strength of the reinforcement is reduced with a temperature depending factor, taking into account the decrease in concrete section, reinforcement and concrete strength. By including this consideration for spalling, the results for the roof align with those shown in Figure 14. However, the damaged volume of concrete in zones 2 and 3 increases to 100%.

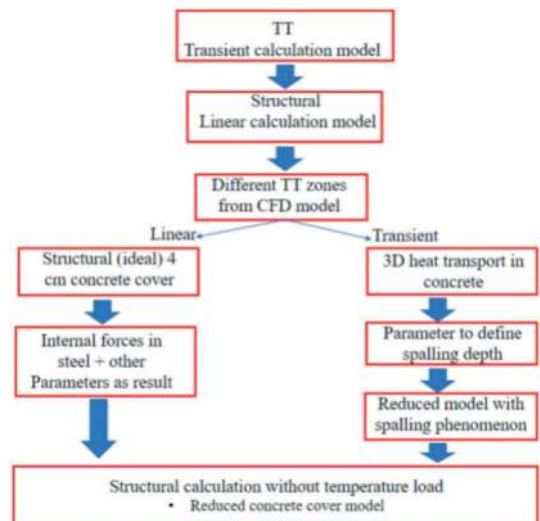

Figure 16. Implementation of spalling in general tunnel model.

6 IMPROVEMENT OF FIRE RESISTANCE

Figure 17. Location and required temperature limit.

Utilizing fire-resistant materials is a highly effective strategy for preventing spalling and enhancing structural stability. The study examines two scenarios: case 1, where the train ignites on the right railway track, and its mirrored counterpart, case 2, with the train igniting on the left railway track. In both cases, a manual iterative procedure is employed to determine the bending moment lines for various combinations of temperature heat loads. Analysis of the bending moment lines reveals that case 1 is decisive, requiring a Roof-Wall combination of 250-300 °C. On the other

hand, case 2 requires a maximum temperature of 380° C. To enhance fire resistance, different fire resistant panels and coatings are assessed, with material thickness identified as the primary parameter influencing the fire resistance. Figure 17 illustrates the specific temperature limits on the concrete lining and their corresponding locations.

7 CONCLUSIONS

Siemens NX 12.0 thermal-structural environment proves to be a valuable tool for investigating fires involving burning M6 train carriages in the NSRT connection. However, it is important to acknowledge that the software has certain limitations when it comes to accurately modelling material and environmental characteristics. By utilizing the HRR curve of the M6 train carriage, a CFD simulation is conducted. This simulation enabled the identification of various TT zones along the concrete lining. Consequently, spalling is discussed, it is established that the depth of spalling is dependent on the specific spalling scenario under consideration. In order to improve fire safety, precise combinations of Roof-Wall (TT) curves are identified to minimize the necessary thickness of fire resistant materials and mitigate the temperature reducing effect. By employing these specific TT curves, the structural impact of a fire is reduced compared to using the RABT curve, resulting in a diminished requirement for fire protective materials. It is also concluded that oversized standard fire curves lead to overestimations in fire

protection and structural improvement. However, it is a matter of debate whether intensive computational 3D finite element model calculations are required for implementing fire protection. To reduce costs, fire safety engineering only (mostly) investigates the highest temperatures and not the temperature evolution in longitudinal direction through the tunnel model. Further research can find ways to implement spalling into the NSRT model, to accomplish fire analysis that better represent reality. Improving the structural calculation techniques from the linear SOL 101 to a non-linear environment (e.g. SOL 106) leads to a more correct analysis of the bending moment lines by regenerating the stiffness matrix in every calculation-step. The process of extracting bending moment lines from 3D finite element analysis is a laborious and a time-intensive task that needs to be automated using software code.

A seismic damage classification for post-damage assessment of rock tunnels

Dinesh A. Reddy*

Research Scholar, Department of Civil Engineering, Indian Institute of Technology, Roorkee, India

Aditya Singh

Ph.D., Assistant Professor, Department of Civil Engineering, Indian Institute of Technology, Roorkee, India

ABSTRACT: The rock tunnels were partially or completely damaged by earthquakes such as the ones that struck Kern County, Duzce, Chi-Chi, Wenchuan, and many others. The damage degree and classification are important factors in determining how vulnerable rock tunnels are to earthquakes. Based on the amount of damage, researchers modified the damage degree and descriptions in the post-seismic damage classifications of rock tunnels after each seismic event. These classifications are specific to one or a maximum of three seismic events. This suggests that the existing post-seismic damage classifications are not standardized or coherent. In this research study, a seismic damage classification of rock tunnels for post-damage assessment is proposed. This classification is accomplished by utilizing the data of 285 rock tunnels from 26 different earthquakes throughout the world and is the largest seismic damage database of rock tunnels created to date. Further, this classification can be applied to any seismic event as it is linked to seismic and rock parameters. This classification highlights the extent of damage with clarity and can offer a comprehensive account of the performance of rock tunnels after an earthquake. This classification categorizes seven seismic damage levels for rock tunnels ranging from Extremely High (EH) to Lowest (LO). Seismic damages with thorough descriptions are associated with each damage level, along with seismic, rock parameters, and accessibility of the tunnel. This research will help in characterizing the tunnel performance after an earthquake.

Keywords: Earthquake, Rock Tunnels, Seismic Damages, Seismic Damage Assessment

1 INTRODUCTION

The tunnels are one of the major parts of infrastructure for roads, railways, hydropower, and many more. The rock tunnels are generally considered to be seismic resistant and are invulnerable to earthquakes. This traditional point of view was questioned when the tunnels were being posed with risks related to seismicity, especially in the mountainous region. Earthquakes like the 1952 Kern County, 1999 Duzce, 1999 Chi-Chi, 2008 Wenchuan, and many more have damaged tunnels to various extents (Dowding and Rozen, 1978; Wang et al., 2001; Wang et al., 2009). A few of the pictorial representations of damaged tunnels are shown in Figure 1. It is evident that the tunnels are also vulnerable to earthquakes. These damaged rock tunnels led to huge social and economic losses. Hence, the assessment for seismic damage to rock tunnels residing in a seismic zone is an important issue for rock and tunnel engineers all over the world. To understand the vulnerability of rock tunnels, various

researchers have proposed the seismic damage classification for tunnels after seismic events.

2 PROBLEM STATEMENT

Numerous researchers as detailed in Table 1, such as Dowding and Rozen (1978) categorized seismic damage into three classes. Sharma and Judd (1991) modified Dowding and Rozen's classification by subdividing the first class which is minor damage into slight damage and moderate damage. Asakura and Sato (1996) proposed the damage classification based on the Kobe earthquake. Based on seismic damages to tunnels due to the Chi-Chi earthquake, Wang et al. (2001) modified Dowding and Rozen's classification based on the functionality of the tunnel after the earthquake, observed length, and width of cracks. Yashiro et al. (2007) and Jiang et al. (2010) modified Asakura and Sato's (1996) classification for the tunnels damaged due to Mid-Niigata

Figure 1. (a,c) Chi-Shue and Taoguan Tunnels before the Chi-Chi, and Wenchuan earthquakes respectively. (b,d) Damages to Chi-Shue and Taoguan Tunnels after the earthquakes (After Wang et al., 2001; Wang et al., 2009; Li, 2012).

Table 1. Literature review of seismic damage classes and classifications of tunnels.

Author	Damage Degree/ Damage Classes
Dowding and Rozen (1978), Owen and Scholl (1981)	No Damage, Minor Damage, and Damage.
Sharma and Judd (1991)	Slight, Moderate, Heavy, and No Damage
Asakura and Sato (1996)	A: Damage Required to Repair, B: Slight Damage, None: No Damage.
Wang et al. (2001), Wang et al. (2009)	A: No Damage/Slight Damage, B: Moderate, C: Severe Damage
Yashiro et al. (2007), Jiang et al. (2010)	A1: Heavy Damage Requiring Repair and Reinforcement, A2: Damage Requiring Repair and Reinforcement, B: Damage not Requiring Repair and Reinforcement, and C: No Damage
Wang and Zhang, (2013), Shen et al. (2014), Yu et al. (2016)	1: None, 2: Slight, 3: Moderate, 4: Severe, 5: Collapse/ Extremely Severe
Shrestha et al. (2020)	Slight, Moderate, and Severe.

Prefecture. Due to the severity of damage to tunnels caused by the Wenchuan earthquake, Wang and Zhang (2013), Shen et al. (2014), and Yu et al. (2016) modified Wang et al. (2001) classification by adding the collapse or extremely severe damage class. The Tunnel Damage (TD) was classified into five classes. Further, Shrestha et al. (2020) modified

Wang et al. (2001) classification as the damage was not so severe and was confined to lining cracks and spalling only. The damage degree or damage classes used for all these classifications are shown in chronological order in Table 1.

From Table 1 and the above literature survey, it can be concluded that researchers periodically adjusted the damage classes and descriptions in post-seismic damage classifications based on the quantity and extent of tunnel damage. This suggests that for determining the degree of damage to rock tunnels, there is not a universal or consistent post-seismic damage classification that suits all seismic events. Based on damage data from one or a maximum of three seismic events, the current post-seismic damage classifications are in place (Wang et al., 2001; Wang and Zhang, 2013). These classifications lack a comprehensive understanding of the issue since they are particular to the location and the seismic event that occurred. A significant amount of data on damaged tunnel cases is required in order to evaluate the seismic damage of rock tunnels. To better comprehend the various levels of damage to rock tunnels, a new Post-Seismic Damage Classification of Rock Tunnels is presented in this work. This damage categorization is based on data from 285 rock tunnels damaged as a result of 26 earthquakes, which is the largest post-seismic damage database of rock tunnels in the world. Figure 2 displays the distribution of rock tunnels from each earthquake that were used to create a database. This work is part of Reddy and Singh (2023) and for detailed information on this work, the authors would recommend reading their future journal article.

Figure 2. The list of 26 earthquakes along with the number of rock tunnels used in each is listed in the damage database.

3 SEISMIC DAMAGE TO TUNNELS

Earthquake-induced tunnel damage patterns include lining shearing off, tunnel collapse, cracks with different spatial distributions on lining and portals, spalling in the lining, deformation of side walls or inverts, and water leakage (Wang et al. 2021, Wang and Pan, 2022). From the database created, earthquakes like the 1923 Great Kantō earthquake, the 2008 Wenchuan earthquake, and others, the damages like avalanches sliding toward the tunnel portal, Rock falls, and portals were completely buried by large slumps of rock/soil mass are observed (Dowding and Rozen, 1978; Wang and Zhang, 2013; Shen et al., 2014). Figure 3 (a-f) displays the visual depictions of seismic damage to tunnels. According to the created database, lining cracks are the most common type of damage observed in rock tunnels (31%), followed by spalling (26%), and the lowest being slope failure-induced collapse (1%). The most severe damage type, shear failure of the lining (7%), has the potential to collapse the tunnels.

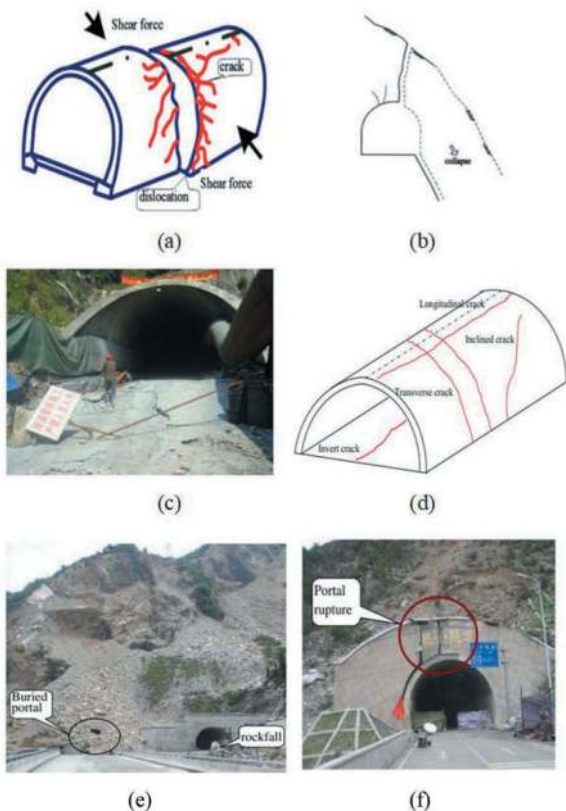

Figure 3. (a) Shear Failure in the Lining (after Shen et al., 2014) (b) Slope Failure Tunnel Collapse (after Wang et al., 2001) (c) Pavement Damage (after Li, 2012) (d) Different patterns of cracks in tunnel lining (after Roy and Sarkar, 2017) (e and f) Types of Portal Damage (after Shen et al., 2014).

4 A NEW POST-SEISMIC DAMAGE CLASSIFICATION OF ROCK TUNNELS

The aim of this research is to suggest a post-seismic damage classification system that can be applied to any forthcoming seismic event of any scale. It is based on the biggest damage database ever assembled. The damage description of this classification uses the amount or extent of damages that were suggested in previous classifications by Wang et al. (2001) and Wang and Zhang (2013). Previous damage descriptions lack information pertaining to rockfalls, slopes, and portals are either sparse. The proposed classification includes a detailed and highlighted breakdown of the damage caused by rockfalls, slopes, and portals in each class. For a new damage classification, a methodical arrangement of damages and damage descriptions taken from the various studies are combined. With comprehensive damage descriptions listed in Table 2, this study presents seven tunnel damage classes for damage degrees: None, Very Slight, Slight, Moderate, Severe, Extremely Severe, and Collapse Classes. In this classification shown in Table 2, the “Very Slight” degree is added for the first time, and the “Extremely Severe” and “Collapse” degrees coexist. In addition, this damage classification provides a qualitative description of parameters such as rock mass, the distance between the tunnel and the ruptured fault zone, as well as a quantitative description of moment magnitude and the accessibility of the tunnel in each class following an earthquake. For more detailed information on this work, the authors would suggest to refer Reddy and Singh (2023)

Table 2. A New post-seismic damage classification of rock tunnels.

DC*/DD**	Damage Description	Role of Rock, Seismic Parameters, and Tunnel Accessibility
1 / None (N)	No damage is caused due to an earthquake. The tunnel is in an undamaged state.	Found in tunnels in exceptionally competent rock mass, far away from the ruptured fault zone ($M_w < 6.2$). Shortly after the seismic event, the tunnel is readily accessible.
2 / Very Slight (VS)	Very slight cracks ($w_c < 3\text{mm}$, $l_c < 1\text{m}$), Small-scale overhead raveling of rock in mountain tunnels, and no groundwater leakages observed.	Found in tunnels of harder or competent rock mass that are far away from the ruptured fault zone ($M_w \geq 6.2$). Immediately following the seismic

(Continued)

Table 2. (Continued)

DC*/ DD**	Damage Description	Role of Rock, Seismic Parameters, and Tunnel Accessibility
3 / Slight (SL)	Cracks ($w_c < 3\text{mm}$, $l_c < 5\text{m}$), slight palling, stones falling and stocking up in front of a portal in mountain tunnels, and slight seepage of groundwater can take place.	event, the tunnel is easily accessible. Found in tunnels of harder or competent rock mass that are far away from the ruptured fault zone ($M_w \geq 6.2$). Immediately following the seismic event, the tunnel is easily accessible.
4 / Moderate (M)	Cracks ($3 < w_c < 30\text{mm}$, $5 < l_c < 10\text{m}$), moderate spalling, deformation in the lining ($d_b < 0.25\text{ m}$), and invert uplift ($h_u < 0.2\text{ m}$), moderate rock falls, massive gravel, or many stones stocked up in front of a portal, and dripping groundwater might take place.	Found in softer and harder rock mass tunnels, these tunnels are located close to the ruptured fault zone ($M_w \geq 6.2$). After the seismic event, the tunnel is accessible with numerous signs of caution and regulations.
5 / Severe (SE)	Multiple cracks ($w_c > 30\text{mm}$, $l_c > 10\text{m}$), severe spalling up to a crushed range area of $< 2\text{ m}^2$, a roof can cave in tunnel sections, slight to moderately exposed reinforcement, horizontal dislocation in the lining ($d_b < 0.8\text{ m}$), invert uplift ($h_u \leq 1\text{ m}$). Accompanied by portal ruptures, and rock falls, most part of the tunnel portal is buried. The continuous inflow of groundwater.	Found in softer and harder rock mass tunnels or at the interface of rocks, these tunnels are located close to the ruptured fault zone ($M_w \geq 6.2$). After the seismic event, the tunnel is not accessible.
6 / Extremely Severe (ES)	a) Continuous cracks at multiple locations ($w_c > 35\text{mm}$, $l_c > 15\text{m}$), extremely severe spalling up to a crushed range area of $> 2\text{ m}^2$, severely exposed reinforcement, extremely severe tilting of concrete blocks, horizontal and vertical dislocation in the lining ($d_b < 2\text{ m}$), and	Found in tunnels with weaker or softer rock masses, tunnels that pass through or are very near to the ruptured fault zone ($M_w > 6.5$). After the seismic event, the tunnel is not accessible.

(Continued)

Table 2. (Continued)

DC*/ DD**	Damage Description	Role of Rock, Seismic Parameters, and Tunnel Accessibility
	invert uplift ($h_u > 1\text{ m}$). b) Accompanied by portal collapse, Slope failure-induced tunnel collapse, heavy rock-falls, a completely buried tunnel portal, and a continuous inflow of groundwater.	
7 / Collapse (CO)	a) The tunnel can be completely collapsed in the weaker section. b) The lining can be sheared off or dislocated vertically and horizontally to the highest extents ($d_b > 2\text{ m}$). Inrush of groundwater.	Found in fault fracture zones in the weaker rock masses and in tunnels passing through ruptured faults ($M_w > 6.5$). Following the seismic event, the tunnel is unusable and might even be abandoned entirely.

Remarks: DC*- damage class, DD**- damage degree, w_c - Width of Crack, l_c -Length of Crack, d_b - Displacement, h_u - uplift height, M_w – Moment Magnitude.

This damage classification is easy to use, has the potential to be applied to any seismic event due to its connection to seismic and rock parameters, highlights the extent of damage with clarity, and can offer a comprehensive account of how rock tunnels perform after an earthquake. The proposed classification's damage description does not base the amount of damage on a single or few particular seismic events. It is predicated on 26 distinct seismic events, of which the database contains 83% of damaged cases and 17% of undamaged cases. Figure 4 displays the distribution of 285 rock tunnels along with their tunnel damage

Figure 4. The total number of tunnels in each tunnel damage class of the classification.

classes following the application of this classification. In class 3, there are more rock tunnels than in classes 1 and 2, and in classes 6 and 7, there are fewer.

5 CONCLUSIONS

Large-scale seismic damage data are gathered from rock tunnel locations by means of a thorough review of the literature. It served as the foundation for creating the biggest damage database, suggesting new damage classification schemes, and linking to parameters that affect seismic damage to rock tunnels. Additionally, the common seismic damages are noted, clarified, and identified. In summary, the suggested categorization is easy to apply, doesn't necessitate complex computations, can be applied to any given event of any size, and offers a thorough explanation for comprehending the various degrees of damage to rock tunnels following an earthquake. This work is part of Reddy and Singh (2023) and for detailed information on this work, the authors would recommend reading their future journal article.

The numerical-physical coupling method in investigation of the response of the tunnel structure under fire scenarios

Linxi Wang* & Zhiguo Yan

Department of Geotechnical Engineering, Tongji University, Shanghai, China

State Key Laboratory for Disaster Reduction in Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: Tunnel structures undergo increased safety hazard when subjected to fire, highlighting the critical need to study their structural responses under such scenarios. However, conducting full-scale fire tests in the laboratory is often impractical due to various limitations. The numerical-physical coupling method, which integrates numerical simulation and physical testing, has emerged as a promising alternative for investigating the structural behaviour of the tunnel structure under fire scenarios. In this study, virtual tests are conducted to validate the feasibility of the numerical-physical coupling method under different fire scenarios, including the simple one, where the fire area involves only the key segment affected by thermal conduction, and the complex one, which includes adjacent segments affected by both thermal convection and thermal radiation. The results of the virtual tests indicate that under both scenarios, the material parameters and boundary loads obtained gradually converge towards the reference results as the time steps progress. The final responses gained by the numerical-physical coupling method, including stress fields and displacement fields, are consistent with the reference thermo-mechanical response, with average errors below 5%. The results indicate the promising prospects of the numerical-physical coupling method in investigating the response of the tunnel structure under fire scenarios, while emphasizing the need for future experimental verification.

Keywords: Tunnelling, Thermo-mechanical behaviour, Hybrid fire test, Numerical simulation, Physical testing

1 INTRODUCTION

Fire is one of the main threats affecting the safety of tunnel. A fire incident in a critical infrastructure may cause considerable structural damage, leading to catastrophic losses (Kirkland, 2002; Vuilleumier et al., 2002). The actual response of tunnel is fraught with uncertainties in both material properties and component capacities under extreme fire scenarios, which increases the risk of structural failure. Hence, a well-grounded understanding of tunnel performance, especially the thermo-mechanical characteristics under fire scenarios, is necessary to answer the need for safety requirements.

Various conventional methods have been applied for the investigation of thermo-mechanical behaviour of tunnel structures, including numerical simulation (Maraveas and Vrakas, 2018), component testing (Siemon and Zehfuß, 2017; Yan et al., 2016) and reduced-scale or full-scale testing (Yan et al., 2012). However, the existing methods have their limitations.

The component testing fails to reveal the interactions between components and the exact boundary conditions, while the numerical simulation lacks fidelity for structures with unknown or unstable properties. The reduced-scale testing and full-scale testing are considered the relatively credible methods, but are still difficult to faithfully replicate the surrounding loads and thermal boundaries. Inspired by the concept of hybrid test (Takanashi and Nakashima, 1987; Xu et al., 2021) in the seismic field, the hybrid fire test (Mostafaei, 2013a; 2013b), which combines the component testing and numerical simulation, has been introduced. However, existing research on hybrid tests mainly focused on simple frame constructions, making it unsuitable for tunnel structures. Moreover, the stability of hybrid fire tests is also hampered by the split of numerical and physical substructures and the inadequate interaction. To address this challenge, researchers have proposed different improvements to the method (Saucu et al., 2017; Schulthess et al., 2020). Furthermore, several studies (Saucu et al., 2020; Faghihi and Knobloch,

*Corresponding author: 1910332@tongji.edu.cn

2019) have used virtual tests, where numerical simulations of relevant components with real parameter values temporarily replace the physical tests, to investigate the interactions between physical test and numerical simulation.

To fully leverage the advantages of both numerical simulation and physical testing, this research aims to propose a new adaption of the hybrid test as the Numerical-Physical Coupling Method (NPCM), for investigating the behavior of tunnel structure under fire conditions. Subsequently, the feasibility and effectiveness of the NPCM are preliminarily validated via the virtual test.

2 METHODOLOGY OF NPCM

2.1 Basic concept

In this paper, the NPCM comprises several modules: the Physical Structure (PS), the Numerical Structure (NS), the Physical-to-Numerical (PtN) module, and the Numerical-to-Physical (NtP) module. In the PS, test components are selected with a focus on parts with unknown material properties and complex stress or thermal conditions, such as weak segments or joints in tunnel structures. Through physical test, the actual performance of materials and components under target conditions is reliably demonstrated. In the NS, numerical simulation is used to simulate the entire structure, considering the interactions between components and providing exact boundary conditions that match the real-time scenario. Different from the existing hybrid fire test method, the NS in NPCM contains the entire structure, including the components which are tested in PS.

For interaction modules, the PtN module aims to adjust the numerical model in NS based on the actual

measurements obtained from PS. In this study, the goal is to find the optimal set of parameters that results in the highest similarity between the values on corresponding survey points in PS and NS during the current test step. The modified parameters are suggested to be decided based on sensitivity analysis where the variables that have the most significant impact on mechanical behaviors or measurements can be clarified. On the other hand, in the NtP module, the equivalent loading commands are calculated based on the corresponding boundary stress states of the components in the NS. These commands are then sent to the loading equipment and applied to the tested components in the PS to achieve equivalent loading conditions. In this study, boundary conditions are equivalent and simplified according to Saint Venant's Principle in the NtP module. It is assumed that the static equivalent replacement on the boundary surface only affects the near-end stress distribution within a range of 1 times the thickness of the segment from the adjusted boundary surface, while the far-end stress distribution remains authentic.

In existing hybrid fire test, the components selected for physical tests are excluded from the numerical simulation. The entire structure tends to be treated as separate numerical and physical substructures, interacting only at the intersection of the two parts. Unfortunately, this division of numerical and physical substructures may lead to a lack of interaction between the simulation and test, which can limit the accuracy of the method, particularly for complex structures including tunnel structures, and may even result in divergence. Different from the existing research, the proposed NPCM redefines and reorganizes the division of PS and NS. Moreover, the NPCM focuses on real-time interaction modules, ensuring convergence of both PS and NS through overlapping parts.

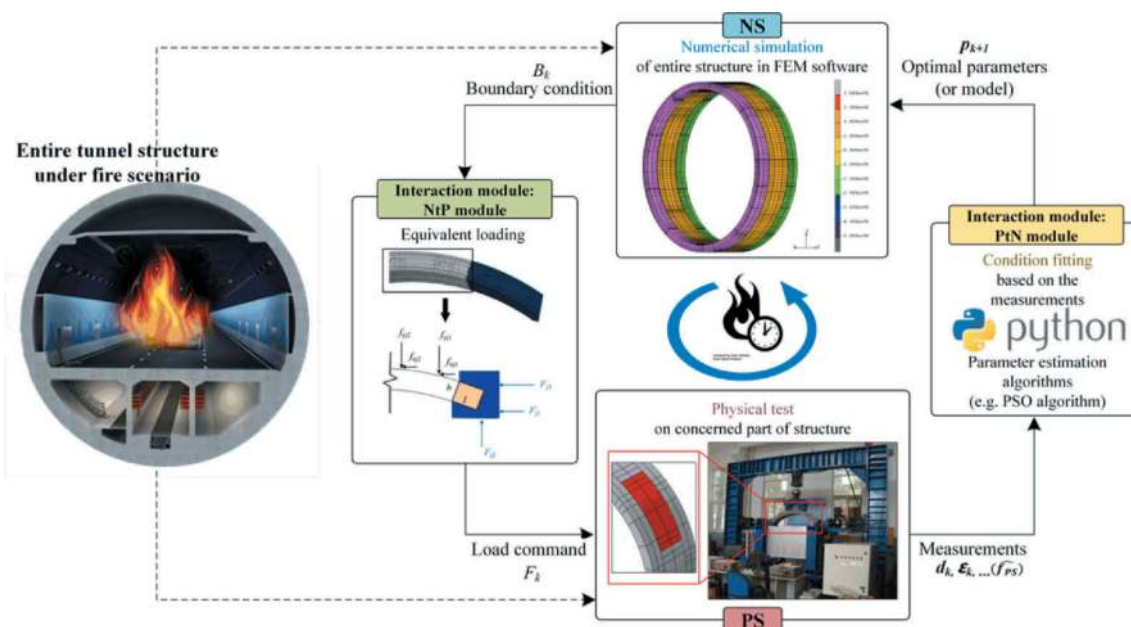

Figure 1. Basic concept of NPCM.

2.2 Boundary conditions and similarity

During the NPCM process, component test in PS and numerical simulation in NS progress simultaneously whilst the interaction modules provide the adjustment and constraint, ensuring that both PS and NS can converge to the actual response of the structure. The consistency between NS and PS turns out to be the base for NPCT, thus requirement in both boundary conditions and similarity need to be satisfied.

To be consistent with the NS, loads on component should be adjusted to keep the boundary conditions of PS in step as follows:

$$\sigma_{PS}^B = \sigma_{NS}^B \quad (1)$$

$$\varepsilon_{PS}^B = \varepsilon_{NS}^B \quad (2)$$

Where σ^B, ε^B represent the stress and strain of certain boundaries and the subscribe *PS* indicates the data from physical structure whilst *NS* indicates the numerical structure.

When the physical field of the overlap part (i.e., numerical part of the physically tested components) in NS turns out to coincide with PS, the NS can then be considered to represent the actual performance of the full structure under target conditions. Therefore, the similarity index, *SI*, is proposed to evaluate the consistency between the two spaces. *SI* should represent the difference of physical quantities and the general expression can be defined as:

$$SI = \sum s(\hat{f}_{PS}, \hat{f}_{NS}) \quad \hat{f} \in (\hat{d}, \hat{\varepsilon}, \hat{\sigma}, \hat{F}, \hat{M}, \dots) \quad (3)$$

where \hat{f} represents the field of concerned quantities, which can be chosen from displacement, strain, stress, force, moment, et al. Function *s* evaluates the difference between the data of fields. For ideal conditions, it requires:

$$SI = 0 \quad (4)$$

During the test, the boundary conditions should be satisfied and the *SI* needs to be minimized at each time step. When optimization algorithm is adopted in PtN module, *SI* can serve as the aim object for the evaluation of parameter values.

3 CASE STUDY

To offer a comprehensive demonstration of the NPCM process and primarily validate its feasibility and effectiveness in thermo-mechanical

investigation, a virtual test is conducted. In this test, numerical simulations of relevant components with real parameter values temporarily replace the physical specimens (PS) in the investigation of a tunnel structure under fire scenarios.

3.1 General information

The prototype structure for the case study is a large, deep-buried shield tunnel. The tunnel has an outer diameter of 15.2 meters and an inner diameter of 13.9 meters. A complete ring consists of ten precast segments, including one top segment, two adjacent segments, six standard segments, and one bottom segment, as is illustrated in Figure 2. Each segment has a thickness of 0.65 meters and a width of 1.2 meters. The segments are made of C60 concrete while reinforced longitudinally with HRB400 steel bars. Adjacent segments are connected with three M36 grade 8.8 angled bolts, totally thirty bolts per ring.

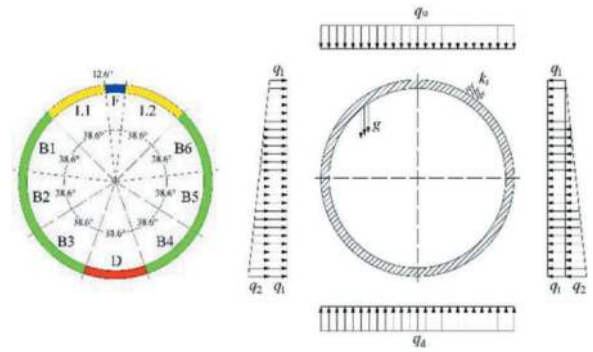

Figure 2. Tunnel construction.

The loads acting on the tunnel lining include the overburden pressure q_u , the subgrade reaction pressure q_d , the lateral uniform earth pressure q_1 , the lateral triangular earth pressure q_2 and the gravity g . Accordingly, $q_u=651$ kPa, $q_d=695$ kPa, $q_1=268$ kPa, $q_2=142$ kPa, $g=9.8$ m/s². The resistance from the surrounding stratum is simulated via non-linear earth spring with compressive stiffness only. The stiffness per unit area, denoted as k_r , is determined based on the foundation coefficient as 19500 kN/m³.

Two fire scenarios are considered and simulated in the case study, as illustrated in Figure 3. In Case A, only the top segment, which is considered to be directly affected by thermal conduction, is taken into account as the fire-affected area. In Case B, the inner surface of top segment undergoes the thermal conduction while the inner surfaces of the adjacent segments are influenced by thermal convection and thermal radiation. In both cases, the thermal emissivity ε is set as an intermediate value 0.8 according to the European Standards (Cen, 2004) while the surface heat transfer coefficient h is calculated as follow:

$$h = 7.05 \times e^{\left(\frac{T}{372.35}\right)} + 0.84 \quad (5)$$

Where T represents the temperature at the corresponding moment t . The temperature variation on the inner surface due to thermal conduction follows the HC heating curve, as represented by the following formula:

$$T = 20 + 1080(1 - 0.325e^{-0.167t} - 0.675e^{-2.5t}) \quad (6)$$

Figure 3. Fire scenarios.

3.2 Numerical model

A two-dimensional plane strain model is employed for the calculations. In FE model, the concrete material is simulated via four-node plane strain elements, while the embedded bar is simulated via two-node truss elements. Tied contact is used for the contact between concrete segments and embedded contact is used for the contact between concrete and steel bar.

In the numerical model, both concrete and steel are treated as ideal elastoplastic materials. Their densities remain constant throughout the fire testing process, with values set at 2400 kg/m³ for concrete and 7800 kg/m³ for steel. The thermal conductivity and specific heat capacity of concrete and steel are sourced from European Standards (CEN, 2004). The thermal expansion coefficients are calculated using the formula proposed by Lie (1996) as follows:

$$\alpha_c = (0.008T + 6) \times 10^{-6} \quad 20^\circ\text{C} \leq T \leq 1200^\circ\text{C} \quad (7)$$

$$\alpha_s = \begin{cases} (0.004T + 12) \times 10^{-6} & T < 1000^\circ\text{C} \\ 16 \times 10^{-6} & T \geq 1000^\circ\text{C} \end{cases} \quad (8)$$

Where α_c and α_s refer to the thermal expansion coefficients of concrete and steel respectively.

At ambient temperature, steel has a yield strength of 360 MPa and an elastic modulus of 200 GPa, while bolts are assumed to have a yield

strength of 640 MPa and an elastic modulus of 210 GPa. Both materials share a Poisson's ratio of 0.3. The reduction factors of steel properties under elevated temperature conditions are set based on European Standards (CEN, 2004). Notably, the mechanical properties of concrete at elevated temperatures, such as the elastic modulus and yield strength, can significantly influence structural deformation and internal forces. Thus, these parameters are decided to be modified during the NPCM process, as explained in detail in the subsequent subsection.

3.3 Set up of the virtual test

In Case A, testing is limited to the top segment in the PS. However, in Case B, testing involves both the top segment and the adjacent segment, requiring more complex coordination with the overall NS. In both cases, the test duration is fixed at 30 minutes and divided equally into 6 steps. During each step, the parameters of concern are modified in PtN module and interaction between NS and PS is conducted.

Based on existing research findings concerning the mechanical properties of concrete under elevated temperatures, the reduction in its elastic modulus and peak compressive strength at temperature T is modeled as follows:

$$E_0^T = \begin{cases} (1 + a(T - 20))E_0 & 20^\circ\text{C} \leq T \leq 800^\circ\text{C} \\ (1 + 780a)E_0 & T > 800^\circ\text{C} \end{cases} \quad (9)$$

$$f_c^T = f_c / (1 + 2.5(T - 20)^6 \times 10^{-17}) \quad (10)$$

Where E_0^T and f_c^T refer to the elastic modulus and peak compressive strength of concrete at temperature T , E_0 and f_c refer to the elastic modulus and peak compressive strength of concrete at ambient temperature, a refers to the fitting coefficients. During the virtual test, E_0 , f_c and a are selected as the parameters under modification. In Case B, to consider a more complex scenario, different parameter values are assigned to the concrete material of adjacent segments compared to the top segment, while the parameters of the remaining segments are kept consistent with the top segment. The initial value, reference value and range for modification of each are provided in Table 1. Notably, the parameters are set as the initial values before the virtual test while the reference values remain unknown throughout the test process.

In this virtual test, the standard particle swarm optimization (SPSO) algorithm is selected as the intelligent algorithm for parameter modification in PtN module. In terms of test settings, parameters of the PSO algorithm are selected from experience

Table 1. Values of parameters.

Component	Parameter	Initial value	Reference value	Range
Top segment	$E0$ (Gpa)	25	36	[25,50]
	a	-7.1×10^{-4}	-11.5×10^{-4}	$[-12.7 \times 10^{-4}, -6.93 \times 10^{-4}]$
	fc (Mpa)	25	38.5	[25,50]
Adjacent segment	$E0$ (Gpa)	50	32	[25,50]
	a	-12.5×10^{-4}	-10.0×10^{-4}	$[-12.7 \times 10^{-4}, -6.93 \times 10^{-4}]$
	fc (Mpa)	50	35	[25,50]

and trial run. The population size m and max generation mg are set to 10 and 8, the learning factor c_1 , c_2 are set as 2 equally. The SI for optimization is calculated according to the displacement on survey points in both PS and NS as follows:

$$SI = \frac{1}{2N} \left(\sum_{j=1}^N \frac{|d_j^{(NS,in)} - d_j^{(PS,in)}|}{|d_j^{(NS,in)} + d_j^{(PS,in)}|} + \sum_{j=1}^N \frac{|d_j^{(NS,out)} - d_j^{(PS,out)}|}{|d_j^{(NS,out)} + d_j^{(PS,out)}|} \right) \quad (11)$$

Where N represents the number of survey points on each side; j represents the index of survey point; d represents the displacement on corresponding survey point. Additionally, Superscripts NS and PS indicate the source of measurement data, superscripts in and out indicate the surface where the measurement point is located.

For test segments in PS (simulated via numerical model in this study) and the corresponding components in NS, survey points are uniformly arranged at on both the inner and outer surface of segment. Specifically, there are 7 points on each side for top segment and 11 points on each side for adjacent segment, as illustrated in Figure 4. Notably, in order to mitigate the influence of boundary conditions, two survey points that were originally situated closest to the boundaries on each surface are removed from the adjacent segment.

Figure 4. Arrangement of survey points.

The detailed procedures of the NPCM implementation for the virtual test is illustrated in Figure 5.

3.4 Results and analysis

The variations of NS and PS during NPCM process for Case A and Case B are illustrated in Figure 6 and Figure 7, respectively. In Case A, the initial values of all parameters deviate by more than 30% from the reference values. However, as the analysis progresses, the modified parameters gradually approach the reference values, with errors of less than 1% by Step 6. Similar trends can be observed in PS. Notably, from Step 3 to Step 4, an evident increase in error is observed due to the changes in reference values for boundary loads, which results from the material degradation. However, subsequent NPCM iterations successfully reconverge the loads to the reference values. In Case B, due to the involvement of multiple test components and parameters, the convergence rate of parameters has slightly decreased. Consequently, the overall error is somewhat higher compared to Case A, but it remains below 5%. In the PS, evident variations in boundary loads occur on both the top segment and adjacent segments in Step 2, resulting in fluctuations in load commands provided by NPCM. The error in bending moments for the adjacent segment reaches a maximum of 22.1%. However, after Step 5, the error of axial forces consistently remains within 0.3%, while the error of bending moments stays within 1.3%, indicating a relatively steady state.

The vertical displacements of survey points on the inner and outer surfaces of target segments are compared both between NS and PS, and between the NPCM results and reference values. The differences are illustrated in Figure 8 and Figure 9. The data for the top segment in Case B is omitted as it closely resembles the conditions in Case A. In Case A, as observed in the figures, middle-region displacements of the top segment are generally consistent between NS and PS, with differences below 0.02 mm. However, displacement differences increase for points near the ends of the segment. Throughout the test progression, NPCM results fluctuate around the reference values. Overall, errors on the outer surface are smaller than those on the inner surface, but their patterns remain largely consistent. In Case B, for the adjacent segment, the boundary effects are relatively significant. In the middle region of both the inner and outer surfaces, the displacements are also

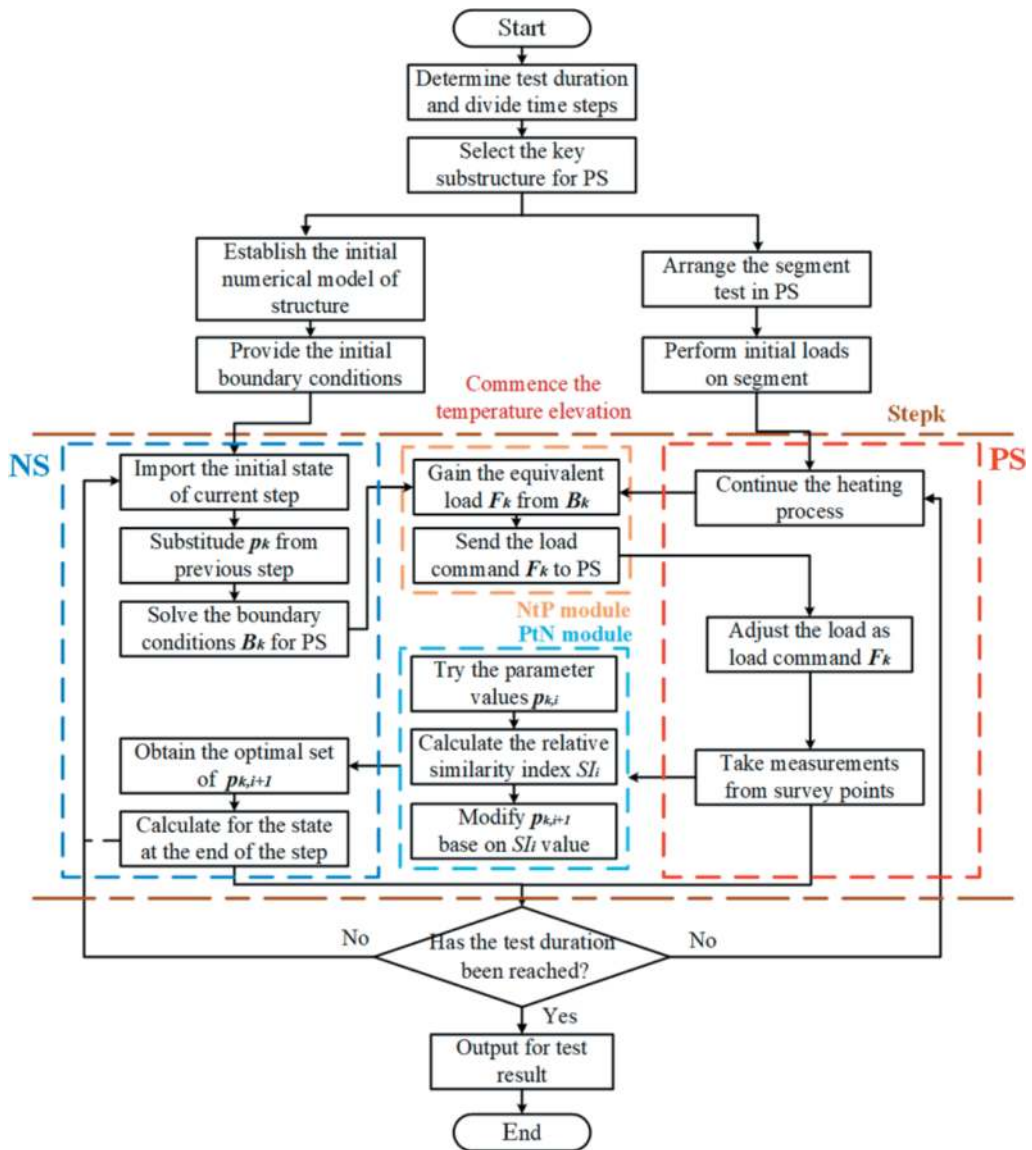

Figure 5. Procedures of NPCM implementation.

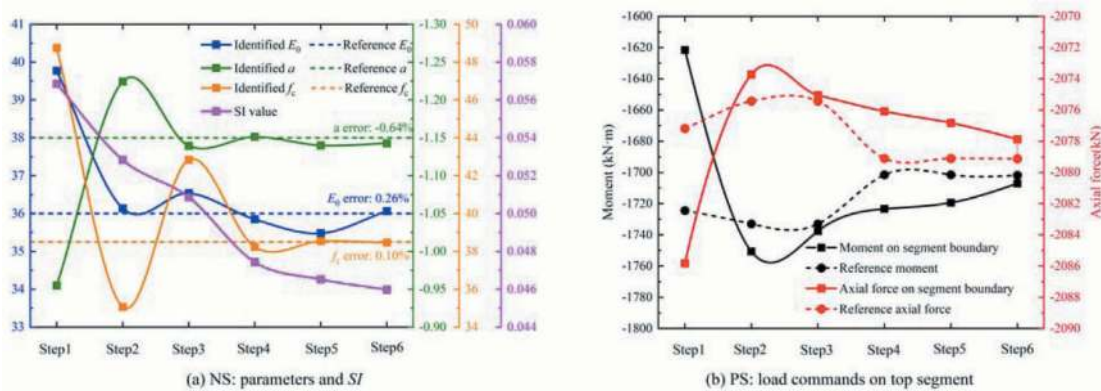

Figure 6. Variation during NPCM process for case A.

consistent, with differences within 0.1mm. Near boundaries, differences between NS and PS increase, with a maximum difference of 0.65 mm. Still,

NPCM results closely match reference values with errors below 0.05 mm for most survey points, except for points near the boundary on the inner surface.

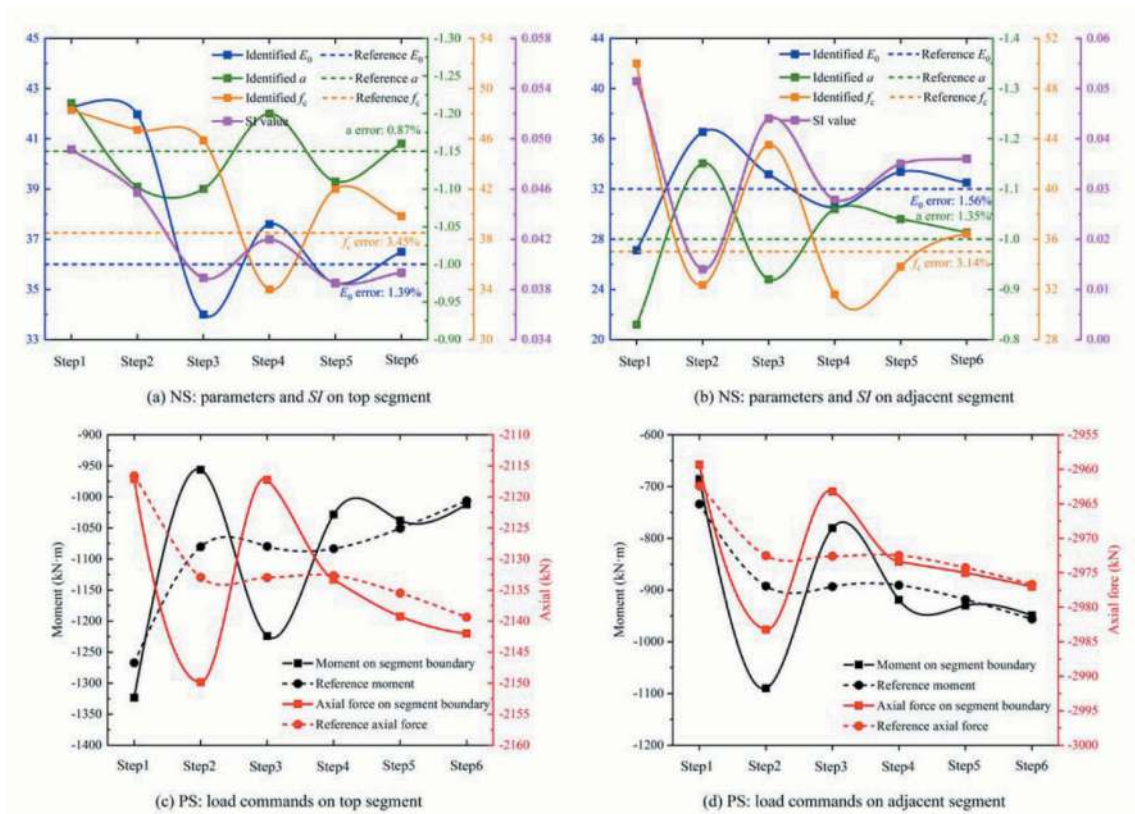

Figure 7. Variation during NPCM process for case B.

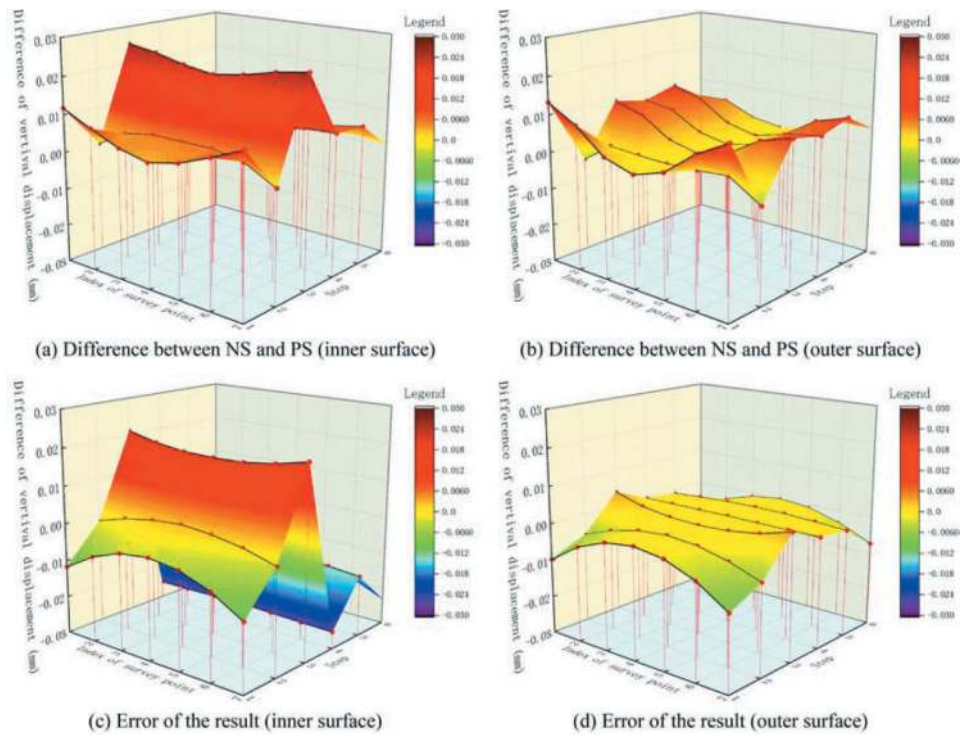

Figure 8. Difference of the displacement on top segment (case A).

The errors of the NPCM results for the entire structure at the end of step 6 are provided in Table 2. For the displacement field and stress field of the

overall structure, final errors of less than 5% are exhibited in both Case A and Case B. The proportion of errors exceeding 10% is also found to be below

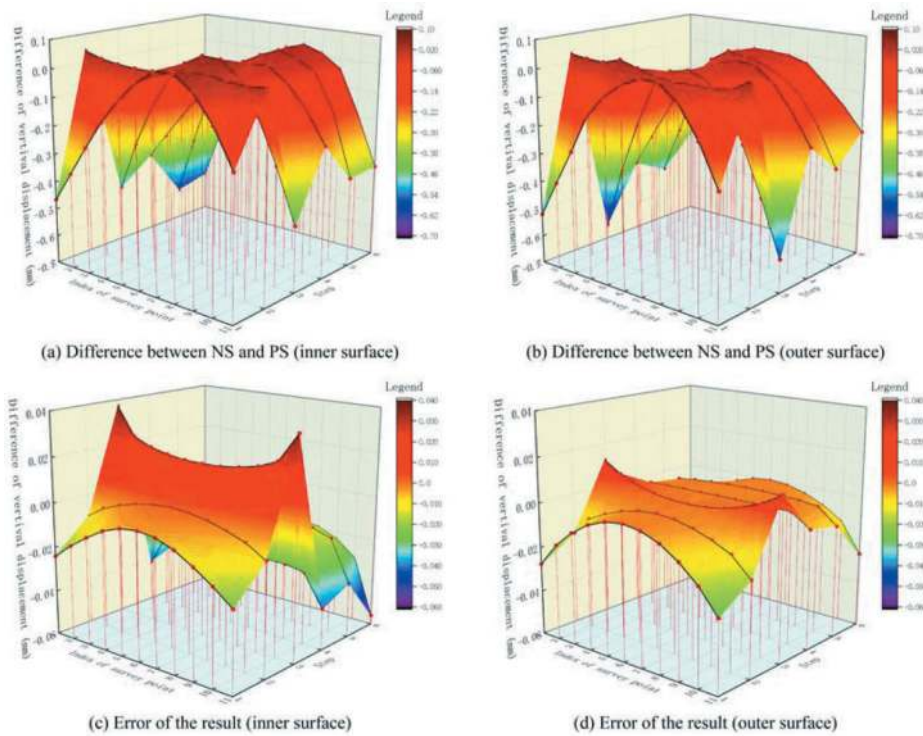

Figure 9. Difference of the displacement on adjacent segment (case B).

Table 2. Final error of NPCM results for entire structure.

	Displacement		Stress	
	Average error	Error rate (>10%)	Average error	Error rate (>10%)
Case A	4.6%	7.7%	3.1%	6.1%
Case B	3.3%	7.0%	5.4%	8.1%

10% in both cases. It can be concluded that in 6 time steps, NPCM effectively provides the actual thermo-mechanical response of the tunnel structure in both Case A and Case B.

In summary, the observed variations throughout the process and the results indicate that the stability of the NPCM may be influenced by boundary effects and the redistribution of forces during the fire test. Nevertheless, despite these influences, the proposed method effectively facilitates a considerably reliable understanding of the actual response of the entire structure by combining physical testing on local components with numerical simulation of structure under different fire scenarios.

4 CONCLUSION

1. A novel NPCM, which combines physical testing with numerical simulation, is proposed in this

paper. In the proposed NPCM, the numerical simulation of the entire structure forms the NS whilst the physical test of the concerned component(s) forms the PS. Different from conventional hybrid test, the NS and PS achieve two-way, real-time interaction by specifically designed NtP module and PtN module throughout the test process. This allows for the effective and feasible investigation of the thermo-mechanical behaviour of the entire tunnel structure with relatively low cost.

2. The case study has preliminarily validated the feasibility and effectiveness of the proposed NPCM, with a focus on assessing its stability and accuracy in different scenarios. Despite potential errors arising from factors including the involvement of multiple test segments, the boundary effect and the redistribution of forces, the method demonstrates remarkable stability and accuracy within 6 time steps for both Case A and Case B. When considering the displacement and stress fields of the overall structure, the final errors remain below 5% for both cases. These highlight the potential of the NPCM as a reliable method for investigating the thermo-mechanical behaviour of large tunnel structures.

Admittedly, at this stage, factors such as time delays and experimental errors have not been taken into account. In future research, further validation will be undertaken to evaluate the practical implementation of the proposed method using specifically constructed facilities.

Research on fire compartmentation of hyperscale public area in underground rail transit hub

Kaiqi Wei* & Liwei Ji

China Railway Design Corporation, Tianjin, China

Yongyu Fu & Yongzhong Deng

Shenzhen Metro Construction Group Co., Ltd, Shenzhen, China

ABSTRACT: With the rapid development of urban rail transit, more and more modern underground rail transit hubs are being planned, constructed or put into operation. The underground hub of rail transit integrates multiple rail lines and various modes of transportation. It has the characteristics of large space volume, complex structure and dense personnel, making it difficult for personnel evacuation and fire rescue in case of fire. Especially when the hub is integrated with other functions such as underground slow space, the hyperscale public area formed brings greater challenges to its own fire protection design. How to integrate the fire protection design of such buildings with safety, economy and rationality has always been a difficult problem for architects to explore. Combined with the construction practice of Huangmugang Hub, Gangxia North Hub and Yujiapu Hub, this paper summarizes the fire protection problems in the hyperscale public area of underground rail transit hub, studies and summarizes the fire protection design experience in the hyperscale public area, such as fire compartmentation, and provides new ideas for the future fire protection design of the hub.

Keywords: underground hyperscale space, rail transit hub, fire protection

1 INTRODUCTION

As the name card of the city and the region, the underground hub of rail transit can not only show the appearance of the city and create a comfortable and beautiful travel environment for passengers, but also have increasingly high requirements for the quality of architectural space, the overlap of functional organization, the convenience of transfer, and the connection with the surrounding land. While improving the quality of hub, it also brings new challenges to the traditional hub fire protection design. How to integrate safety, economy and rationality into the fire protection design of such buildings has always been the theme explored by architects. Recently completed projects such as Gangxia North Hub and Huangmugang Hub in Shenzhen and Yujiapu Hub in Tianjin have explored new fire compartmentation methods, providing new ideas and more possibilities for the fire protection design of future hubs.

2 CHARACTERISTICS AND PROBLEMS OF UNDERGROUND HUB PUBLIC AREA

2.1 *Hyper scale; high space quality requirements*

Large underground transportation hubs often integrate a number of rail lines and a variety of transportation modes into one, assuming the function of traffic conversion, while its public areas also integrate some urban functions such as slow space. In order to meet the characteristics of complex functions and huge passenger flow during peak hours, the public area of the hub is often larger than that of ordinary rail transit stations, and the space quality requirements are high.

Shenzhen Gangxiabian Hub is a comprehensive hub for the transfer of 4 lines of rail transit line 10, 11, 14 and 2, with a total floor area of 41,700 square meters in the public area of the underground three to the mezzanine ring corridor. Huangmugang Hub is a comprehensive transfer hub for Line 7, Line 14 and Line 24. The hub is integrated into the urban walking space, and the public area from the first underground

*Corresponding author: Weikaiqi@qq.com

floor to the fourth underground floor has a construction area of about 63,000 square meters. The comprehensive transportation hub of Yujiapu Station in Tianjin is a large-scale comprehensive hub integrating intercity railway, urban rail transit, bus, taxi and other transportation modes. The total construction surface of the public area connected from the first underground floor to the third underground floor is far beyond the conventional metro station.

In summary, the public area of the three hubs has exceeded the requirements of 5000 square meters of a single fire protection zone and 2.5 times of the public area of the single-line standard station hall in the current norms. Therefore, in order to meet the requirements of the overall fire safety of the building, it is particularly important to organize the fire compartmentalization method of the super large public area of the hub under the premise of being a fire protection zone.

2.2 Low safety performance; difficult evacuation

Compared with the above-ground buildings, the public space of underground transportation hubs has its own disadvantages. The traditional underground stations have tight space, poor natural lighting and ventilation conditions, poor sense of direction, and poor passenger experience. From the point of view of fire evacuation, the smoke exhaust of underground buildings is not smooth, and the “chimney effect” is easy to form at the evacuation gate during fire, which threatens the evacuation safety of personnel. Underground buildings are mostly artificial lighting, the reliability and visibility are relatively low, especially under the influence of fire smoke visibility is worse, traffic hub underground transfer area personnel flow lines criss-cross, the underground space is not strong direction is easy to make people lost in the state of emergency, resulting in serious consequences.

Figure 1. Traditional underground stations.

2.3 Atrium space cannot meet the requirements of smoke exhaust

In order to enhance the internal space effect of the building, the common design method of the hub public area is to set up an atrium on the station hall floor. The

current national standards for subway stations are generally based on the fire protection design of the station hall floor as a safe area for evacuation. However, as the hub is equipped with an atrium, the smoke exhaust and evacuation mode of the station are difficult to be completely designed according to the conventional subway station, and the design mode is not clearly stipulated in the current national fire protection technical standards. Whether the station hall floor can meet the requirements of being a safe area needs to be discussed, and it is essential to study the reasonable fire compartmentalization of the public area of the station hall.

Figure 2. Atrium space in hub.

3 FIRE COMPARTMENTALIZATION STRATEGIES

A mature research system has been formed in commercial buildings for the oversized fire safety problems in fire protection zones. At the same time, in the ground traffic buildings such as airports, high-speed rail stations and terminal passenger stations, there are more studies on the fire separation of oversized fire zones, and there are more mature solutions. Due to the limitation of function and space layout, the expansion of fire protection zone will inevitably lead to the difficulty of fire prevention and control. Therefore, what kind of fire separation plan should be adopted in the expanded underground public area to achieve the fire safety goal while ensuring the smooth traffic flow of the station hall needs to be further studied.

In the traditional design method of fire compartmentalization, the super large underground space is divided into a number of fire-resistant partitions less than 5000 square meters, and the partitions are separated by firewalls, which has a great impact on the indoor landscape and is difficult to meet the functional needs of visual transparency. If the fire shutter is used for separation, it is necessary to use a large number of large-span fire shutter. Considering the problem of low reliability exposed in the use of fire shutter and the unreliability of fire protection facilities themselves, this kind of separation is generally not used in the design of fire protection separation in large space public areas.

According to the characteristics of different buildings, Gangxiabian, Huangmugang and Yujiapu transportation hubs have created a series of new methods and new concepts of fire compartmentation, such as fire isolation zone, smoke control zone and sub-safety zone. The emergence of these new fire compartmentation strategies makes some architects' space design concepts and fire design better integrated together, using different architectural Spaces to find different fire design solutions, creating a better internal space environment.

3.1 Fire isolation zone

Shenzhen Gangxiabian Hub is a comprehensive hub for the transfer of 4 lines of rail transit line 10, 11, 14 and 2, with a total floor area of 41,700 square meters in the public area of the underground three to the mezzanine ring corridor. The design method of fire compartmentation is to use the space form of the mezzanine ring corridor in the public area of the station hall, and set up "fire isolation zone" on both sides of the mezzanine ring corridor as the interface, and divide the station hall into four fire prevention units of less than 5,000 square meters.

Figure 3. Gangxiabian Hub plan.

Fire isolation zone is a blank area with a certain width. In this area, certain measures are taken to ensure that when a fire occurs on one side, the fire will not spread to the other side of the fire isolation zone.

Figure 4. Fire isolation zone.

In order to realize the fire isolation zone as the fire compartmentation method of hyperscale public area in underground rail transit hub, in addition to the use of the natural spatial form of the mezzanine ring corridor, a series of fire protection strengthening measures have been taken.

(1) Enhanced smoke exhaust

The public area of the station hall is naturally divided into four smoke exhaust areas by the fire isolation zone. The mechanical smoke exhaust system is set up according to the area, and the stack start-up mode is adopted to ensure the smoke exhaust reliability of the station hall. Multiple smoke vents are set on both sides of the fire isolation zone, and the calculated smoke exhaust volume is taken as a strengthening measure to ensure that the smoke is effectively blocked at the isolation zone. In case of fire, open the smoke exhaust fan in the corresponding area to exhaust the smoke, and supplement the air through the sunken square and the entrance and exit.

(2) Strengthen fire sprinkler system

Strengthen the fire sprinkler system in the fire isolation zone: In general, the spray intensity is 8L/min-m², the working area is 160 square meters, and the rapid response sprinkler is used. Enhanced measures were adopted in the Fire isolation zone to increase the functional area to 260 square meters.

3.2 Smoke control zones

Huangmugang Hub is a comprehensive transfer hub for Line 7, Line 14 and Line 24. The public area from the first underground floor to the fourth underground floor has a construction area of about 63,000 square meters. The underground floor of the hub will expand the station hall floor area and integrate it into the urban slow walking space, with a construction area of 28,000 square meters. The new concept of "smoke control zone" is put forward by using its own structural spatial relationship.

Firstly, the public area of the hub platform and station hall is divided into smoke bay according to the area of no more than 2000 square meters. On the basis of smoke bay, the public zoning of the station hall is divided into several "smoke control zones" by using the suspended lane structure and other facilities, and between the smoke control zones, the suspended lane structure or the smoke baffle wall with the height of the suspended lane bottom surface are separated.

Considering the small headroom height of the projection area of the suspension lane, its smoke emission can be included in the adjacent smoke bay, and the smoke exhaust is set in the adjacent smoke bay. The smoke exhaust system of the station hall can exhaust smoke from any two adjacent smoke control zones at the same time.

When a fire occurs on the lower floor, the smoke exhaust system of the smoke control zone at the fire is

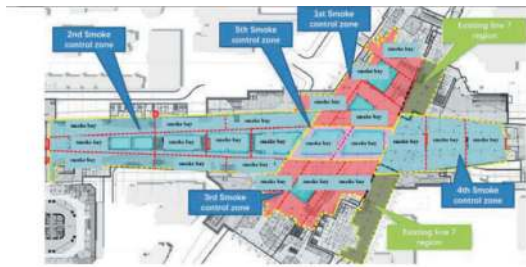

Figure 5. Huangmugang hub plan.

Figure 6. Suspended lane structure.

started. When the smoke spreads to other smoke control zones and triggers the smoke alarm, the smoke exhaust fans of the corresponding smoke control zone are stacked and started. When a fire occurs in the public area of the underground floor of rail transit, the air supply system, return exhaust fan and platform exhaust pipe in the public area of the station should be closed, the smoke exhaust fan should be opened, and the smoke should be removed by the exhaust pipe of the station hall. Fresh air flows from the entrance to the station hall, and passengers evacuate in the direction of the entrance.

In addition, Huangmugang Hub is an upper and lower overlapping station, and the fire compartmentation between platforms should be considered. The escalator from the third floor underground to the first floor underground station is separated by fire-proof glass with a fire resistance limit of 2h when it passes through the second floor underground. The escalator holes of the underground second floor connecting the underground third floor are separated by fireproof rolling curtains except the escalator entrance, and the other parts are separated by fireproof glass with a fire resistance limit of 2h. The entrance of the escalator in the middle transfer node of the third floor underground is divided by a combined double-track double-curtain with a fire resistance limit of 3h projected along the hole of the second floor underground.

3.3 Sub-safety zone

The underground transfer hall of Yujiapu Transportation Hub is mainly used as an evacuation area with less fixed fire load, and the possible combustibles are mainly passenger luggage and temporary kiosks, etc.

Figure 7. Huangmugang hub section.

The fire risk itself is relatively low, and automatic sprinkler system and smoke exhaust system are set up, so that the underground transfer hall forms a safer transition area for personnel evacuation. In case of fire, the flow of people is evacuated through the transfer hall, which is in line with people's habitual psychology and is not easy to cause chaos. Therefore, Yujiapu Hub will use the transfer hall as a "sub-safety zone".

Commercial room in the transfer hall For the transfer hall, the commercial room is the main area where the fire load is large and the electrical equipment is large. The sprinkler protection fireproof glass system is used to separate the store from the public area, and the fire alarm, automatic sprinkler and mechanical smoke exhaust system are set inside the store. A number of shops connected on the same side are separated from other shops by firewalls to form independent units. Similarly, the national railway waiting area and the transfer hall are also separated by a spray protection fire glass system.

Figure 8. Yujiapu hub plan.

The glass sprinkler system uses water cooling sprinkler head to protect the glass. When a fire occurs, the sprinkler head is heated and opened, and the cooling water is evenly sprayed to the glass, so as to effectively reduce the temperature of the glass and increase the fire resistance time. The combination of fireproof glass and glass sprinkler head is selected on the side of the shop towards the transfer hall, which does not affect the transparent building effect, and also has certain fire prevention ability in the case of fire.

The separation scheme of "fireproof glass separation and spray protection" requires setting up an independent spray cooling system to protect the glass. The spray system adopts a fast response sprinkler, the spacing of the sprinkler is not more than 2m, and the protection length can be determined according to 1.5 times the actual length of the shop with the longest glass pavement along the corridor and is not less than 30m, and the continuous spraying time is not less than 1.5h.

Through the above methods, the fire can be restricted to a certain area as far as possible, so that the impact caused by the fire can be localized and the spread of the fire can be limited.

Figure 9. Fireproof glass separation and spray protection.

4 SIMULATION ANALYSIS

In order to scientifically and comprehensively verify the fire compartmentation method mentioned above and the feasibility of safe evacuation of the entire hub, it is necessary to start from the theory of fire engineering, use the calculation simulation software to simulate and analyze the relevant scenes in the building, and finally draw a conclusion.

Firstly, the fire risk of the building should be analyzed, and a reasonable fire scene should be set according to the fire risk. Then, the parameters of fire smoke, temperature and so on are calculated by computer simulation program, and the available evacuation time (T_{ASET}) is obtained. Then, according to the set fire scenario, the corresponding personnel evacuation scenario is set up, and the personnel evacuation simulation software is used to calculate the evacuation situation under the set evacuation scenario, and the necessary evacuation time (T_{RSET}) is obtained. When $T_{ASET} > T_{RSET}$, it can be considered that the fire protection design in the building can ensure the safety of personnel evacuation and is feasible. The following takes Huangmugang Hub as examples for analysis.

Figure 10. Huangmugang hub fire simulation.

4.1 Huangmugang hub

(1) Fire scene setting

Based on the actual situation of Huangmugang Hub, such as the building structure, the distribution of various functional areas and the size of fire risk, a total of 9 fire source locations were set, and 18 fire scenarios were analyzed and determined.

(2) Evacuation scenario setting and simulation analysis

The design principle of evacuation scenario is to find out the most unfavorable situation for safe evacuation of personnel

Table 1. Fire scene setting.

Fire scene	Fire source	Scene description	Fire growth coefficient (kw/s^2)	Maximum fire heat release rate (MW)

	atrium	>1800		527		

to judge the safety of evacuation in each region.

Figure 11. Huangmugang hub smoke simulation.

(3) Summary

According to the analysis results, if the smoke exhaust system is effective, for each set fire scenario and evacuation scenario, the personnel in the building can be evacuated to the safe area through the nearby safety exit before the danger is imminent. When all smoke exhaust systems fail or one of them fails, the available evacuation time of personnel is significantly reduced, and the smoke has a significant impact on personnel evacuation.

The fire compartmentation strategy of the smoke control zone adopted by Huangmugang Hub in the large public area can form an effective separation effect in the fire stage, so as to achieve the purpose equivalent to the fire division and meet the requirements of fire safety.

5 CONCLUSION

To sum up, aiming at the fire protection problem in the public area of the station hall, the three major hubs adopt fire compartmentation measures such as fire isolation zone, smoke control zones, and sub-security zones according to the construction space composition, so as to achieve the purpose equivalent to dividing fire protection zones. Through the design of fire scene and evacuation scene, the computer software is used to simulate and verify the scheme. The results show that the new fire evacuation model of the hub public area meets the requirements of fire safety when the comprehensive fire protection measures are perfect.

From the perspective of architectural space, the above model uses different architectural Spaces to find different fire design solutions and create a better internal space environment. At the same time, these new fire compartmentation methods ensure the continuity and permeability of the public space inside the hub, better create the interior space landscape effect, truly realize the integration of design concept and fire design, and provide new ideas and more possibilities for the future fire protection design of underground hyperscale hubs.

Experimental study on the applicability of the combined tunnel ventilation system of complementary ventilation and shaft

Yunxiao Xin & Yaqiong Wang
Chang'an University, Xi'an, China

ABSTRACT: To study the applicability of the combined ventilation system of complementary ventilation and shaft, and the effect of the shaft on complementary ventilation, the tunnel model (1:10) was set up based on the principle of flow similarity. According to the change in wind speed flow field, we carried out reasonable ventilation design when a fire occurred in different parts of the tunnel. The experiment determined the four working conditions by changing the way the shaft was supplied or exhausted and the frequency of the fan. The results show that the air supply shaft can adjust the pollutant concentration, and the smoke exhaust shaft can effectively reduce the smoke exhaust distance. Therefore, a reasonable combination shaft is used in the project to meet the ventilation and smoke exhaust requirements. When a fire occurs in different parts of the tunnel, a reasonable ventilation design is required, which is more energy-efficient.

Keywords: Road tunnel, Tunnel ventilation, Model experiment, Complementary ventilation system, Shaft, Wind speed

1 INTRODUCTION

The construction of highway tunnels has a trend of long and deep development, and a certain slope, which leads to a great difference in pollutant concentration between the uphill and downhill tunnels. Zhang & Tian (2011) put forward the concept of air exchange mode, this method uses the cross channel exchange the air to meet the air quality requirements of the two tunnels. The idea of “two-tube complementary” and the proposal of “air exchange mode” had attracted wide attention. Researchers began to analyze the characteristics of complementary ventilation using different methods, such as ventilation mode, volume, scope, and economic level (Hu et al., 2011; Zhang et al., 2011). Using the method of on-site testing, Wang et al. (2014) analyzed the test data and found the function and existing problems of the ventilation channel under the twin-tube tunnel complementary ventilation mode. Xie et al. (2015) and Wang et al. (2015, 2019) established a scale model based on the similarity theory to verify the feasibility and reliability of the complementary ventilation mode. Adopted finite element simulation analysis method, Ren et al. (2018) studied the effectiveness and influencing factors of the complementary ventilation system with reference to the concentration distribution of particulate matter.

Field testing of highway tunnel ventilation system is difficult and most of them lack measured data. The method of numerical simulation is different from the actual engineering and has unreliability. Therefore,

these empirical biases require experimental analysis and physical model are established by taking into the model deflection, test site and technical feasibility. In this paper, the applicability of combined ventilation system with complementary ventilation and shaft is studied in single slope tunnel under unbalanced ventilation condition. Based on the similarity theory, we derived the proportional relationship between prototype and model, and established the scale model test (Li et al., 2011; Liu et al., 2012; Liu D et al., 2015; Zhang et al. 2015). At the same time, we increased the resistance grid can be appropriately to shorten the model length (Lai, 2015).

In view of the insufficiency of the study on the ventilation characteristics of the composite ventilation system in the above-mentioned, we established a 1:10 reduced-scale Ying'erling tunnel model according to the principle of flow similarity. In this paper, we studied the applicability of the complementary and shaft mixing ventilation methods and the effects of shaft on the complementary ventilation. At the same time, when fire occurs in different areas of the tunnel, we have given an appropriate ventilation scheme to provide the theoretical basis for subsequent optimization design.

2 TUNNEL MODEL SCALE

In a ventilation physical model, the mechanic's condition is said to be similar to those in the prototype

*Corresponding author: hapoaaa@foxmail.com

of a highway tunnel, so the three conditions of geometric similarity, motion similarity, and dynamic similarity are satisfied. These three similar conditions constitute similar mechanical phenomena in physical processes. The basics of motion similarity are geometric similarity, and the necessary premise of dynamic similarity is motion similarity. Therefore, if the two systems satisfy the dynamic similarity, the shape similarity and motion similarity of the two systems will inevitably exist.

The long-term air demand of the right tunnel is $1092 \text{ m}^3/\text{s}$, and the left is $465.54 \text{ m}^3/\text{s}$. The air demand of the two tunnels varies greatly, with a ratio of 2.35. The wind speed in the right line tunnel exceeds 10 m/s . According to the engineering situation, a hybrid ventilation system combined with complementary ventilation with a shaft is proposed. The hybrid ventilation system includes an uphill tunnel, downhill tunnel, air interchange cross-passage, ventilation shaft, etc. The hybrid ventilation system is based on longitudinal ventilation, and the tunnels are connected into a system through two air interchange cross-passages. The abundant fresh air uphill of the downhill tunnel is transported to the uphill tunnel through the air interchange cross-passage to increase the ventilation in the uphill tunnel. The dirty air of the uphill tunnel can transport to the downhill tunnel through the air interchange cross-passage to fully use the surplus air volume of the downhill tunnel to dilute the pollutants and reduce the contaminants at the wind speed in the uphill tunnel. According to the Ying'erling tunnel's air demand characteristics and the disaster prevention and rescue requirements, the complementary ventilation technology meets the daily operation ventilation. The smoke exhaust shaft meets the specification requirements.

Considering the deflection of the model, test site, and technical feasibility, the final ratio of the model is 1:10, including two main tunnels, two complementary cross channels, and one shaft. The main geometric dimensions of the prototype and model are reported in Table 1, and the model diagram is shown in Figure 1.

Table 1. Main geometric dimensions of the prototype and model of Ying'erling tunnel (Units: m).

Item		Prototype	Model
General section	Section height	9.83	0.983
	Section width	10.91	0.109
	Equivalent diameter	9.72	0.972
Ventilation section	Section height	9.83	0.983
	Section width	5.00	0.500
	Section area	44.90	0.449
	Equivalent diameter	6.53	0.653

Figure 1. The schematic of ventilation tests system.

In the ventilation system of highway tunnels, the airflow is in a viscous flow state, and the automation simulation of the flow process is one of its main characteristics. After determining the similarity criterion, the values change in a certain range without destroying the similarity between the prototype and the model in the process of automatic simulation. When the Reynolds number $Re < 2320$, $\lambda = 64/Re$, the variation of λ is only affected by Re . In this case, the viscous fluid of incompressibility can be defined as the first self-mode region of pressurized flow.

The Reynolds number critical value of the second self-model area of the physical model system can be calculated according to the theory of self-model area. Experimental studies were conducted by selecting the main tunnel model with a section of normal ventilation. The equivalent diameter is 0.972 m . The air temperature in the laboratory is 20° , and the air density is 1.2047 kg/m^3 . Based on the above conditions, the aerodynamic viscosity can be calculated. $\nu = 1.56 \times 10^{-5} \text{ m}^2/\text{s}$, so the critical Reynolds number in the second self-model region can also be calculated $Re = 2.13 \times 10^5$. The critical wind speed entering the second self-model region is calculated in Eq.(1).

$$V = Re \cdot \nu / D = 3.42 \text{ m/s} \quad (1)$$

3 EXPERIMENTAL DESIGN

The Ying'erling tunnel is 5.6 km long. Considering the technical feasibility, the scale of the test site and other factors, the model ratio is 1:10, and the test model is 560 m long. Taking into account the economic and difficult degree of instrument position adjustment, the equivalent friction principle is adopted to establish resistance grids in the appropriate part. The resistance grid can replace the length of the tunnel, thus shortening the length of the model. In each tunnel, 14 resistance grids are added. The resistance grid spacing should not be less than $3D$ (D is the equivalent diameter) so that it is 3.6 m . The final model length is 77 m . Each resistance grid is equivalent to 34.5 m . In the tunnel, the zone between two ventilation complementary cross channels is called a short track, which is

10 m long in the model. The model and fan fit together as a whole through a flexible connection. The layout of the model is shown in Figure 2. Through a Y-shaped structure, the shaft can supply and exhaust air to two main tunnels. The length of the ventilation crossover between the two main tunnel is 3m, and the axis of the complementary cross channel is perpendicular to the axis of the main tunnel. Each model segment is connected by a stainless-steel beam.

Figure 2. Physical model overall layout.

In order to meet the ventilation requirement in the model test, 5 fans are required, three of which were 3 axial fans and 2 centrifugal fans. The power equipment in the cross channel is an SD64-11 series axial fan, and one SDS-112K series axial fan is used in the shaft. At the same time, centrifugal fans are at the entrance of two tunnel models to simulate the natural wind and traffic wind in the tunnel.

The test signal is converted into an electrical signal by the test element. The converter can be connected to the adjustment adapter through a shielded wire, and then connected to the indicator to read the test data. The simulation process of tunnel ventilation physical model test is dynamic, and the section wind speed and wind pressure are constantly changing. Therefore, timely and accurate data collection is very important. The experiment uses PCI 6224 data acquisition cards developed by Ni company of the United States and its supporting development platform LabVIEW (LabVIEW). The system realizes the input, data acquisition, real-time display, storage, playback, and result report output of the test system.

Figure 3. Model test section.

In order to observe the change in wind speed, and control the spread distance of the fire smoke, the tunnel is divided into six parts. We measured 10 representative sections, and the test section model and layout are shown in Figure 3. During the test, the centrifugal fan power remained unchanged, and the natural wind was simulated at an average wind speed of 2 m/s. The 2#, 3#, and 5# axial flow fans are adjusted, and the frequency variation of the axial fan is: 20Hz, 25Hz, 30Hz, 35Hz, 40Hz, 45Hz.

Figure 4(a). Uphill tunnel shafts air supply.

Figure 4(b). Downhill tunnel shafts air supply.

Figure 4(c). Uphill tunnel shafts air exhaust.

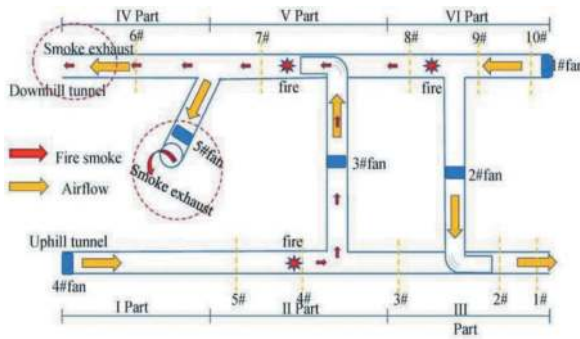

Figure 4(d). Downhill tunnel shafts air exhaust.

The experiment is divided into four operating conditions: the first is uphill tunnel shaft air supply (Figure 4(a)); the second is downhill tunnel shaft air supply (Figure 4(b)); the third is uphill tunnel shaft air exhaust (Figure 4(c)); the fourth is downhill tunnel shaft air exhaust (Figure 4(d)). Each condition is separated into six conditions: 2#axis fan frequency of 20 Hz, 3#axis flow fan at 30 Hz, and the frequency of the 5#axis fan ran from 20 Hz to 45 Hz. So there are a total of 24 small working conditions, and the typical data of each condition is compared and analyzed. According to the change of wind speed field under different conditions, reasonable ventilation design is carried out when different tunnel parts are on fire. The design layout of the ventilation test system is shown in Figure 4.

4 RESULTS AND DISCUSSION

4.1 The uphill tunnel shaft air supply

Figure 5 shows that with 5 # fans frequency raised, the variation trend of wind speed of each section is identical. The wind speed of the uphill tunnel increases first, then decreases, and then rises gradually along the tunnel direction. Figure 6 shows that with 5 # fans frequency is raised, the static pressure of each section increases, and the trend is almost identical.

The wind speeds in the 4# and 5# Section increases, while the 3# Section decreases due to the increase in air volume in the cross channel, indicating that the pollutants migrated from the uphill to the downhill. The wind speed of the 1# and 2# section increases, which is to rapidly discharge the pollutants from the outlet of the uphill tunnel. The wind speed of the downhill tunnel increases first and then decreases, then rises gradually and then decreases along the tunnel. The wind speed of the 9# and 10# Sections increases, while the 8# Section decreases due to the increase in air volume in the cross channel,

indicating that the pollutants migrated from the downhill to the uphill. The wind speed of the 6# and 7# section increases, which is to rapidly discharge the pollutants from the outlet of the downhill tunnel.

Figure 5(a). Wind speed of uphill tunnel.

Figure 5(b). Wind speed of downhill tunnel.

Figure 6(a). Static pressure of uphill tunnel.

Figure 6(b). Static pressure of downhill tunnel.

Figure 7(b). Wind speed of downhill tunnel.

The wind speed of the 4# section is 3.495 m/s, and the 3# section is 1.372 m/s. The wind speed of the 4# section is higher than that of the 3# section, which effectively prevents short-track backflow. When a fire occurs in Sections II and III, the difference of wind speed ensures that the fire smoke spreads along the uphill tunnel and is discharged from the outlet quickly.

The static pressure of the 8# section is 61.562 Pa, and the 9# section is 62.706 Pa. The pressure difference between the two sections is small. When the fire occurs in Section VI, in order to shorten the smoke exhaust distance, fire smoke enters the uphill tunnel from the cross channel under the action of 2# fans. Fire smoke will not continue to spread to the downhill tunnel, but will be discharged from the uphill tunnel outlet.

4.2 The downhill tunnel shaft air supply

Figure 7 shows that with 5 # fans frequency is raised, the wind speed of each section increases, and the variation trend is identical. The shaft air supply increases the air volume and reduces the concentration of pollutants in the tunnel; the increase of air speed effectively discharges pollutants. The shaft can coordinate with the complementary cross channel to regulate the concentration of pollutants, which can be used in normal operation.

Figure 7(a). Wind speed of uphill tunnel.

Figure 8(a). Static pressure of uphill tunnel.

Figure 8(b). Static pressure of downhill tunnel.

Figure 8 shows that with 5 # fans frequency is raised, the static pressure of each section increases, and the variation trend is identical. When the fire occurs in Section IV, the fire smoke discharges from the down tunnel outlet as soon as possible. The static pressure of the 7# section is 31.223Pa, and the 6# section is 2.072 Pa. The static pressure of the 7# section is

greater than the 6# section, which ensures that the fire smoke spreads along the downhill tunnel. The wind speed in the 6# and 7# section increases, ensuring that the fire smoke is quickly discharged from the outlet.

4.3 The uphill tunnel shaft air exhaust

Figure 9 shows that with 5 # fans frequency is raised, the variation trend of the wind speed is identical. The wind speed of the uphill tunnel increases first along the tunnel direction, then reduces, and then rises gradually. The wind speed of the downhill tunnel decreases along the tunnel direction, then rises, and then reduces. The wind speed of the 3# section is 1.364m/s, the 4# section is 3.711m/s, and the 7# section is 3.185m/s. The wind speed from the 4# to 3# section decreases rapidly, and the wind speed of the 7# section increases. This explains that the air volume enters the downhill tunnel through the cross channel, which is beneficial to the adjustment of the pollutant concentration of the downhill tunnel.

Figure 9(a). Wind speed of uphill tunnel.

Figure 9(b). Wind speed of downhill tunnel.

Figure 10 shows that with 5 # fans frequency is raised, the static pressure of each section decreases, and the variation trend is identical. When the fire occurs in section I, the fire smoke is discharged from the shaft as soon as possible. The static pressure of the 5# section is 3.498 Pa, and the 4# section is 3.711 Pa. The static pressure of the 4# section is greater than the 5# section, but the change is very small, and the speeds of the two sections are similar. The above conditions ensure that fire smoke does not spread along the uphill tunnel. Under the action of the 5# shaft, fire smoke is quickly discharged from the shaft, which effectively shortens the distance of smoke exhaust.

Figure 10(a). Static pressure of uphill tunnel.

Figure 10(b). Static pressure of downhill tunnel.

4.4 The downhill tunnel shaft air exhaust

Figure 11 shows that with 5 # fans frequency is raised, the wind speed in the uphill tunnel decreases, and in the downhill tunnel is stable, and the variation trend is identical. The wind speed of the uphill tunnel increases first along the tunnel direction, then reduces, and then rises gradually. The wind speed of the downhill tunnel reduces along the tunnel direction, then rises, and then decreases.

Figure 11(a). Wind speed of uphill tunnel.

Figure 12(b). Static pressure of downhill tunnel.

Figure 11(b). Wind speed of downhill tunnel.

Figure 12(a). Static pressure of uphill tunnel.

Figure 12 shows that with 5 # fans frequency is raised, the static pressure of each section decreases, and the variation trend is identical. When the fire occurs in Section II, the fire smoke enters the downhill tunnel and is discharged from the outlet. The static pressure of the 4# section is 30.757Pa, and the 3# section is 56.814Pa. The static pressure of the 4# section is less than the 3# section, which ensures that

the fire smoke will not spread along the uphill tunnel. Under the action of 3# fans, the fire smoke enters the downhill tunnel along the cross channel and is discharged from the outlet quickly. When the fire occurs in V and VI sections, the fire smoke is discharged from the shaft under the action of the 5# fan, which effectively shortens the smoke exhaust distance.

5 CONCLUSIONS

1. The wind speed of 3# Section decreases due to the increase in air volume in the cross channel, indicating that the pollutants migrated from the uphill to the downhill. The wind speed of 1# and 2# section increases, which is to rapidly discharge the pollutants from the outlet of the uphill tunnel. The wind speed of 8# Section decreases owing to the increase in air volume in the cross channel, indicating that the pollutants migrated from the downhill to the uphill. The wind speed of the 6# and 7# section increases, which is to rapidly discharge the pollutants from the outlet of the downhill tunnel.
2. The air supply shaft can regulate the concentration of pollutants by increasing the air volume and wind speed in the tunnel so that pollutants can be quickly removed from the tunnel. The air exhaust shaft can shorten the distance of smoke exhaust, and remove the fire smoke effectively. So, the use of the combined shaft can not only meet the ventilation needs and fire smoke emission requirements but be more energy-saving and cost-effective.
3. When a fire occurs in the I part, the fire smoke is quickly discharged from the shaft when the uphill shaft exhausts. When a fire occurs in the II and III parts, the fire smoke is quickly discharged from the uphill outlet when the uphill air supply. To shorten the smoke distance, the downhill shaft exhaust, the fire smoke that occurs in II enters the downhill tunnel through the cross channel and is discharged from the outlet. When a fire occurs in the IV part, the fire smoke is quickly discharged

from the downhill outlet when the downhill shaft exhausts. When a fire occurs in the V and VI parts, the fire smoke is quickly discharged from the shaft when the downhill air exhausts. To shorten the smoke distance, the uphill shaft supply, the fire smoke that occurs in V enters the uphill tunnel through the cross channel and is discharged from the outlet.

ABSTRACT: The frost-resistant fortification length of tunnels in cold areas is highly correlated with experience. Currently, the determination of fortification length is mainly based on engineering analogies, which is not fully combined with the distribution law of temperature field inside the tunnel. By selecting 2 typical tunnel sites with different lengths and slope conditions in the railway projects operating in high latitude and severe cold areas, continuous testing of the longitudinal temperature field distribution in the tunnel was carried out. The temperature field distribution law along the longitudinal direction in the cold areas tunnel was analyzed, and the control equation for the temperature field distribution along the longitudinal direction in the cold areas tunnel was obtained by fitting the curve. Combined with the engineering practice, the temperature standard for frost resistance protection inside the tunnel was verified. The research results show that: 1) The meteorological characteristic parameter values used in the anti-freezing design of tunnels in cold areas should be collected and analyzed based on meteorological statistical data from the area where the tunnel is located for at least 30 years. 2) The relative height difference between the both ends of the tunnel caused by the longitudinal slope of the line is one of the main factors affecting the temperature field distribution inside the tunnel in cold regions. 3) The fifth-order polynomial parabolic equation obtained by fitting the longitudinal distribution curve of the average temperature inside the tunnel in January can be used as the control curve equation for the anti-freezing design of the tunnels in cold regions, with the constant term corrected by the average temperature of the coldest month in the region. 4) The length of anti-freezing fortification for the tunnel structure in cold area can be determined according to the temperature inside the tunnel not higher than $-15.2\text{ }^{\circ}\text{C}$, while the fortification length of the thermal insulation drainage and anti-freezing system can be determined according to the temperature inside the tunnel not higher than $-13.8\text{ }^{\circ}\text{C}$.

1 INTRODUCTION

Unlike the climate in mild areas, cold regions generally experience large changes in environmental temperature every year. The summer environmental temperature may be above freezing for a long time, while the winter environmental temperature may be below freezing for a long time. This climate change has adverse effects on the tunnel in cold regions, mainly manifested as follows: during the cold season, the anti-drainage system of the railway tunnel needs to consider the possibility of freezing and blockage in the drainage system under continuous negative temperature environment conditions, which is manifested as ice hanging on the lining wall or contact network, and ice accumulation on the roadbed caused by

freezing of the drainage ditch. In addition to considering the temperature stress caused by large temperature differences in the tunnel structure, when the tunnel is in a frost heave sensitive formation and the moisture content of the formation exceeds a certain range, or there are local cavities behind the lining and water accumulation inside the cavities, problems such as lining surface cracking, peeling, and falling off occur, which is not conducive to the safe operation of the tunnel. Because of the waterproof and drainage system and structure inside the tunnel in cold regions are greatly affected by the temperature changes inside the tunnel, it is necessary to take targeted measures for structural frost resistance and anti-freezing engineering measures for the waterproof and drainage system based on the distribution and changes of the

*Corresponding author: ycxyxcyx007@sina.cn

longitudinal temperature field inside the tunnel according to local conditions.

Relevant engineering technicians and scholars at home and abroad have continuous research on the distribution law of temperature field inside tunnels in cold regions, and have obtained a series of research results. Zhang et al.^[1] studied the influence of thermal potential difference and static pressure difference at the entrance of a tunnel on the temperature field changes in cold regions through measured data and numerical analysis. Sun et al.^{[2][4]} conducted research on the distribution law of temperature field and buried depth of drainage ditches in cold region tunnels under the condition of thermal fluid solid coupling effect, exploring the influence of initial ground temperature and thermal conductivity of surrounding rock on the distribution of temperature field in cold region tunnels. Li et al.^[5] assessed the influence of thermal parameters of surrounding rocks, such as thermal conductivity, specific heat capacity, and freezing temperature, on the radial temperature distribution within tunnels in cold regions. Yu et al.^[6] derived a heat transfer model for the airflow temperature field of wind flow in tunnels in cold regions, and explored the effect of ventilation and surrounding rock conditions on the distribution of temperature field within tunnels in cold regions. Guo et al.^[7] analyzed the influence and patterns of tunnel length, air temperature, and wind speed on the longitudinal temperature field distribution of tunnels in cold regions through indoor model test.

The summary of the technical research results conducted on the temperature field of tunnels in cold regions can be roughly divided into the following two categories: one mainly combines the relevant theories of heat transfer and derives the temperature field distribution control equation of tunnels in cold regions based on several assumptions, while the other mainly combines the numerical simulation analysis and is supplemented by a small number of on-site temperature data validation to carry out research on the distribution law of temperature field in cold zone tunnels. Due to a series of boundary conditions or assumptions set during the above studies, the conclusions have greater limitations, which are often difficult to fully apply when applied to specific projects of tunnels in cold regions.

Aiming at the above problems, this paper proposes to carry out continuous testing of the longitudinal temperature field distribution inside the tunnel by selecting 2 typical tunnels with different lengths and slopes in high-latitude frigid region railway projects operating in high latitude and severe cold region through research, analysis, and other methods. analyze the temperature field along the longitudinal distribution pattern inside the tunnels in cold regions by measuring the temperature data inside the tunnels. Get the control equation for the longitudinal distribution of the temperature field inside the tunnel in cold region by fitting the curve . The temperature standard for the anti-freezing defense was verified by combining with the engineering practice. It is expected to provide valuable reference for anti-freezing defense of tunnels in cold regions.

2 ANALYSIS OF FACTORS INFLUENCING THE TEMPERATURE FIELD DISTRIBUTION INSIDE TUNNELS

Engineering practice has proved that the temperature field inside the tunnels in cold regions is mainly affected by the combined effects of changes in the surrounding rock temperature field (including the groundwater temperature field) and regional environmental temperature changes, etc. The surrounding rock temperature field is generally in a relatively stable state for a certain time after tunnel excavation, while the ambient temperature in cold region generally cyclical changes over time, which is the main influence of the temperature field changes inside the tunnel. Moreover, this influence is caused by external natural wind flowing along the longitudinal direction of the tunnel, resulting in an overpressure difference in the airflow pressure at the entrance. The thermal potential difference formed by the temperature difference inside and outside the tunnel is superimposed and passes through the tunnel in the form of wind,, heat exchange occurs along the longitudinal and radial directions respectively, thereby changing the temperature field inside the tunnel.

2.1 *Hyperstatic differential pressure effect*

When the height difference between the two ends of the tunnel is not significant, it is usually considered that the air density is a constant. When the atmosphere in the vicinity of the tunnel is at a static state, the air pressure difference formed by the height difference between the two ends of the tunnel can be called the static pressure difference. However, if there is a natural wind outside the tunnel, the airflow pressure difference at the both ends of the tunnel caused by the natural wind direction caused by is called the super-static pressure difference P_{ss} , and its calculation is shown in equation (1).

$$P_{ss} = p_1 - p_2 - \rho gh \quad (1)$$

In the formula: P_1 and P_2 are the air pressure at the both ends of the tunnel, Pa; ρ is the average air density at the both ends of the tunnel, kg/m^3 ; h is the relative height difference at the both ends of the tunnel, m.

2.2 *The role of thermal potential difference*

The measured data shows that there is generally a significant temperature difference between the inside and outside of tunnels in cold regions. In winter, the temperature inside of the tunnel is generally significantly higher than the ambient temperature outside of the tunnel. At this time, the air outside the tunnel enters the tunnel from the low entrance, pushing the air inside the tunnel out from the high entrance, resulting in a significant buoyancy effect. In summer, the temperature inside the tunnel is generally

significantly lower than the ambient temperature outside the tunnel, which is exactly the opposite of the cold season. The air inside the tunnel flows from the high entrance end to the low entrance and pushes out of the tunnel, forming a sinking effect.

When the temperature changes, the air density will also change: as the temperature rises, soluble gases fully diffuse, the ambient air pressure decreases, and the density decreases within a certain range. This kind of airflow pressure difference caused by the obvious difference between the ambient temperature inside and outside the tunnel, as well as the relative height difference at the tunnel entrance, can be called as the thermal potential difference. According to the hydrostatic method, the thermal potential difference P_{hot} in the tunnel can be calculated according to equation (2).

$$P_{hot} = \left(\frac{\rho_1 - \rho_2}{2} - \rho \right) gh \quad (2)$$

In the formula: ρ_1 and ρ_2 are the air density at both ends of the tunnel, kg/m^3 ; ρ is the air density at the highest air temperature point in the tunnel, kg/m^3 ; h is the relevant height difference between the both ends of the tunnel, m.

It should be noted that both the atmospheric superstatic pressure difference and thermal potential difference between the two tunnel entrances are related to the height difference of the tunnel entrances, and change in real-time with the meteorological conditions in the region where the tunnel is located, which also leads to changes in the temperature field inside the tunnel in the cold region.

3 SELECTION OF TESTING SITES

Due to the weak solar radiation in the high latitude areas of the northern hemisphere during the winter half of the year, the surface of the Eurasian continent rapidly cooled, and the high latitude areas in Northeast China are affected by the accumulation of cold air in favorable terrain areas such as the Mongolian Plateau and eastern Siberia, forming the main source of cold air in China. In the winter half year, westerly or northwest winds prevail, forming a dry, cold, snowy, and low-temperature climate environment

that lasts for about half a year, making it the coldest natural region in China. The Harbin-Mudanjiang high-speed railway in Heilongjiang Province, located in the northernmost part of China, is generally oriented in a west to east direction, which is basically consistent with the main winter wind direction in the region. The project is distributed in multiple tunnels of different lengths and slopes, which is conducive to conducting temperature tests inside the tunnel and comparing and analyzing the influence of different longitudinal slopes on the distribution of temperature fields inside railway tunnels of different lengths.

3.1 Project overview

The Harbin-Mudanjiang Railway connects Harbin and Mudanjiang from west to east, the line standard is a high-speed railway with a speed of 250km/h, and the effective area of clearance in the tunnel section is 92m^2 . There are a total of 39 double-track tunnels along the line, with a total length of 68.505km. The longest tunnel is the Hufengling Tunnel, with a length of 8.755km. The projects operate EMUs, and during the test period, there are 32 pairs of trains on the Harbin-Mudanjiang Railway.

Combined with the tunnel characteristics of the projects, the Mabei, and Hufengling tunnels of the Harbin-Mudanjiang Railway was selected as typical tunnel sites to conduct longitudinal temperature distribution testing research inside the tunnels. The basic overview of the testing sites is shown in Table 1.

3.2 Overview of work sites

3.2.1 Mabei Tunnel

The Mabei Tunnel of Harbin- Mudanjiang Railway is located in Hengdaohezi Town, Hailin City, Heilongjiang Province, with a total length of 2202 m. The average temperature of the coldest month over the year in the tunnel area is $-17.2\text{ }^\circ\text{C}$, and the maximum freezing depth of the soil is 1.91 m. The plan and longitudinal section of the tunnel are shown in Figure 1.

3.2.2 Hufengling Tunnel

The Hufengling Tunnel OF Harbin-Mudanjiang Railway is located in Hengdaohezi Town, Hailin City,

Table 1. Overview of temperature testing sites in the tunnel of railways operating in cold regions.

Tunnel Name	Design speed	The name of the railway line	Tunnel length/m	Tunnel alignment	Maximum burial depth/m	The main winter wind direction	Longitudinal Slope Setting	The difference in height of hole/m
Mabei	250km	Harbin-Mudanjiang	2202	Northwest to southeast	141	West, Northwest	Uphill with the wind	16
Hufengling	250km	Harbin-Mudanjiang	8755	Northwest to southeast	275	West, Northwest	Uphill with the wind	103

Note: “-” in the table indicates that the tunnel inlet is higher than the outlet.

Figure 1. Schematic diagram of the plan and longitudinal section elements of the Mabei Tunnel on Harbin-Mudanjiang railway.

Figure 2. Schematic diagram of the plan and longitudinal section elements of Hufengling Tunnel on Harbin-Mudanjiang railway.

Heilongjiang Province, with a total length of 8755 m. The average temperature of the coldest month of the year in the tunnel area is $-17.2\text{ }^{\circ}\text{C}$, and the maximum freezing depth of the soil is 1.91 m. The plan and longitudinal section of the tunnel are shown in Figure 2.

4 TEMPERATURE TESTING PROGRAM IN THE TUNNEL

Due to the characteristics of the Harbin-Mudanjiang Railway, have the characteristics of operating EMUs, the line adopts the characteristics of fully enclosed, large machine maintenance and comprehensive maintenance, it is required that the temperature testing instrument in the tunnel has the function of automatically recording data continuously at certain interval. In this test, the Testo174T temperature recorder is selected, which has the ability to automatically record real-time temperature testing data every 30 minutes and store 16,000 sets of data, ensure that the test duration is not less than one winter.

Considering that the tunnel is a linear structure buried underground, the longitudinal test section can start from the first inspection well at the tunnel entrance, and a temperature test section can be laid at every 16 inspection wells (about 480m long) longitudinally.

In addition, in order to ensure the safety of the high-speed EMU operating in the test site, temperature testing instrument can be placed in the communication signal cable trough under certain waterproof measures.

5 ANALYSIS OF TEMPERATURE TEST DATA

5.1 Analysis of the longitudinal distribution of the temperature field

Combined with the specific situation of the 2 railway tunnels selected for testing and operation, continuous tests were conducted on the longitudinal distribution of the temperature fields in the 2 tunnels during the winter seasons of 2018~2019. Considering the randomness of temperature changes and the current situation in the field of civil engineering, where the climate environment is generally divided based on the average temperature of the coldest month in the region. After obtaining the effective test data for each test section along the longitudinal distribution of the 2 tunnels, the monthly average temperature of each measurement point was determined according to the arithmetic mean, and the longitudinal distribution curve of the monthly average temperature inside the 2 tunnels were plotted as shown in Figure 2.

Meanwhile, the statistical analysis of the average temperature of the coldest month of the cumulative year in the area where the 2 tunnels are located in comparison with the average temperature of the coldest month (January) of the actual measurement period is shown in Table 2.

From the analysis of Table 2 and Figure 3, it can be concluded that the temperature inside the tunnel of the railway tunnel operating in the high-latitude cold region has the following distribution pattern along the longitudinal direction:

- 1) Because of the regional meteorological law is obtained through probability and statistical

Table 2. Comparison of the average temperature of the coldest month during the survey period and the measured coldest month.

Tunnel Name	Measured average temperature of the coldest month/°C	Average temperature of the coldest month of the year/°C
Mabei	-9.07	-17.2
Hufengling	-11.69	-17.2

analysis of historical meteorological data, it is generally required that the meteorological statistical period is long enough to obtain relatively stable and representative meteorological characteristic parameter values. Therefore, currently, WMO generally stipulates 30 years as the shortest period for obtaining meteorological characteristic values. As shown in Table 2, the average temperature in January at each measuring point in the 2 typical tunnels during the test period is significantly lower than the average temperature in the coldest month (January) analyzed by the collected meteorological data in the survey period. This indicates that conducting short-period meteorological data testing and analysis of

meteorological characteristic parameters near the tunnel site area cannot be directly used to guide the anti-freezing design of the tunnel. Instead, regional historical and multiyear meteorological statistical data should be used to analyze meteorological characteristic parameters.

- 2) According to the meteorological statistical data, December to February of the following year is the coldest season in mainland China, with January being the coldest month on the mainland. At this time, the average temperature distribution in the tunnel in the real survey and mapping tunnel in December, January and February along the longitudinal distribution of the three curves of the change law is basically the same, only showing up and down fluctuations. Among them, the temperature field distribution curve in the tunnel is basically at the lowest position in January, which can be used as the control curve for tunnel anti-freezing design.
- 3) In the cold season, the highest temperature point in the 2 tunnels appeared on the side of the high-end entrance, while the negative temperature section of the entrance at a relatively low-end of the tunnel was significantly longer than that at a relatively high-end of the tunnel, showing

Figure 3. Measured monthly average air temperatures in the 2 operational cold tunnels along the longitudinal distribution curve.

a obvious correlation with the longitudinal slope distribution of the line. The main reasons for the problem are related to the air pressure difference (superstatic pressure difference) caused by the height difference between the two ends of the tunnel, as well as the thermal potential difference caused by the temperature difference between the inside and outside of the tunnel during the cold season. This causes natural wind sources to continuously blow of from the relatively low-end openings to the relatively high-end openings, resulting in a chimney like effect. As a result, the temperature inside the tunnels, which is a longer range from the relatively low-end openings, is more affected by the ambient temperature outside the tunnel. Therefore, the relative height difference between the tunnel at both ends caused by the longitudinal slope of the line is one of the main factors affecting the distribution of temperature field in the tunnel in the cold region.

5.2 Control equation for temperature field distribution along the longitudinal direction

The above analysis shows that the temperature distribution curve inside the tunnel in the cold regions

obtained in January can be used as the control curve for the anti-freezing design of the tunnel in the cold regions. Moreover, the relative height difference between the both ends of tunnel caused by the longitudinal slope of the line is the dominant factor affecting the distribution pattern of the longitudinal temperature field inside the tunnel in the cold regions. In order to ensure the uniformity of the longitudinal distribution pattern of the temperature inside the tunnels in the cold area, and to overcome the influence of the relative height difference at the tunnel entrance on the longitudinal distribution of the temperature inside the tunnel, the longitudinal distribution curves of the average temperature in the tunnel in January were drawn according to the opening from low to high, and the curve was plotted as shown in Figure 4.

After regression analysis on the longitudinal distribution curves of the average temperature in January in 2 typical tunnels, it was determined that the polynomial Equation (3) could be used for curve fitting, and it has a high correlation coefficient. After fitting, the elements of the longitudinal distribution curve of the average temperature in January in each measured tunnel are shown in Table 3.

$$t_x = t_0 + a_1x + a_2x^2 + a_3x^3 + a_4x^4 + a_5x^5 \quad (3)$$

Figure 4. Schematic diagram of the longitudinal distribution curve and regression curve of the measured January average air temperature in the 2 operating cold tunnels.

Table 3. List of elements of longitudinal distribution curves of air temperature in January in railway tunnels of different lengths in high-latitude cold regions.

Curve element						Coefficient of complex correlation R_2	Tunnel length/m	Tunnel name
$t_0/^\circ\text{C}$	a_1	a_2	a_3	a_4	a_5			
-9.02276	-5.617E-04	2.711E-05	-4.330E-08	2.664E-11	-5.706E-15	0.9893	2202	Mabei
-10.58947	6.273E-04	2.071E-06	-8.205E-10	1.223E-13	-6.375E-18	0.9066	8755	Hufengling

In the formula: t_x - temperature of the tunnel at xm from the low-end opening, $^\circ\text{C}$; t_0 - constant, $^\circ\text{C}$; $a_1 - a_5$ - are constants, determined by the measured data plotting curve fitting, and the tunnel is located in the geographic location, the relative height difference of the entrance, the flat longitudinal line type, the relationship between the dominant wind direction and the line direction, the enclosing rock geothermal field, the seepage field, and the role of the train piston winds and other factors related to the temperature, $^\circ\text{C}$.

According to the analysis in Tables 2 and 3, it can be seen that the constant t_0 in the curve is the average temperature measured at the tunnel entrance in January. As shown in the previous analysis, the results of short-cycle meteorological data testing and analysis in the vicinity of the tunnel site are unstable and unrepresentative, which can not be used to guide the anti-freezing design of tunnels directly. Instead, multi-year statistical meteorological parameters should be used.

Therefore, the constant t_0 can collect the meteorological data of cities near the tunnel site area for the past 30 years, and the statistical analysis shows that the average temperature of the coldest month in the tunnel site area over the years is used as a meteorological characteristic parameter to modify the derivative into Equation (1). The temperature inside the tunnel, which is used as the anti-freezing engineering measures and defense length for long tunnels in cold regions, is controlled along the longitudinal direction using Equation (4). The temperature inside the tunnel is controlled along the longitudinal direction, as shown in Figure 5, and the curve elements are shown in Table 4.

$$t_x = t_a + a_1x + a_2x^2 + a_3x^3 + a_4x^4 + a_5x^5 \quad (4)$$

6 ENGINEERING APPLICATIONS

In order to adapt the harsh climate environment in cold regions, achieve energy conservation, environmental protection and facilitate maintenance, the tunnels in the cold regions should adopt targeted anti-freezing design in combination with the distribution law of temperature field inside the tunnel. The key technology mainly adopts anti-freezing engineering measures within a certain range of the tunnel entrance.

6.1 Typical Tunnel Anti-Freezing Design and Operation Practices

6.1.1 Anti-freezing measures for insulation and drainage systems

The main insulation, drainage, and antifreeze measures for the 2 typical tunnels are detailed in Table 5.

6.1.2 Structural anti-freeze measures

The main structural frost protection measures for 2 typical tunnels are detailed in Table 6.

6.1.3 Operational practices

Since the opening of Harbin-Mudanjiang Railway on December 25, 2018, Mabei, and Hufengling tunnels have been in good operating condition, except for

Figure 5. Schematic diagram of temperature control curves along the longitudinal direction in the 2 operating cold-zone tunnel caves.

-17.2	6.273E-04	2.071E-06	-8.205E-10	1.223E-13	-6.375E-18	0.9066	8755	Hufengling

Table 5. List of major insulation and drainage measures against freezing in 2 typical tunnels.

Tunnel Name	Center gully	Drainage system behind the lining
Mabei	Installation of deep buried ditch in central with an inner diameter of 80cm through the length of the tunnel	Circumferential $\phi 80$ perforated corrugated water permeable blind pipe + longitudinal $\phi 100$ perforated corrugated water permeable blind pipe + side wall parts every 12m ~ 16m a width \times depth of 0.5m \times 0.5m ring gravel blind trench
Hufengling	The inlet and outlet of each 1500m range set up the center of the inner diameter of 80cm deep buried ditch; the rest of the lots set up the use of thermal insulation groove wrapped, the inner diameter of 60cm thermal insulation center ditch	Circumferential $\phi 80$ perforated corrugated permeable blind pipe + longitudinal $\phi 100$ perforated corrugated permeable blind pipe + inlet and outlet of each 1500m range of the side wall parts every 12m ~ 16m, a width \times depth of 0.5m \times 0.5m circumferential gravel blind ditch.

Table 6. List of main structural frost protection measures in 2 typical tunnels.

Tunnel Name	Lining frost protection	Lining Temperature Expansion Joints	Radial grouting	Structural insulation
Mabei	The lining of the range of 1km from the entrance of the tunnel is C35 reinforced concrete	It is set up in a range of 1km from the tunnel entrance, and which is set up every 100m longitudinally, and the width of the joint is 1.5cm	The III~V grade surrounding rock section is set 1km away from the entrance, and the radial reinforcement arch wall excavation contour line is within 3m range	The tunnel opening and the tunnel body are located in the shallow buried soil and broken stratum section, and the insulation layer of 5cm thick rigid polyurethane insulation board is sandwiched between the initial support of the arch wall and the secondary lining by a double-layer waterproof board

a small number of diseases such as leakage, water and ice. which shows that the anti-freezing measures of the tunnel taken by the design for the meteorological characteristic parameters in the region are basically reasonable.

6.2 Verification of frost protection design with measured temperature field

Based on the above analysis, the temperature distribution control equation along the longitudinal direction in 2 typical tunnel openings is determined. Based on the above analysis, the temperature distribution control equation along the longitudinal direction in 2 typical tunnel openings is determined, and the temperature at each typical position inside the tunnel is calculated. Compare the measured temperatures at low and high openings, 1km away from the opening, and 1.5km away from the opening, as shown in Table 7.

According to the analysis of Tables 5-7 and Figure 5, it can be seen that for the Mabei and

Hufengling tunnels with a difference in height of 16m and 103m respectively, the ratios of the calculated air temperatures between the low portal and the high portal are 0.93 and 1.32, and that the calculated air temperature ratios for the two tunnels at a distance of 1km from the portals are 1.03 and 2.2 respectively, indicating that the winter air temperature inside the high-end entrance of a long tunnel with a large difference in the relative height of the opening is significantly higher than that at the same location from the low-end entrance. Therefore, the insulation and drainage system and structural frost resistance design of the high-end entrance of a long tunnel with a large slope difference have certain optimization conditions.

Further analysis shows that there were no obvious frost damage problem during the operation period of the 2 typical tunnels, which indicates that the anti-freezing fortification measures and length of the tunnels in the design are basically reasonable. combined with the anti-freezing fortification length of the four

Table 7. List of calculated control temperatures in four typical tunnels.

placement	Calculated temperature inside the tunnel/°C	
	Mabei	Hufengling
Low altitude portal	-17.2	-17.2
1km away from the low altitude entrance	-13	-15.2
1.5km away from the low altitude entrance	-11.6	-13.8
Middle of the tunnel	-12.8	-8.9
1.5km from the entrance of the tunnel at a high altitude	–	-6.3
1km from the entrance of the tunnel at a high altitude	-12.6	-6.9
High altitude portal	-18.4	-13
Low/High	0.93	1.32
1km low/1km high	1.03	2.2

Note: High and low caves are distinguished by the actual elevation of the cave.

tunnel structures are considered as 1km, and the temperature is $-15.2\text{ }^{\circ}\text{C} \sim -13\text{ }^{\circ}\text{C}$. Therefore, the anti-freezing fortification length of the tunnel structure in the cold area can be determined according to the calculated temperature in the tunnel is not higher than $-15.2\text{ }^{\circ}\text{C}$, and in the same way, the length of thermal insulation drainage and anti-freezing fortification can be determined according to the air temperature in the cave is not higher than $-13.8\text{ }^{\circ}\text{C}$.

7 CONCLUSIONS AND RECOMMENDATIONS

To analyze the longitudinal distribution law of temperature field inside the tunnel in cold regions, selected 2 typical tunnels construction sites with different lengths and slopes in the railway project of operating in high-latitude and cold region for longitudinal temperature field distribution tests in the tunnel in cold regions, which the continuous test of the longitudinal temperature field distribution in the tunnel obtained the longitudinal distribution control equations of temperature field in the tunnel, and verified the temperature standard for anti-freezing setup in the tunnel through engineering practice.

The main conclusions and recommendations are as follows:

- (1) Due to the large dispersion of regional meteorological parameters obtained from the analysis of short-cycle meteorological data, the values of meteorological parameters used in the anti-freezing design of tunnels in cold regions should be collected and analyzed from meteorological statistical data of the region where the tunnel is located for at least 30 years.
- (2) The relative height difference between the both ends of the tunnel caused by the longitudinal

slope of the line is one of the dominant factors affecting the distribution of the temperature field inside the tunnel in cold regions.

- (3) The analysis of the measured data shows that the three curves of average temperature distribution in the tunnel in December, January and February are basically consistent, with only upward and downward fluctuations. Among them, the temperature field distribution curve in the tunnel is basically at the lowest position in January, and the 5th-order polynomial curve equation obtained by curve fitting can be used as the control curve equation for the tunnel anti-freezing design after adopting the average temperature value of the coldest month in the region.
- (4) The length of anti-freezing defense fortunnel structures in the cold area can be determined based on the temperature in the tunnel not higher than $-15.2\text{ }^{\circ}\text{C}$, while the length and drainage anti-freezing defense can be determined based on the temperature in the tunnel not higher than $-13.8\text{ }^{\circ}\text{C}$.

ABSTRACT: The extra-long highway tunnel shields the surrounding environment, forming a driving environment with monotonous vision and less interference, and long-term driving in an extra-long tunnel has a great influence on driving vision and driving psychology, which is easy to causes visual fatigue and depressive feelings. There are more and more tunnels that are designed with landscape belts to alleviate driving discomfort. However, there are few studies on the landscape design inside tunnel and the mechanism of impact of landscape zones on the human body is unclear. Given this, this paper takes the landscape design scheme of the Qinling Zhongnanshan Highway Tunnel as the benchmark. It adopted the driving simulation test method, taking the driver's pupil and heart rate as indicators to evaluate the impact of landscape belt on driving comfort. The design length and position of the landscape belt in the extra-long highway tunnel were studied. The results show that the maximum length of landscape belt in extra-long highway tunnels should not exceed 3 minutes of driving duration, and the minimum length should not be less than 14 seconds of driving duration; the spacing of landscape belts in extra-long highway tunnels are arranged in a gradually decreasing trend along the tunnel exit direction, which is conducive to increasing driving comfort.

Keywords: Landscape inside tunnel, Driving simulation test, Comfort, Pupil diameter, Heart rate index

1 INTRODUCTION

According to the Statistics Bulletin of the Development of the Transportation Industry in 2022, by the end of 2022, there were 1,752 highway extra-long tunnels in the country with 7,951,100 liner meters (China 2023). The existing specifications refer to tunnels above 3km as extra-long tunnels. With the rapid development of China's highway traffic industry, highway tunnels above 10km are becoming more and more common. Long time's driving in tunnel easily causes visual fatigue, acceleration behaviour and escape psychology, bring hidden dangers to driving safety. Moreover, the inner walls of tunnel generally applied grey-black concrete, and the colour in tunnel is lack of variety, which is easy to cause the driving environment in the tunnel to be monotonous and depressed. Therefore, beginning with the Qinling Zhongnanshan Tunnel, more and more long highway

tunnels in our country are decorated with landscape to improve the driving environment inside the tunnel.

In order to study the interaction between landscape and drivers, domestic and foreign scholars have carried out some relevant studies. Vegetation coverage is proportional to drivers' tolerance, and large-area vegetation can improve drivers' driving psychology (Cockowski et al., 2003). When the road environment changes little and vegetation is single, it is easy to cause aesthetic fatigue and driving fatigue conducted by driving simulation experiments (Thiffault et al., 2003). Extensive survey and statistics results of urban roads show that traffic accidents have a large reduction after the improvement of road landscape environment (Mok et al., 2006). The open landscape is the friendliest to driving by analysing driving behaviours as the indicators evaluating driving safety (Antonson et al., 2009). Road environment does have a certain impact on driving behaviours, but a single road condition with beautiful environment will also cause

*Corresponding author: liujialari@163.com

driving distraction (Liu et al., 2009). The landscape types on both sides of the road would bring different driving experience to the driver, but also produce different safety risks by analysing the lateral position and speed of the vehicle (Bella, 2013).

In terms of drivers' physiological characteristics, driving in a single environment will reduce the tension of driving based on the monitoring data of blood pressure and heart rate, but driving in a single environment for a long time will cause certain driving safety problems (Yamakoshi et al., 2009). In order to evaluate the driver's driving state, the methods of auditory test, EEG and ECG index detection were adopted to establish the relationship between the driver's driving state and driving time (Schmidt et al., 2009). The colour brightness of the tunnel entrance had a direct impact on the driver's heart rate, and the proper increase of the heart rate was conducive to the driver's concentration by using the driving simulation experiment method (Tao et al., 2015 a, b).

To sum up, domestic and foreign researches on the interaction between landscape and driver have made some achievements, but they mainly focus on natural landscape, highway landscape and tunnel entrance landscape. However, the research on the influence of landscape design in tunnel on driving comfort is almost in the blank stage. In view of this, based on the design scheme of a extra-long highway tunnel in China, this paper adopts the driving simulation experiment method and uses Eye Tracking Glasses (ETG) and heart rate belt equipment to extract the change rule of the driver's pupil diameter and heart rate when passing through the tunnel, and analyses the design length and design position of the landscape in the tunnel. In order to provide some reference for the landscape design and evaluation of long highway tunnel.

2 SUPPORTED PROJECT OVERVIEWS

Qinling Zhongnanshan highway tunnel has specially set up with three 150-meter-long landscape belts. Through changes in lights and patterns, it creates a "blue sky and white clouds" scene, reducing the driver's monotony in the tunnel and alleviate driving fatigue (Frank et al., 2013; Jensen et al., 1993). The landscape belt inside the tunnel is shown in Figure 1.

Figure 1. Qinling Zhongnanshan tunnel.

3 MATERIALS AND METHODS

3.1 The experimental schemes of landscape belt

At present, there is no unified standard for the design position and design length of the landscape belt in the tunnel. The actual design process is relatively random and the driving experience is ignored. Therefore, 2 experiments were conducted intending to study the impact of length and location of the landscape belt on driving experience in the extra-long highway tunnel. The experimental design is as follows:

3.1.1 Experiment 1

Based on the basic principles of dynamic vision and traffic psychology, and drawing on the principle of "555" (Jia et al., 2007), with Qinling Zhongnanshan extra-long highway tunnel as a supporting project, two tunnel interior decoration schemes are designed without any decoration and the whole section of blue sky and white clouds decoration in Figure 2. Provide suggestions on the maximum length of the landscape belt and the reasonable design position according to the physiological characteristics of participants.

(a) No decoration

(b) Full decoration

Figure 2. Experiment 1 of landscape design.

3.1.2 Experiment 2

The length of this landscape belt of Qinling Zhongnanshan tunnel is 150m. This article uses 150m as a benchmark and considers the driving speed and the driver's dynamic visual characteristics. Three experimental schemes are set, which length of landscape belt are 150m, 300m, and 500m respectively (Figure 3). Each experimental program contains two landscape belts. These schemes are mainly to study the impact of minimum length of landscape belt on driving comfort and safety.

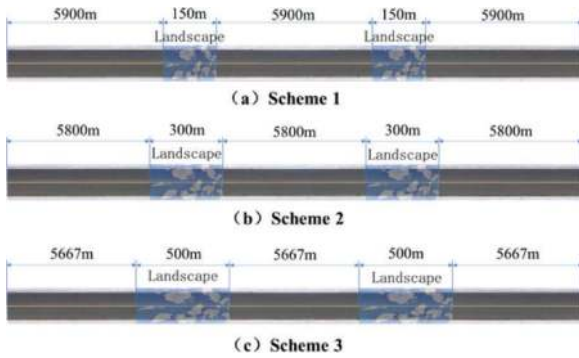

Figure 3. Experiment 2 of landscape design.

3.2 Experimental installation

(1) Driving simulator

The experiment uses a self-developed tunnel landscape environment simulation driving simulation system, as shown in Figure 4. The driving simulation experiment system can customize driving simulation scenes, and a random flow of cars will be generated during driving. It greatly restores the real tunnel traffic scene and can simulate the psychological state of real driving to the greatest extent.

Figure 4. Driving simulation equipment.

(2) Eye tracking glasses

In the experiment, the German ETG eye tracker was used to record the participants' eye movement data during driving, as shown in Figure 5. Glasses eye trackers can reduce the interference to participants during the experiment.

Figure 5. Eye tracker.

(3) Heart rate band

In the experiment, a Polar heart rate belt was used to measure the heart rate. The heart rate

belt is a Finnish product and reaches the medical level (Figure 6). The heart rate value is a manifestation of the heartbeat, that is, the amplified value of the electrocardiogram (ECG) signal generated by the heartbeat. The electrodes on the chest strap have better anti-interference and are extremely sensitive to ECG signals, so as to obtain accurate heart rate readings.

Figure 6. Heart rate band.

3.3 Participants

In this experiment, 20 college students with driving experience were selected as the main subjects. The aesthetic convergence between different groups has been confirmed (Frank et al., 2013; Vodak et al., 1985; Jesen et al., 1993;). Scholar Schroeder H (Schroeder et al., 1981) also pointed out that students' driving feelings can represent the driving feelings of the general public.

3.4 Experimental process

(1) Testing resting heart rate

Before the experiment, the participants closed their eyes and sat and rested, and began to test the resting heart rate when they were calm. Each participant tested for 5 minutes, and the average value was taken as the resting heart rate.

(2) Familiar with driving simulation equipment

Inform the participants of the correct operation method of the driving simulator, and ask participants to drive freely for 15 minutes in the road simulation scene, as shown in Figure 7.

Figure 7. Familiarity training of participants.

(3) Eye tracker calibration

After the participants are familiar with the operating methods of the driving simulation system, let them rest for 10 minutes outdoors to restore their normal physical and psychological state. Then perform a three-point calibration of the eye tracker, and the formal experiment can only be carried out after the calibration is qualified. The calibration process is shown in Figure 8.

Figure 8. Calibration process of participants.

(4) Formal experiment

After the preliminary work is ready, start the formal experiment. The vehicle started driving 2 kilometres before entering the entrance of the tunnel and stopped after passing through the tunnel. Participants scored based on driving experience. After resting for 15 minutes, continue to the next tunnel driving scene. The test process is shown in Figure 9.

Figure 9. Test scenario.

4 RESULTS AND DISCUSSIONS

4.1 Maximum length and reasonable position of landscape belt

(1) Eye tracking data analysis

The eye tracking glasses records data every millisecond thus generating a large amount of data, so the average pupil diameter every 6 seconds is taken as a recording point. The average pupil diameters of the 20 participants in the two scenarios are shown in Figure 10.

Figure 10. Average pupil diameter of participants.

Due to individual physiological differences, the average pupil diameters of the participants are different, however, the pupil diameter in fully decorated tunnel environment is generally smaller than that in an undecorated tunnel environment. Therefore, full decoration is more comfortable than no decoration (Murata et al., 2001; Choi et al., 2015).

In order to study the driving comfort of the two schemes, the pupil diameter change rate is used for analysis. According to the existing research results (Zhao et al., 2007; Pan et al., 2006; Pan et al., 2005; Zhen et al., 2003), the threshold value of the pupil area changes rate U when the driver is comfortable, tight and very tight during driving is defined as: ①When comfortable, $U < 20\%$; ②When nervous $20\% \leq U \leq 40\%$; ③when very nervous $U > 40\%$. The shape of the human pupil is approximately circular, so the pupil diameter change rate D_i is used instead of the pupil area change rate for driving safety analysis, which is calculated by the following formula (1).

$$D_i = \frac{d_i - \bar{d}}{\bar{d}} \times 100\% \quad (1)$$

Where, D_i is the pupil diameter change rate of the participant when driving in the tunnel at all times (%); d_i is the pupil diameter of the participant when driving in the tunnel at all times (mm); \bar{d} is the average pupil diameter of the participant without driving (mm).

So adjust the driving comfort threshold to: ①When comfortable, $D_i < 10\%$; ②When relatively nervous, $10\% \leq D_i \leq 18\%$; ③when very nervous, $D_i > 18\%$. Through the analysis of experimental data, it is found that the pupil diameter changes of different participants are consistent, so the pupil data of participant 2 will be analysed below. As shown in Figure 11, the pupil diameter change rate (D_i) of no decorated environment is larger than full decoration, and most of the time, the pupil change rate exceeded 10% for both schemes and even exceeded 18%. indicating that the participant is already in a very nervous and depressed state, so both design schemes have safety hazards.

Figure 11. Pupil diameter change rate of participant 2.

In order to further study the changes in the pupil diameter of the participants, the pupil diameter growth rate E_i was used to analyse the relationship between the pupil diameter growth of the participants and the driving duration. The calculation formula is formula (2), and the result is shown in Figure 12.

$$E_i = \frac{e_{i+1} - e_i}{t_{i+1} - t_i} \times 100 \quad (2)$$

Where, E_i is the pupil diameter growth rate of the participant when driving in the tunnel at time i , (%); e_{i+1} is the pupil diameter of the participant when driving in the tunnel at time $i+1$, (mm); e_i is the pupil diameter of the participant when driving in the tunnel at time i , (mm); $t_{i+1} - t_i$ is driving duration, taking 6s in this experiment.

No decoration scheme: After entering the tunnel, the pupil diameter growth rate of the participants fluctuates greatly, and it decreases after 1 minute and 24 seconds. At 6 minutes 18 seconds, the pupil diameter growth rate fluctuates again and continues to 8 Minutes. At 10 minutes and 24 seconds, the growth rate of pupil diameter begins to have large fluctuations until leaving the tunnel exits.

Therefore, it can be considered to set up a landscape belt aiming to reduce the driver's feeling of depression and relieve the driving fatigue where the pupil diameter fluctuates greatly. When entering the tunnel, a landscape belt should be set up to buffer the driving pressure caused by the huge differences in visual environment inside and outside the tunnel. When traveling to the position of 6 minutes 18 seconds, it is recommended to set up a landscape belt. When setting landscape belt in the middle and rear part of the extra-long tunnel, it is recommended that the spacing between landscape belts be gradually reduced. Full decoration scheme: After entering the tunnel, the driver's pupil diameter growth rate changes slightly; at 1 minute and 42 seconds, the pupil diameter fluctuates briefly. At 3 minutes and 24 seconds, the pupil diameter growth rate begins to change drastically, lasting to 4 minutes and 36 seconds. At 7 minutes and 48 seconds, there was a sudden change again until 8 minutes and 42 seconds. The last big fluctuation occurred at 14 minutes and 42 seconds, until leaving the tunnel exit.

It can be concluded that even if tunnel walls decorated with murals are beneficial to driving comfort, driving fatigue and depressed state will still occur after long-term driving. Therefore, it is not recommended to driving in tunnel decorated with mural exceeding 3 minutes.

Comparing the two design schemes, it is found that when entering the tunnel, the pupil diameter of the full decoration is significantly smaller than that of no decoration, indicating that the use of mural decoration when entering the tunnel will increase driving comfort. Taking into account the "black hole effect", drivers not only need to adapt to changes in light and darkness, but also need to focus on observing the

Figure 12. Growth rate for pupil diameter of participant 2.

linearity and road conditions of the road surface, and process various information in a short period of time. Murals would increase the amount of information for driver. It is recommended not to use murals with too bright colors and complex textures at the entrance of the tunnel.

(2) Heart rate data analysis

The heart rate belt records data once every second, and we take the average heart rate every 6 seconds as a recording point. Through data processing, we find that the heart rate change trends of participants are roughly similar. Therefore, the heart rate data of participant 2 will be analysed below. Figure 13 shows the heart rate and heart rate growth rate of participant 2 in the no decorated and fully decorated tunnel environment. It can be seen that in most of the time, the heart rate of the whole section of blue sky and white cloud decoration is lower than that of no decoration.

It also can be seen from Figure 13 that the heart rate growth rate of the no decorated (calculated by formula 3, and the absolute value) is significantly greater than that of the full decorated solution. Whether it is an no decorated or fully decorated tunnel environment, the heart rate growth rate of participants is relatively large. When the heart rate growth rate is greater than 20%, there are already a certain driving safety risk.

$$N_i = \frac{n_{i+1} - n_i}{t_{i+1} - t_i} \times 100 \quad (3)$$

Where, N_i is the heart rate growth rate of the participant when driving in the tunnel at time i , (%); n_{i+1} is the heart rate of the participant when driving in the tunnel at time $i+1$, (bpm); n_i is the heart rate of the participant when driving in the tunnel at time i , (bpm); $t_{i+1} - t_i$ is driving duration, taking 6s in this experiment.

Figure 13. Heart rate curve of participant.

4.2 Minimum length of landscape belt

Through data processing, we find that the pupil diameters of participants are roughly similar. Figure 14 shows the pupil 2diameters of participant 2 of each scheme in experiment 2.

Figure 14. Pupil diameter of participant for different length landscape.

The average pupil diameter of participant 2 in the scheme 1 is 4.2mm, the second scheme is 3.9mm, and the third scheme is 3.7mm. Scheme 1 has the largest pupil diameter, so it is less comfortable than schemes 2 and 3.

In order to analyze driving safety, the normal pupil diameter of the person is measured to be 3mm, and the change rate curve of the pupil diameter is calculated as shown in Figure 15.

It can be seen from Figure 15 that the pupil diameter change rate is the highest under a 150m landscape belt, and most of the time is above 18%. 500m landscape belt is second highest, and most of the time lies between 10% and 18%. 300m landscape belt has the lowest pupil diameter change rate, and most of the time below 10%.

Further analyze the participant's pupil diameter growth rate, as shown in Figure 16. It can be seen that the fluctuation range of the pupil diameter growth rate of scheme 2 and scheme 3 is smaller than that of scheme 1.

It can be seen from experiment 2 that in the 18-kilometer tunnel, the impact of landscape belt of driving comfort with a length of 300m (travel time

Figure 15. Pupil diameter change rate of participant for different length of landscape.

Figure 16. Growth rate for pupil diameter of participant for different length landscape.

of about 14s) and 500m (travel time of about 23s) is better. Landscape belt with a length of 150m has lower driving comfort and a large rate of change of pupil diameter, which poses certain safety risks.

5 DISCUSSION

Analysis of the results of experiment 1 shows that the pupil diameter of drivers in the tunnel varies. When entering the tunnel, pupil diameter changes dramatically and lasts for some time. Pupillary behavior is closely related to psychological stress

(Pedrotti et al., 2014). In addition, there is a corresponding relationship between pupil diameter change and visual comfort. The relative variation of pupil diameter is smaller when visual is comfortable (Tian et al., 2020). Therefore, it is suggested to set up a landscape belt at the tunnel entrance to alleviate the huge visual environment difference between the inside and outside the tunnel and alleviate the driver's sense of visual blockade. With the increase of driving time in the tunnel, drivers' escape psychology will gradually increase, and bad mood will become more obvious. It is suggested that the design position of the landscape belt in the tunnel should be arranged at a gradually decreasing distance, and the design location of the landscape belt at the rear of the tunnel should be more compact than the landscape design location in the front half of the tunnel.

It can be concluded from the results of experiment 1 that the setting length of landscape belt should not exceed the driving time of 3min.

The results of experiment 2 show that scheme of 300 and 500 significantly alleviated visual discomfort relative to 150m, while the scheme of 300 perform better than 500. Therefore, it is recommended that the minimum length of the landscape belt in the long tunnel is about 300m, and the driving time can be 14s according to the tunnel speed limit of 80km/h. According to the experimental conclusions, the recommended setting lengths of landscape belts in tunnels with different speed limits are shown in Table 1.

Table 1. Recommended length of landscape in extra-long tunnel.

Tunnel speed limit (km/h)	60	70	80	90
Minimum length of landscape strip (m)	230	270	310	350
Maximum length of landscape belt (m)	300	350	400	450

6 CONCLUSIONS

Based on the Qinling Zhongnanshan Tunnel in Shaanxi Province, two experiments were designed to study the design location and design length of the landscape belt in the extra-long tunnel. The following conclusions were drawn:

- (1) Whether tunnel environment is no decoration or full decoration, there is certain safety risks, it is recommended that the same landscape decoration should not exceed 3 minutes of driving time;
- (2) It is suggested that necessary decorations should be carried out when entering the extra-long tunnel. As the driver's psychological unease and irritability will increase with driving time in the tunnel, it is suggested that the decorative spacing of landscape belts should be arranged in a decreasing trend;

- (3) In the 18-kilometer-long tunnel, recommended length of the landscape belt is 300m (driving duration is about 14s) to 500m (driving duration is about 23s), which could better improve driving comfort. Therefore, it is recommended that the minimum length of the tunnel scenic belt is not less than 14s driving duration.

Full life cycle multi-hazard scenarios and structural response analysis of metro shield tunnels

Tongsheng Yu, Zhiguo Yan* & Hehua Zhu

State Key Laboratory of Hazard Reduction in Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: The article proposes a method to construct a multi-hazard scenario for the whole life cycle of subway shield tunnels based on a large amount of hazard and defect research data. Taking the tunnel health state field and sudden hazard scenarios as the basic multi-hazard scenario framework, it focuses on summarizing the sudden hazard scenarios that metro shield tunnels may face during the whole life cycle, and gives the determination methods for different tunnels in combination with Bayesian theory. Subsequently, a simplified multi-hazard scenario is employed to analyze the tunnel's structural response. The computational findings reveal that accounting for tunnel defects results in greater structural damage. Moreover, the structural damage is significantly amplified when multiple hazards effects are taken into account, thus underscoring the importance of considering multi-hazard scenarios in the analysis of structural damage.

Keywords: Metro Shield Tunnels, Multi-hazard Scenarios, Structural Analysis

1 INTRODUCTION

MTR tunnels are susceptible to various hazards throughout their operational lifespan, including progressive hazards and material deterioration that occur over time. Additionally, sudden hazards such as earthquakes, train impacts, internal and external explosions, and fires pose significant threats to both the structural integrity of the tunnel and the safety of MTR operations. While numerous studies have focused on analyzing structural damage caused by specific hazards or conditions, the reality often involves a more complex multi-hazard scenario.

On the one hand, as the service time of the tunnel increases, progressive defects and material deterioration will occur in the tunnel structure. At this time, the ability of the structure to resist hazards will be reduced to different degrees compared with the initial period of tunnel construction. For example, Wang et al. (2021) and Liu et al. (2022) investigated the seismic capacity of a tunnel structure considering segment dislocation and material deterioration, respectively, and the results showed that the load carrying capacity of a tunnel in less than optimal health is significantly affected. On the other hand, Hazard scenarios in which multiple sudden hazards act simultaneously or successively on the structure within a short period of time cannot be ignored. Hazard

scenarios of this kind have been studied more for superstructures, the most typical case is the fire after an earthquake (Kamath et al., 2015). As for tunnel structures, there are similar cases. For example, the Montreal subway tunnel fire in Canada in 1971 was a typical multi-hazard accident in which the subway collided with the tunnel wall and then caused a fire, and the Baocheng Railway fire in China in 2008 was a continuous hazard accident in which an earthquake indirectly led to a fire, etc. Hazard scenarios such as the above are subjected to multiple forms of hazard loading within a short period of time, including impact, high temperature, cyclic loading and unloading, etc., and the resulting structural damage is usually much larger than that of the case of considering individual hazards. Unfortunately, there has been limited research in this area thus far.

To address this deficiency, a method for constructing multi-hazard scenarios for the whole life cycle of subway shield tunnels is firstly proposed based on a large amount of research data on hazards and defects. Subsequently, it focuses on summarizing the sudden hazards scenarios in the multi-hazard scenarios and gives the method of determining the sudden hazards scenarios for different tunnels. Finally, the damage form and mechanical response of tunnel structure under multi-hazard scenarios are analyzed through a simple case study.

2 FULL LIFE-CYCLE MULTI-HAZARD SCENARIOS FOR METRO SHIELD TUNNELS

Depending on the duration and intensity of hazards, the hazard scenarios in metro tunnels can be categorized into two main types. The first type involves progressive defect and material deterioration that persist throughout the tunnel's life cycle. This type is characterized by low-intensity hazard loads occurring over a short period but persisting throughout the operational cycle. The second type comprises catastrophic loads resulting from natural or accidental factors, such as earthquakes, explosions, fires, vehicle impacts, and combinations thereof forming a catastrophic chain. These events have high-intensity impacts occurring over a short duration, causing significant damage to the structure. However, the probability of their occurrence is extremely low, typically happening once or twice during the tunnel's entire life cycle. Moreover, the two types of hazard loads are essentially uncorrelated. Therefore, the multi-hazard scenario for the full life cycle of a metro tunnel can be represented as a coupled tunnel health state field combined with sudden hazard loads, as depicted in Figure 1.

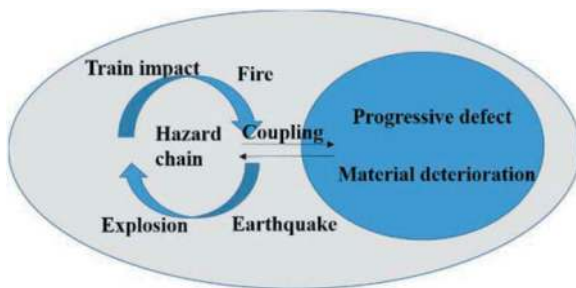

Figure 1. Multi-hazard scenarios for metro shield tunnels.

2.1 The tunnel state health field

The description of the tunnel health state field primarily focuses on progressive defect states and material deterioration. Progressive defects encompass longitudinal uneven settlement, radial convergence, cracking (cracks and breaks), misalignment, and water seepage in tunnels. A comprehensive analysis of the parametric state of each defect is provided in an article authored by the same author (Yu et al., 2023). It presents a methodology for generating a progressive defect state field using random field theory. This field serves to describe the potential defect conditions in a tunnel under construction or predict future defect conditions during operation. Figure 2 illustrates a collection of random tunnel condition fields generated for a tunnel under construction, utilizing geological parameters and similar tunnel condition data.

The material deterioration state of shield tunnels encompasses concrete carbonation, tube sheet reinforcement corrosion, and joint bolt corrosion. Among the various joints in shield tunnels, bolts are

Figure 2. Three-dimensional view of the progressive defect state field.

considered the weakest link, and therefore, bolt corrosion serves as a reference indicator for tunnel deterioration (Liu et al., 2023). Specific strength and cross-sectional variation models for bolt corrosion over time can be found in the literature sources of Ricker (Ricker, 2010).

2.2 Tunnel sudden hazard scenarios

In tunnels, there are two primary types of sudden hazard scenarios: single hazards and chains of multiple hazards. While individual hazards have been extensively studied, there is relatively limited research on defining hazard chains, their development patterns, and the magnitudes of hazard loads. A total of 61 cases were investigated and, based on the results, the following hazard chains and typical cases are summarised in Table 1. All case data have been uploaded to the website: <https://github.com/yutongsheng/Statistics-of-accident-cases-in-tunnels.git>. Based on the above case characteristics, sudden hazards scenarios are categorized into two main types, namely, individual hazards and hazard chains, according to the types of hazards involved and their spatial and temporal distribution characteristics. Among them, the Hazard chain scenarios mainly cover the following two situations. One is that a certain kind of hazard leads directly or indirectly to another kind of hazard. For example, a train derailment impact causes a carriage fire. The other type of scenario is that one type of hazard is repeated in different spaces at the same time, and at the same time there is a causal relationship between them. For example, a fire in a single carriage ignites other carriages or even other trains. The nodes in these hazard chains include earthquakes (EA), explosions (EX), collision of train (CO), and fires. Due to the substantial variations in spatial distribution and power of the hazard loads, they are further categorized as single carriage fires (SCF), multi-carriage fires (MCF), and multi-train fires (MTF).

Summarizing the data in Table 1, based on historical hazard data, the form of action of sudden hazards contains a total of four individual sudden hazard loads and seven hazard chain loads. Figure 3 counts the percentage of all cases involving the number of different hazard chain nodes, 43.3% of the cases involve only one hazard chain node, and 56.7% of the cases involve more than two hazard chain nodes. This also demonstrates the necessity of considering chained hazard occurrences in multi-hazard scenarios.

Table 1. Typical sudden-onset hazard chain scenarios for shield tunnels.

Hazard scenarios	Count	Typical cases
EA	3	In 1985, the 7.8 magnitude earthquake in Mexico caused structural damage to the subway tunnels.
EX	5	In 2004, terrorist bombings inside the Moscow metro.
SCF	17	In 1994, fire in the shield machine of the Danish metro tunnel, damaging 16 rings of pipe segments.
CO	1	In 1982, Derailment and wall crash on Washington DC subway, USA
EX→SCF	1	In 1981, New York underground, fire after motor failure causes explosion.
SCF→EX	1	In 1996, Fire and explosion in Washington DC Metro.
SCF→MCF	27	In 2003, Daegu underground line 1 fire, destroying all trains.
CO→SCF	1	In 1972, fire in Alexanderplatz underground tunnel, Germany, after derailment and collision with wall.
SCF→MCF→MTF	1	In 2005, a train on line 13 of the Paris metro caught fire, spreading to another train.
CO→SCF→MCF	2	In 1971, the Montreal underground collided with a tunnel, causing a short circuit and a fire that destroyed 24 cars.
CO→SCF→MCF→MTF	1	In 1945, London Metro tunnel train collision and fire, resulting in damage to two trains.

Note 1: The article considers only hazards that have an impact on the structure.

Note 2: See above for a description of the hazard chain nodes.

Figure 3. Percentage of number of nodes in different hazard chains.

The data in Table 1 covers the historical cases of major accidents in metro shield tunnels. However, due to the limited number of major hazard cases occurring

in metro shield tunnels, the author also investigated a number of hazard cases including road tunnels, railroad tunnels, and metro stations. To add the possible but not historical case situations in subway tunnels, the relevant cases and Hazard scenarios are summarized in Table 2. According to the results of the above analysis, all the sudden hazards scenarios chain relationships that the subway shield tunnels may face are summarized in Figure 4, which contains a total of 6 Hazard scenarios chains, according to which all the possible sudden hazards field scenarios in the subway shield tunnels can be obtained. It should be noted that explosions are categorized into explosions from inside the tunnel and explosions from outside the tunnel according to the location of the source, which are represented by EX-in(Explosion internal) and EX-ex (Explosion external), respectively. As well as although there is a fire → explosion scenario in the aforementioned case study, the subsequent hazard scenarios do not consider this hazard chain. As the main hazard effect affecting the structure in this case is fire, the impact loads caused by the explosion of electromechanical equipment are small and have a limited effect on the structure.

Table 2. Supplement to possible sudden hazards scenarios of hazards.

Hazard type	Hazard scenarios	Existing cases or typical scenarios
Single hazard	Explosion (source outside tunnel)	Bomb attacks against shallow tunnels; explosion of adjacent gas pipeline
Hazard Chain	EA→CO	The 2008 Baocheng Railway was indirectly caused by the Wenchuan earthquake, which led to a train derailment and wall crash, followed by a massive fire and explosion. Subway trains are also subject to such risks.

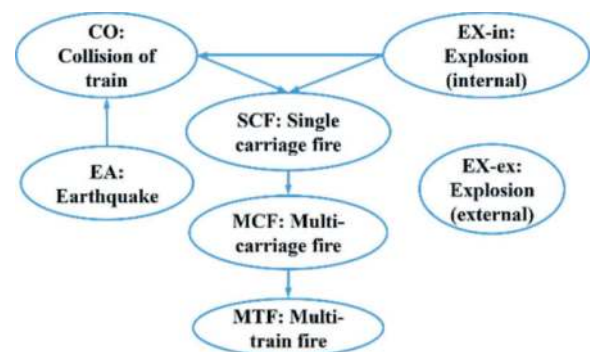

Figure 4. Hazard scenarios and their chain triggering relationships.

Sudden multi-hazard scenarios that need to be considered in metro shield tunnels are given in Figure 4. However, for tunnels with different operating conditions, the types of hazards that need to be considered

may be different. To address this issue, this paper provides a Bayesian network to determine the sudden hazards scenarios that need to be considered specifically for a particular tunnel. The details are shown in Figure 5, which shows that the network consists of eight input node parameters and seven hazard response nodes. For deterministic tunnels, i.e., where all input conditions are known, there are only two scenarios: either some kind of sudden hazard scenario needs to be considered or not. In other words, there is no ambiguity or probability in the deterministic process. In addition, the conditional probabilities of the Bayesian network are determined based on the propagation rules, which are shown in Table 3. Once the values of the eight input parameters are determined, the Bayesian network can be utilized to obtain the corresponding unexpected hazardous situations that need to be considered for that particular tunnel. This approach allows for a more targeted and accurate assessment of the potential hazards facing the tunnel.

Figure 5. Bayesian network diagram for determining sudden hazards scenarios.

With regard to the rules for taking the conditional probabilities in Table 3, there are several elements that need to be clarified.

- (1) EX-in and EX-ex only consider the situation caused by human factors, which are the explosion scenarios caused by terrorist attacks and deliberate retaliation against the community and other factors. The reason for this is that the explosion load caused by the failure of electromechanical equipment is small, much smaller than the impact load caused by the human carrying of explosives, and is not considered for scenarios in which the tunnel structure is the main object of analysis.
- (2) Train derailment cases can have various causes, including earthquakes, endogenous explosions, vehicle-related factors (such as wheelset wear, bearing failures, brake cylinder failures), and rail line-related factors (such as track unevenness, turnout damage, rail breakage, tie-breaker damage, ballast bed failure, external barrier intrusion, etc.). Existing standards provide methods for quantitative risk evaluation in such situations. The risk evaluation system for vehicles and rail lines, categorized into four grades (major, significant, average, and minor), can be found in the Measures for the Management of Safety Risk Rating and Control and Hidden Trouble Detection and Management for Urban Rail Transportation Operations (Ministry of Transport of the People's Republic of China, 2019). Figure 5 illustrates the classification rules for train derailment events based on different risk levels, peak ground vibration acceleration, and train running speed. The values for whether to consider derailment

Table 3. Bayesian network node probability propagation rules.

Hazard node	Influencing factors	Probability Transfer Calculation Rules
EA	Regional seismic defense conditions and structural self-resonance periods	Calculate the peak acceleration to be considered according to Code for Seismic Design of Urban Rail Transit Structures (GB 50909-2014)
EX-in	Human factor	Refers to situations of hazards caused by subjective human factors, such as terrorist attacks, deliberate retaliation against society, etc. It is mainly determined by the current level of social stability.
EX-ex	(1) Tunnel depth (2) Human factors	(1)The impact of human factors is the same as the EX-in node. (2) Tunnel depth less than 7m explosion will have an impact on the structural safety of the tunnel, more than 7m is considered to have no effect(Yang et al., 2010) .
CO	(1) Peak seismic acceleration (2) Risk level of vehicle and track line (3) Operating speed (4) EX-in	Whether or not the CO case needs to be considered is shown in Figure 6
SCF	(1) CO (2) Risk level of electro-mechanical equipment (3) Human factors (4) EX-in	Single carriage fire conditions need to be considered when one of four scenarios exists: consideration of human factors, consideration of CO, consideration of EX-in, or high or significant risk level of electromechanical equipment
MCF	(1) SCF (2) Human factors; (3) Maximum heat release rate	(1) MCF is considered when SCF needs to be considered and the maximum heat release rate is greater than the critical power for booming (2) MCF is considered when human factors are considered.
MTF	(1)Tunnel section form (2)MCF	Consider MTF only if you have a single hole with two lines and MCF is considered

events, assuming an average risk level, can be obtained based on the results of Li et al. (2021).

- (3) For the MCF node, if the SCF condition needs to be considered, the determination of whether a multi-carriage fire (MCF) needs to be considered depends on whether the maximum heat release rate exceeds the critical heat release rate that can cause the carriage to ignite with a boom. If the maximum heat release rate is below the critical threshold, it is considered that the fire can be controlled within a short period of time and will not result in a multi-carriage fire. Conversely, if the maximum heat release rate exceeds the critical threshold, the possibility of a multi-carriage fire needs to be considered. The calculation of the critical heat release rate for specific carriage ignition can be conducted using the method described by Zhou (2021). The value of the maximum heat release rate can be calculated based on the total amount of combustible materials in the vehicle and the time it takes to reach the maximum heat release rate (Li et al., 2018). However, in human-caused fire scenarios, where additional fuel is usually present, the heat release rate often exceeds the critical threshold for the occurrence of a roaring ignition, and thus the consideration of a multi-carriage fire is necessary.

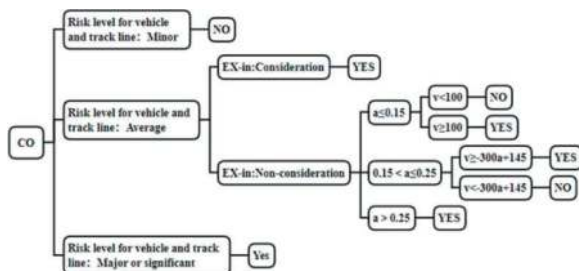

Figure 6. Bayesian network probability transfer rule for train derailment events.

3 CASE STUDIES

Based on the previous analysis, it can be seen that the multi-hazard scenarios that a metro shield tunnel may face throughout its lifetime are extremely complex, but the basic framework is in the form of a tunnel structural health state field superimposed on a sudden hazards field. In this section, the structural response of the tunnel in different health states as well as hazard chain scenarios are considered separately with fire as the main type of sudden hazard. The structural health state simulation includes the tunnel joints opening, the presence of cracks in the tube segments and the material deterioration, while the hazard chain only includes the case where the structure is subjected to train impact followed by a fire, and the specific analyzed cases are shown in Table 4.

The fire load adheres to the BART curve, with a peak heat release rate ranging from 10 to 20 MW, dependent on the specific metro fire scenario under consideration (Li and Ingason, 2016; Shi et al.,

Table 4. Multi-hazard analysis working conditions table.

No.	Simulation of working conditions
Case-1	Consider fire only, BART curve, max. temperature 500°C.
Case-2	Consider joints open and heat intrusion in the joint section in the event of a fire.
Case-3	Consider bolt deterioration with a 1mm diameter reduction and a strength discount of 0.9646, followed by fire
Case-4	Consider the initial cracking, followed by fire
Case-5	Consider structural damage from Case-2 to Case, followed by fire
Case-6	Consider structural damage from Case-2 to Case, followed by train impact fire

2020). The maximum temperature threshold is set at 500°C, and for simplicity, only the capped and adjacent blocks are deemed subject to heating. The numerical calculation model used in the article only considers 3 rings, the width of the tube segment is 1.5m, the section of the tube segment is shown in Figure 7, and the form of through-seam assembling is adopted. The outer diameter of the tunnel is 6.1m, the inner diameter is 5.4m, the depth of the tunnel is 20m, the groundwater is located at 4m below the surface, and the soil pressure is calculated according to the way of soil-water integration. The concrete model is C50, solid unit is used for simulation, the model of this structure adopts the built-in concrete damage plasticity model in Abaqus, the plasticity parameter is shown in Table 5. The compressive and tensile stress-strain relationships are referenced from Appendix C of the Code for the design of concrete structures GB 50010-2010 (2010). The model only embodies the setting of annular rebar, and does not model the hoop bar, the rebar material adopts HRB400E, the upper layer of The rebar material is HRB400E, the upper layer of rebar is 12φ20, and the lower layer of rebar is 10φ22. The truss unit is used for simulation, and it is connected with concrete by built-in way. The bolts are bent bolts M30, mechanical grade 8.8, simulated using solid units, connected to the concrete by means of bolts with both ends built into the concrete, and pretensioned using the method of adjusting the temperature loads applied to them. The thermal parameters of the materials involved in the subsequent simulations, i.e., the specific heat capacity, thermal conductivity, coefficient of expansion, and mechanical properties of the concrete, reinforcement, and bolts as a function of temperature decrease, are described in detail in the literature (Zhang, 2022) and will not be repeated. The ring and longitudinal joints are simulated in the form of contact surfaces, and the normal direction of the contact surfaces is simulated by “hard contact”, and the tangential direction is simulated by Cloumb friction, with the friction coefficient set to 0.4 (Shi et al., 2022; Shi et al., 2016). The numerical model is shown in Figure 8.

Table 5. Plasticity parameters in the concrete damage plasticity model.

Parameter	Value
Dilatation angle	30°
Flow potential offset	0.1
Biaxial to uniaxial compressive ultimate strength ratio	1.16
Unvariable stress ratio	0.667
Coefficient of viscosity	0.01

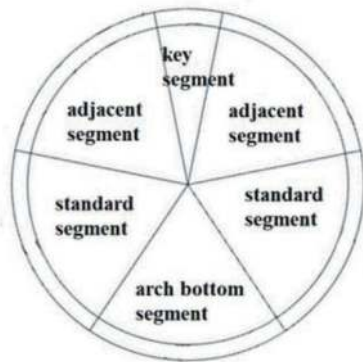

Figure 7. Tunnel section form.

Figure 8. Model schematic.

Figures 9 and 10 compares the temperature field and structural damage with and without joint opening, and it is clear that taking into account the structural base damage has a significant effect on the structural hazard response. The maximum value of concrete compression damage is approximately 0.61 when considering only the fire condition, while the maximum value is approximately 0.90 when all basic structural damage conditions are taken into account.

Comparing the cross-section bending moments of the six cases in Figure 11, it can be seen that the cross-section bending moments under the hazard loading will increase significantly. The different initial damage states also have different effects on the response of the structure at high temperature, and it can be seen that the bending moments of the high temperature response of the structure under the six cases are basically divided into three situations. They are case1, case3 and

Figure 9. Comparison of temperature fields for case 1 and case 5.

Figure 10. Comparison of damage conditions for case 1 and case 5.

case4 bending moment values are basically the same, case2 and case4 bending moment values are basically the same, and case6 bending moment values are basically the same as case2 and case4 except for the different bending moment values in the interval of 324~342° due to the train impact load. From the above results, it can also be seen that considering the joint opening, the presence of thermal intrusion in the joint portion in the event of a fire has the greatest impact on the high temperature response of the final structure. The reason for this is that the structural damage and bending moments under the six hazard conditions are mainly generated by high temperature effects, and the presence of thermal intrusion will change the temperature field of the structure under high temperature

Figure 11. Bending moment for different cases.

loading. While the main impact area of train impact is the standard block, the superimposed impact of the two is essentially smaller because the fire location is mainly the capped block and the adjacent block. Both hazards only affect the damage and structural internal force in the main action region. Similarly, the axial force diagrams for different working conditions in Figure 12 can lead to the same conclusion.

Figure 12. Axial force for different cases.

4 CONCLUSIONS

The article takes the subway shield tunnel structure as the research object, carries out the multi-hazard scenario construction method and structural response analysis research, and mainly obtains the following conclusions.

- (1) Based on a large number of hazards and defects research data, the article proposes a method for constructing multi-hazard scenarios during the whole life span of metro shield tunnels. Taking the tunnel health state field and sudden disaster scenarios as the basic multi-hazard scenario framework, it focuses on summarizing the sudden hazard scenarios that metro shield tunnels may face during their whole lifespan, and gives the corresponding determination methods in combination with Bayesian theory.
- (2) By conducting a simple case study, the article compares the damage to the structure when considering different multi-hazard scenarios. The calculation results demonstrate that when tunnel defects are taken into account, the structural damage becomes more severe. Furthermore, the structural damage is greater when multiple hazards occur consecutively compared to individual hazards acting alone. This finding highlights the importance of considering multi-hazard scenarios during the analysis of structural damage.
- (3) Although the method of determining the multi-hazard scenarios is given, considering the randomness of the hazard loads, the method of taking the value of each hazard load, as well as a variety of hazard loads with correlation, should be further improved.
- (4) The case studies of multi-hazard scenarios given in the article are relatively simple, and a more comprehensive investigation of structural

response in multi-hazard scenarios should be carried out at multiple scales, such as materials, components and systems.

Research on China's extra-long separate construction tunnel emergency evacuation and rescue technology

Yi Yuan* & Shaohua Chen

China Railway First Survey and Design Institute Group Co., Ltd, Xi' an, China

ABSTRACT: For enclosed and lengthy tunnel projects, disasters can lead to significant economic losses and adverse societal impacts. This is especially true for tunnels exceeding 20 km, where the design of disaster prevention, evacuation, and rescue operations is of paramount importance. China's specialized techniques for tunnel emergency evacuation and rescue have evolved alongside the continuous development of tunnel projects in the country. Drawing from exemplary international engineering experiences while considering its unique characteristics, China has formulated its own set of techniques. This article compiles the historical evolution of domestic disaster prevention and rescue efforts and provides detailed comparisons of typical specialized tunnel rescue stations both domestically and internationally. It offers comprehensive discussions on their structural layout, disaster prevention ventilation and smoke extraction systems, electromechanical equipment, and emergency management. By meticulously comparing various parameter technical indicators within the disaster prevention, evacuation, and rescue framework, the article evaluates and summarizes China's proficiency in disaster prevention and evacuation within extra-long tunnels. Furthermore, it delves into an in-depth analysis of the contentious issue of internal crossing line placement within tunnels. This analysis serves as a reference for the design and standard formulation of China's railway tunnel disaster prevention and rescue engineering, while addressing significant controversies.

Keywords: Railway tunnel, Disaster prevention and rescue, Designated evacuation, Emergency rescue station, Crossing line

1 INTRODUCTION

As China's railway network continues to develop, the number of lengthy and large-scale railway tunnels, as well as tunnel complexes, has grown dramatically. These tunnels are becoming increasingly larger in scale. Among the ongoing railway projects, a significant number of extra-long tunnels have emerged. Whether considering individual tunnel lengths or the proportion of tunnel routes, these figures have reached historical highs (Hanley et al., 2022). Given the characteristics of China's railway transportation, including inter-regional and inter-railway bureau (corporation) operations, and long passenger distances, challenges arise for disaster response and evacuation in the case of incidents within enclosed long tunnels. Due to the potential difficulties in rescue and evacuation during disasters and the substantial impact of losses, ensuring operational safety has remained a significant challenge in railway safety operations. China's design, construction, and management entities place great

emphasis on disaster prevention, evacuation, and rescue engineering within tunnels. Drawing from successful operational experiences and technological achievements, as well as learning from deficiencies and shortcomings identified in previous designs and emergency drills, these entities have essentially developed a scientific and comprehensive set of emergency evacuation and rescue technology.

China's regulations require a technical and economic comparison between single-bore dual-track and twin-bore single-track configurations for newly constructed tunnel projects that exceed 10 km in length. Currently, for high-altitude railway tunnels, tunnels with a length greater than 15 km are generally advised to adopt separate construction schemes. In cases where a joint construction approach is employed due to specific geological conditions, a connecting passageway should be established. Considering the significant advantages of separate construction tunnels in disaster prevention, rescue operations, and operational

*Corresponding author: yuanyi.yy@crcc.cn

maintenance, the majority of specialized tunnels exceeding 20 km in length have adopted separate construction schemes (Zhao et al., 2021). To further assess the design proficiency of China's long and large specialized tunnels in terms of disaster prevention and rescue, and to understand the current state of railway tunnel emergency evacuation and rescue technology in the country, it is necessary to compile and compare the achievements and successful experiences related to disaster prevention and rescue techniques for these specialized tunnels. This involves identifying deficiencies and shortcomings in the ongoing construction and operation of disaster prevention and rescue engineering, with the goal of enhancing disaster prevention, evacuation, and rescue capabilities within tunnels, improving the reliability of disaster prevention and rescue engineering, and ensuring the operational safety of railway tunnels.

2 THE HISTORICAL EVOLUTION OF RAILWAY TUNNEL EMERGENCY EVACUATION AND RESCUE TECHNOLOGY IN CHINA

Before 1990, China had a relatively small number of tunnels, with few long and large tunnels, mostly consisting of single-track configurations. At that time, extra-long separate construction tunnel emergency evacuation and rescue technology were not common. The earliest involvement in tunnel fire prevention on railways can be traced back to the Daoyaoshan Tunnel on the Hengguang-Fuxian Line. As the construction of the Qinling Extra-Long Tunnels on the Xikang Railway progressed, China's research and design of tunnel disaster prevention began to take its initial steps. A system of measures targeting fire prevention, suppression, and evacuation rescue was adopted, with each railway bureau establishing its respective safety management measures for tunnels.

Entering the 21st century, China saw the emergence of long and large tunnels. A notable project was the Wushaoling Tunnel (20 km) on the Lanwu Second Line. During the construction period from 2003 to 2006, a design scheme emphasizing "fire alarm and designated evacuation" was established. Around the same time, comprehensive research on tunnel emergency evacuation and rescue technology was conducted during the construction of the Taihangshan Tunnel (2005-2009) and the Dayaoshan Tunnel Complex (2005-2009). Emergency rescue stations were established both inside the tunnels and at their entrances. Additionally, comprehensive disaster prevention and operational management techniques were studied for the underwater Shizi Yang Tunnel (2006-2011).

In the past decade, railways have entered a phase of rapid development. With the promulgation of the

"Design Specification for Railway Tunnel Disaster Prevention, Evacuation, and Rescue Engineering" (TB10020), tunnels such as Guanjiao, Chenglan, and Lanyu Railways have undergone tunnel disaster prevention, evacuation, and rescue design according to the specification's requirements. International technical consultation has been introduced to enhance and improve disaster prevention and rescue engineering design. The design and implementation of disaster prevention, evacuation, and rescue for long and large tunnels have gradually become standardized and governed by systematic technical regulations.

As of the end of 2021, China Railway Engineering Consulting Group (CRECG), along with the First, Second, and Fourth Railway Survey and Design Institutes, has collectively completed project designs for 127 tunnel emergency evacuation and rescue technology engineering endeavors. These projects encompass a total tunnel length of 9,433.958 km and 929 tunnel structures. Among these, 40 emergency rescue stations have been designed within tunnels, while 123 emergency rescue stations of the entrance type have been established. Furthermore, a total of 958 emergency exits (refuge points) have been included in the designs. In conjunction with achieving disaster prevention and evacuation goals for railway stations, a total of 27 projects have been undertaken, with 5 of them pertaining to underground stations and 22 to entrance stations.

3 DOMESTIC AND INTERNATIONAL EXEMPLARY EMERGENCY EVACUATION AND RESCUE TECHNOLOGY ENGINEERING FOR EXTRA-LONG SEPARATE CONSTRUCTION TUNNELS

3.1 *Domestic exemplary separate construction tunnel emergency rescue station - New Guanjiao Tunnel*

3.1.1 *Tunnel overview*

The New Guanjiao Tunnel spans a total length of 32.645 km and is designed as a twin-bore single-track tunnel with a center-to-center spacing of 40 m. It is the longest tunnel in China's high-altitude regions. The tunnel employs a ventilation and smoke extraction strategy using both tunnel supply air and vertical shaft balanced smoke extraction. It has introduced a technical system for the evacuation and rescue command system and established a design pattern for rescue stations in high-altitude, long tunnels. The construction of the New Guanjiao Tunnel took place from 2007 to 2014.

3.1.2 *Emergency evacuation and rescue engineering design*

The tunnel system has studied the entire process from spontaneous fire occurrence to completing personnel rescue. From an operational and management perspective, comprehensive design integration has

been conducted for civil, mechanical, communication, and fire protection systems.

To ensure the safe evacuation of personnel, an emergency rescue station was established near Shaft No. 6, spanning a length of 550 m. Evacuation cross-passages are located every 50 m within the emergency rescue station. Protective doors have been installed at both ends of all cross-passages, capable of withstanding blast loads of not less than 0.1 MPa and having a fire resistance limit of no less than 3 h. Electrically operated ventilation dampers are positioned above the protective doors, while jet fans are placed at the air-stream facing positions within the 12 evacuation cross-passages. A dedicated smoke exhaust duct has been set up within the emergency rescue station, and a high-pressure fine water mist fire hydrant and emergency telephone are installed at both ends of each evacuation cross-passage. Two sectional contact switches are positioned at the tunnel ends of the twin-bore sections, each serving one tunnel. The comprehensive layout of the New Guanjjiao Tunnel 's emergency rescue station is depicted in Figure 1 (Chen, 2016).

Figure 1. Diagram of the structural layout of the New Guanjjiao Tunnel emergency rescue station.

An emergency rescue command center has been established within the Qinghai-Tibet Railway Company to manage the entire evacuation and rescue operation. The command center oversees daily training and drills, as well as emergency response coordination, remote control of tunnel equipment, and monitoring. The main monitoring station conducts centralized remote monitoring of tunnel equipment, tracking relevant parameters, and issuing alarms for various mechanical and electrical equipment malfunctions or anomalies.

Throughout the tunnel, nine guide signs have been positioned along the left side in the direction of travel to accurately guide trains to a smooth stop at the emergency rescue station. Optical image signs are placed at the midpoint of the two cross-passages within the rescue station area, indicating distances in two directions. Directional guidance lines made of reflective material have also been installed.

Fixed lighting, evacuation signage illumination, identification lighting, and evacuation lighting are implemented within the tunnel. Gun-type cameras

have been installed at appropriate locations at the entrances of both left and right tunnel bores, in the rescue cross-passages, and near Shaft No. 6. The real-time video monitoring images captured are transmitted to the Qinghai-Tibet Company's emergency command center and the local public security bureau command center.

Within the emergency rescue station area, a smoke exhaust vertical shaft is positioned on the tunnel crown every 100 meters, connected through transverse smoke exhaust ducts that link the vertical shafts with longitudinal smoke exhaust ducts. These longitudinal ducts are further connected to Shaft No. 6, allowing smoke to be expelled from the tunnel. An anti-smoke electrically operated damper within the transverse smoke exhaust duct enables both tunnel bores to share a single smoke exhaust channel (Chen, 2016). A high-pressure fine water mist fire protection system has been installed in the emergency rescue station, along with fire extinguishers placed in various chambers within the tunnel, and firefighting water reservoirs at tunnel entrances.

An electrical phase division has been implemented in the emergency rescue station within the tunnel, near the roof and extending to the power supply arm at the New Guanjjiao Tunnel. Prior to activating the fine water mist fire pump for firefighting, the emergency rescue command center issues a command to the traction power dispatching station to cut off power and ground the overhead contact system within the emergency rescue station.

3.1.3 Summary

The disaster prevention design of the New Guanjjiao Tunnel primarily employs the method of separate construction with designated evacuation and rescue points. In the tunnel, an emergency rescue station is positioned at the main tunnel near Shaft No. 6 for designated evacuation and rescue purposes. Smoke exhaust vertical shafts and ducts are installed on both sides of the tunnel roof, and water-based firefighting is conducted within the rescue station. Smoke extraction and ventilation are managed through the use of separate shafts, ensuring a clear separation between people and smoke within the tunnel.

3.2 Typical separate construction tunnel: *In-Tunnel rescue station - Saint Gotthard Tunnel*

Drawing from comprehensive engineering cases in developed countries including Europe, foreign ultra-long tunnels mostly utilize separate construction methods, with only a few tunnels being constructed using joint methods. The following example of the Saint Gotthard Tunnel will be used to illustrate and analyze this approach.

3.2.1 Tunnel overview

The Gotthard Base Tunnel is an exceptionally long railway tunnel traversing the Alps from Basel,

Switzerland, to Milan, Italy. Comprising two parallel single-track tunnels with a center-to-center spacing of 40 m, the tunnel is 57 km in length (57.104 km for the east tunnel and 57.017 km for the west tunnel). A cross-passage is situated every 330 meters along the tunnel. The tunnel features a zigzag longitudinal slope, with a maximum gradient of less than 7‰. Designed for passenger trains, the tunnel allows for a maximum operational speed of 250 km/h. The construction of the tunnel took place from 1996 to 2017.

3.2.2 Tunnel safety factors and preventive and mitigative measures

The safety considerations for the Saint Gotthard Base Tunnel primarily encompass various potential hazards within the tunnel environment, including train derailment, fire, train or equipment malfunctions, terrorist attacks, passenger incidents, hazardous material leaks, etc. Among these, fire, due to its high occurrence likelihood and significant impact, has been a focal point of tunnel safety protection. The preventive measures for the tunnel include barring hazardous trains from entering, employing dual tunnels, train signaling, and automatic control systems to prevent collisions, limiting the number of crossover tracks and optimizing their layout to minimize derailment risks, and ensuring freight and passenger trains travel at the same speed to mitigate risks from hazardous material transportation.

Safety zones have been established through the presence of two multifunctional stations, cross-passages every 325 m, and a disaster prevention ventilation system, providing passengers with safe areas and facilitating self-rescue. Specially equipped rescue trains are stationed at tunnel entrances, and simple, standardized emergency management procedures have been formulated and regularly practiced (Zeng and Zhao, 2010).

3.2.3 Disaster prevention and rescue design scheme

The disaster prevention and rescue plan for the Saint Gotthard Tunnel employs a designated rescue station model. The east and west tunnels mutually serve as rescue tunnels. Each tunnel has a shaft located in Amsteg and two multifunctional stations in Sedrun and Faido (Figure 2).

The spacing between multifunctional stations is approximately 20 km. Each multifunctional station consists of two emergency stopping stations, two crossover tracks (allowing tunnel segment maintenance with minimal traffic disruption), vertical shafts, and entrances/exits. Each rescue station is about 450 m long, with a platform approximately 2 m wide. Six evacuation cross-passages are evenly distributed, equipped with fire escape doors that can be remotely controlled. Seven smoke exhaust vertical shafts are situated on top of the rescue stations, sealed using exhaust gates.

The multifunctional stations essentially divide the entire tunnel into approximate thirds, serving three main functions. Firstly, trains can switch between the east and west tunnels as required by operational

Figure 2. The layout of the Gotthard road tunnel rescue station.

scheduling. Secondly, trains affected by fires that cannot exit the tunnel can halt at the emergency stopping stations within the multifunctional station. Passengers can evacuate into the evacuation passages and wait for rescue at the emergency stopping stations on the non-affected side of the tunnel. Thirdly, both operational and emergency ventilation can reach the emergency rescue station through the vertical shafts and entrance tunnels.

Each crossover track is equipped with specialized doors, as shown in Figure 3. These doors remain closed during normal operations but can be opened when required by dispatching needs.

Figure 3. Fire Door within Crossover Tracks of the Gotthard Base Tunnel.

The Gotthard Tunnel has established behavioral guidelines for both trains and personnel during emergencies in operational conditions. The tunnel's disaster prevention ventilation aims to maintain sufficient positive pressure within the multifunctional stations, preventing smoke from entering the safe tunnel through the opened cross-passages.

The ventilation scheme for emergency rescue stations has been optimized to create smoke-free escape passages and improve self-evacuation conditions (e.g., platform area temperature not exceeding 50°C, CO

concentration less than 150 ml/m³, visibility exceeding 5 meters in the platform area). Disaster prevention ventilation is based on the presence of two multifunctional stations (emergency rescue stations) located within the tunnel at Sedrun and Faido, and it employs different ventilation modes depending on whether a train is stopping at a rescue station or at any other point.

In conclusion, the Gotthard Base Tunnel adopts a dual-track separate construction approach, and its disaster prevention and rescue model involves designated emergency rescue station stops.

4 ENGINEERING COMPARATIVE STUDY

4.1 *Comparison of civil structure, evacuation methods, and smoke exhaust methods in separate construction tunnels*

Both domestic and international separate construction tunnels generally adopt the emergency rescue station stop rescue mode.

For foreign ultra-long tunnels, most employ separate construction methods. Examples include the foreign Saint Gotthard Tunnel and Brenner Base Tunnel. Domestically, tunnels like the New Guanjiào Tunnel, West Qinling Tunnel, and Ping'an Tunnel follow the same pattern. However, there are also single-tube dual-track tunnels exceeding 20 km in length domestically, such as the under-construction Yuntunbao Tunnel and Ganqing Tunnel.

Considering the rescue mode, except for early domestic Qinling Tunnels and the foreign English Channel Tunnel that initially didn't have designated stops, opting for mutual rescue between the two tunnels, both domestic and foreign tunnels now mostly utilize the designated station stop rescue mode. Emergency rescue stations are established for evacuation and rescue, with the distance between them being less than or equal to 20 km.

Both domestic and foreign separate construction tunnels utilize encrypted cross-passages for mutual rescue purposes. In the event of a fire disaster inside the tunnel, trains halt at the nearest emergency rescue station when they cannot exit the tunnel. The evacuation route involves individuals entering the evacuation cross-passages and moving to designated waiting areas for rescue. To achieve smoke separation from people, fresh air is supplied through separate auxiliary adits or isolated auxiliary adit ducts. Within the scope of each emergency rescue station, smoke exhaust vertical shafts and longitudinal smoke exhaust ducts are positioned on the crown of the left and right single-line tunnel sections. Smoke is expelled to the outside through auxiliary adits.

4.2 *Comprehensive comparison of disaster prevention measures*

To conduct a more comprehensive comparison, categorizing by the processes of prevention, mitigating

impacts, facilitating evacuation, and promoting rescue, we compare the disaster prevention measures of the foreign Gotthard Tunnel (**A**) and the domestic New Guanjiào Tunnel (**B**). The comparative analysis of their measures is detailed as follows:

- Dangerous Goods Train Management: **A**-Prohibition of dangerous train entry into tunnels; **B**-Handled according to "Railway Regulations on the Management of Dangerous Goods Transportation".
- Collision Prevention: **A**-Train signaling and automatic control system; **B**-Automatic block.
- Maintenance Conditions: **A**-During maintenance, workers only operate in one closed tunnel; **B**-Closure or skylight period.
- Vehicles: **A**-Fire-resistant locomotive vehicles; **B**-Fire-resistant locomotive vehicles.
- Fire Extinguishing: **A**-Rescue station and tunnel entrance water firefighting; **B**-Rescue station high-pressure fine water mist, tunnel entrance firewater pool, tunnel fire extinguisher.
- Disaster Ventilation and Smoke Exhaust: **A**-Partial transverse ventilation, complex system, well-equipped; **B**-Partial transverse, well-equipped.
- Operational Ventilation: **A**-Natural ventilation + jet ventilation, selective opening; **B**-Natural ventilation.
- Travel Guide Signs: **A**-Not specified; **B**-Nine guide signs are placed on the left side along the direction of travel in each tunnel.
- Evacuation Signage: **A**-Evacuation signs; **B**-Directional induction lines made of photoelectric images and reflective materials.
- Illumination: **A**-Emergency lighting system; **B**-Emergency lighting, evacuation sign illumination, identification lighting, evacuation lighting.
- Emergency Communication: **A**-GSM-R radio communication and radio, video collection; **B**-Fixed telephone and video collection, railway-specific mobile communication, public mobile communication.
- Inner Tunnel Crossover: **A**-Installed; **B**-Not present.
- Inner Tunnel Station: **A**-Two multifunctional rescue stations at each location; **B**-One emergency rescue station basic equivalent.
- Rescue Station Spacing: **A**- ≤ 20 km; **B**- ≤ 20 km.
- Rescue Station Transverse Passage Spacing: **A**- ≤ 90 m; **B**- ≤ 50 m.
- Platform Width: **A**-2 m; **B**-1.3 m.
- Transverse Passages: **A**-General transverse passage spacing of 325m, 333m; **B**-400-500m.
- Rescue Trains: **A**-Dedicated rescue trains; **B**-Not present.
- Reliability of Power Equipment: **A**-Equipment power supply, cables, etc., meet fire resistance requirements; **B**-Rescue station level 1 power load, other level 2 power load, cables, meet fire resistance requirements.
- Contact Wire Power Off and Grounding: **A**-Segment switching and grounding, remote control;

B-Two contact wire segment switches at rescue station ends, electric phase separation between tunnel stations.

- Equipment Monitoring: **A**-Central control system installed; **B**-Remote monitoring and control.
- Emergency Plans: **A**-Comprehensive; **B**-Comprehensive.
- Command Center: **A**-Operations control center and emergency command post on-site; **B**-Tibet railway company emergency command center.

The above table shows that the disaster prevention, evacuation, and rescue measures of typical projects both domestically and internationally are mostly comparable, with some differences in certain aspects. In the Gotthard Base Tunnel, for instance, four in-track passages are installed (a common practice for long European tunnels), along with dedicated rescue trains. In this regard, some domestic tunnels have only a few high-altitude railways that have planned for backup trains, while others rely on maintenance area backup trains or nearby passenger trains for rescue and evacuation.

The principles for setting up emergency rescue stations, evacuation modes, civil engineering structures, electromechanical facilities, monitoring systems, and emergency management systems are generally consistent for both domestic and international segmented tunnels. Comprehensive disaster prevention and rescue facilities have been established in both cases to meet the requirements for disaster prevention, evacuation, and rescue.

5 ANALYSIS OF INTER-TRACK PASSAGE ISSUE IN SEGMENTED TUNNELS

The significant difference between China and European countries in their ultra-long tunnels lies in the fact that European ultra-long tunnels are all equipped with inter-track passages connecting the left and right tunnel tubes. For example, the Gotthard Base Tunnel in Switzerland and the Lötschberg Tunnel have inter-track passages between the tubes.

On the contrary, Chinese ultra-long tunnels do not have inter-track passages between the tunnel tubes, which differs from the operational safety design in Europe. In light of this, some experts raise the question of whether China's operational safety measures for ultra-long tunnels are less effective compared to Europe. The following analysis aims to provide a comprehensive examination of the necessity of inter-track passages in ultra-long tunnels.

5.1 Reasons for setting up inter-track passages in Europe

Channel Tunnel: The entire tunnel is equipped with 4 cross passages to connect the two tracks, allowing trains to switch tracks or reverse (Dai, 2001).

Purpose of inter-track passages in the Gotthard Base Tunnel and Lötschberg Tunnel: When one tunnel requires maintenance, the other tunnel can ensure continuous operation; in case of emergencies, the alternate tunnel offers flexible operational possibilities (Chen, 2006).

From the above discussion and analysis, the purpose of setting up inter-track passages is to enhance the flexibility of transportation and maintenance in tunnels. The decision to transfer trains to adjacent tracks should be determined based on the requirements of maintenance work or the characteristics of incidents occurring within the tunnel.

Figure 4. Schematic layout of the Lötschberg tunnel.

5.2 Safety assurance after implementing the cross-passage system in Europe

The cross-passages are integrated into the signal system, and the operation of the protective doors (located in the middle of the cross-passage tunnel) is interlocked with the signal system, ensuring safety.

5.3 Reasons for the absence of cross-passage system in China

Taking into account the characteristics of railway tunnel projects in China, railway operations, maintenance, and disaster handling regulations, the reasons for not implementing the cross-passage system within tunnels in China are summarized as follows:

- (1) China operates its railways on a single line section basis. Currently, there is no need for tunnel stations due to the extended length of tunnels. As a result, the requirement to maintain operations through the installation of cross-passages for long tunnels does not exist in China. Maintenance of equipment is carried out during scheduled maintenance windows, and for dual-bore single-line tunnels, a “V” type maintenance arrangement is commonly adopted where one tunnel bore is under maintenance while the other remains operational. This obviates the need for cross-passages for maintenance purposes.

- (2) The railway operation and management practices in China differ from those in Europe. Emergency rescue stations cannot be integrated into the train control system. Consequently, the implementation of a cross-passage system within tunnels cannot be incorporated into the train control system operationally.
- (3) When one tunnel bore is affected by a fire, the other safe tunnel bore is required for evacuation and rescue operations. Under such circumstances, the safe tunnel bore cannot be maintained for normal operations, rendering the need for a cross-passage system unnecessary.
- (4) After the completion of emergency evacuation and rescue operations, the remaining work within the affected tunnel bore is similar to equipment maintenance. In this scenario, one tunnel bore is used for post-fire disaster relief and recovery operations while the other remains operational. This interval can be maintained in single-line operation mode without requiring a cross-passage system.
- (5) If a cross-passage system is installed within a tunnel and a fire incident occurs, activating the cross-passage system would result in the interconnectedness of the two tunnel bores. This would necessitate the installation of complex independent ventilation systems between the two tunnel bores, leading to higher engineering investment, greater technical complexity, higher maintenance requirements, increased operational expenses, and stringent operational demands.
- (6) Similar to Europe, there is a shared understanding that the more cross-passages are installed on a line, the less conducive it is to railway operational safety. Therefore, even in the case of the Saint Gotthard Tunnel, efforts are made to control the number of cross-passages. For instance, in the feasibility study of the Wushaoling Tunnel on the Lanzhou-Xinjiang Railway, a cross-passage solution was initially proposed but was later abandoned due to operational safety considerations.
- (7) The tunnels with emergency rescue stations and cross-passage systems are typically long mountain tunnels. If cross-passages were to be installed in the middle of such tunnels, it would require strict control of the longitudinal gradient within a certain range near the turnouts. This could have implications for tunnel alignment considerations.

Considering factors such as operational requirements, safety, economic feasibility, and operational management, it is not necessary to implement cross-passage systems connecting the up and down tracks within China's railway long tunnels.

6 CONCLUSIONS

- (1) The specific measures of emergency rescue stations in China have continually evolved and improved with the progression of time. The

development has transitioned from the early days of single-bore tunnels to the mutual rescue of dual-bore tunnels, and subsequently to the later implementation of "fixed-point evacuation." The designs for disaster prevention and evacuation during various periods have been continuously refined, drawing inspiration from excellent engineering examples abroad. Notably, projects such as the Taihang Mountain Tunnel, the New Guanjiao Tunnel, and the Chengdu-Lanzhou Railway Tunnel have also received international technical consultations, resulting in a constant elevation of technical proficiency. Each of these projects represents the pinnacle of their respective eras.

- (2) By comparing the disaster prevention, evacuation, and rescue projects of typical long and large tunnels both domestically and internationally, it is evident that the principles, evacuation modes, civil structures, electromechanical facilities, monitoring systems, and emergency management systems for segmented and fully-bored tunnels are fundamentally consistent. Comprehensive disaster prevention and rescue facilities have been established in both scenarios, fulfilling the requirements for disaster prevention, evacuation, and rescue.
- (3) Due to variations in economic development and differences in domestic and international operational management methods, there are certain disparities in the design patterns of disaster prevention, evacuation, and rescue projects. After careful analysis and research, it is concluded that the inclusion of track crossovers near emergency rescue stations is not aligned with China's railway operational management model. In China, the practice of not installing in-tunnel crossovers in segmented tunnels and not dedicating separate rescue trains is consistent with the national context.

ABSTRACT: High geothermal tunnel (HGT) refers to the tunnels where the temperature of surrounding rock mass is higher than 28°C. The normal way for utilizing the heat resource and isolating heat conduction to the tunnel lining is to set up a circular system of ground source heat pump (GSHP). Here, an innovative system to harness geothermal energy with thermoelectric modules (TEMs) was proposed. The proposed system could convert the geothermal energy from surrounding rock into electricity based on Seebeck effect. Conceptual design of the system was introduced firstly. With the help of Multiphysics module of a finite element software, the technical feasibility of the system was verified, and the influences of temperature fields in high geothermal tunnels and parameters of TEM on generation performance were analyzed through numerical simulation. The results can be concluded that (1) The amount of electricity generated by this system was considerable. A thermoelectric power system with 51020 TEMs, occupying an area of 1000 square meters, could reach a maximum output power of 9132 W when the surrounding rock temperature was 90 °C; (2) The generation performance of the system was positively correlated with the temperature difference between the two sides of thermal insulation layer (TIL), and had little to do with the hot side temperature of TIL; (3) The maximum output power of the TEM model first increased and then decreased when the height of TE legs increased. The optimal height of TE legs in high geothermal tunnels was found to be 1.6 mm.

1 INTRODUCTION

For the past few years, with the implementation of national major projects such as the West-to-East Power Transmission Project and the Western Development Program (WDP), railway traffic has begun to extend to the mountainous areas with complex geological conditions located in southwest China. Moreover, tunnels tend to be deep-buried and super-long (Ou et al., 2021), and many tunnels have to pass through geothermal anomaly areas. Due to frequent geological activities, these areas have extremely complex geological conditions and abundant geothermal resources (Zhang et al., 2022). Therefore, the emergence of a large number of high geothermal tunnels not only poses challenges for construction, but also provides opportunities for geothermal energy exploitation.

Currently, GSHP is the main method to utilize geothermal energy in tunnels (Walch et al., 2022; Yang et al., 2019, Revesz et al., 2016, Lee et al., 2016). It uses geothermal energy to provide hot water, heating, cooling and other services for buildings. However, GSHP can only utilize geothermal energy through heat exchange (Ogunleye et al., 2020), which somewhat restricts the application range of geothermal energy in high geothermal tunnels. Furthermore, due to the

unbalanced heating and cooling loads, the GSHP system may release more heat to the underground during the cooling season than it absorbs from the underground during the heating season, causing a heat imbalance and lowering the performance of the GSHP system (Wang et al., 2010; Yuan et al., 2012). Xi et al. monitored the two-year operating performance and the variation in the underground thermal environment of a GSHP system installed in an office building in Hangzhou. They found that the heat imbalance rate of the system was approximately 24% in the first year and 53% in the second year. Additionally, the underground temperature around the heat exchanger area increased by 1.1 °C after two years of system operation, which led to a decrease in performance of the GSHP system (2017). Therefore, a more stable technology that can utilize geothermal energy in a wider range of applications is required to harness geothermal energy effectively in high geothermal tunnels.

In recent years, thermoelectric (TE) technologies have attracted widespread attention because they can directly convert thermal energy into electrical energy without any noise, vibration or emissions (Wu et al., 2022). This technology bases on the Seebeck effect, which occurs when a temperature gradient is formed along TE materials, causing the migration of charge

*Corresponding author: 2232571@tongji.edu.cn

carriers (electrons in n-type materials and holes in p-type materials) from the hot side to the cold side, thereby generating an electrostatic potential (He et al., 2019a). Compared to other energy converting technologies, TE devices have simple configurations, require no maintenance, operate in a solid-state manner and provide high reliability. These features give TE devices significant advantages in thermal energy harvesting for the recovery of waste heat (Jouhara et al., 2021) and utilization of clean energy (He et al., 2019b). In geothermal energy exploiting field, Li et al. designed a six-layer geothermal-TEG apparatus and tested its generation performance at a geothermal well. The entire six-layer device could generate about 500 W electricity with a temperature difference of about 152 °C (2021). Catalan et al. investigated the suitability of a geothermal thermoelectric generator with passive phase change heat exchangers on the shallow Hot Dry Rock (HDR) field of Timanfaya National Park (Spain). The device has been in operation without maintenance for 2 years now, producing more than 520 kWh of energy (2023). These indicate that thermoelectric technology exhibits a highly stable performance in the field of geothermal energy exploitation.

Since geothermal energy is renewable and stable (Mahmoud et al., 2021), there is always a large temperature difference between the surrounding rocks and the interior of the high geothermal tunnel. Therefore, TE devices can be used to harvest and convert the geothermal energy into electrical energy, which can then be used to power the operation of tunnels. Additionally, employing TE devices in high geothermal tunnels can address the issue of long-distance power supply. The main purpose of this article is to propose a concept for a thermoelectric power system in high geothermal tunnel, verify the feasibility of such a system, and analyze its main influencing factors on power generation performance. The results indicate that the thermoelectric power system is a promising technology for harnessing geothermal energy in high geothermal tunnels.

2 CONCEPT

The thermoelectric power system in high geothermal tunnels consists of thermoelectric modules (TEMs), thermal insulation layer (TIL), heat conducting blocks and bearing modules. Since TIL is generally filled with materials of low thermal conductivity, it can effectively block the heat transferred from the surrounding rock to the tunnel, and a certain temperature difference will be formed between the two sides of TIL. Therefore, based on Seebeck effect, TEMs can be installed in the TIL of the tunnel to convert the heat from the surrounding rock into electricity, which could be stored by the electrical storage module for tunnel operation. The positional relationship of each part of the system is shown in Figure 1.

Figure 1. Cross-section diagram of the thermoelectric power system in high geothermal tunnel.

The temperature difference between the two sides of TIL is positively correlated with its thickness, and furthermore, when the thickness is less than 10 cm, its impact on the temperature difference becomes more obvious (Ma et al., 2023). Temperature difference is critical to the generation performance of TEMs, so it is significant to maintain the thickness of TIL during the operation of tunnels. However, thermal insulation materials and TEMs have low compressive strength, making them prone to deformation under the surrounding rock pressure. This deformation leads to a decrease in the thickness of TIL, resulting in a reduced temperature difference between the two sides of TEMs. Therefore, in order to withstand the pressure from surrounding rock and maximize the temperature difference, bearing modules made of materials with low thermal conductivity and high mechanical performance are required. Bearing modules and TIL are arranged alternatively between the initial lining and the secondary lining, as shown in Figure 2. The sizes and spacings of bearing modules are determined based on the surrounding rock pressure.

Figure 2. A design diagram of the thermoelectric power system in the direction of tunnel axis.

A TEM generally consists of many thermoelectric couples, connected by copper strips and packed by two ceramic plates (Luo et al., 2020). The thickness of a single TEM is generally 5 mm, while the TIL usually has a thickness of 5~10 cm. Therefore, in order to make the best use of the temperature difference between the two sides of TIL, it is necessary to add two heat conducting blocks between the ceramic plates of TEM and the tunnel linings, as shown in Figure 3. Through the heat conducting block attached to the surface of the initial lining, heat can be transferred from the surrounding rock to the hot side of TEM effectively. Furthermore, the heat transferred from the hot side of TEMs to the cold side through the couples and medium between the two ceramic plates accumulates at the colder ceramic plate, thereby reducing the temperature difference between the two sides of TEMs. Subsequently, this

heat can be transferred from TEMs to the secondary lining through the heat conducting block attached to it and carried away by the air flow in the tunnels, thus maintaining the temperature difference between the two sides of TEMs.

Figure 3. A detailed diagram of the thermoelectric power system in high geothermal tunnel.

The surfaces of the ceramic plates, the heat conducting blocks and the tunnel linings are not smooth planes. There are a lot of tiny bumps and depressions in the planes, so the heat transfer efficiency will be significantly reduced due to point contact. To increase the contact area and reduce the thermal resistance in heat transfer, the gap between these surfaces should be filled with silicone thermal grease or high thermal conductivity graphite sheets. In addition, the temperature difference between the surrounding rock and the air in the tunnel leads to heat transfer from the hot side of TEMs to the cold side. Therefore, the empty space between the two ceramic plates of TEM should be filled with thermal insulation materials to maintain the temperature difference and ensure stable generation performance.

Additionally, the low voltage and instability of the direct current generated by the thermoelectric effect of TEMs do not meet the requirements of general electrical appliances in tunnels. It needs to be boosted and stabilized before it can be used for tunnel operation.

3 MODELING

A finite element software was used to model and simulate the thermoelectric power system in high-geothermal tunnel. A heat transfer model of high geothermal tunnel and a thermoelectric power system model were established during the analysis. By using the former model, the thickness of TIL was decided and the temperature of the both sides of TIL under different temperature conditions of surrounding rock were obtained. These results were then utilized as the temperature boundary conditions for the latter model to verify the feasibility of the thermoelectric power system in high-geothermal tunnels. Subsequently, the influences of temperature difference, the temperature of hot side, and the height of TE legs on the generation performance of the thermoelectric power system were analyzed.

3.1 Heat transfer model of high geothermal tunnel

Since the heat transfer in the axial direction of the tunnel is much smaller than that in the radial

direction, a two-dimensional(2D) plane model was used. Because thermoelectric power systems are designed to use during the operation of high geothermal tunnels, a steady-state solver was utilized for computation, and only solid heat transfer was considered in this process. The solid heat transfer between the surrounding rocks, linings, and TIL is governing by the following equation,

$$\rho C_p \frac{\partial T}{\partial t} + \nabla \cdot \vec{q} = \dot{q} \quad (1)$$

Where, C_p is specific heat capacity, \vec{q} is heat flux vector, ρ is the density, T is temperature and \dot{q} is the heat generation rate per unit volume.

3.1.1 Geometric and material parameters

The geometric parameters and material parameters referred to the literature (Lin et al., 2022). The dimensions of the entire model were 100 m × 100 m. The width and height of the tunnel cross-section were 10.8 m and 8.1 m, respectively. The initial lining had a thickness of 20 cm, while the secondary lining had a thickness of 45 cm. Additionally, TIL was between the initial lining and the secondary lining. The model is shown in Figure 4. The material parameters are shown in Table 1. C25 concrete was used for the initial lining, and C30 concrete was used for the secondary lining.

3.1.2 Thickness of TIL

According to the Standard TB 10068-2010, the air temperature in railway operating tunnels should not exceed 28 °C, thus the temperature inside the tunnel was set at 28 °C. The convective heat transfer coefficient of concrete surface was 13 W/m²·°C. The boundary temperatures of the model were set at 50 °C, 60 °C, 70 °C, 80 °C and 90 °C, respectively and remained constant. The temperature differences between the two sides of TIL for various thicknesses of TIL under different boundary conditions are shown in Figure 5. It can be observed that the temperature difference between the two sides of TIL was positively correlated with the thickness of TIL. However, as the thickness of TIL increases, the impact of TIL on temperature difference gradually diminished. When the boundary temperature of model was 90 °C, the temperature difference was only 9.14% larger when the thickness of TIL was 12 cm compared to when it was 10 cm. Therefore, considering the economy, the thickness of TIL of the model was set at 10 cm in the subsequent numerical simulations. The temperatures of both sides of TIL and the temperature differences between the two sides of TIL under different conditions are shown in Figure 6.

3.2 Thermoelectric power system model

A part of the thermoelectric power system in high geothermal tunnel was modeled to analyze the

Figure 4. The heat transfer model of high geothermal tunnel.

Table 1. Material parameters of the heat transfer model for high geothermal tunnel.

	Specific heat (J/kg·K)	Thermal conductivity (W/mK)	Linear expansion coefficient	Density (kg/m ³)
Surrounding rock	707	2.3	0.6e-6	2000
TIL	1720	0.0222	1e-5	32
C25 concrete	960	2.94	1e-5	2100
C30 concrete	960	2.94	1e-5	2500

Figure 5. The relationship between the thickness of TIL and temperature difference between its two sides under varying surrounding rock temperatures.

Figure 6. Temperature difference between the two sides of TIL under varying surrounding rock temperature when the thickness of TIL was 10 cm.

generation performance of the system. The thermoelectric effect interface of the finite element software was utilized for research. This interface couples the solid heat transfer field with the electric field. The entire model boundary was adiabatic. Electric charge continuity equation is expressed as follows,

$$\nabla \cdot \left(\vec{J} + \frac{\partial \vec{D}}{\partial t} \right) = 0 \quad (2)$$

where \vec{D} is the electric flux density vector and \vec{J} is the electric current density vector.

The following thermoelectric constitutive equations are used to couple the Equation. (1) and (2),

$$\vec{q} = T[\alpha] \cdot \vec{J} - [\kappa] \cdot \nabla T \quad (3)$$

$$\vec{J} = [\sigma] \cdot \left(\vec{E} - [\alpha] \cdot \nabla T \right) \quad (4)$$

where $[\kappa]$ is the thermal conductivity matrix, $[\alpha]$ is the Seebeck coefficient matrix, and $[\sigma]$ is the electrical conductivity matrix.

The model consisted of TIL, heat conducting blocks and TEMs. The material parameters of TIL were identical to those of the heat transfer model for high geothermal tunnels made in the section 3.1.

The TEM model was based on the geometric parameters of the commercial TEP1-1264-3.4, as provided in the literature (He et al., 2019b). The geometric parameters are listed in Table 2. The thermoelectric material used in this TEM was bismuth telluride, which has the best performance for low-temperature operations ($T < 500$ K). And the temperature-dependent material parameters were also based on the literature, and are expressed by cubic polynomial functions listed in Table 3. The TEM model consisted of 126 pairs of p- and n-type Bi₂Te₃ legs connected electrically in series by copper blocks, which were used as equivalent substitutes for wires, and thermally in parallel, as illustrated in Figure 7. The ceramic plates of the TEM were made of aluminum oxide. The parameters of the non-thermoelectric materials mentioned above are presented in Table 4.

The TEMs were located in the middle of the TIL, and they were connected electrically in series by copper blocks. An iron block with adjustable resistivity was used as the load resistance. Heat conducting blocks were positioned at both the top and bottom of the TEMs. The heat conducting blocks were made of copper, and its material parameters were the same as those used in TEM models. The voids between the ceramic plates of TEMs were filled with thermal insulation materials. The system model with four TEMs is depicted in Figure 8. The dimensions of the entire model were 66 cm×24 cm×10 cm. The thermal resistance and electrical resistance at the contact surfaces were $2 \times 10^{-4} \text{ m}^2\text{KW}^{-1}$ and $6.5 \times 10^{-9} \Omega \cdot \text{m}^2$ respectively.

4 RESULTS AND DISCUSSION

In this section, the generation performance of the thermoelectric power system in high geothermal tunnel under different conditions was obtained through the model established in the previous parts

of this paper, and then the factors affecting the generation performance were analyzed, including the temperature difference between the two sides of TIL, the hot side temperature of TIL and height of TE legs.

4.1 Generation performance

The temperature differences between the two sides of TIL under different temperature boundary conditions which were obtained in section 3.1 were utilized as the boundary conditions to calculate the generation performance of the thermoelectric power system in high geothermal tunnels. The temperature on the cold side of the model remained constant at 28 °C. Figure 8 shows the open-circuit voltages and maximum output powers of the model with different numbers of TEMs under various temperature conditions of surrounding rock. It can be seen from Figure 8 that the maximum output power and open-circuit voltage are proportional to the number of TEMs in the model. Therefore, to generate electricity on a larger scale, more TEMs are needed. The model with one TEM could generate 0.179 W electricity when the temperature of surrounding rock was 90 °C, and the open-circuit voltage could reach 1.428 V. Based on the simulation results, assuming the TEMs are 10 cm apart, as in the model, we can conclude that a thermoelectric power system with 51020 TEMs, occupying an area of 1000 square meters, could generate approximately 9132 W of electricity when the surrounding rock temperature is 90 °C. Meanwhile, the abundant geothermal energy in the high geothermal tunnel ensures a stable generation performance of the system, making it more attractive. Additionally, a positive correlation between open-circuit voltage and maximum output power with the temperature of surrounding rock can also be observed. This is because when the temperature inside the high geothermal tunnel remains constant, an increase in the surrounding rock temperature will result in a greater temperature difference between the two sides of TIL. Consequently, this enhancement improves generation performance of the TEMs. Therefore, the higher the temperature of surrounding rock, the better the generation performance of this system.

Figure 7. Schematic of the TEM model. (a) Overall diagram of the TEM model, and (b) internal structure of the TEM model.

Figure 8. Schematic of the thermoelectric power system model with four TEMs. (a) Overall diagram of the system model, and (b) internal structure of the system model.

The temperature distribution of the model when the surrounding rock's temperature boundary condition was set at 90 °C is depicted in Figure 9. It can be observed that the temperature gradients primarily concentrated in the TEM location in the model, which is mainly contributed to the lower thermal conductivity of thermoelectric materials compared to other materials. Moreover, the temperature variation across the copper heat conductor was 2.62 °C, accounting for only 8.49% of the total temperature difference between the two sides of the model. This indicates that the copper heat conductors are highly efficient in heat transfer, and have almost no thermal loss. Therefore, heat conducting blocks made of high thermal conductivity should be placed between the TEMs and linings to improve generation performance of the system.

4.2 Effect of temperature conditions

The temperature of the surrounding rock in high geothermal tunnels varies due to different geological conditions, and the internal temperature requirements for tunnels of various uses also differ. These factors may affect the temperatures at both sides of the TIL. Since the Seebeck coefficient, electrical conductivity and thermal conductivity of thermoelectric materials are temperature-dependent,

changes in the temperature on both sides will result in variations in the generation performance of the system. Therefore, this section analyzed the generation performance of the system under different temperature conditions.

The influences of the temperature difference between the two sides of TIL and the temperature at the hot side of TIL on the open-circuit voltage and maximum output power of the model with one TEM are shown in Figure 10. As depicted in Figure 10, the variation in temperature difference between the two sides of the TIL had a great impact on the generation performance of the model. The open-circuit voltage of the model was proportional to the temperature difference. The maximum output power showed a positive correlation with the temperature difference and essentially follows a quadratic function relationship. For example, when the hot side temperature was 60 °C, the open-circuit voltage of the model with a temperature difference of 30 °C was triple that with a temperature difference of 10 °C and the maximum output power was nine times that with a temperature difference of 10 °C. Therefore, in order to improve the generation performance of thermoelectric power systems in high geothermal tunnels, it is necessary to increase the temperature difference between the two sides of the TIL.

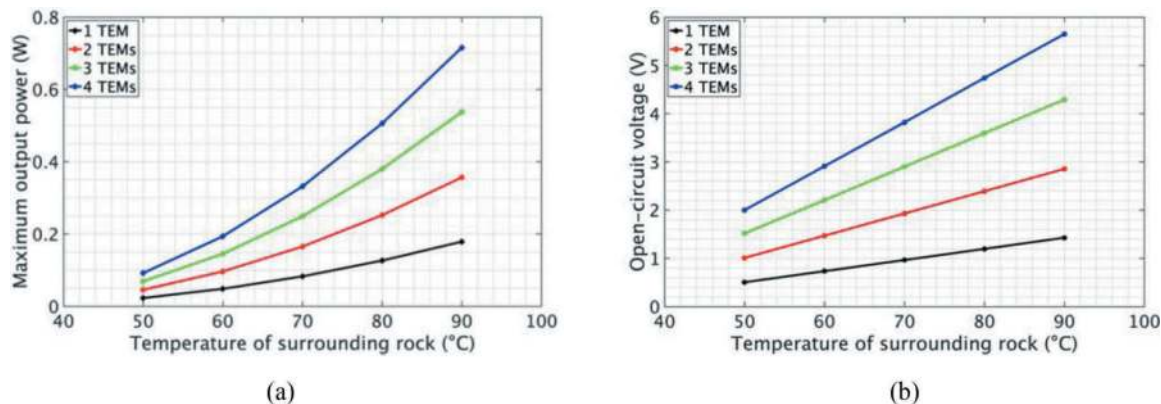

Figure 9. Generation performance of the thermoelectric power system model with different number of TEMs under various surrounding rock temperatures. (a) The open-circuit voltage, and (b) the maximum output power.

Figure 10. Temperature distribution of the system model when the temperature of surrounding rock was 90 °C.

It can also be observed that under the temperature conditions of high geothermal tunnels, changes in the hot side temperature had little impact on the power generation performance of the model. When the temperature difference between the two sides of the TIL was 30 °C, the maximum output power of the model with a hot-side temperature of 60 °C was only 3.13% lower than that with a hot-side temperature of 40 °C,

and the open-circuit voltage differed by only 0.68%. Therefore, as long as there is a sufficient temperature difference for thermoelectric power systems to generate electricity, the same power generation performance can be achieved regardless of the temperatures on both sides of the TIL. This further expands the application range of thermoelectric power systems in the field of tunnels.

4.3 Effect of height of TE legs

The generation performance of the thermoelectric power system in a high geothermal tunnel is not only related to the temperature difference but also influenced by the geometric factors of the TEMs. This section analyzes the effect of the height of the TE legs on the system's generation performance.

Figure 11 illustrates the correlation between the generation performance of TEM model and the height of TE legs. It can be observed that the open-circuit voltage of the TEM model was positively correlated with the height of TE legs, while the maximum output power of the TEM model first increased and then decreased when the height of TE

Figure 11. The relationship between the generation performance of the system model with one TEM and the temperature conditions. (a) The open-circuit voltage, and (b) the maximum output power.

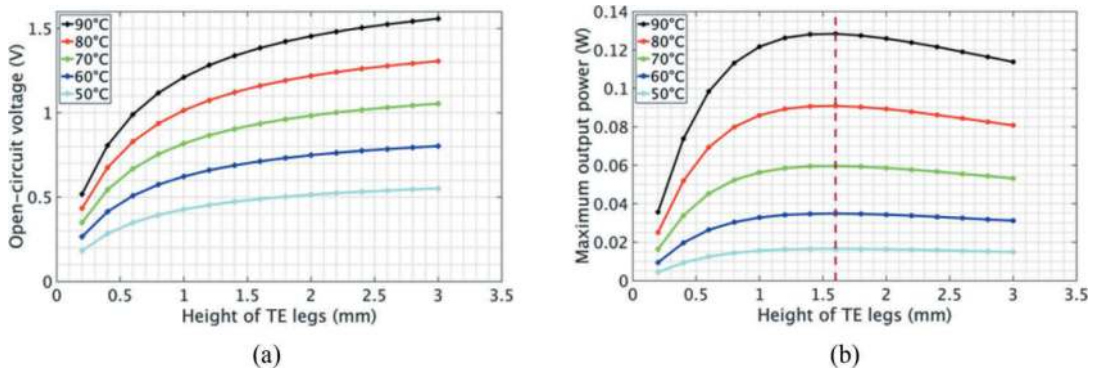

Figure 12. The relationship between the generation performance of the TEM model and the height of TE legs. (a) The open-circuit voltage, and (b) the maximum output power.

legs increased. This is because the height of TE legs is related to the thermal resistance and electrical resistance of the TEM, which have different effect on generation performance. When the height of TE legs increases, both the thermal resistance and electrical resistance increase. As a result, the higher thermal resistance leads to a greater temperature gradient across the thermoelectric couples, resulting in an increased open-circuit voltage of TEM. However, the increase in electrical resistance decreases the maximum output power of TEM. Additionally, according to Figure 15, it can be observed that the optimal height of TE legs was 1.6 mm. When the temperature of surrounding rock was set at 90 °C, the maximum output power of the TEM model with a height of 1.6 mm for the TE legs was 5.51% higher than that of the TEM model with a height of 1.0 mm for the TE legs.

5 CONCLUSIONS

This paper proposes a conception of thermoelectric power system in high geothermal tunnel as an innovative design. To evaluate the generation performance of the thermoelectric power system in high geothermal tunnel, a three-dimensional finite element numerical simulation of the system under various surrounding rock temperatures and number of TEMs was carried out. Meanwhile, the factors that influence the generation performance of the system was analyzed. The results indicates that:

- 1) Based on the simulation results, we can speculate that a thermoelectric power system with 51020 TEMs, occupying an area of 1000 square meters, could reach a maximum output power of 9132 W when the surrounding rock temperature was 90 °C. The stable performance and considerable electricity generated by the system made the thermoelectric power system a promising way to harness the geothermal energy in high geothermal tunnels and alleviate the power supply problems of these tunnels.
- 2) The maximum output power of the system was positively correlated with the temperature difference, and they followed a quadratic function relationship. Therefore, increasing the temperature difference is an effective method to improve the performance of the system.
- 3) The hot side temperature had little effect on the generation performance of the system under temperature fields of high geothermal tunnels. Regardless of the temperature of the hot side, the system can achieve essentially the same power generation performance with a consistent temperature difference.
- 4) The maximum output power first increased and then decreased when the height of TE legs increased. And the optimal height of TE legs for the system in high geothermal tunnel was 1.6mm.

ABSTRACT: Aiming at the current technical status that currently treating defects in existing railway tunnels is mainly done by hand with high operation intensity, low efficiency and a lack of safety guarantee, this Paper develops a series of complete equipment for mechanized construction of defect remediation in existing railway tunnels. This series of equipment is able to do self-access to and self-walk on existing railways. Based on modular design concept, drilling, slotting, green cutting, arch installing and concrete spraying modules are designed with a quick functional interchangeability, realizing the mechanized construction of key processes in whole construction process of common treatment technology for tunnel defects, increasing the construction efficiency by 2-3 times when compared with traditional operation methods and reducing the number of operators by more than 50%. In addition, cleaning hole by high pressure water, dust removal by spraying high pressure water and other measures are used to greatly decrease the construction dust discharge and improve the working environment in tunnels.

Keywords: Railways in operation, defect treatment, mechanized construction, complete equipment

1 INTRODUCTION

By the end of 2022, the total operating mileage of railways has reached 155 000 km in China. To be specific, 17 873 railway tunnels have been put into operation, with a total length of 21 978 km as shown by Gong J. F., et al. (2023). With the gradual transition from the peak period of tunnel construction to the peak period of tunnel repair in China, the common defects of water leakage, lining cracking, and back cavity in tunnels are becoming more and more serious. When diseases occur, railway operators often treat them by bolting and shotcreting support or molded lining technology. The main procedures involved include construction of the work platform, drilling of bolt holes, chipping and slotting of lining, installation of bolts and drill rods, fixation of reinforcing meshes, erection of steel formwork, pouring or shotcreting of concrete, spraying of waterproof

coatings, etc. At present, the above procedures are still mainly manual operations with low construction efficiency, high operation intensity, and high risks in safety construction, which is obviously difficult to provide operational safety guarantees for the rapidly developing transportation network as shown by Gao J.R., et al. (2018). Based on the above situation, in the paper, a complete set of equipment for treating the defects of operating tunnels was developed targeting the key procedures, such as drilling, chipping, slotting, arch frame installation, and concrete shotcreting, which currently restrict the construction efficiency of treating the defects of operating tunnels as shown by Gao J.R., et al. (2019). For the first time in China, full-face mechanization of the key procedures of treating the defects of operating railway tunnels was realized.

This series of equipment was composed of a guide assembly, a double rotation assembly,

*Corresponding author: 648309437@qq.com

a mechanical arm assembly, a drilling, chipping, and slotting assembly, etc. It could be controlled flexibly due to its high degree of spatial freedom, and had the functions of quickly getting on and off the existing lines and walking by itself, which reduced the construction difficulty and labor intensity of treating the defects of operating tunnels, and improved the construction efficiency, quality, and operation safety. Compared with traditional manual operation modes, by using the developed series of equipment, the construction efficiency of single machine for the bolt hole drilling procedure was increased by 8-10 times, and the number of operators was reduced by more than 60%; the construction efficiency of the lining slotting procedure was increased by 7-8 times, the number of operators was reduced by more than 50%, and the tunnel lining slotting operation was dust-free; under the same construction efficiency of the lining chipping, arch frame installation, and concrete shotcreting procedures, the number of operators could be reduced by more than 80%, and high-pressure water was used for dust settling by spraying, which effectively improved the working environment in the tunnel.

2 EQUIPMENT SCHEME DESIGN

2.1 Design principles

- (1) The complete equipment for treating the defects of operating tunnels shall have the functions of drilling, chipping, slotting, arch frame installation, and concrete shotcreting.
- (2) The complete equipment for treating the defects of operating tunnels shall have the function of walking by itself, and shall not intrude into the rolling stock clearance for railway in the process of entering or exiting the tunnel (in a non-operating state).
- (3) The complete equipment for treating the defects of operating tunnels shall be able to avoid the carrier cables and overhead lines to carry out operations on the tunnel roof (drilling, chipping, slotting, arch frame installation, and concrete shotcreting).
- (4) The operating range of the complete equipment for treating the defects of operating tunnels shall be able to cover all areas of the circular section the tunnel.
- (5) The complete equipment for treating the defects of operating tunnels shall be designed based on the modular design concept, through universal interfaces of different function modules, to realize fast conversion of the functions of drilling, chipping, slotting, arch frame installation, and concrete shotcreting of the multifunctional operation trolley.
- (6) The complete equipment for treating the defects of operating tunnels shall be designed with emergency and safety guarantee devices, which can effectively and quickly move the equipment out

of the operation area to avoid the impact on train operation in case of equipment failure during operation.

2.2 Main technical parameters

- (1) Total weight of equipment: 10, 200kg
- (2) Operating range of equipment: maximum height 8m, maximum width 6.1m
- (3) Total equipment power: 65kW
- (4) Drilling range of equipment: 41-102mm
- (5) Maximum drilling depth of equipment: 25m
- (6) Drilling efficiency of equipment: 1m/min (average)
- (7) Chipping efficiency of equipment: 70m²/h
- (8) Maximum chipping depth of equipment: 20mm
- (9) Gouging efficiency of equipment: 0.2m/min (drainage channel with regular size)
- (10) Maximum gouging width of equipment: 200mm
- (11) Maximum gouging depth of equipment: 200mm
- (12) Concrete shotcreting efficiency of equipment: 8m³/h
- (13) Maximum unit weight of installed arch frame of equipment: 1t
- (14) Installation efficiency of arch frame of equipment: 4-5 trusses/h.

2.3 Scheme design

The overall design scheme is shown in Figure 1. The equipment was mainly composed of a crawler-type road-rail transport platform, drilling assembly, slotting assembly, chipping assembly, arch frame installation and concrete shotcreting assembly, as well as emergency rescue equipment. Considering cost and safety, a crawler excavator was used as the carrier, and a special guide mechanism was designed to realize the excavator's getting on and off the lines and walking by itself on existing rails. The equipment was more flexible, and it had a short production and manufacturing cycle and high reliability. It was more suitable for the characteristics of small work amount, large number and wide distribution of works of treating the defects of operating railway tunnels.

2.3.1 Design of the road-rail excavator refitted transport platform

Considering that the equipment for treating defects needed to crawl along the railway ballast to the track, while taking into account the cost of equipment procurement, it was planned to use the excavator caterpillar chassis, excavator boom, and existing hydraulic control system for reconstruction design, and making full use of the existing equipment. After the defects were treated, the equipment could quickly restore the function of an excavator.

- (1) Selection of excavator

The cross-section dimensions and clearance requirements of the tunnels of single-track

railway, while taking account of the flow and pressure parameters of the hydraulic system of the selected excavator. It is recommended to use excavators between 10t and 13t for the tunnels of single-track railway, and 20t excavators for the tunnels of double-track railway.

(2) Design of guide system

The designed guide system used a hydraulic motor of the excavator to provide power with a maximum walking speed of 30km/h and a braking distance of 5m at the maximum operating speed, which effectively shortened the time of preparation for defect treatment in the early stage and scaffolding mobilization and demobilization.

Figure 1. Model diagram of the overall plan of the trolley.

Figure 2. 3D model of rear guide assembly.

2.3.2 Design of bolt drilling assembly

(1) Design of propelling beam

According to the cross-section dimensions of the tunnel, the propelling beam was designed to have a total length of 4.5m, and the one-time drilling depth without rod extension was 3.5m, which could meet the design length of most bolts. The maximum drilling depth after rod extension reached 20m. The three-dimensional model of the propelling beam assembly of the rock drill is shown in Figure 3.

Figure 3. Propelling beam assembly.

(2) Selection of rock drill

A hydraulic rock drill was preliminarily selected for drilling. On the basis of thorough research on various rock drills, considering the purchase cost and product performance, the Finnish Doofor DF530 rock drill was selected. The technical parameters are shown in Table 1.

Table 1. Technical parameters of DF530 Doofor hydraulic rock drill.

Model	Rated power (kW)	Oil pressure (Mpa)	Flow (L/min)	Rotation torque (N.M)	Drilling diameter (mm)
Hydraulic rock drill DF530	10	10-13	45-55	70-269	45

(3) Design of double rotation mechanism

In order to adjust the spatial orientation of the rock drill, especially for the construction of radial bolt holes of the tunnel, the pitching motion of the rock drill was adjusted using the rotation bearing and the arm oil cylinder of the excavator. SWE9 rotation bearing was selected based on the weight of the propelling beam to be selected.

2.3.3 Design of the slotting, chipping, arch frame installation, and concrete shotcreting assembly

The design of this part mainly includes the design of the universal floating boom and the design of various functional components.

(1) Design of the floating boom

As shown in Figure 4, the floating boom adopted a two-stage telescopic mode and used a hydraulic cylinder to provide power. The telescopic boom end was designed with universal interfaces for the functional components. The telescopic boom had a pitching function, which was used to realize the movement of all functional components along the cross-section of the tunnel. The telescopic boom was also designed with a rotation mechanism, which adopted a rotation support to provide rotation power. When the equipment entered and exited the site, the telescopic boom was parallel to the trolley boom through the rotation mechanism. When the trolley reached a defect treatment

work point, the telescopic boom was rotated parallel to the tunnel cross-section direction through the rotation mechanism.

Figure 4. Floating boom model.

- (2) Design of the chipping functional component
As shown in Figure 5, the chipping heads were arranged in quincunx. Compared with traditional manual operations, at each punch of chipping points, the chipping points were even and the chipping depth was controllable. Each hydraulic chipping heads had a retractable mechanism that could realize the self-adaptation of different lining surfaces.

Figure 5. Chipping functional component model.

- (3) Design of the slotting functional component
The slotting functional components mainly included a combined-type one-time cutting tool installed on the floating boom, a hydraulic motor driving the tool to rotate, and a mechanical limiting device, etc., as shown in Figure 6.

Figure 6. Slotting functional component model.

- (4) Design of the shotcreting component
The design of the shotcreting component is shown in Figure 7. It was mainly composed of a nozzle, a brushing mechanism, a 240° rotation mechanism, and a 360° rotation mechanism, which could flexibly realize shotcreting operations at various angles.

Figure 7. 3D model of the shotcreting component.

- (5) Design of the arch frame installation component
The arch frame installation component is shown in Figure 8. It mainly included a chuck, a pitching mechanisms, a 360° rotation mechanisms, etc., which could install the vault and the arch frame by bypassing the overhead lines.

Figure 8. 3D model of the steel arch frame installation component.

2.4 Working principle

- (1) Walking and braking of the complete equipment for treating the defects of operating tunnels
The developed complete equipment for treating the defects of operating tunnels was based on a road-rail excavator refitted transport platform (as shown in Figure 9), which adopted a crawler-type and wheel rail-type dual power mode. It realized the function of getting on and off the line and walking by itself on the existing line through hydraulic power switching. When the equipment reached a defect treatment work point, hydraulic braking was used.
- (2) equipment for treating the defects of operating tunnels
The developed complete equipment for treating the defects of operating tunnels was designed with

Figure 9. Road-rail transport platform.

a pitching boom, a folding boom, and a telescopic boom. When walking, these booms were collapsed to ensure that the overall size of the trolley did not intrude into the tunnel clearance. When operating, they were expanded to ensure that the scope of mechanization could cover the entire tunnel cross-section (as shown in Figure 10).

Figure 10. Schematic diagram of the operating range of the multifunctional operation trolley for operating tunnel maintenance.

- (3) The principle of switching between different functions of the complete equipment for treating the defects of operating tunnels
The developed complete set for treating the defects of operating tunnels adopted a modular design and shared a common transport platform. The switching of the functions of drilling, chipping, slotting, arch frame installation, and concrete shotcreting of treating tunnel defects could be realized by switching between different functional modules according to the requirements of the tunnel defect treatment procedures.
- (4) Principle of efficient drilling of the complete equipment for treating the defects of operating tunnels

The developed complete equipment for treating the defects of operating tunnels realized precise positioning and construction of radial holes on the tunnel vault by replacing drilling functional components, with a 360° double mechanism, and a laser-assisted positioning system. The drilling efficiency of the rock drill was ensured by using control systems such as real-time monitoring of system pressure, anti-trapping drill rod for surrounding rock breaking, and automatic drilling linkage (as shown in Figure 11).

Figure 11. Drilling operation of complete equipment for treating the defects of operating tunnels.

- (5) Principle of efficient chipping of the complete equipment for treating the defects of operating tunnels
By replacing the chipping functional component, the developed complete equipment for treating the defects of operating tunnels used an independent air-leg type floating mechanism to drive the hydraulic driven rotary punch-type chipping heads. All chipping heads were arranged in quincunx. Under the action of the floating boom, they could automatically adapt to the tunnel lining surface segment and closely adhered to the tunnel lining surface, and completed the tunnel lining chipping operation under the repeated vibration of the chipping heads (as shown in Figure 12).

Figure 12. Chipping operation of the complete equipment for treating the defects of operating tunnels.

- (6) Principle of efficient slotting of the complete equipment for treating the defects of operating tunnels

By replacing the slotting functional component, the developed complete equipment for treating the defects of operating tunnels used a combined-type high-speed rotary concrete cutting head. By adjusting the thickness of the cutter head and the depth of the feed, the mechanical one-time cutting and slotting of the steel arch frame installation groove or drainage channel could be realized. Precise alignment of the cutter head could be realized quickly by using a mechanical arm horizontal state monitoring system and a telescopic boom vertical auxiliary control system (as shown in Figure 13).

Figure 13. Slotting operation of the complete equipment for treating the defects of operating tunnels.

- (7) Principle of arch frame installation of the complete equipment for treating the defects of operating tunnels

By replacing the arch frame installation functional component, the developed complete equipment for treating the defects of operating tunnels realized the alignment, installation, and fixation of the arch frame in the tunnel by using a hydraulic claw to clip the arch frame and adjusting the spatial position of the arch frame through a telescopic mechanical boom, a rotation mechanism, and a pitching mechanism (as shown in Figure 14).

Figure 14. Slotting operation of the complete equipment for treating the defects of operating tunnels.

- (8) Principle of concrete shotcreting of the complete equipment for treating the defects of operating tunnels

By replacing the concrete shotcreting functional component, the developed complete equipment for treating the defects of operating tunnels realized concrete shotcreting with remote control through the combination of nozzle rotation and telescopic boom movements (as shown in Figure 15).

Figure 15. Concrete shotcreting operation of the complete equipment for treating the defects of operating tunnels.

3 ENGINEERING APPLICATION AND ECONOMIC ANALYSIS AND COMPARISON

3.1 Engineering application

Up to now, the series of complete equipment for treating the defects of operating tunnels have been applied in dozens of railway tunnel defect treatment projects such as Shanghai-Kunming, Baoji-chengdu, and Neijiang-liupanshui. The on-site applications are shown in Figure 16. The equipment exhibited stable performance, which improved the efficiency of operation, maintenance, and construction, and reduced the safety risk of the construction for treating the defects of the existing railway tunnels.

Figure 16. Photos of the equipment operating on the construction site.

3.2 Analysis of economic benefits of applications

Based on the data of the existing traditional manual operation procedures of the project, only the operational benefits of the drilling and slotting procedures were analyzed as shown by Zhang L., et al. (2022).

3.2.1 Analysis of economic benefits of drilling

To make the economic comparison and analysis of the mechanized bolt drilling operation and traditional manual pneumatic drill bolt construction operation, statistical analysis was made with the mechanized construction and manual pneumatic drill operation by the same construction team as an example, as shown in Table 2. It can be seen that the mechanized drilling operation is more than 8 times more efficient than the manual pneumatic drill operation.

3.2.2 Analysis of economic benefits of the slotting equipment

With the construction of the drainage channel for treating the defects of a tunnel of the Chengdu-Kunming Railway as an example, based on the on-site measurement of the efficiency of manual steel arch frame installation groove of a nearby tunnel, the efficiency of mechanized slotting and manual slotting was compared, as shown in Table 3. It can be seen that the efficiency of mechanized slotting operation was about 6 times that of manual operation, and the former had significant advantages in construction efficiency.

4 CONCLUSION AND PROSPECT

- (1) The complete equipment for treating the defects of operating tunnels that integrated functions such

Table 2. Comparison of efficiency and staffing between manual and mechanical slotting.

Compared item	Drilling of traditional manual pneumatic drill	Drilling of mechanized equipment	Remarks
Number of equipment	4 sets	1 set	
Staffing	8 persons (operated by 2 persons per equipment)	1 person	The auxiliary personnel were not counted.
Drilling duration	300min	70min	Pure operation duration
Work amount of drilling	36m (based on average quantity)	66m (based on average quantity)	
Average hole formation efficiency	0.12m/min	0.94m/min	Converted to per linear meter
Average duration of single hole formation	25min	3min	Calculated based on 3m bolt hole uniformly
Working environment	The exhaust noise of drilling was mostly around 120dB, and the oil used for lubricating the rock drill was directly discharged into the air. In addition, high-pressure air cleaning holes were used, which seriously polluted the working environment.	The noise of the hydraulic rock drill was generally below 90dB. High-pressure water cleaning holes were used, which significantly improved the working environment in the tunnel.	

Table 3. Comparison of efficiency and staffing between manual and mechanical slotting.

Compared item	Traditional manual slotting	Mechanized equipment gouging	Remarks
Groove type	Steel arch frame installation groove	Drainage channel	
Preliminary preparation duration	60min	30min	Including mobilization, demobilization and erection duration
Pure operation duration	50min	70min	The machinery did not require scaffolding
Technical parameters of the groove	Groove depth 200mm, groove width 160mm	Groove depth 80mm, groove width 80mm	
Work amount of gouging	0.5m	15m	
Staffing	4 persons	1 person	For manual operation, 2 persons per group, not including auxiliary personnel
Measured gouging efficiency	0.01m/min	0.2m/min	
Comparison of efficiency after converting earthwork	0.016m ³ /h	0.09m ³ /h	Efficiency after converting into the same slotting earthwork based on the measured data.

as drilling, slotting, chipping, arch frame installation, and concrete shotcreting, and had the functions of getting on and off and walking by itself on existing railway lines. Corresponding mechanized construction methods and technologies were proposed to improve the efficiency, quality, and operational safety of tunnel defect treatment.

- (2) To avoid short board effect, the research and development on mechanized treatment equipment for the defects at the bottom of tunnels are continued to be carried out. After gradually realizing the mechanization of key procedures for defect treatment, the comprehensive rail cars for treating the defects of operating tunnels will be developed actively, which have the function of synchronous and rapid treatment of multiple types of defect, to further significantly improve the efficiency of comprehensive treatment of tunnel defects.
- (3) Based on the developed complete equipment for treating the defects of operating tunnels and supporting mechanized construction technology,

a rapid repair technology for common flaws and defects of operating railway tunnels will be proposed, forming a technical system for treating the structural flaws and defects of operating tunnels, so as to promote the progress of operating tunnel maintenance technology.

Research trend and prospect of reconstruction and expansion technology of existing highway tunnels

Zekun Zhang*

School of Highway, Chang'an University, Xi'an, Shaanxi, China

ABSTRACT: The rapid development of the social economy leads to the increasingly obvious contradiction between highway transportation demand and capacity mismatch, and the reconstruction and expansion of existing highway tunnels has become a long-term effective means to improve the future highway transportation environment. The development trend and research dynamics of highway reconstruction and expansion are clarified through the literature search and statistical analysis of typical reconstructed and expanded highway tunnels. The current situation and shortcomings of the research on highway tunnel expansion schemes are pointed out, and the proposed expansion schemes are put forward based on the scheme comparison. Combined with four typical expansion methods and tunnel expansion coefficients, the proposed construction methods for expanding existing highway tunnels are presented. The research dynamics and shortcomings of mechanical response of surrounding rock, blasting vibration control are described. The application prospects of BIM technology, artificial intelligence technology, and green carbon neutral concepts in the reconstructed and expanded tunnels are proposed. It is pointed out that standardization of construction standards, intelligence of expansion plans, innovation of construction methods are the key research directions in the future.

Keywords: Highway tunnel, Reconstruction and expansion technology, Construction method, Surrounding rock stability

1 INTRODUCTION

In the past 10 years, the annual mileage of road tunnels in China has increased by 1,100 km. Urbanization has brought new challenges to the transport capacity of highway traffic. The capacity of the original tunnels can no longer meet the needs of transport, and tunnel expansion and reconstruction have gradually become an effective method to solve this problem (Li et al., 2012).

Tunnel alteration and expansion refers to the original tunnel whose construction standard cannot meet the traffic demand to be altered and expanded, and the original tunnel structure is removed to realize the expansion of the tunnel section (Peng et al., 2010). Due to the early completion of the tunnel by the design standards and construction level of the limitations of some tunnels construction cycle is short, and the quality of the project is insufficient, resulting in the tunnel operation process of the lining cracks, deformation, water seepage, concrete block spalling and many other defects. Coupled with the

influence of highway alignment and urban environment, expanded highway tunnels often face construction problems such as close connection to existing highways, large cross-sections, small clearances, tunnel clusters, and opening to traffic while construction is in progress (Zhang et al., 2020).

Reconstruction and expansion of tunnels will destroy the force balance of existing tunnels, resulting in the accumulation of damage to the surrounding rock, and then deformation and support structure overstressed, poor stability, and other problems (Li et al., 2014), increasing the difficulty of reconstruction and expansion of tunnels. China's research on road tunnel reconstruction and expansion technology is relatively small. It mainly focuses on the basic laws of tunnel expansion construction mechanics based on on-site monitoring and numerical analysis, expansion program and excavation method, and other primary research levels, lack of matching design specifications, and construction basis (Ell et al., 1999). The mechanical response characteristics of the surrounding rock of the reconstruction

*Corresponding author: 993606695@qq.com

and expansion construction, blasting vibration control technology, and monitoring support measures are not enough to explore, which hinders the development of tunnel reconstruction and expansion.

This paper clarifies the research content by reviewing the typical cases of reconstruction and expansion of highway tunnels at home and abroad in the past 20 years. It focuses on the research deficiencies in the reconstruction and expansion tunnel scheme, reconstruction and expansion excavation method, and tunnel surrounding rock stability. Finally, based on BIM technology, artificial intelligence technology, and the concept of green carbon neutrality, it puts forward the key research directions for the future.

2 DEVELOPMENTS AND RESEARCH DYNAMICS OF RECONSTRUCTION AND EXPANSION TUNNELS

2.1 Development trend

The earliest origin of tunnel expansion was the railroad tunnels in the 1990s. In order to meet the requirements of train limits and improve the transportation capacity, followed by speed up and expansion of existing railroad tunnels, such as the White Haven and Rockport railway tunnels in the U.S. (Elliott et al., 1999), the Rufenen railway tunnel in Switzerland (Deng et al., 1997), the Tower Nominee railway tunnel in Japan (Xian et al., 1996).

At the beginning of the 21st century, the reconstruction and expansion of highway tunnels gradually appeared. Overseas, the Tennoz tunnel (Xian et al., 1996) of the Meishin Expressway in Japan, the original tunnel was reconstructed and expanded due to the deformation and contraction of the cross-section. In 2004-2007, the Nazzano road tunnel (Lin et al., 2018) was widened in Italy, with a cross-sectional area of 158 m² after widening. In China, the expansion of the Damaoshan (Zhong et al., 2019) Tunnel on the Quan-Xia Expressway began in 2008. A new four-lane tunnel was built in the middle of the original separated two-way four-lane tunnel, and the original two-lane tunnel on the right was expanded in situ to four lanes, which became China's first four-lane highway tunnel combination reconstruction and expansion project. In 2018, the Housi Tunnel of the Xia-Rong Expressway was expanded from a two-lane to a four-lane tunnel, with a width of 20 m from 9 m, and an expansion length of 1002 m, which is the longest in-situ reconstruction and expansion of highway tunnels in China. In 2019, the Wenling Loushan Tunnel was completed reconstruction and expansion, which became the first case of in-situ reconstruction and expansion around a large cross-section with four lanes expanding to eight lanes in both directions in China (Cheng et al., 2020).

Table 1 summarizes the cases of domestic road tunnel reconstruction and expansion projects in the past 20 years and summarizes the characteristics of road tunnel reconstruction and expansion projects as follows:

Table 1. Typical engineering cases of tunnel reconstruction and expansion.

Type	Scheme		Project name (time)	Forward and backward forms	Tunnel parameters (W×H/m or S/m ²)	Enclosed rock grade/ Excavation method	Causes and characteristics

(1) The number of road tunnels to be reconstructed and expanded will gradually increase. With China's early road tunnels to meet the 25~40 years of service period, many road tunnels are facing reconstruction and expansion. Around 2035, road tunnel reconstruction and expansion will usher in an active period. (2) Highway tunnel reconstruction and expansion can improve capacity and ease traffic congestion. High-grade highway tunnels pay more attention to the quality of highway service and traffic efficiency(Zhang et al., 2022). Low-grade highway tunnels through reconstruction and expansion to solve the problems caused by the service life of the disease and have the role of improving construction standards at the meantime. (3) High-grade highway tunnels are mostly in-situ reconstruction and expansion, and new construction around the dual-hole four-lane expansion of eight lanes is given priority. Low-grade highway tunnels are mostly in-situ reconstruction and expansion to a single-hole, single-lane, two-lane expansion. Its expansion's length and cross-section size are higher than that of high-grade highway tunnels.

2.2 Research dynamics

In order to clarify the research dynamics of road tunnel reconstruction and expansion projects, CNIK, SCIE, ASCE, and other databases were searched. Taking "highway tunnel" and "reconstruction and expansion" as keywords, the literature between 1990 and 2021 was searched, and 178 pieces of literature were obtained, which can be divided into seven categories according to the research content, as shown in Figure 1.

Figure 1 shows that before 2010, the road tunnel reconstruction and expansion project was in the beginning stage, the attention to the problems faced by the reconstruction and expansion project was small, and academic research was low. After 2010, the number of road tunnel reconstruction and expansion projects increased, the attention increased significantly, and academic research is at a high level of growth. Analysis of the research content found that the existing research is more concerned about the stability of the surrounding rock, blasting vibration stability and excavation method, construction technology, and program selection. Due to the early stage of tunnel expansion, theoretical research and engineering experience still need to be improved, and we still need to pay in-depth attention to the expansion method, and construction technology. Existing research on the expansion of safety risk assessment and the application of BIM in the expansion of tunnels is relatively tiny. Pre-expansion of the existing tunnel safety assessment and monitoring of the stability of the surrounding rock in the construction process is still the focus of the research.

Figure. 1. Research trends in reconstruction and extension tunnels.

3 DYNAMICS OF TUNNEL EXPANSION TECHNOLOGY RESEARCH

3.1 Dynamics of research on conversion and expansion programs

3.1.1 Status of the study of the alteration and expansion program

According to the division of the reference factors for selecting the reconstruction and expansion program, the current selection mainly includes the construction stability analysis method and the comprehensive social analysis method.

(1) construction stability analysis method

Relying on the Chongqing Goose Ridge Tunnel, Gao et al. (2010) analysed the unilateral in-situ expansion, bilateral in-situ expansion, and the new small-clearance tunnels on the left and right sides respectively. They concluded that the unilateral in-situ expansion is the optimal solution, which aligns with the viewpoints of Zhu et al. (2012). Under topographic factors, Yang et al. (2013) found that the stress state of in-situ expansion is better than surrounding new construction. Using a similar model test, Sun et al. (2012) investigated the construction mechanical behaviours of surrounding in-situ expanded tunnels, unilateral in-situ expanded tunnels, and newly built tunnels. Considering the flow-solid coupling effect, Lai et al. (2019) verified the superiority of the small-clearance expansion scheme in terms of peripheral rock stress, deformation, and protection of groundwater resources.

The above scholars compare the construction stability of different expansion schemes to choose a relatively safe expansion scheme. However, some scholars (Xu et al., 2018) believe that although different expansion schemes have caused a certain amount of deformation of the surrounding rock, they did not affect the tunnel's safety. It can be seen that the construction stability analysis method is an objective quantitative analysis, but there is no uniform criterion for the safety of the expansion plan, and the analysis factors are relatively single, without considering the

interrelationship between the tunnel and the surrounding natural and social environment.

(2) Integrated social analysis method

The integrated social analysis method considers the connection and influence of the expansion program and the environment around the tunnel and has the characteristics of qualitative analysis. Lu et al. (2008) pointed out that the reconstruction and expansion of highway tunnels should meet the requirements of “safety, economy and environmental protection” and fully use the original tunnels to achieve sustainable project development. Zhang et al. (2019) compared and analysed ten kinds of continuous arch tunnel expansion schemes from the perspectives of traffic safety, reuse of the original project, and traffic organization. Wu et al. (2017) conducted an intuitionistic fuzzy preference study of the reconstruction and expansion scheme based on the TOPSIS method and established evaluation indexes for the reconstruction and expansion of mountainous highway tunnels relying on the Xia-long Expressway Reconstruction and Expansion Project, as shown in Figure 2. In addition, Xue et al. (2016) concluded that the unilateral in-situ expansion scheme has the advantages of sufficient space for expansion and a simple support structure, which belongs to the ideal highway tunnel expansion scheme.

The comprehensive social analysis method usually prioritizes factors such as the natural and social environment around the tunnel, project cost, construction period, and traffic volume. It belongs to a subjective qualitative scheme comparison method. For this reason, establishing a comprehensive, integrated quantitative evaluation of the advantages and disadvantages of different expansion programs is the critical research content of the future tunnel expansion program selection.

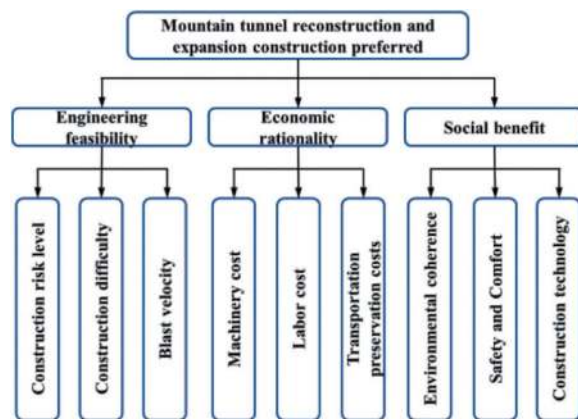

Figure 2. Evaluation index of expressway tunnel reconstruction and expansion in mountainous areas (Wu et al., 2017).

3.1.2 Comparative analysis of alteration and expansion options

Through the general analysis of the typical cases of road tunnel expansion, taking the two-lane road

tunnel as an example, the typical expansion schemes are shown in Table 2 (“a” represents the clearances).

At present, road tunnel expansion mainly involves high-grade and low-grade highway tunnels, and different scenarios of the expansion tunnel affect and determine the selection of the expansion program, which can be seen in Figure 5: For high-grade highway tunnels: (1) When there is enough space for expansion, the magnitude of the highway alignment adjustment is large, and the geologic conditions are poor, it is preferred to select the new surrounding program. (2) When the expansion space is insufficient, and the magnitude of alignment adjustment is small, the in-situ reconstruction and expansion program is preferred. (3) When the surrounding environment is complicated and has many constraints, the combined reconstruction and expansion plan is preferred. (4) The combination expansion or new construction around the program is preferred for highway tunnels with large traffic volumes and high operational demand. Low-grade highway tunnel: Due to the lower construction standards, and smaller traffic volume, the original tunnel disease is relatively prominent, preferred in-situ reconstruction and expansion program. The in-situ reconstruction and expansion program is adopted for municipal highway tunnels with narrow construction space, complex surrounding environments, and many adjacent buildings.

Table 2. Typical engineering cases of tunnel reconstruction and expansion.

Alteration and expansion program		Schematic of the program	
In-situ reconstruction and expansion	Single		
	Bilateral		
Surrounding			
New construction around	Horizontal		
Combined conversion and expansion			

3.2 Dynamics of tunnel excavation methods for re-expansion and expansion of tunnels

3.2.1 Division of excavation methods

(1) Conventional excavation method

The excavation division of the road tunnel expansion is shown in Figure 3, with the shaded portion being the backfill portion. Unlike conventional new road tunnels, large cross-section road tunnels with poor surrounding rocks are backfilled to the arch waist before in-situ expansion. Then, the widened portion is excavated according to the conventional method, and the backfilled portion improves the pressure on the surrounding rocks and enhances the stability of the tunnel. The double sidewall guide pit, CRD, and CD methods better control surrounding rock stability and deformation. However, the construction procedure could be more convenient, and the construction period is costly, which is suitable for highway tunnels with a large widening section, small clear distance, and poor surrounding rock stability. On the contrary, the full section and step methods have simple construction procedures and are suitable for highway tunnels with small expansion sections and better surrounding rock conditions.

Figure 3. In-situ expansion and excavation method.

(2) Jump drilling method

The expansion form of the trench jumping excavation method is shown in Figure 4. Tan et al. (2013) combined with the Yuzhou tunnel reconstruction and expansion project to determine the reasonable trenching length and the reserved spacing length of the trench jumping excavation. The slot-jumping excavation method utilizes the original tunnel support structure, which improves the stability of the surrounding rock during expansion excavation, and the slot partition can be used as a new construction section. This method is suitable for highway tunnels with large expansion sections and poor stability of surrounding rock. However, the number of segments using the trench jumping excavation method is larger, which requires higher construction management.

Figure 4. Jump drilling method.

(3) Layer peeling method

Figure 5 shows the excavation sequence of the layer peeling method, which is more suitable for a unilateral in-situ tunnel expansion program. The tunnel is first divided into longitudinal sections and then expanded horizontally in layers. However, the excavation steps of the layer peeling method are more, and the excavation section should not be too large. The safety and stability of the construction are greatly affected by the width and length of one horizontal excavation. Therefore, determining reasonable excavation parameters is the key to applying this method.

Figure 5. Layer peeling method.

(4) Keep unobstructed expansion method

The biggest problem of tunnel expansion construction is to affect the existing traffic operation. How to reconstruct and expand the tunnel under the condition of keeping the line alive and preserving the traffic is the focus of the research. Tonon (2010) introduced the method of expanding and excavating the tunnel while maintaining the traffic operation and its engineering application worldwide. Zhu et al. (2018) introduced the widening method used in the Nazzano tunnel in Italy, which separates the excavation face from the transportation face by installing a traffic shield. A cutting arm with a unique chain of teeth is installed in front of the shield to cut the broken surrounding rock, and the support tube sheet is installed with the help of a multifunctional mechanical transportation device, as shown in Figure 6. In addition, the tunnel expansion unit combination system was successfully used to expand the Kuckucksly railroad tunnel in Germany (Vetter et al., 2020), as shown in Figure 6 (b). The "Enlargement of live line tunnel method" was adopted in Japan to expand the Daizo Tunnel (Kamuro et al., 2001).

Figure 6. (a) Construction method of Nazzano tunnel (Lin et al., 2018) (b) Tunnel enlargement unit combined system (Vetter et al., 2020).

3.2.2 Excavation method selection

Considering the construction method of the built-in-situ reconstructed tunnel and the geological conditions of the surrounding rock, the expansion coefficient M is proposed to characterize the degree of expansion of the tunnel section.

$$M = \frac{B_2 H_2}{B_1 H_1} \quad (1)$$

Where: M is the tunnel expansion coefficient; B_2 is the net width of the reconstructed tunnel; H_2 is the net height of the reconstructed tunnel; B_1 is the net width of the original tunnel; H_1 is the net height of the original tunnel.

From equation (1), M is related to the tunnel's clear height and width before and after the reconstruction. The cross-section dimensional characteristics of the road tunnel can be confirmed based on the reconstruction and expansion plan.

Based on the established studies and engineering cases, M can be classified into two levels, as shown in Table 3. Level A has a larger increase in section size, generally adding 1 or 2 lanes to a single tunnel. Level B is mainly found in highway tunnels where only the excavation profile is enlarged without changing the number of lanes due to disease management or upgrading of the roadway grade.

Table 3. Grade table of tunnel amplification coefficient.

M	Level
$1 < M < 2$	B
$2 \leq M$	A

Combined with the constructed projects, the recommended excavation methods under different surrounding rocks and reconstruction grades are shown in Table 4. With the development of construction technology, future reconstruction tunnels are more inclined to the excavation methods with fewer excavation divisions and higher construction efficiency (Zhang et al., 2020)

3.3 Dynamics of surrounding rock stability research in reconstruction and expansion tunnels

3.3.1 Characterization of the mechanical response of the surrounding rock

Surrounding rock stress: In the process of in-situ tunnel reconstruction and expansion, the pressure of the surrounding rock in each part of the tunnel decreases with the demolition of the old lining and the expansion of the surrounding rock in that part of the tunnel, and then increases significantly with the application of the new lining and is significantly asymmetrically distributed, and the axial force of the anchor rods on the outer side of the tunnel is about 4-5 times of that on the inner side. The lining structure of the original tunnel can be used to play the role of temporary support during the expansion process. Local reinforcement measures can be taken for the part with high pressure on the surrounding rock. After the completion of the reconstruction and expansion, the plastic zone of the surrounding rock occurs in the inner side of the arch foot (Shu et al., 2012), the pressure of the surrounding rock generally increases, the structural bias is serious, and the stresses of the surrounding rock in the arch roof and arch waist are large. The compressive stress concentration occurs on both sides of

the tunnel, and the bottom plate and arch top compressive stress is minimal and tends to transition to tensile stress (Cheng et al., 2020). The center rock column is the weakest when the expansion forms a small-clearance continuous arch tunnel, and the upper step excavation has the greatest impact on its stability. Under the influence of the new tunnel, the pressure and stress of the surrounding rock near the center rock column increased significantly. When the clear distance is more than 0.5 times the span, the stress state of the center rock column is less affected by the clear distance (Shu et al., 2012).

Surrounding rock deformation: Influenced by the existing tunnel, the center line of the surface settlement groove curve is slightly shifted to the side of the expansion excavation, showing an asymmetric distribution of “single-peak, skew-normal.” When the reconstruction and expansion form a continuous arch tunnel, the surface settlement caused by the excavation of the backward hole is larger, and the maximum settlement occurs on the side of the forward hole. The problem of arch bottom uplift is more prominent when large section tunnels are rebuilt and expanded (Zhang et al., 2019). Sun et al. (2016) establish a mathematical model for the arch displacement of in-situ rebuilt and expanded tunnels:

$$U_R = \left[1 + \exp\left(\frac{x}{0.36R}\right) \right]^{L1} U_R^M \quad (2)$$

Lin Congmou et al. [70] regarded the surface settlement as the superposition of the settlement caused by the excavation of the existing tunnel and the excavation of the expansion tunnel and obtained a mathematical model for predicting surface settlement based on the Peck formula:

$$S(x) = \frac{A_{11}V_{11}}{\sqrt{2\pi i_1}} \exp\left(\frac{(x - D_1)^2}{2i_1^2}\right) + \eta \frac{A_2V_{12}}{\sqrt{2\pi i_2}} \exp\left(\frac{(x - D_2)^2}{2i_2^2}\right) \quad (3)$$

3.3.2 Surround rock blasting vibration control

The blasting excavation of the reconstructed tunnel has a significant impact on the adjacent buildings (structures), so how to reduce the disturbance of the blasting vibration on the adjacent tunnels to ensure the safe operation of the original tunnel is the construction difficulties.

Wang et al. (1996) proposed that the static crushing method applied to the tunnel expansion can achieve the construction effect of no sound and no vibration. Zhang et al. (2010) effectively controlled the blasting vibration caused by the expansion of the Dahuashan small clear-distance tunnel group through the reasonable use of single and compound wedge-shaped hollowing. Liu et al. (2016) found that by canceling the hollowing eyes when blasting in the expansion part, the blasting parameters lower than the standard value of the specification also achieved a better blasting effect. Li et al. (2012) suggested that the blasting speed can be effectively controlled by increasing the number of blasts by installing vibration-damping holes. The contradiction of this method is that with the increase in drilling and blasting, the cumulative damage to the rock mass increases compared to large-scale blasting.

Table 5 shows the peak vibration velocity and the fitting parameters of Sadovsky’s formula for the existing reconstructed tunnel. It can be seen that the existing reconstruction and expansion of the tunnel peak vibration velocity and fitting parameters K and α are smaller than the “Blasting Safety Regulations” in the recommended tolerance values.

Table 5. Blasting vibration velocity and fitting parameters.

Surrounding Rock Classification	Project Name	Peak vibration velocity / $\text{cm}\cdot\text{s}^{-1}$		Sadovsky parameters			
		Measured value	Standardized value	K	Standardized value	α	Standardized value
III	A certain tunnel	0.92	10~20	220.00	150~350	1.6	1.5~2
IV	Yuzhou tunnel	1.96		150.01		1.80	
	Damaoshan tunnel	/		132.71		1.32	
	Jinjishan tunnel	5.71		101.90		1.54	
V	Damaoshan tunnel	15.78		63.23		1.43	
	Loushan tunnel	15.93		125.00		1.39	

4 RESEARCH PROSPECTS

Under the current “Carbon Neutral, Carbon Peak” background, green construction technology has attracted wide attention. With the innovation of artificial intelligence technology, the green construction and rapid construction technology of reconstruction and expansion tunnels will have a broad development prospect. The future development of highway tunnel reconstruction and expansion is expected:

- (1) Standardization of construction standards. Based on the active, passive, and forward support methods, we propose excavation and support structure design methods suitable for different peripheral rock conditions. Then, we form norms and standards to guide the expansion tunnels’ design, construction, and support.
- (2) Intelligent expansion program. Construct an intelligent evaluation system based on artificial intelligence and deep machine learning that considers construction characteristics, social economy, and environmental coordination. Consider using urban civil defense tunnels, air defense tunnels, and other abandoned tunnels to expand and develop urban underground transportation space.
- (3) Innovative construction methods. Develop assembly-type large-scale excavation expansion machinery and promote the practical application of the innovative “Bao Tong Expansion and Excavation Method.” Combine the concept of “carbon neutral and carbon peak” to propose green reconstruction and expansion technologies. Promote the application of BIM technology in the whole life cycle of reconstruction and expansion tunnels.

5 CONCLUSIONS

- (1) In the future, the number of highway reconstruction and expansion tunnels will gradually increase and develop in the direction of large cross-sections, small clearances, and tunnel clusters. The research content is enriched, and construction safety risk assessment and BIM technology application are new research dynamics.
- (2) There needs to be uniform quantitative standards for selecting and evaluating road tunnel expansion programs, and there is still a need for comprehensive social analysis combined with construction safety and stability of the program evaluation method. Considering the expansion space, natural and social environment, construction technology, and other factors, a comprehensive comparison of the reconstruction and expansion programs selection is needed.

- (3) Common excavation methods for tunnel expansion include the traditional excavation method, jump drilling method, layer peeling method, and expanding the excavation to protect the passage. It should be combined with the tunnel expansion factor and engineering geological conditions to select the expansion excavation method reasonably.
- (4) The stress distribution and deformation law of the surrounding rock in the reconstructed tunnel is complicated and variable, which has not yet been involved in deep theoretical research, and few scholars have carried out research on the stability of the surrounding rock in the process of dismantling the original supporting structure.

Reliability study of full jet longitudinal smoke exhaust system for a road tunnel over 5 km long

Xinyue Zhang, Liangliang Tao, Mingrui Luo & Yanhua Zeng

School of Civil Engineering, Southwest Jiaotong University, Chengdu, China

Key Laboratory of Transportation Tunnel Engineering, Ministry of Education, Southwest Jiaotong University, Chengdu, China

ABSTRACT: In China, road tunnels over 5 km utilize shafts for smoke extraction. In order to study the feasibility of full jet longitudinal smoke exhaust for road tunnels over 5 km in length, tunnel ventilation effect tests and fire tests were carried out in a tunnel. Field tests show that when the fire scale is 1.2 MW, the back-layered smoke flow can be effectively controlled by turning on 3 sets of fans downstream of the fire source, with air velocity of 2.4 ~ 3 m/s. When the jet fans are fully switched on, the ventilation step effect is significant, with a maximum air velocity of approximately 7 m/s at each test section. Numerical analysis of the smoke exhaust in the tunnel at a fire scale of 30 MW with different numbers of jet fans on was carried out. In the presence of longitudinal wind, the temperature and CO concentration in the tunnel have less impact on the escape of people upstream of the fire source. When 3 sets of fans are switched on, the flue gas flows backwards and sinks without effective control. When six groups of fans are turned on, the air velocity in the tunnel reached 3.5 m/s, which are able to control the back-layered smoke flow without accelerating the spread of smoke downstream and can provide favorable conditions for personnel evacuation.

Keywords: extra-long road tunnel, tunnel fire, full jet longitudinal smoke exhaust, field test, smoke control

1 INTRODUCTION

In recent years, more and more extra-long tunnels have been built to meet the country's transport as well as strategic needs. By the end of 2020, China had built 1394 extra-long tunnels (Transport, 2022). Due to the special long and narrow structure of tunnels, a fire will bring a great threat to the safety of people inside the tunnel. For the disaster prevention and smoke evacuation of road tunnels, scholars at home and abroad have carried out a large number of studies, mainly focusing on the characteristics of smoke flow (Hu et al., 2008; Tanaka et al., 2021), temperature distribution law (Liu et al., 2021), smoke evacuation efficiency (Tao and Zeng, 2022), personnel evacuation (Zhang et al., 2023) and other aspects.

The specification of "Guidelines for Design of Ventilation of Highway Tunnels" (China, 2014) in China gives the provisions: the tunnel with the length of the unidirectional traffic not more than 5 km can adopt the longitudinal ventilation scheme of the full jet; the maximum travelling distance of the smoke in the tunnel should not be more than 5 km in the fire case. Currently, most road tunnels in China over 5 km

utilize shafts for sectional smoke extraction (Wang et al., 2015; Wang et al., 2020; Zhang et al., 2018). The construction of the shaft will greatly increase the cost of the project, and when the geological conditions of the tunnel site area are poor, the construction of the shaft is prone to inducing geological disasters, resulting in casualties (Cao et al., 2020). The possibility of adopting full jet longitudinal ventilation for road tunnels with a length of over 5 km has become an issue of wide concern among experts and scholars.

For the ventilation and smoke exhaust effect of the full jet longitudinal ventilation method, some scholars have conducted research. Li et al (Li et al., 2022) established a numerical model to investigate the influence law of different operation modes of jet fans on the flue gas, temperature and CO concentration in the tunnel. Weng et al (Weng et al., 2020) investigated the effect of different spacing of jet fans on the temperature and wind speed in the tunnel and optimized the spacing according to the tunnel characteristics. Zhang et al (Zhang et al., 2011) conducted smoke evacuation tests in a 6 km long submarine tunnel and found that the use of sectional longitudinal ventilation

can better control the spread of smoke. Cao et al (Cao et al., 2019) conducted field tests and verified that it is feasible to use full jet longitudinal smoke extraction when a 20 MW fire occurs in a tunnel with a length of more than 5 km. In summary, there are almost no full jet smoke extraction tests for road tunnel fires over 5 km.

This paper carries out on-site fire tests relying on the Fenghuangling Tunnel, analyses the smoke spread, CO concentration distribution and temperature changes in the tunnel using numerical simulation software in the case of a 30 MW fire with different numbers of jet fans turned on and the reliability of the more than 5 km highway tunnel using a full jet longitudinal smoke exhaust method was studied, with a view to providing a reference for similar projects.

2 FIELD EXPERIMENT

2.1 Project overview

Fenghuangling Tunnel is located in Xinzhou City, Shanxi Province, is located in the mainline section of Xinfu Expressway, the tunnel is a two-hole unidirectional dual carriageway, the left line is 5885 m long, longitudinal slope of 1.8%, the right line is 5760 m long, longitudinal slope of -1.8%, the design speed of 80 km/h. The tunnel adopts full jet longitudinal ventilation, with 44 sets of Φ 1120-37 kW jet fans installed in the left line of the tunnel and 30 sets of Φ 1120-37 kW jet fans installed in the right line.

2.2 Test scheme

2.2.1 Fire source setting

In this test, two wooden stacks with length, width and height of 2000 mm \times 500 mm \times 60 mm were set up as combustible materials, erected at a height of 1 m, and diesel fuel was used as fuel to ignite the stacks, and the power of the fire source for the test was about 1.2 MW. The location of the ignition source is shown in Figure 1, and the ignition point is set near the pedestrian crosswalk in consideration of the safety of the test personnel.

Figure 1. Fire source setting.

2.2.2 Working condition setting

The longitudinal gradient of the Fenghuangling Tunnel is 1.8%. When a fire occurs, the downslope tunnel is more unfavorable for smoke exhaust, so the right tunnel was chosen to carry out the full jet longitudinal smoke exhaust test. The right tunnel was blocked during the test, and the test conditions were set as shown in Table 1.

Table 1. Working condition setting.

Number	Working conditions	Fan number switched on
1	No fan on	/
2	Switch on 3 sets of reversing fans	1#~3#
3	Switch on 3 sets of forward fans	4#~6#
4	Switch on 1 sets of reversing fans	1#
5	Switch on 1/5th of the number of forward fans	4#~6#
6	Switch on 2/5th of the number of forward fans	4#~9#
7	Switch on 3/5th of the number of forward fans	4#~12#
8	Switch on 4/5th of the number of forward fans	4#~15#
9	Switch on all forward fans	1#~15#

2.2.3 Test methods

There are 39 monitors in the Fenghuangling Tunnel, with longitudinal spacing ranging from 100 m to 200 m, which can be used to observe the smoke flow situation in various sections of the tunnel at different moments (Figure 2(a)). In order to observe the smoke flow situation after the fire, two personnel were arranged to photograph and record the smoke flow upstream and downstream of the fire source point respectively. Smoke flow observation stations were set up at the source of fire and at the exit of the tunnel for continuous filming throughout the test (Figure 2(b)).

Four wind speed test sections were set up, as shown in Figure 3, with the fire point located near the #5 pedestrian crossing. Due to the continuous spread of smoke to the downstream of the tunnel after the smoke emission, and in consideration of the safety of the on-site testers, the fourth group of testers was first tested at the dotted line and then transferred to the exit of the tunnel by the vehicle to conduct the wind speed test. The test was conducted simultaneously at each section, with one person reading and one person recording multiple sets of wind speed data.

2.3 Test results and analysis

In order to test the smoke removal capability of a full jet fan when a fire occurs in a tunnel over 5 km long, the smoke flow state in the tunnel was observed and the wind speed was tested, and the results are shown in Figures. 4-6, which can be divided into the following five stages of the smoke removal process.

(a) monitoring center

(b) Smoke flow shooting

Figure 2. Records of the smoke flow situation in the tunnel.

Figure 3. Location of jet fan and test section arrangement.

Figure 4. Wind speed change under different jet fan switching on conditions.

Stage before fan on (22:00-22:10): after ignition, all the fire smoke streams flowed in the direction of the tunnel exit due to the influence of the natural wind and without the jet fan on. As shown in Figure 3, the wind speed in the tunnel was measured to be between 1.2 ~ 2.1 m/s during this period.

Condition 1 (22:10-22:20): To reverse the flow of flue gases, switch on the reversing fan set by set. When the 2 sets of reversing fans are switched on, the smoke flow is directed upwards in a vertical direction. The smoke flow was completely reversed after switching on the 3 sets of reversing fans, and the wind speed was measured to be around -1.2 m/s during this period. Thermal buoyancy is the main driver of smoke diffusion as it spreads upstream. Under the influence of thermal buoyancy, the flue gas gradually rises and hits the roof and then spreads radially. Blocked by the roof and sidewalls, the flue gases accumulate downwards, while the buoyancy of the hot flue gases forces them to flow upwards, thus forming a flue gas layer (Figure 5 (a)). In this process, the smoke below the roof is constantly rolled and sucked air, and at the same time by the wall viscous resistance, the smoke flow rate is gradually reduced, resulting in a reduction in the temperature and pressure of the smoke front. The smoke layer close to the fire source is more affected by thermal buoyancy and is denser, while the smoke front is less affected by thermal buoyancy and is sparser (Figure 5(b)).

(a) Initial stage of reverse flue gas

(b) The end of the reverse flue gas

Figure 5. The reverse flue gas on site.

Condition 2 (22:20-22:36): To test the number of fans that need to be switched on to control smoke flow reversal, the forward fans are switched on group by

group. After switching on the 1 set of fans, the smoke stream gradually stood up at the fire point. After switching on the 2 sets of fans, the smoke flow gradually became upright. After switching on 3 groups of fans, the wind speed is between 2.4 ~ 3 m/s, in which the backflow of flue gas can be controlled.

Condition 3 (22:44-23:00): In order to control the continued spread of the smoke flow, the 3 sets of forward fans were switched off at 22:36, and the wind speed in the tunnel began to decrease but remained positive. Group 1# reversing fan was switched on at 22:44, and the wind speed began to drop continuously and reversed around 22:50. At this time, the wind speed in the tunnel is very small, but the smoke flow at the fire point is constantly flowing vertically and spreading, forming a chimney effect.

Smoke extraction stage (23:00 - 00:05 the next day): Turn off the group 1# reversing fan, turn on all the jet fans in the tunnel in turn to exhaust the smoke, at this time the wind speed in the section as shown in Figure 6. Due to the limitations of the test conditions, less data were available for the test section 4 in the Fuping direction. When only 3 sets of fans are switched on, the wind speed in the tunnel is the lowest, between 3.1 and 3.9 m/s. With the increase of the number of jet fan opening groups, the wind speed of each test section increases continuously. For the test section in different locations, the measured wind flow rule of change is consistent, the size of the wind speed difference is not large, this is due to the flow of wind flow is different from the movement of solid matter, between the gas is through the air molecules between the microscopic transmission to achieve. During the actual test, the wind flow at each test section started to change almost simultaneously. The step effect of full jet ventilation in the tunnel is very significant. At 0:00 all the jet fans were switched on, the wind speed at each test section reached about 7 m/s, and the smoke evacuation was completed at 0:05 the next day.

Figure 6. Wind speeds with different numbers of jet fans on.

3 NUMERICAL ANALYSIS OF 30 MW TUNNEL FIRE

3.1 Numerical modelling

As shown in Figure 7, the tunnel height is 5 m, the width is 10.25 m, the tunnel length is set to be

600 m, and the fire point is located in the middle of the tunnel. Considering the calculation accuracy as well as the calculation time consuming, grid-independent calculations were carried out and the grid size was set to 0.2 m × 0.2 m × 0.2 m.

(a) Tunnel section dimensions

(b) Numerical modelling of tunnels

Figure 7. Schematic diagram of the numerical modeling.

3.2 Working conditions

Considering the safety of this tunnel field test, it was not possible to carry out a field fire test with a high power source. The effect of smoke evacuation in the tunnel was analyzed by numerical simulation when the power of the fire source is 30 MW. Combined with the results of on-site wind speed tests, the smoke spreading and wind speed in the tunnel were studied under the condition of different numbers of jet fans on.

Table 2. Numerical simulation of working conditions.

Number	Number of fans on/sets	Wind speed in the tunnel/(m/s)
1	3	2.5
2	6	3.5
3	9	4.5

3.3 Results and analysis

3.3.1 Flue gas field

Figure 8 (a) shows the diffusion of smoke in the tunnel when 3 sets of jet fans are switched on, and the wind speed is about 2.5 m/s at this time. At 30 s there was already a reverse flow of smoke. At 60 s the downstream flue gas spreads less than 300 m, and the length of the back-layered smoke flow increases. At 90 s the upstream low-temperature smoke mixed with air sank further, causing unfavorable evacuation of people upstream. At 420 s the upstream flue gas is already close to the ground, and the length of the back-layered smoke flow is more than 100 m, so the spread of the flue gas is not effectively controlled under such working conditions.

When 6 sets of jet fans are opened, the longitudinal wind speed in the tunnel is increased to 3.5 m/s, the upstream flue gas is slightly refluxed at 45 s, and the length of the back-layered smoke flow is unchanged by 60 s. Compared with condition 1, the increase in the number of fans on accelerated the downstream smoke spread, and the length of the downstream smoke spread exceeded 300 m at 60 s. The length of back-layered smoke flow increases slightly at 210 s, and is basically unchanged at 420 s, at which time the flue gas buoyancy and inertia of the gas flow have reached equilibrium (Figure 8(b)). Under this condition, the backflow length is short, the interface between smoke and air is obvious and there is no sinking, which can provide favorable conditions for the escape of people upstream.

When 9 groups of jet fans were switched on (Figure 8(c)), no flue gas backflow occurred upstream at 420 s due to large ventilation rates, but the rate of smoke roll-up of low-temperature air downstream of the fire source was accelerated, and the rate of flue gas diffusion and sinking increased. In comparison, switching on 6 sets of fans can control the backflow of smoke nor accelerate the spread of smoke, and can achieve better control of the fire in the case of a 30 MW fire in the Fenghuangling Tunnel. Meanwhile, the longitudinal wind speed of 3.5 m/s in the tunnel can be used as the control critical wind speed in case of a 30 MW fire.

Figure 8. Flue gas diffusion with different number of jet fans on.

3.3.2 Temperature field

When a fire occurs, the temperature inside the tunnel will rise sharply. In order to study the safety of personnel evacuation under different conditions of jet fan opening, the temperature change at a height of 2 m inside the tunnel was analyzed, and the temperature exceeding 60 °C was taken as a judgement indicator of the danger of personnel evacuation (China, 2017). Under the effect of longitudinal wind, the temperature at a height of 2 m upstream of the fire point is always less than 60 °C, which is able to guarantee the evacuation safety of the upstream people (Figure 9).

With longitudinal winds, the temperature in the tunnel is greater than 60 °C for a range of 10 m downstream of the fire source and decreases in this range as the number of jet fans switched on increases. Temperatures 10 m downstream of the fire source do not vary much for different numbers of fans switched on. For the range of 10 m ~ 30 m downstream of the fire source, there is a small section of temperature lower than 60 °C at the height

(a) 60 s

(b) 420 s

Figure 9. Temperature distribution with different numbers of jet fans on.

of 2 m, which may be due to the fact that the temperature is lowered by more fresh air being sucked in here. The temperature has increased at a height of 2 m outside the 30 m range downstream of the fire source, and is also greater than 60 °C 100 m downstream, so people downstream should drive away from the tunnel as soon as possible.

3.3.3 CO concentration field

The environment inside the tunnel is relatively closed, the oxygen supply is insufficient, and in the event of a fire, insufficient combustion is likely to generate a large amount of CO, which poses a threat to the safety of personnel. With longitudinal winds, CO concentrations have little effect on the escape of people upstream of the fire source, and three sets of jet fans on are sufficient to control the CO concentration upstream of the fire at a height of 2 m to less than 50 ppm (Figure 10).

In the presence of longitudinal winds, the maximum CO concentration is concentrated within

10 m downstream of the fire source. At 60 s, the CO concentration at the fire source at a height of 2 m was about 2600 ppm when 3 sets of jet fans were switched on, and about 2000 ppm when 9 sets of jet fans were switched on. At 420 s, the CO concentration at the fire source at a height of 2 m was about 2200 ppm when 3 sets of jet fans were switched on, and about 1700 ppm when 9 sets of jet fans were switched on. The CO concentration decreased as the number of jet fans switched on increased as well as the time. Although the CO concentration is high here, the speed at which people downstream of the fire source drive away from the tunnel is relatively fast and will have essentially no detrimental effect on the escape of people. CO concentrations 10 m downstream of the fire source are slightly higher than upstream, but are still at low values, with a maximum of only 151 ppm, which has a low impact on human safety. Therefore, CO concentration has little effect on the escape of people.

4 CONCLUSION

The feasibility of full jet longitudinal smoke evacuation in road tunnels exceeding 5 km has been investigated through on-site fire tests in the Fenghuangling Tunnel and numerical simulation analysis under the condition of switching on different numbers of jet fans, and the following conclusions have been drawn:

- (1) For a 1.2 MW fire in the Fenghuangling Tunnel, switching on three sets of fans will be able to effectively control the backflow of smoke, when the wind speed is 2.4 ~ 3 m/s.
- (2) When 6, 9, 12 and 15 sets of jet fans are switched on respectively, the wind speed in the tunnel can reach 3.5 m/s, 4.5 m/s, 5.5 m/s and 7 m/s respectively.
- (3) During the field test, although the measured natural wind was shown to be the smoke exhaust power, the calculated number of jet fans that need to be turned on when the fire size is 30 MW is 6 groups, which is far less than the number of 15 groups of fans installed in the tunnel. The full jet longitudinal smoke evacuation can provide favorable conditions for the evacuation of people.
- (4) In this paper, the reliability study of using full jet longitudinal smoke evacuation in road tunnels over 5 km has been carried out only for the Fenghuangling Tunnel, and the universality of the study needs to be further verified.

Resilience assessment of shallow-buried subway stations under earthquake disasters

Chenlong Zhang, Dongming Zhang & Zhongkai Huang*

Key Laboratory of Geotechnical and Underground Engineering of Ministry of Education, Department of Geotechnical Engineering, Tongji University, Shanghai, China

ABSTRACT: This study aims to provide a comprehensive resilience assessment framework for evaluating the robustness and rapid recovery capabilities of shallow-buried subway stations under earthquake disasters. The proposed framework utilizes the ABAQUS software to establish numerical models of relevant subway stations. Subsequently, an extensive numerical analysis is conducted using selected seismic motions to generate vulnerability functions related to Peak Ground Acceleration (*PGA*) for these subway stations. Ultimately, the resilience assessment is completed by considering the vulnerability and recoverability of subway stations. The framework presented in this work contributes to the development of resilience-based design and management strategies for subway networks, facilitating their adaptation to seismic disasters.

Keywords: Subway stations, Resilience, Earthquakes, Fragility, Restoration

1 INTRODUCTION

The underground subway transportation system constitutes a vital component of modern urban transport networks, playing a crucial role in urban economic development and facilitating personnel mobility. In response to the escalating demands of rapidly growing cities, the construction and development of subway transportation systems are progressing at an unprecedented pace. Historically, engineers did not consider seismic design as a mandatory step for underground structures, believing that underground structures were less susceptible to damage compared to their above-ground counterparts (Hashash et al., 2001). However, this confidence was shattered by the catastrophic consequences of severe seismic disasters. A notable example is the 1995 Great Hanshin Earthquake in Japan, which caused extensive damage to underground tunnels, leading to the complete collapse of the Daikai station (Chen et al., 2023). In light of such tragedies, it has become imperative to conduct resilience assessments for critical hubs in urban underground transportation systems, such as subway stations, to mitigate the potential reoccurrence of similar disasters.

The overall reliability of subway transportation systems under seismic disasters has become increasingly challenging to predict (Iida et al., 1996). To

enhance the safety of construction and operational services for subway transportation systems and as a crucial component of seismic performance-based design, the theory of seismic resilience has witnessed significant development in recent years (Psyrras et al., 2018). Seismic resilience is typically defined as the ability of a structure to withstand, respond to, and rapidly recover from seismic disasters (Cimellaro et al., 2020). In the context of subway stations, seismic resilience is manifested in specific ways, aiming to reduce economic losses and infrastructure damage caused by disasters, and to achieve the seismic design goal of rapid post-disaster recovery. This concept has gradually been incorporated into the design timelines and operational procedures of relevant transportation infrastructure.

Generally, performance indicators associated with the damaged state of engineering structures are commonly employed to assess the infrastructure's capacity to absorb damage, recover post-disaster, and adapt to new conditions (Argyroudis et al., 2021; Ayyub et al., 2015). These performance indicators are also linked to resilience curves, which further characterize the structural robustness and the speed of post-disaster functional recovery, taking into account the full life-cycle resilience of infrastructure during both construction and operational phases

*Corresponding author: 5huangzhongkai@tongji.edu.cn

(Ayyub et al., 2014; Yang et al., 2019). Currently, resilience assessment frameworks addressing single or multiple hazards have been proposed and extensively applied to various infrastructure systems (Anwar et al., 2020; Ekhlaspoor et al., 2021), including bridges (Argyroudis et al., 2020; Chienkuo et al., 2021), transportation networks (Alipour et al., 2016; Capacci et al., 2002) and other critical engineering structures (Panteli et al., 2017). In the context of tunnels, Huang and Zhang (Huang et al., 2016) considered resilience-influencing factors under extreme loading conditions, refining the stages of tunnel resilience evolution. Huang (Huang et al., 2022) proposed a resilience assessment framework for interval tunnels, specifically designed to evaluate seismic performance in tunnel structures under earthquake disasters. To the best of the author's knowledge, there is currently no quantified resilience framework proposed in the literature for subway stations under seismic disasters.

To bridge the gap between current research and practical needs, this study proposes a practical and feasible resilience assessment framework for subway stations. The framework is applied specifically to a double-deck, double-span subway station exposed to seismic disasters. Furthermore, the research evaluates the robustness and rapid recovery capability of shallow-buried subway stations under seismic disasters. Recommendations for further research are also discussed.

2 STATION RESILIENCE ASSESSMENT FRAMEWORK

The resilience assessment framework for subway stations proposed in this paper consists primarily of three components, as illustrated in Figure 1. Firstly, geological and station-specific physical information is gathered to establish finite element numerical simulations, yielding dynamic response results for the station structure under various seismic loads. Secondly, based on the results of numerical analysis, the relationship between seismic intensity indicators (IM) and the probability of station damage states is determined. Finally, the construction of station loss and recovery functions is employed to define the utility function, and the resilience assessment of the station is completed through the integration of this utility function. This resilience framework allows for the evaluation of a subway station's ability to absorb and recover from seismic-induced damage through vulnerability analysis and the development of utility functions. These components will be elaborated upon in subsequent sections.

2.1 Numerical simulation analysis

In the numerical simulation analysis section, it is imperative to gather various physical information pertaining to the station under evaluation. This information encompasses station dimensions,

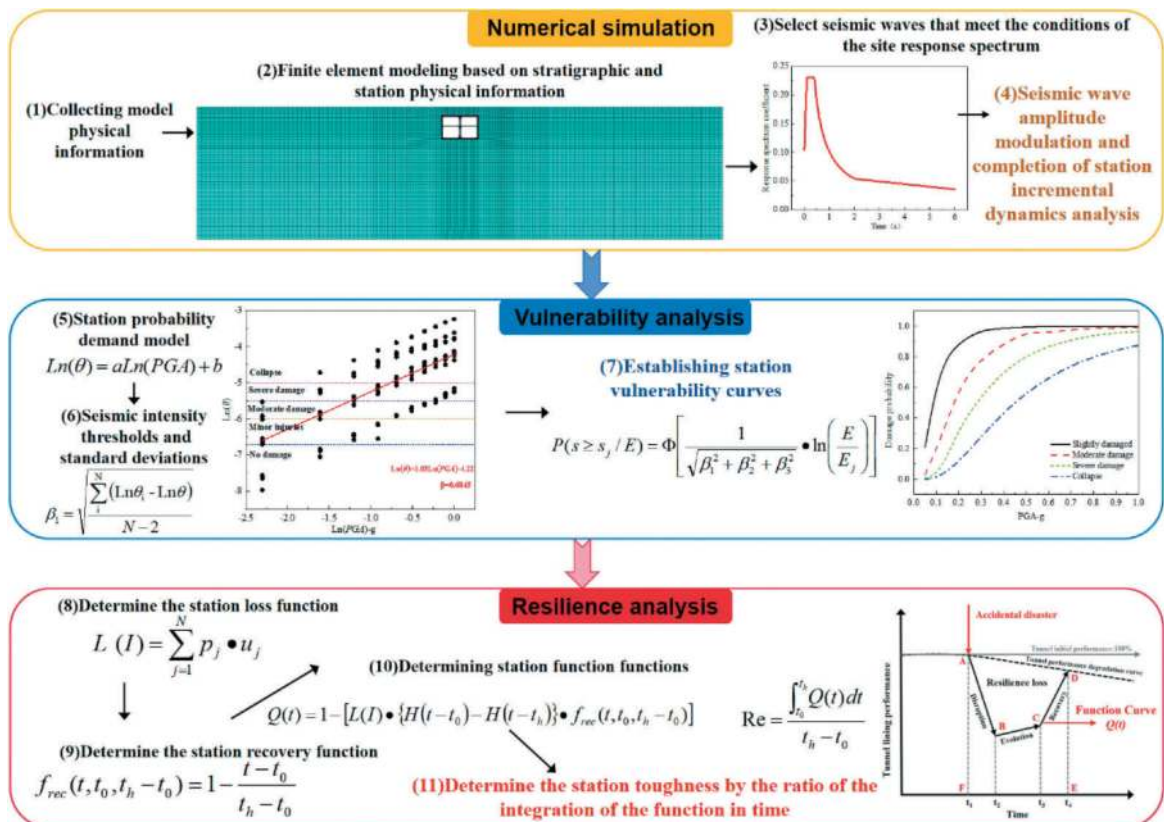

Figure 1. Framework for seismic resilience assessment of metro stations.

reinforcement ratios, material properties, as well as surrounding geological conditions. On this foundation, a finite element numerical model is established. The specific modeling approach is guided by the research methodologies of scholars such as Lysmer and Kuhlemeyer (Lysmer et al., 1969).

Furthermore, it is essential to utilize information regarding the surrounding geological conditions and the geographical location of the station to determine the site response spectrum. This involves selecting 10 or more seismic waves that satisfy the site response spectrum, thereby accounting for the uncertainty associated with seismic loads. Ultimately, the seismic wave amplitudes are adjusted to input seismic loads, completing the incremental dynamic analysis of the station.

2.2 Vulnerability analysis

The seismic vulnerability analysis of station structures signifies the probability of surpassing various damage thresholds for subway stations under different intensities of seismic motions. This probability is expressed by Equation (1). Incremental dynamic analysis based on numerical simulation methods is a commonly employed approach to ascertain the seismic vulnerability of subway stations (Hu et al., 2023).

$$F_i(x) = P(S \geq s_i/IM = x), \quad i = 1, 2, \dots, n \quad (1)$$

In Eq. (1), S is the engineering demand parameter of the station after a seismic hazard, S_i is the threshold value of the i th damage state corresponding to the station, IM is denoted as the intensity of the seismic wave, and n is the number of damage states of the station.

Under seismic loading, subway stations primarily experience damage in the form of inter-story displacement, making it the predominant mode of failure. Building upon the success of prior research and applications (Jiang et al., 2023; Jiang et al., 2021), this paper employs the inter-story displacement angle as a measure of damage and an engineering requirement parameter. The calculation formula is expressed as follows:

$$\theta = \frac{W}{H} \quad (2)$$

In Eq. (2), θ is the inter-story drift angle (IDR), W is the horizontal displacement of the station top plate relative to the bottom plate, and H is the station floor height.

The seismic intensity index is crucial for discerning structural damage and conducting vulnerability analyses. Jiang et al. (Jiang et al., 2023) examined 15 seismic intensity indicators, including PGA , PGV , and PGD . They concluded that, for vulnerability analysis of shallow-buried subway station structures, PGA is the most efficient and practical intensity measure. Consequently, this paper also adopts PGA as the seismic intensity indicator.

In seismic vulnerability analysis, it is commonly assumed that the structural dynamic response under seismic hazards follows a lognormal distribution (Hu et al., 2023; Huang et al., 2022). Therefore, incorporating Equation (1), the seismic vulnerability function is expressed as follows:

$$P(s \geq s_j/IM) = \Phi \left[\frac{1}{\sqrt{\beta_1^2 + \beta_2^2 + \beta_3^2}} \cdot \ln \left(\frac{IM}{IM_j} \right) \right] \quad (3)$$

In Eq. (3): P denotes the exceedance probability of a station reaching a particular damage state for a given seismic intensity IM ; Φ is a standard normal distribution; IM_j is the average value of seismic intensity corresponding to different damage state thresholds of the station; β_1 is the standard deviation characterizing the seismic uncertainty; β_2 is the standard deviation characterizing the uncertainty of the construction quality; β_3 is the standard deviation characterizing the uncertainty introduced by the uncertainty of the material and the analysis model standard deviation.

2.3 Resilience analysis

The term “seismic resilience,” as a professional concept, primarily delineates the robustness and rapid recovery of underground stations amidst seismic disasters. This paper employs well-established analytical definitions widely utilized in the field. The calculation formula is presented as follows (Hu et al., 2023; Huang et al., 2022):

$$Re = \frac{\int_{T_0}^{T_2} Q(t) dt}{T_2 - T_0} \quad (4)$$

In Eq. (4), R represents the station resilience, $Q(t)$ represents the functionality function of the station during the seismic hazard restoration period, T_0 is the time of the earthquake, and T_2 is the time of the end of the station restoration.

Table 1. Damage status and interlayer displacement angle threshold of subway stations (Du et al., 2020).

Limit states	S_1 -No	S_2 -Minor damage	S_3 -Moderate damage	S_4 -Severe damage	S_5 -Collapse
Inter-story drift ratio limit (θ)	$\theta < 0.08\%$	$0.08\% \leq \theta < 0.29\%$	$0.29\% \leq \theta < 0.62\%$	$0.62\% \leq \theta < 0.96\%$	$\theta \geq 0.96\%$

Huang et al. (Huang et al., 2016), through on-site disaster analysis, observed a delay between the occurrence of the disaster and the immediate initiation of repair activities. This interval between disaster occurrence and restoration is defined as an evolutionary phase. Referencing Huang et al.'s (Huang et al., 2016) study, this paper considers the presence of a pre-repair preparation phase, presuming no alteration in station performance during this preparatory period. Figure 2 illustrates the conceptual definition diagram of seismic resilience for subway stations, where T_1 represents the onset of station repair activities.

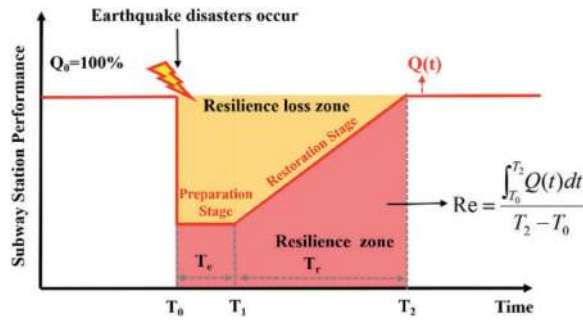

Figure 2. Definition of resilience concept for subway stations.

2.3.1 Loss function

When calculating the functionality of structures under seismic disasters, Cimellaro et al. (Cimellaro et al., 2010) propose that a building's functionality can be assessed based on the computation of direct economic losses. This conceptual framework has been extensively employed in studies related to seismic resilience assessment (Hu et al., 2023; Huang et al., 2022; Kassem et al., 2023; Cimellaro et al., 2010). Drawing inspiration from this approach, the structural loss function for the station is formulated as follows:

$$L(I) = \sum_{j=1}^N p_j \bullet u_j \quad (5)$$

Table 2. Repair coefficient of stations with different damage states (Huang et al., 2022).

Damage state (DS _{<i>i</i>})	S ₁ -No	S ₂ -Minor damage	S ₃ -Moderate damage	S ₄ -Severe damage	S ₅ -Collapse
Repair coefficient(<i>u_j</i>)	0	0.10	0.25	0.75	1

Table 3. Repair time of stations with different damage states (RISN-TG041-2022).

Damage state	S ₁ -No	S ₂ -Minor damage	S ₃ -Moderate damage	S ₄ -Severe damage	S ₅ -Collapse
Recovery time (Days)	0	0.5	2.4	45	210

In Eq. (5): $L(I)$ denotes the station loss function; P_j represents the probability of the station transitioning to damage state j and u_j denotes the repair coefficient required when the station reaches the damage state j . The precise correlation coefficients for this calculation are delineated in Table 2.

2.3.2 Recovery functions

The recovery function serves to characterize the repair progress and rate of subway stations during the recovery phase following seismic disasters. The representation of recovery duration and functionality is crucial for assessing seismic resilience (Kassem et al., 2023). Cimellaro et al. (Cimellaro et al., 2010) have pointed out in their research that, due to a lack of information on disaster management and available resources, linear functions are commonly employed to assess building functionality. Therefore, this paper similarly adopts a linear recovery function to characterize the station's recovery process, expressed as follows:

$$f_{rec}(t, T_1, T_2 - T_1) = 1 - \frac{t - T_1}{T_2 - T_1} \quad (6)$$

In Eq. (6), T_1 is the station recovery start time, and T_2 is the end time. The total time required for the recovery process is defined as shown in the following equation[20]:

$$T_r = T_2 - T_1 = \sum_{j=1}^N t_j \bullet p_j \quad (7)$$

In Eq. (7): t_j is the time required to repair the station completely when its damage state is j . Detailed insights into the various station damage states and their corresponding probabilities, denoted as P_j . Referring to the Chinese standard "RISN-TG041-2022 Guidelines for Seismic Resilience Assessment of Urban Engineering Systems" (2022), the required repair times for various damage states of the station are determined, as presented in Table 3.

2.3.3 Station function functions

When establishing the functional function of the station, it is commonly assumed that there is no performance loss before the occurrence of seismic disasters. This implies the exclusion of considerations related to functional degradation due to aging of the subway station. Additionally, it is assumed that the station's performance will be fully restored after the completion of the repair process. The station's functional function can be computed using the formula proposed by Cimellaro et al. (2006), as expressed below:

$$Q(t) = \begin{cases} 1 - L(I) & T_0 < t < T_1 \\ 1 - [L(I) \cdot \{H(t - T_1) - H(t - T_2)\} \cdot f_{rec}(t, T_1, T_2 - T_1)] & T_1 < t < T_2 \end{cases} \quad (8)$$

In Eq. (8): $L(I)$ and $f_{rec}(t, T_1, T_2 - T_1)$ denote the station loss function and recovery function, respectively, which will be described in detail in Eqs. (3-7) below; $H(x)$ is the Heaviside step function, as follows:

$$H(x) = \begin{cases} 1 & x \geq 0 \\ 0 & x < 0 \end{cases} \quad (9)$$

Based on the subway station functional function formulated in Equation (8), a quantitative assessment of the subway station's resilience index can be obtained by integrating over the time during which performance is impaired. This paper will utilize the actual structural parameters and geological parameters of a specific subway station in Wuhan. The dynamic response process of the station under seismic disasters will be analyzed, applying the seismic resilience assessment framework proposed in this study. This will facilitate a quantitative resilience analysis of the Wuhan subway station.

3 CASE AND MODELLING ANALYSIS

This paper selects a subway station in Wuhan, China, for resilience assessment. The chosen station exhibits a typical double-layer, double-span structure, with a depth of 4.61 meters, an overall width of 21.3 meters, and a height of 13.69 meters. The detailed structural dimensions and cross-sectional reinforcement are illustrated in Figure 3.

The appropriate constitutive relationship accurately reflects the stress-strain behavior of materials. For the characterization of the nonlinear dynamic response process of the station-soil coupled numerical model under seismic loads, the correct choice of constitutive models is crucial for the overall coherence and validity of the paper.

The Concrete Damage Plasticity (CDP) constitutive model is based on isotropic elastic damage and isotropic tension-compression plasticity theories to represent the material's inelastic deformation. It characterizes the stiffness degradation resulting from

(a) Structural dimensions of the station

(b) Reinforcement drawings of the station

Figure 3. Structural dimensions and reinforcement details of metro station (mm).

damage by quantifying the interaction between damage evolution and plastic slip through the introduction of damage variables. The main structure of the station employs C50 grade concrete. In this study, the CDP constitutive model is selected to simulate the lining, with the relevant concrete material properties set according to the Chinese Concrete Structure Design Code (GB50010-2010).

The station structure's reinforcement is predominantly composed of HRB335 steel. Following the guidelines outlined in the Chinese Concrete Structure Design Code (GB50010-2010) and relevant research findings, a plastic constitutive model is employed to simulate the behavior of the reinforcement.

The surrounding strata are selected to represent the actual site conditions of the subway station. The Mohr-Coulomb constitutive model is employed to simulate the soil behavior, with the layer thickness of various soil strata chosen as the average thickness from site investigation results. The detailed variations of elastic modulus, unit weight, cohesion, and friction angle with depth across the entire site are depicted in Figure 4.

A finite element numerical model (2D) considering the interaction between soil and tunnel is established using ABAQUS software. The entire numerical model has a height of 74m and a width of 300m. The bedrock position at the bottom boundary

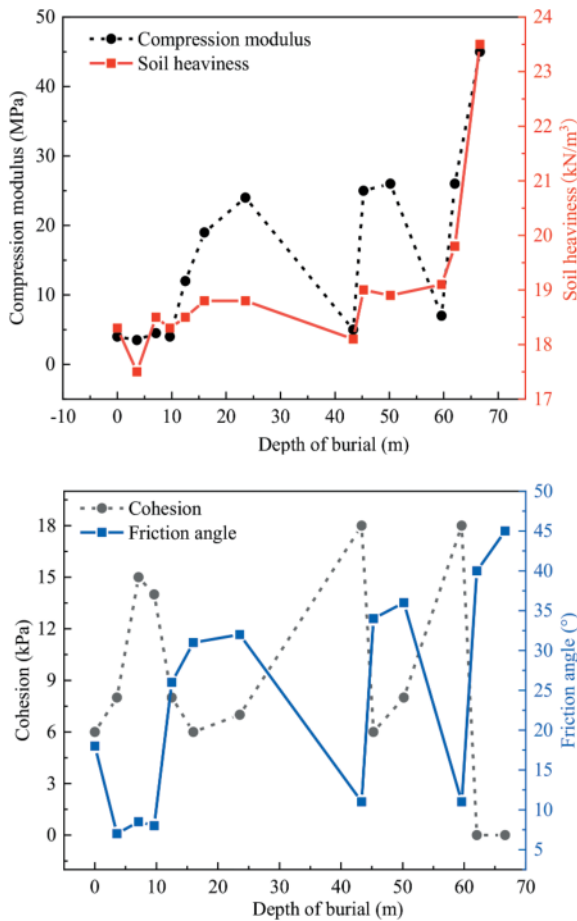

Figure 4. Relationship between soil material properties.

of the model is determined using the method proposed by Lysmer and Kuhlemeyer (Lysmer et al., 1969), treating it as an elastic foundation by appropriately setting dampers. Seismic loading on the model is applied by subjecting the dampers to seismic oscillations. The lateral boundaries of the finite element model are coupled using Motion Projection Constraints (MPC) to ensure simultaneous movement at both ends (Huang et al., 2022). The detailed model dimensions and boundary conditions are illustrated in Figure 5.

Figure 5. Numerical model dimensions and boundary conditions.

The finite element model employs plane strain elements (CPE4R) for both the station and the soil. Steel reinforcement elements are modeled as two-dimensional truss elements (T3D2). The mesh dimensions adhere to the requirements outlined in the study by Lysmer et al. (Lysmer et al., 1969) to ensure grid sensitivity. In terms of interaction, the reinforcement is embedded within the station lining using an embedded approach. The contact between the lining and the surrounding soil is characterized by both normal and tangential behavior. Normal behavior is modeled using a hard contact relationship, while tangential behavior is represented by a penalty function relationship with a friction coefficient set to 0.6 (Huang et al., 2022).

For an accurate assessment of subway station resilience under seismic actions, it is crucial to identify a sufficient and reasonable number of seismic waves. Generally, selecting 10 seismic waves is considered adequate to meet the requirements for computational needs. In this study, ten seismic waves satisfying the response spectrum criteria were chosen from the Pacific Earthquake Engineering Research (PEER) database (<https://ngawest2.berkeley.edu/>). The seismic waves were selected based on their source site conditions and similarity to the modeled subgrade bedrock. The amplitudes were scaled in increments of 0.1g, ranging from 0.1g to 1.0g. Subsequently, the resulting 100 scaled seismic waves were input into the finite element model to conduct incremental dynamic analysis.

4 STATION RESILIENCE ANALYSIS

4.1 Vulnerability analysis

The extracted relative horizontal displacements were used to calculate the inter-story drift angle based on Formula 2. The logarithmic relationship between PGA and inter-story drift angle was plotted, and a linear regression analysis was conducted, as illustrated in Figure 6. According to Figure 6, the probabilistic seismic demand model for the subway station is obtained as shown in Formula 10:

$$\ln(\theta) = 1.365\ln(PGA) - 4.207 \quad (10)$$

The probabilistic seismic demand model for the subway station represents the evolutionary process of its damage indicators with increasing seismic intensity.

Figure 6. Logarithmic linear regression analysis.

To characterize the uncertainty of seismic waveforms, β_1 was calculated as 0.631 based on Formula 11 and Figure 6. Using Table 1 and Formula 10, the seismic intensity mean values (IM_j) corresponding to different damage state thresholds for the underground station were determined.

$$\beta_1 = \sqrt{\frac{\sum_{i=1}^N (\text{Ln}\theta_i - \text{Ln}\theta)^2}{N - 2}} = 0.631 \quad (11)$$

Based on the obtained values of $\beta_1, \beta_2, \beta_3$, and the seismic intensity mean values (IM_j) corresponding to different damage state thresholds, the exceedance probabilities for various damage states of the subway station were calculated according to Formula 3, as illustrated in Figure 7. From Figure 7, it is evident that the probabilities of different damage states for the subway station increase with the continuous growth of seismic intensity. When the seismic intensity is below 0.2g, the probabilities of severe damage and collapse are at most 5.4% and 3.8%, respectively, indicating a relatively low threat to personnel and property safety, and limited damage to the subway station. However, when the seismic intensity exceeds 0.4g, the probabilities of severe damage and collapse soar to 14.6% and 20.7%, respectively, highlighting a heightened risk of damage to the subway station, and emphasizing the significance of addressing safety concerns.

4.2 Function function determination

The seismic fortification standards in China's "Code for Seismic Design of Buildings" are

Figure 7. Logarithmic linear regression analysis.

proposed to be 6, 7, 8, and 9 degrees. In this study, fortification standards of 7, 8, and 9 degrees were specifically chosen to assess the seismic resilience of the subway station at the designated location. These fortification standards correspond to I_1 (0.1g), I_2 (0.2g), and I_3 (0.4g) peak ground accelerations (PGAs), respectively.

4.3 Station resilience analysis

In the event of an earthquake disaster, a preparatory phase exists between the occurrence of the disaster and its restoration due to aftershock disturbances, immediate rescue efforts, and subsequent maintenance activities at subway stations. Huang et al. (Huang et al., 2016) defined this phase as the post-disaster evolution stage. This study posits a correlation between the duration of the preparatory phase for subway station maintenance and the extent of station damage. Specifically, it is assumed that the more severe the station damage, the longer the required preparation time for disaster relief and maintenance. Additionally, the preparatory phase time for subway stations is assumed to be equal to the restoration time.

Based on Equation 4 and Figure 7, the schematic representation of subway station resilience under different fortification standards is illustrated in Figure 8. From Figure 8, it is evident that with an increase in peak ground acceleration (PGA), the seismic resilience of the subway station significantly decreases. The primary reason for this decline is the occurrence of severe structural damage in the subway station due to higher seismic intensity. This damage is further reflected in the robustness of the subway station, leading to a reduction in its seismic resilience. It is noteworthy that the seismic fortification intensity for the subway station in this location is 7 degrees. At this seismic intensity, the seismic resilience of the subway station is 0.957. According to the study by Huang et al. (Huang et al., 2022) (as shown in Table 4), the station exhibits high seismic resilience under these conditions.

Figure 8. Results of resilience of subway stations under different seismic fortification standards.

Table 4. Definition of resilience grade (Huang et al., 2022).

Grade	High resilience	Moderate resilience	Low resilience
Range	$0.9 \leq R < 1.0$	$0.6 \leq R < 0.9$	$R < 0.6$

5 CONCLUSION

This paper presents a feasible and practical resilience assessment framework for evaluating the robustness and rapid recovery of subway stations in the event of earthquake disasters. The resilience assessment framework adopts inter-story displacement angle as a performance indicator and allows for vulnerability analysis of subway station structures with various configurations, such as single-span multi-story and double-span multi-story structures. It facilitates the quantification of resilience indicators for subway stations.

Autostrade per l'Italia S.p.A., Roma, Italy

ABSTRACT: The upcoming challenges in the transport infrastructures industry will surely include the maintenance and rehabilitation of the existing tunnels, furthermore, a consistent approach in accordance with the best practices in Asset Management is key to maintain the tunnels for continued serviceability, defining a proactive and effective maintenance plan within budget constraints. Italy is the second country worldwide in terms of tunnels numerosity. Autostrade per l'Italia S.p.A. operates 595 tunnels, half of them built before 1970. In August 2022, the National regulations introduced a multilevel assessment approach for tunnels, including a simplified risk analysis. In the authors' opinion, these new Standard became crucial to develop of a decision support tool that aims to be robust, and user-friendly. The tool is fed by asset overall information, conditions and defects distribution. Defects are characterized by extension (k_1), intensity (k_2), severity (G) and are used to run the simplified risk analysis in terms of hazard, vulnerability, exposure of six different thematic areas (structural, seismic, geotechnical, etc.). Deterioration models are defined and included based on the age of the tunnel, waterproofing techniques, construction materials etc... Cost and intervention model are included for rehabilitation works as well (TRS – Tunnel Renewal Strategy) and/or “detect and repair” works (IRS/IMS). The tool can assess the current and foreseen monetary value of the asset starting from the gross replacement cost, giving an overview of the tunnels and a medium and highly detailed summary broken down for a tunnel or groups of tunnels. The tool aims to identify and prioritize tunnels that should be maintained in the upcoming years to optimize the lifecycle of the asset based on a short term and a long-term asset management planning analysis towards targeted level of service. A multicriteria analysis will be also included in a future development to account service disruption, reputation, environmental impact.

Keywords: Life Cycle, Deterioration, Risk, Residual Value, Cost Model, Intervention Model

1 INTRODUCTION

The Autostrade per l'Italia S.p.A (ASPI) infrastructural asset is nowadays exposed to climate change effects, seismic and geological hazards and, finally, aging of the materials. ASPI is the major Italian motorway concessionaire in charge for the operation and maintenance of about 595 tunnels.

Aging and deterioration of the infrastructures play a key role in the civil engineering industry also due to the most recent collapses that hardly hit ASPI. These events lead to a new regulation in the bridges and viaducts as well as in the tunnel industry:

- 17th December 2020 “Linee guida per la classificazione e gestione del rischio, la valutazione della sicurezza ed il monitoraggio dei ponti esistenti”;
- 23rd August 2022 “Linee guida per la classificazione e gestione del rischio, la valutazione della sicurezza ed il monitoraggio delle gallerie esistenti”, hereinafter referred to as “LLGG”;

This scientific work is focused on the development of a decision support tool for tunnel asset management even though the methods and approaches herein analysed are applicable to any kind of civil

*Corresponding author: daniela.difiore@tecneautostrade.it

asset in general. The purpose is to base the tool on the new Guidelines, which represent the common rules for all the Owners/Concessioners of road tunnel asset in Italy.

The new regulation is classified into different layers (1 to 4) characterized by an increasing level of detail:

- **Level 0** – Asset overall information such as location, length, lining material, construction age etc...;
- **Level 1** – Asset condition in terms of scored defect detected during the visual inspection. In this phase extension (k_1), magnitude (k_2) and severity (G) of the defects are collected in forms for further analyses;
- **Level 2** – The levels 0 and 1 gathered information feeds a process whose purpose is to assign a simplified risk score to each 20 m long segment of the tunnel for each thematic area (structural global and local, geological, seismic, hydraulic and transport related). The score can be low, mid-low, mid-high or high. The six thematic areas (except for hydraulic) are then combined into a global risk rate;
- **Level 3 & 4** – whenever risk rate coming from level 2 is mid-high a preliminary safety evaluation is performed to better investigate the parameters which lead to such rate of risk in the specific thematic area. If the risk rate is confirmed engineering judgement and calculation are put in place to identify the mitigation measures, or eventually monitoring systems, needed to keep the risk acceptable (Level 4). When the risk rate is high level 3 is glossed over.

The new regulation is promoting further actions ensure the implementation of more reliable approach to asset management “*Si raccomanda inoltre che detti modelli possano essere anche aggiornati in tempo reale, costituendo quindi un banca dati aggiornata per le necessarie azioni di asset management*”.

Italy is the second country worldwide in terms of tunnels numerosity. Autostrade per l'Italia S.p.A. runs 595 tunnels, half of them built before 1970. In this picture, the need for a decision support tool arose within the engineering company of Autostrade per l'Italia Group (Tecne S.p.A).

The decision support tool is feed by the information required by the LLGG among the ones used for the multilevel analyses. Data coming from levels 0, 1 and 2 are necessary to assess the condition of the asset at time 0.

Deterioration models are then implemented to evaluate the foreseen condition of the asset in the most reliable way compatible with knowledges and data available today. The aim is to have a set of models dedicated to specific assets (ie. customized by construction age, liner materials or waterproofing technology).

Cost and intervention models are needed to compare alternative scenarios where Tunnel Renewal Strategy (TRS) or Detect and Repair approaches (IRS/IMS) are possible.

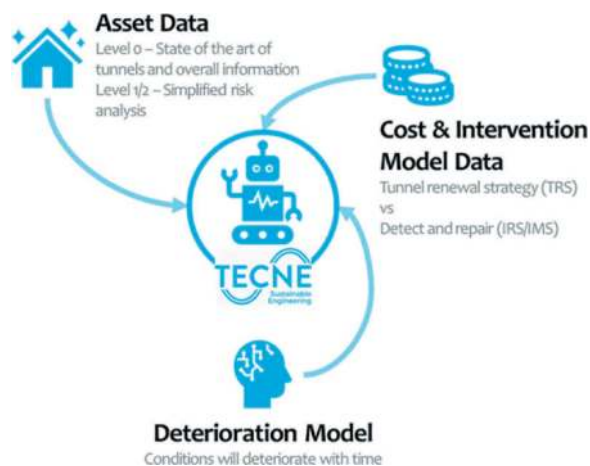

Figure 1. Tool input.

The decision support tool is aimed to compare several parameters such as current and foreseen monetary value of the asset, Capital (CapEx) and Operative (OpEx) discounted expenditures, disruption, environmental impact, effects on reputation etc, in different operating scenarios (including no intervention at all).

Inputs feeds Outputs and vice versa into a never ending loop of asset lifecycle.

Developing a Life Cycle Cost Analysis (LCA) tool brings multiple advantages to the Organization. Herein some of them:

- No bias in the decision making processes concerning intervention planning and design;
- Easy access to the assumptions underlying the algorithm;
- Data driven processes based on the state of the art of the asset management industry.

At this stage, the tool is a mock-up version developed with Visual Basic for Application.

2 ASSET DATA

The LLGG new regulation involves national road tunnels over 200 m long. Autostrade per l'Italia S.p.A. is in charge of the maintenance and management of 595 motorway tunnels, 450 of which have been triggered by the new Guidelines.

LLGG provide a roadmap and a defined timeline for the market operators to fulfil the requirements of each level.

Assets are grouped by age:

- Tunnels built before 1970;
- Tunnels built between 1971 and 1990;
- Tunnels built after 1991.

Timeline is given in the following table:

Table 1. LLGG requirements.

Construction age	Level 0	Level 1 & 2
Ante 1970	Within 3 months	Within 6 months
1971-1990		Within 12 months
Post 1991		Within 18 months

Level 0 need to be fulfilled in 3 months since the LLGG were issued whilst Levels 1 and 2 have different deadlines according with Asset construction age.

As already mentioned, the Guidelines include four main layers (five considering resilience analysis of the transport system) characterized by an increasing level of detail. Collection of the main overall information related to tunnels (Level 0) in a structured database is the first step for the simplified risk analysis. Level 0 includes 617 data that need to be collected in a standard layout and submitted to the Ministry of Infrastructures and Transport.

The set of data includes (but is not limited to) the following list:

- ID number of tunnel, name, location, coordinates, Concessionaire, construction age, designer name, length, lanes number;
- Max speed, curvature change rate (CCR), peak ground acceleration, water table elevation, geology of the area, lining material, presence of rebars, water proofing system, pavements material and international roughness index (IRI);
- Average number of vehicles per day, percentage of trucks and commercial users etc. .

This give a preliminary knowledge of the Asset, where it is located, when it was constructed and so on.

Some of the collected data from Level 0 (about 53) are needed, together with Level 1 visual inspection, to perform the simplified risk analysis (Level 2).

3 SIMPLIFIED RISK ANALYSIS

The purpose of Level 1 and 2 is the evaluation of a simplified risk rate of the asset combination of six different disciplines:

- **SGG** – Global structural and geotechnical risk;
- **SLO** – Local structural risk;
- **GEO** – Geological risk;
- **SIS** – Seismic risk;
- **STD** – Transportation risk;
- **IDR** – Hydraulic risk.

In order to do so about 53 indicators (primary and secondary) are gathered and combined to understand the hazard (H), vulnerability (V) and exposure (E) of each area.

The risk rate, called “Classe di attenzione”, ranges from low to high depending on the combination of H, V, E (Figure 2).

Figure 2. Definition of “classe di attenzione”.

Figure 3. Visual inspection.

Vulnerability is mainly linked to condition of the asset. Condition is assessed through visual inspections (Figure 3).

Visual inspection is the first step of Level 1. During the first inspection all the water sheets and screens are dismantled to have an open view of the tunnel liner. The company in charge for the activity, after high pressure watering of the surface, start a close distance inspection hammering and marking all the noticeable structural and water related defects.

Relevant defect clusters are listed and described (with support of case study images) in LLGG – Annex B where some information on the following parameters (to be assigned during inspection) shall be provided:

- **Relative size k_1** – In percentage compared with the characteristic size of the elementary section¹ of the tunnel;

¹ A tunnel is usually broken down into 20 m long elements.

- **Intensity k_2** – Can be 0.2 (low), 0.5 (mid) or 1.0 (high) depending on the magnitude of the defect.

Defects are listed in a spreadsheet and represented into a 1 m by 1 m grid plan layout. Defects are then grouped by type evaluating the size and intensity of the cluster as follows:

$$k_{1,t} = \sum_{i=1}^n k_{1,i} \quad (1)$$

$$k_{2,t} = \sum_{i=1}^n (k_{2,i} \cdot k_{1,i}) / k_{1,t} \quad (2)$$

Where $k_{1,i}$ and $k_{2,i}$ are referred to the defects belonging to the same cluster.

Engineering and expert judgement play a role in the evaluation of the defect's severity (G). G can range from 1 to 4 and has an impact on the results in terms of SGV vulnerability.

Similarly to k_1 and k_2 , also G is assigned to each defect and then summarized to have a cluster representative value:

$$G_t = \sum_{i=1}^n G_i \cdot k_{1,i} / k_{1,t} \quad (3)$$

These parameters are then combined, at Level 2, to have a vulnerability rate (low to high). For instance, in Table 2, the combination matrix used in the SGV area to assess the condition of the liner.

Table 2. SGV vulnerability combination matrix.

G_t	k_2	k_1		
		0.2	0.5	1.0
1	0.2	Low	Low	Mid-low
	0.5			
	1.0			
2	0.2	Low	Mid-low	Mid-low
	0.5			
	1.0			
3	0.2	Mid-low	Mid-low	Mid-low
	0.5			
	1.0			
4	0.2	Mid-high	Mid-high	Mid-high
	0.5			
	1.0			
3 & 4 (critical area ²)	0.2	High	High	High
	0.5			
	1.0			

2. Critical area is the projected area of the road on the liner.

4 DETERIORATION MODEL

The development and use of an asset is divided into stages. Typically, the sequence of events through the life of the asset progress as follows:

1. concept;
2. design;
3. construction;
4. operation and use;
5. disposal or renew.

Throughout the tunnel lifecycle, the major costs are borne after construction, in the operational phase, and they may exceed the initial construction cost.

Prediction on future level of service of the asset (condition/performance) is needed to obtain a benefit during "operation and use" timeframe.

Tunnel deterioration is a gradual process through the life of a structure in which routine maintenance and repair actions are performed. While routine maintenance does not improve quality level of a structure but rather keeps it on an operational level repair/remediation works are intended to increase structure performance level (Sandra Skaric Palic et al.).

Define a reliable deterioration model of the Asset is the most difficult goal to achieve for a comprehensive Life Cycle Cost Analysis (LCA).

Tunnel deterioration affects conditions/level of service and depends on many factors (environment, aging of materials, external pressure etc..) and understanding the different implication of asset deterioration is important to address a consistent maintenance plan.

Figure 4 shows the solutions that might be applied across an asset's life cycle.

Figure 4. Deterioration and life cycle interventions.

Condition is defined on a scale of 0 to 100 where 100 represents a new tunnel.

Typically, preventive tunnel maintenance processes should be applied while asset is in good condition (Figure 4 – *Optimal maintenance*).

Please note that many high regular quality data observations over many years are needed to produce such deterioration curves for infrastructure. The forecast degradation rates may be uncertain, leading to uncertainty as to when intervention is required.

Uncertainties in the decision-making process may be decreased by using information from monitoring which are used to establish triggering thresholds for the structure passing performance levels (Sandra Skaric Palic et al.).

Both deterministic and probabilistic models available which can be used to simulate the structural degradation. The tool is fed by deterministic models but, near future developments could allow the use of both.

Conditions are defined according to the possible mechanism of collapse defined in the new guidelines for a tunnel liner:

- **Global** mechanism, causing failure of the structure.
- **Local** mechanism which results in a temporary “out of service” of the asset.

These mechanisms are covered according to the disciplines SGG and SLO mentioned in the previous section. Increasing in degradation leads to an unacceptable level of service intended as higher structural failure risk both for global and local mechanism.

Not all the parameters affecting hazard, vulnerability and exposure are representative of the structural condition of the asset. Whatever could change in between of two subsequent inspections has a role in the asset condition evaluation.

The parameters affecting SGG and SLO that meet this assumption are:

- **SGG** – Level of structural defect – from LOW (state = 1) to HIGH (state = 4)
- **SLO** – Level of structural defect + Under thickness of the liner – from LOW (state = 1) to HIGH (state = 4).

For instance, SGG condition state evaluation, based on defect affecting global risk of “failure”, is shown by Table 2, similarly for SLO.

The degradation of the asset may be accelerated by water leakage, the landslide interference with the lining as well as seismology of the surrounding area.

Conditions are then related to percentage condition bandwidths:

1. From 100% (good as new) to 80%;
2. From 80% to 60 %;
3. From 60% to 40%;
4. From 40% to 20%.

The remaining 20% to 0% is the area beyond the minimum level of service (Figure 5).

Figure 5. Percentage of condition vs time.

The minimum set of degradation models needed to catch the differences in construction age and waterproof techniques of Autostrade per l’Italia Asset is:

- Ante ’70 NO waterproofing;
- ’71 to ’90 NO waterproofing;
- ’71 to ’90 with waterproofing;
- Post ’91 with waterproofing.

Different degradation should be used for global (SGG) and local (SLO) mechanism for a total of 8 deterioration models.

Unfortunately, the data set available to the scope is not currently sufficient. The new Guidelines were published one year ago and only a first visual inspection was carried out so far for both Ante ’70 and ’70-’90 tunnels giving an instant picture of the present conditions of the asset. Even if an assumption can be made on the original condition of the asset (100 % when built) the lower condition index (4) cannot be related to a “failure” (many tunnels have one or more section in condition state 4 but still operating). Treatments are usually performed before “failure”, so that is difficult to assess the time a section remains in the lowest condition.

Even if often in practice, when it comes to decision making, a simple analysis based on expert judgment of experienced engineers is used to determine the transition into a lower condition level, herein a tentative of fitting degradation curves based on available data is presented.

The Markov model helps assessing the mean time to “failure” of the asset. “Failure” may mean that a section of the tunnel in the worst condition is a strong candidate for replacement or subject to a life extension action such as rehabilitation works (TRS). Markov model makes few assumptions herein mentioned:

1. Condition is determined periodically;
2. Over any single interval, a unit of the asset either remains in same condition state or jumps to one of the other states;
3. The probability of jumping from any one state to any other state is a constant.

The first two of these assumptions are dictated by routine data collection practices so they are easy to

accept. The Guidelines give a visual inspection frequency timeframe based on the risk class SGG+SLO according with Table 3.

Table 3. Inspection frequency according with LLGG.

CdA SGG+SLO	Ordinary inspection	Detailed inspection
Low	12 months	6 years
Mid-low	6 months	4 years
Mid-high	3 months	2 years
High	2 months	1 year

The third one, called the “memoryless assumption” requires more thought. A fourth assumption can be made to simplify the transition state matrix: in the wider time window (12 months) between two inspections the asset moves only from a condition state to the direct following one.

In our case the transition probability matrix is unknown but, it is possible to correlate the present condition of the asset to the starting condition ($\approx 100\%$) at the age of construction to obtain the transition probability matrix.

The Ante '70 first visual inspections, carried on 173 tunnels in early 2023, has given the condition states distribution of sections that follows (e.g. SGG only NOT previously involved by significant rehabilitation works asset):

- 21% of sections are in condition 1;
- 25% of sections are in condition 2;
- 0% of sections are in condition 3;
- 54% of sections are in condition 4.

The data set is 59 years old (on average). It is possible to back define the transition probability matrix (for SGG and SLO conditions) which repeatedly multiplied gives the aforementioned states distribution (Figure 6).

The mean time a section of the tunnel stays in the state j can be evaluated as:

$$T_{state,j} = \frac{\log(0.5)}{\log(P_{jj})} \quad (4)$$

where p_{jj} is the transition state probability.

Assuming the mean time in state j it is possible to define a deterioration curve accordingly (Figure 7).

Figure 6. Percentage by condition vs time SGG Ante '70.

The deterioration model assigned to the asset parts (tunnel section) remain the same during life cycle assessment unless a rehabilitation work is performed (TRS).

Figure 7. Deterioration model SGG & SLO Ante '70.

In this phase, waiting for the analysis of the data set coming from the first inspection of the clusters '70-'90 and collection of post '91 one, the related deterioration models are assumed by the authors based on the engineering judgement and on the results obtained on the Ante '70 tunnels (e.g. SGG in Figure 8).

Figure 8. SGG deterioration model of the asset.

The starting condition of a tunnel section at Time = 0, with a condition rate between 1 and 4, is the corresponding bandwidth average (if rate = 4 then condition = 30% etc..) unless the condition rate is the one expected according with the age of the asset (the % starting condition will be evaluated directly on the deterioration curve inside the related bandwidth).

The section deterioration at time > 0 follow the curve of the chosen model.

The decision support tool allows to consider additional effects on degradation of the asset:

- a) Landslide interfering with the tunnel – GEO;
- b) Seismology of the area – SIS;
- c) Water leakages through the lining.

These effects enter the algorithm by speeding up the degradation of the sections by them involved following the equation (5).

$$\Delta_{D,year} = \rho \cdot (Rate - 1) \quad (5)$$

Where p is the additional deterioration due to a), b) or c) (e.g. 0.20%/year user defined) whilst *Rate* is the CdA in case of a) and b) (GEO and SIS) or the presence of water leakages for effect no. c).

The choice is left to the user who will eventually include (or not) by checkboxes all (or some) of the additional effects on degradation.

If a TRS is performed effect. c) is automatically omitted by the algorithm from there on.

The main outcomes and benefits of implementing deterioration models in the decision support tool are:

- prediction on conditions of each 20 m long section of the tunnel (both SGG and SLO) enabling intervention strategy based on risk of structural “failure”. Any worst section value below “*minimum level of service*” (20% condition) determines the remaining useful life (RUL) of the tunnel;
- prediction on structural risk rate which lead the visual inspection frequency and related costs;
- evaluation of residual value of the Asset.

5 ASSET VALUE

Determining the value of a transportation physical assets is important for both financial reporting and transportation asset management (Spy Pond Partners et al.).

The Figure 9 enhance components of asset value, and helps with the nomenclature that will follow.

Figure 9. Components of asset value.

In general, there is no single correct way to calculate asset value. Different approaches are reasonable for evaluating initial value of an asset when obtained (or constructed), estimating how value depreciates, establishing how intervention should be considered and what their effects are.

The best approach to calculate asset value depends on how the valuation will be used. Primarily, in tunnel asset management, asset value supports decision regarding investments to maintain and extend the life of the assets; secondary, this information could provide an account of how the organization is spending resources and what is the return in terms of value for the owner of the asset. Asset

value could be even used to show how proactive preservation strategy could be more cost-effective than reactive maintenance one.

In general, knowing what a physical asset is worth can be very useful both for supporting asset management and financial reporting.

Testing investment strategies, performing a life cycle cost analysis (LCA), are the main purpose of the decision support tool. The result of a strategy can be summarized by its net present value (NPV). NPV is the sum of the discounted benefits of the strategy less the sum of discounted costs. NPV can be used to compare investment scenarios that result in different condition and remaining useful life (RUL). However, asset value alone is insufficient for prioritizing, it needs to be used in conjunction with cost and intervention models.

Thus far, we have discussed how value can support asset management but not what it represents.

There are mainly three perspectives on asset value:

1. Cost perspective – what does/did it cost to construct and maintain the asset?
2. Economic perspective – what value does the asset provide to travellers and society?
3. Market perspective – where a market exists, for how much can the asset be sold?

For supporting transport asset management, owners tend to use current replacement cost. The cost perspective helps an organization directly relate its expenditures on asset to changes in their value. Also, it is the cost most relevant to an asset manager trying to make decisions that involve spending today’s money.

The basic issue with cost perspective is that is flattening the relation between cost and value, e.g. the value derived from spending 10 million in reconstruct a tunnel will be 10 million ignoring benefits generated by the asset on society. However, assuming that an existing asset is worthy of maintenance (and this is the case for motorway’s physical assets), the expectation is that its benefits will be equal or exceed its replacement cost.

The purpose of the tool is to support in evaluating intervention-related decisions on the tunnel’s lining based on Life Cycle Cost Analysis (LCA). Initial value of the asset will be calculated as Current Replacement Cost of the tunnel according with its peculiarities (lining material, geometry, surrounding soil properties, waterproofing techniques etc..).

6 COST AND INTERVENTION MODELS

One of the key factors of lifecycle cost analysis is the time value of money. In economic decision-making, people value near-term revenue and near-term cost more highly than money that changes hands in the futures.

The mathematical formulas for computing life-cycle cost are well known in asset management applications. The discount factor is calculated from:

$$\delta(t) = \frac{1}{(1+i)^t} \approx \exp(-i \cdot t) \text{ for } i \ll 1 \quad (6)$$

Where i is the real discount rate and t the number of years from the instant we want to evaluate different scenarios. In Figure 10 the discount factor for different discount rate.

Figure 10. Discount factor for different discount rates vs time.

To compute the net present value (NPV) of future investments, costs, and benefits should be discounted. There are many possible approaches for discounting future benefits and costs, the most common in Italy is the *social rate of time preference* (SRTP) which establishes that there are two effects to consider when selecting the discount rate:

- Pure time consumption;
- Economic growth.

The pure time consumption is purely psychological and accounts for the weight that an individual assigns to future utility compared with present utility. On the other hand, the criteria of economic growth accounts for the fact that as access to resources increases with time, the marginal utility of future investments (costs) becomes smaller (Mauricio Sánchez-Silva & Georgiana Klutke).

The decision support tool allows the user to input the desired discount rate.

Guidelines sets a strict frequency rate for visual inspection of the asset. The frequency is related to the structural risk of “failure” both for global and local mechanisms. Lower is the risk lower will be the number of times visual inspection is required on the asset consequently, lower will be the associated cost.

Reactive or corrective maintenance imply actions after a fault and it relies on data collected mainly through inspections. Proactive or preventive and predictive maintenance is based on probability theory and on the economic assumption that it is better to

invest now, to prevent structure damage or its progress, to save money later (Sandra Skaric Palic et al.).

Good management practice should include making optimum use of resources, provide a sustainable program of work and assist in achieving Stakeholders long term policies.

In general, the interventions approaches can be classified in a) “do nothing repair philosophy”, b) “regular holding repairs” and c) “one off, full refurbishment”.

Three different type of intervention strategy are included in the supporting decision tool:

- **IMS** – Local and relatively small intervention, useful to minimize risk for SLO mechanism mainly (extraordinary maintenance effect);
- **IRS** – Structural reinforcement, higher impact on condition reducing risk for both local and global “failure” mechanisms;
- **TRS** – *Tunnel Renewal Strategy* (Figure 11) – Replacement of the lining with a new one characterized by higher structural performance and strength (impact on condition “good as new”).

Figure 11. TRS castello I (A10).

For each kind of strategy, the user is required to input the impact on tunnel section conditions $+\Delta\text{Cond}$ (%) in terms of global and local mechanism and the impact on deterioration model.

Treatment strategies entails both capital and operation expenditures. The decision support tool allows for input costs of mobilization and demobilization of construction activities and intervention per tunnel section as well as frequency and cost per tunnel section of ordinary maintenance of the treated areas. Costs for maintenance of intervention can be “replaced” when a new treatment is performed or cumulated.

7 SHORT/LONG TERM ASSET MANAGEMENT PLANNING

A case study is here presented to highlight the benefits a life cycle assessment could bring to the organization when different scenarios or strategies of intervention are possible.

Treatments alternatives are so many depending on kind of intervention, timing, number of sections treated per time etc.

A support decision tool is fundamental to analyze and compare as many as possible solutions with a minimum effort of the Practitioner in order to pick the one that leads the organization to its objectives. Herein three scenarios for a relatively short tunnel are presented.

The subject of the simulation is the tunnel “Rapallo” right tube, located on the A12 motorway in the Liguria region. The asset is a two-lane tunnel 204 m long (about 11 sections) built in 1969.

The following intervention scenario are applied:

- 1) “Do nothing”;
- 2) IRS in case at least 5 sections are in condition between 50% and 0% for SGG or SLO risk of “failure”; IMS in case at least 2 sections are in condition between 70% and 50% for SLO risk of “failure”; IRS in each section with conditions lower than 40%
- 3) TRS in each section with conditions lower than 30%

The purpose is to evaluate conditions/risk, costs (OpEx and CapEx) and residual value of the asset at 2038 (short-term). The analyses are performed on 27 years’ timeframe to make some considerations at 2050 as well (long term).

Condition is evaluated for SGG and SLO mechanisms in average and minimum among section values but, here an average of the two structural discipline is presented here to have an overall idea of the structural performance of the asset (Figure 12).

Figure 12. Average SGG & SLO conditions.

The minimum conditions among the tunnel sections is a constrain for the evaluation of the remaining useful life (RUL). The first part of the asset lowering a 20% condition is determining the RUL.

Scenario 1) “Do nothing” does not allow for a minimum level of service of the asset up to 2038 (remaining useful life is 3 years). The organization cannot take such a risk and this option should be disregarded immediately at this stage.

In Figure 13 discounted operation expenditures due to visual inspections and maintenance of installed remediation works are plotted. Scenario 1) do not have treatments but, the operation costs are close to scenarios 2) and higher than 3) due to a very strict visual inspection plan given by the high CdA

SGG+SLO during the life cycle. Scenario 2) has comparable OpEx due to less inspection but maintenance cost related to performed IMS and IRS. Scenario 3) has very low OpEx since the reconstruction of the liner (TRS) bring back the CdA SGG+SLO to its minimum value.

Figure 13. Discounted OpEx.

This is true both at short and long terms whilst discounted total costs (OpEx+CapEx – Figure 14) has a different trend.

Scenario 2) is economically more convenient than scenario 3) at short term whilst at long term the net present cost is approximately the same.

Figure 14. Discounted CapEx + OpEx.

The gross replacement cost of the asset is 4’653’000 € assuming the reconstruction of the liner only. The value of the asset at T=0, since the average condition is 41%, is 1’907’730 € (Figure 15). The residual value after 15 years (short term) is 650’000 € in the scenario 1), 1’117’000 € in scenario 2) and 3’582’000 € in scenario 3).

Figure 15. Asset value.

The residual value can be an interesting parameter for the Owner of the asset, also it can be used to justify a specific intervention strategy (e.g. scenario 3) costs 18% more than scenario 2) at 2038 but in the short term timeframe the residual value will be three times higher.

8 CONCLUSIONS

This study highlighted that decision making can strongly be driven by measurable parameters and Asset Management best practices and fundamentals.

The assumptions made are crystal clear and available to the Practitioner who will use the tool to help in planning maintenance and rehabilitation interventions of the asset.

Parameters are in most cases adjustable and free to be modified by the user, leaving a plenty of room for implementation of specific type of intervention and deterioration models.

This work is only a small piece of the toolbox needed to fully embrace the Asset Management practice and many other aspects need to be addressed among the Organization.

On the Engineering side the definition of a proper deterioration models is still an open topic. The approach used is affected by the fact that inspections conducted by the new standard (LLGG) have started

recently and evolution of degradation based on defects is still not available. Soon, further inspections on the same asset (or group of tunnels) will be available and could be analysed to better fit a more realistic degradation model. Climate change could also be implemented.

A multicriteria analysis will be included in a future release to address all those aspects not strictly related to cost and value (route criticality for impact of the works on traffic, sustainability, etc..) expanding the criteria of the decision-making process and the stakeholders involved.

SMART-Systemic approach to risk management of tunnels

Andrés Marulanda E*
INGETEC, Colombia

ABSTRACT: Tunnels are complex systems. To be effective, risk management should adopt a holistic approach to all project activities and stages. If risk management is restricted to certain activities, stages or part conducted only by part of the project team, one the critical links of the project will break, rendering the risk management efforts ineffective. By implementing a systemic approach to risk management of tunnelling projects, synergies arise, and benefits are maximized. For this to be achieved, risk management should be at the core of the managerial processes of all project activities, implemented more as a philosophical approach to managing the project rather than an isolated effort. This paper presents risk management recommendations and best practices to be implemented in all underground project stages, from initiation to dispute resolution mechanisms.

Keywords: Risk Management, Contracts, Emerald Book, uncertainty, differing site conditions

1 INTRODUCTION

We live in a V.U.C.A world: volatile, uncertain, complex, and ambiguous (Winston, 2023). This reality is especially prevalent in underground works projects- and other megaprojects- affected by conflicting interest of project shareholders, uncertain site conditions, long-term regulatory and legal changes, and macroeconomic fluctuations. Yet many of our design and managerial practices for developing complex infrastructure projects assume that we can predict events and situations with certainty in a deterministic matter.

A risk is an uncertain event or condition, that if it occurs, has a positive or negative effect on a project's objectives (PMI, 2021). Thus, risk management is the art and science of identifying, analyzing and responding to risk factors throughout the life of a project to achieve the project's objectives. Given the uncertain nature of tunnelling and underground works, the implementation of rigorous risk management (RM) practices is especially important in this industry.

Risk management has evolved positively in recent decades in most tunneling projects. However, tunneling projects still face significant cost overruns and delays, preventing reaching project objectives (Flyvbjerg, 2003; Kastbjerg, 1994; Murphy, 2008; Thomas, 2009). Hence, risk management practices still have a long way for improvement. Part of the problem can be attributed to a disjointed

implementation of RM practices throughout the project cycle. RM is often implemented only in some project stages and activities. However, effective RM requires a systems thinking approach, whereas it is understood that a system fails through its weakest link and the different parts are interconnected. Hence, an approach is required whereas RM is implemented not as a separate activity by some members of the project team, but it is practiced at the core of sound project management practices by all team members throughout the project life cycle. The entire tunnel system and its interrelated components should be considered when analyzing risks and devising strategies for their mitigation. With this approach, RM becomes more a philosophy for delivering and managing the project rather than a project activity. A holistic and systemic approach to RM leads to synergies and amplification of benefits from the implementation of the different tools and strategies in the RM toolbox.

A holistic approach evaluates the risks of tunneling and underground projects throughout the project life cycle as shown in Figure 1.

Figure 1. Holistic approach to risk management throughout the project life cycle.

*Corresponding author: andres@ingetec.com.co

Key practices and considerations for RM applicable during the different stages are presented below.

2 RM DURING THE INITIATION AND PLANNING STAGE

Risk management should start during the project initiation and planning stage by the project Owner or Promotor. Some of the good practices that should be considered during this phase should include:

- Recognize and accept uncertainty, especially epistemic (i.e., knowledge). This should formally be accepted as a reality and not minimized.
- The “Ostrich Approach” to RM should be avoided. Risks do not go away or disappear if we hide our heads in a hole, they need to be identified and managed promptly. The sooner a risk management strategy starts the more alternatives to handle risk are available. As a project matures, uncertainty is typically reduced, but as shown in Figure 2 the influence of the project team diminishes as the project advances. Hence, the early stages of project should have special emphasis in RM given that the greatest positive effect can be achieved early on.
- Risks should be assigned to the party best able to manage them. Project Owners and financiers often minimize the cost to transfer a risk to a contractor. Also, many Owners disregard the fact that a transfer risk does not disappear. If it becomes unbearable to the contractor, an Owner could end up with an unfinished project. Moreover, a sophisticated player does not assume projects risk for free, they normally charge a premium to assume risks. Thus, project Owners should evaluate if transferring risks outside a contractor’s control- such a geological risks- is a good practice and in their best interest. Often with such an approach they are materializing a risk and paying for it in advance, even if it does not occur. Also, in many jurisdictions transferring unquantifiable risks exogenous to the contractor contradicts legal dispositions.
- Project Owners should avoid reinventing the wheel. A systematic and rigorous approach to collecting and analyzing lessons learned from other projects should be implemented to improve planning and risk management processes (Marulanda, 2020). Given the uniqueness of each project, the knowledge of projects stays in a tacit and individual way, in a restricted group. A lessons learned

Figure 2. Evolution of influence of the project team to affects costs of a project throughout the project life cycle.

process can aid to make this knowledge explicit and collective for the organization.

- ITA’s Contractual Framework Checklist for Sub-surface Construction Contracts (ITA, 2020) should be consulted. ITA’s WG 3 published a recently updated and revised contractual practices checklist for implementing in tunneling projects that the organization believes are fundamental for the success of subsurface construction projects, independently of the form of delivery and risk allocation used. This document can facilitate Project Owners and Consultants the validation of widely recognized and accepted good contractual practices in the tunneling industry.
- A project Owner should assume the risks that is capable of handling and tolerating as a function of its financial capacity, organizational capabilities and strategic policies. Whenever possible, risks outside of its organizational capabilities and control should in principle be transferred to third parties via contractual arrangements, insurance, or financial instruments.
- The ALARP (as low as reasonably practicable) principle should be implemented to analyze and manage risks. Reasonably practicable involves weighing a risk against the trouble, time and money needed to control it.
- It should be recognized that risks are dynamic. A common problem with RM practices is that risks are often identified and analysed in one project stage, but their evaluation is not revised in later stages. As the information related to a risk evolves (i.e. more geotechnical investigations become available), the evaluation of a risk should be reassessed. The responsible person or party to monitor a particular risk should be clearly identified.

3 DESIGN STAGE

Engineers are trained to be precise. However, in our professional practice, especially when dealing with natural made materials, we seldom have the privilege or capability of precision. This should be openly recognized and acknowledged. Soil and rock mass parameters should not be reported nor used as singular values for analysis and designs, but rather with ranges and statistical variations. By adopting a probabilistic mindset (Watkinson & Konkoly, 2023) we avoid transmitting a false sense of precision.

With today’s sophisticated numerical analysis, engineers should exercise engineering judgement to validate the reasonability of complex model results. The well know acronym GIGO (garbage in- garbage out) should not be forgotten. As Ralph Peck, one of the fathers of geotechnical engineering once said, we should be able to validate FEM results with back on the envelope simplified computations.

However expert judgement, in particular for risk assessments, should also be regarded with skepticism as it is often subjective, and subjective to cognitive biases (Hilbert, 2012); Kahneman, 2013; Vick, 2012).

When reporting results, scenario analyses are recommended, combined with sensitivity analysis. Whenever possible, results should be reported with probability of exceedance data. This practice aids to properly communicate variability and uncertainty in a clear way. This is especially important with budget estimates and schedules. Some agencies, such as the WDOT now demand that cost estimates recognize uncertainty and be reported with a probabilistic distribution (Reilly, 2011). Cost estimates should clearly define what level of engineering they are based on. As the level of engineering matures, uncertainty is reduced, but the project budget can increase. If this is not clearly communicated, changes in the project budget throughout the project life cycle can be perceived by the public as lack of diligence by the parties developing the project and not as a normal project maturation. Unfortunately, politicians typically report project budgets without much care of what are the basis for the numbers. Furthermore, project contingencies should not be estimated using rule of thumbs or standard percentages. A project risk analysis should be used to estimate the contingencies with more rigor and substance. Residual risk results after mitigation strategies have been evaluated can serve as the basis for the project contingency.

It is recommended that risk assessments be initially conducted using qualitative analysis. This allows for a more effective investment of limited resources. The project team can devote more resources and refine the risk assessment with quantitative methods of the risks that result to be more critical. Special attention shall be given to “Black Swans” events, low probability events with high impacts (Taleb, 2007). These events are by definition difficult to detect but they could have devastating consequences for the project.

4 TENDER STAGE

The project Owner should aim for a balanced risk allocation. In the long term, an equitable distribution of risks to the party best capable to handle a risk, results in the lowest project cost for the project Owner (See Figure 3).

Figure 3. Conceptual evolution of project costs depending on risk allocation to the Contractor.

One of the most critical risk management decisions in a project is the selection of the procurement strategy. This involves critical strategic considerations, not only legal concerns. No procurement strategy is in general more favorable than others. The desirability of a specific delivery strategy is project dependent, influenced by the specific project risks and the capabilities and experience of the parties involved.

It is recommended that the recommendations and best practices recommended in the Code of Practice for Risk Management of Tunnel Works (ITA/IMIA, 2023) be adopted as early as possible in the project lifecycle. This document aims to reduce significant project losses by recommending and implementing best practices for managing construction risks in underground works. Many insurers demand compliance with the Code provisions as a pre-requisite for procuring insurance in a project involving underground works.

5 CONSTRUCTION STAGE

It is recommended that project Owners consider adopting the “Emerald Book”- Conditions of Contract for Underground Works (2019), jointly developed by FIDIC and ITA, as the basis for the contractual documents for underground works. The ITA has been advocating for the implementation of good contractual practices since the seventies (ITA, 1988, 1996, 2011). Even though many of these recommendations have permeated the industry, unfortunately, the original intend of some of the recommended principles is sometimes misunderstood or modified in the contract documents due to inexperience or lack of skill from individuals drafting the provisions for a tunneling contract. The Emerald Book puts best contractual practices for tunneling projects in a coherent and harmonic contract.

If due to legal restrictions in certain jurisdictions the complete form of contract cannot be adopted, it is recommended that at least the main conceptual aspects behind the Emerald Book be adopted:

- Allocation of ground related risks to the Owner and performance related risks to the Contractor.
- The ground related risk is assigned via the introduction of a Geotechnical Baseline Report (GBR) as the single contractual source for subsurface physical conditions risk allocation.
- The use of a unit rate compensation structure for ground related activities (i.e., excavation and support), including time related costs. Provision of a detailed schedule of baseline performance measures setting out the production rates anticipated for each of the items measured.
- Assessment of the time to carry out the final quantities of work using the baseline performance measures. This will be applied to the time related

items in the bill of quantities and used to assess whether it results in any delay to Completion.

During construction, the use of risk registers as a project management tool should be encouraged. These registers should be reviewed, revised, and monitored on a regular basis, with clear designated responsible parties to monitor and control specific risks. Moreover, the presence of the designer during construction is of utmost importance. The final design and support implemented in a tunnel depend on the actual conditions encountered during construction. The designer should be present during construction to validate and analyze the conditions encountered at the excavation front.

6 DISPUTE RESOLUTION MECHANISMS

The occurrence of disputes will still arise, even in underground projects that are structured with an equitable risk distribution and incorporate the aforementioned recommendations. For that reason, these instruments need to be complemented with dispute resolution mechanisms that promote an equitable, prompt, and cost-effective resolution of claims and disputes. Without them, the benefits and flexibility of the recommended practices will be hindered.

The issues at hand in a differing site condition claim are typically complex and require a deep understanding of the complexity of underground design and construction. Typical drawbacks of litigation include lengthy and costly processes that in the case of large projects can take several years and large amounts of money in legal fees to be resolved. Moreover, judges and juries typically do not possess the knowledge to understand the technical subtleties behind a differing site condition claim. Thus, it is highly recommended that tunneling projects engage a dispute review board (DRB). Depending on the legal provisions in each jurisdiction, the DRB can be an adjudication or recommendation boards. Disputes that cannot be resolved at the DRB level can escalate to and arbitration proceedings.

The analysis of claims is also facilitated if escrow bid accounts are implemented, whereas bid documents are deposited in a confidential account, but can be consulted by the DRB or arbitration panel to understand the consequences of unforeseen conditions.

7 CONCLUSIONS

Uncertain complex systems like tunneling projects require a probabilistic mindset to develop them successfully. Only with such an approach, whereas uncertainty is explicitly acknowledged, can we anticipate the occurrence of unfavorable

events and conditions and device mitigation strategies to achieve project objectives. Risk management should be at the core of the managerial processes of all project activities, implemented more as philosophical approach to managing the project rather than an isolated effort. Risk management practices have evolved and permeated the tunneling industry in the last decades, but their implementation is still erratic, not uniform, typically applied only at certain project stages or activities, and assigned to a limited part of the project team. This fragmented approach has diminished the effectiveness of RM practices in tunneling projects. Many tools that support good RM practices have been developed and are available to our industry, we need to extend their use in a holistic and systemic way. Only if we spread RM practices to all tunneling project activities, stages, and team members will the performance record of the industry improve to complete projects complying with the triple project restriction: good quality, on time and meeting the budget.

ABSTRACT: Tunnel projects involve high capital investments and take a long time to build therefore constitute a major financial challenge for owners. It is impossible to imagine a “zero-risk project”. Of course, some projects will be high-risk, while others will have less risk, but all projects are by definition risky. The important thing is not to keep risk out of projects, but to ensure that the inescapable associated risks are at a level which is acceptable to the stakeholders. The use of risk management from the early stages of a project is essential. Risk should be managed through appropriate procedures during planning, design, procurement, and construction. Risk management processes can be significantly improved by using systematic risk management techniques throughout the tunnel project development. Using appropriate techniques, potential problems can be clearly identified such that suitable risk mitigation measures can be implemented in a timely manner. The extent of application of specific procedure as the methods and tools used to support risk management depend on the project development phase and project complexity. Since all projects are exposed to risk, successful projects are the ones where that risk is properly managed. In this paper some ideas of the possible approaches are presented with focus on probabilistic risk analysis.

Keywords: risk assessment, risk mitigation, Monte Carlo simulation, TBM, water inflow, fault zones

1 INTRODUCTION

Tunnel projects involve much higher hazards and risks than any other civil engineering construction.

Statistically, most of the tunnel projects, quite all of them, reported cost overruns and claims in a much greater percentage than other civil construction works.

It is impossible to imagine a tunnel project without risk. Of course, some projects will be high-risk, while others will have less risk, but all projects are by definition risky to some extent. The “zero-risk project” is an oxymoron and a logical impossibility – it does not and cannot exist.

Unmanageable cost escalation and construction time extensions could involve massive difficulties for the stakeholders and could imperil the economic and financial equilibrium of the project.

In this scenario, it is fundamental to develop a plan for risk management in any project, starting from the early phases and then throughout the project life cycle; the efforts must extend throughout the life of a project and must be based on quantitative information that is current and complete.

The goal of risk assessment is not to eliminate all risks from the project. Rather, the goal is to recognise the significant risk challenges to the project and to initiate an appropriate planning response to their management and mitigation.

Project risk management is an art involving careful consideration about uncertainties and risks and relies on sound engineering judgment to plan where to focus energy and resources.

Risk management processes can be significantly improved by using systematic techniques throughout the tunnel project development. Using these

*Corresponding author: a.antiga@more-engineering.it

techniques, potential problems could be clearly identified such that appropriate risk mitigation measures can be implemented in a timely manner.

In this paper an outline of possible approaches is presented focusing on probabilistic risk analysis.

2 RISK MANAGEMENT FRAMEWORK

Risk management is a systematic process of identifying, analysing, planning, monitoring, and responding to project risk over the life of the project. It involves processes, tools, and techniques that help to minimise the probability and consequences of adverse events (threats) and maximise the probability and consequences of positive events (opportunities) throughout the life of the project.

Risk management is most effective when started early in the life of the project, where major decisions such as choice of alignment and selection of construction methods can be influenced and continues throughout the project.

The framework is scalable from small and non-complex projects to large and complex projects.

The overall risk management process is repetitive and cyclical. As the project evolves, some risks will be resolved or diminished, while others may emerge and thus be added. The fundamental risk management steps can be applied throughout the project life cycle. The extent of application of each step, as the methods and tools used to support these steps, depends on the project development phase and project complexity.

It must be recognised that risk modelling is not a precise measurement and cannot be reduced to a rigid process; some features of a model used in a specific case might not be transferred directly to another project.

It is also important to recognise that risk management is not “one-size-fits-all”. Since every project has a different level of risk exposure, it is necessary to scale the risk process to meet the risk challenge of each particular project. Projects which are highly risky or strategically important will require a more robust approach to risk management.

In every tunnel project, risk management strategy should be adopted. A recommended strategy is to carry out construction risk assessments at each stage of plan, design, and construction in accordance with the information available and the decisions to be taken or revised at each stage.

In risk management strategy should be included:

- the definition of project objectives,
- a definition of the risk management responsibilities,
- a short description of the activities to be carried out at different stages of the project to achieve the objectives,
- a scheme to be used for follow-up on results obtained by which information about identified hazards (nature and significance) is freely

available and in a format that can be communicated to all parties,

- follow-up on initial assumptions regarding the operational phase,
- monitoring, audit, and review procedures.

2.1 *Phases during the life of the project*

The application of risk management during all project stages, from planning, feasibility, and design through to tendering, contract, and then to construction and maintenance, needs to be considered for every tunnel project (Eskesen et al., 2004).

In the planning and design phase the responsibility of establishing a risk policy, the risk acceptance criteria and carrying out risk assessment is the owner alone. In the tendering phase the owner is still the primary responsible party. In the construction phase the primary responsibility moves on to the contractor to establish a risk management system and to carry out effective risk management. The owner should supervise and participate in this work and should further continue to assess and mitigate risks not covered by the contractor.

2.2 *Main steps*

The most common set of processes would include risk identification, assessment, analysis, mitigation, allocation, monitoring and updating.

An important underlying concept of this approach is that the overall process is repetitive and cyclical. As the project evolves, some risks will be resolved or diminished, while others may emerge and thus be added. These steps are continually applied throughout the project implementation period (EN IEC 31010, 2019 and SAEO, 2018). There are six imperative steps to manage project risk.

1. Risk Management Planning. It is a systematic process of deciding how to approach, plan, and execute risk management activities throughout the life of a project. It is intended to maximise the beneficial outcome of the opportunities and minimise or eliminate the consequences of adverse risk events.

2. Risk Identification. It involves identifying and documenting which risks can affect the project and documenting their characteristics.

3. Risk Analysis. It involves the quantitative or qualitative analysis that assesses impact and probability of a risk. It assists in deriving contingency estimates.

Qualitative risk analysis involves assessing risks for probability of occurrence and impact on project objectives. Risks are measured by their “quality”. It is fundamental understanding the characteristics of individual risks, analysing their level and prioritising them in order to plan appropriate responses to reduce their negative impacts.

Quantitative analysis is used to analyse the most important individual risks in more detail by assuming different scenarios. Quantitative risk analysis is a way of numerically estimating the probability that a project will meet its cost and time objectives. It is based on a simultaneous evaluation of the impacts of all identified and quantified significant risks.

4. Risk Mitigation. It involves analysing risk response options (mainly acceptance, avoidance, mitigation, transference, or sharing) and deciding how to approach and plan risk management activities for a project.

5. Risk Response. It involves developing options and determining actions to reduce threats or enhance opportunities to project objectives. Actions are identified and assigned to parties that take responsibility for the risk response. This process ensures each risk requiring a response has an “owner.” A strategy that is best for each risk must be identified and then select specific actions to implement that strategy.

6. Risk Monitoring and Control. It is the capture, analysis, and reporting of project performance. Risk monitoring and control tracks identified risks, monitors residual risks, and identifies new risks—ensuring the execution of risk plans and evaluating their effectiveness in reducing risk. Risk monitoring and control is an ongoing process for the life of the project.

Figure 1 shows the process described above (SAEO, 2018).

Figure 1. Risk management process.

3 RISK MANAGEMENT OBJECTIVES

Risk can be defined as “*effect of uncertainty of objectives*” (ISO 31000, 2018). Consequently, the first step in the risk management process is not the identification of risk: since risk is defined in terms of objectives, the essential first step is to define those objectives which are at risk. The goal of risk management is quite specific: it is to enable stakeholders to make appropriate decisions in the light of the uncertainties, which could jeopardise objectives of the project.

In principle, risks that could compromise the primary objectives of the project should be examined in the first instance, such as:

1. health and safety of workers and third parties,
2. safeguarding third party property (existing structures, cultural heritage buildings, etc.),
3. preservation of environment (possible land, water or air pollution and damage to flora and fauna),
4. avoidance of the completion,
5. prevention of financial losses and additional unplanned costs.

With reference to the source of the risk, the underground projects must face two broad categories of risks: “technical risks” and “non-technical risks”.

Technical risks can be classified in “external” (risks for which stakeholders have no power to act on the source of the risk) and “internal” (risks whose origin is the responsibility of the parties involved in the project, for example arising from contractor methods and means).

Non-technical risks are political and administrative risks, interface, financial, and similar ones.

For instance, in underground constructions, due to the inherent geological uncertainties, including ground and groundwater conditions, there might be significant cost overrun and delay risks as well as environmental risks. Furthermore, for tunnels in urban areas there is a risk of damage to a range of third-party persons and property, which will be of particular concern where heritage designated buildings are involved. Finally, there is a risk that the problems which the tunneling project cause to the public will give rise to public protests affecting the course of the project.

In general, “geo” risks, particularly in the form of unexpected geological conditions, drive time and costs of many underground constructions.

However, it is important to highlight that also contractual disputes are a significant risk factor; indeed, contractual issues are main hazard for tunnel project comparable with geological ones (Avestedt, 2012).

Anyway, even if in modern tunnels advanced technology is used, the final construction cost is still governed by the cost of the tunnel excavation. In first approximation, it is possible to state that excavation cost represents between 60% to 90% of the final construction cost. Therefore, ground conditions represent the largest element of technical and financial risk in tunneling projects and there is an agreement largely unanimous on the concept that “geo” issues are the key cost drivers for tunneling.

In the following pages, probabilistic risk analysis methodologies will be focused, giving an example of the application of the Monte Carlo method to the excavation of a tunnel with TBM in a geological context characterised by the presence of highly tectonised areas with possible significant water inflow.

4 DECISION-MAKING UNDER RISK

The risk assessment phase has as objective the systematic consideration of risk events and has two main points: their probability of occurrence and the consequences of such occurrences. The first determines the probability of a risk occurring (risk frequency); risks are classified along a continuum from very unlikely to very probable. The second judges the impact of the risk should it occur (consequence severity).

Risks affect project outcomes in different ways. Risk effects are usually apparent in direct project outcomes by increasing cost or schedule. Some risks influence the project by affecting the public, public perception, the environment, or safety and health considerations.

In principle, the risk assessment combines both a qualitative and a quantitative assessment. The qualitative assessment is useful for screening and prioritising risks and for developing appropriate risk mitigation and/or allocation strategies. The quantitative assessment is best suited for estimating the numerical and statistical nature of the project's risk exposure.

4.1 *Qualitative risk analysis*

A qualitative analysis is simpler and less costly.

Performing a qualitative analysis of risks and conditions to prioritise their effects on project objectives. It involves assessing the probability and impact of project risks and using methods such as the probability and impact matrix to classify risks into categories of high, moderate, and low for prioritised risk response planning.

Typically, the qualitative risk assessment recognises some risks whose occurrence is so likely or whose consequences are so serious as to justify further quantitative analysis.

A key purpose of quantitative risk analysis is to combine the effects of the various identified and assessed risk events into an overall project risk estimate. Measuring the probability and consequences of risks and estimating their implications for project objectives. Risks are characterised by probability distributions of possible outcomes. This process uses quantitative techniques such as probability-based analysis, sensitivity analysis, and decision tree analysis.

Usually, the overall risk assessment is used to determine cost and schedule contingency values and to quantify individual impacts of high-risk events.

4.2 *Quantitative risk analysis*

Risks do not usually happen one at a time. Instead, they interact in groups, with some risks causing others to be more likely and some risks making others impossible. For the most part, qualitative risk assessment considers risks individually and allows development of a good understanding of each one (although grouping risks into categories can give

some insights into patterns of risk exposure). It is however sometimes necessary to analyse the combined effect of risks on project outcomes, particularly in terms of how they might affect overall time and cost. Indeed, this is often the only way to obtain an accurate assessment of the overall risk exposure of the project. This is the purpose of the quantitative risk analysis step, since addressing overall project risk exposure requires use of a quantitative model.

Various quantitative risk analysis techniques are available, including Monte Carlo simulation and decision trees. Monte Carlo is the most popular because it uses simple statistics, it often uses existing project data as its baseline. Decision trees are however particularly useful for analysing key strategic decisions or major option points.

One key aspect of quantitative risk analysis models, which is often overlooked, is the need to include both threats and opportunities. If only threats are considered, then the analysis is limited to modelling the potential downside and the result will always be pessimistic. Since the risk process aims to tackle both threats and opportunities, both must be included in any analysis of the effect of risk on the project.

Monte Carlo methods are probabilistic calculations that use random number generators to draw samples from probability distributions. The objective of the simulation is to find the effect of multiple uncertainties on a value quantity of interest (such as the total project cost or project duration). They can reveal, through sensitivity analysis, the impact of specific risk events on the project cost and schedule.

4.2.1 *Input for risk analysis*

Once the risk factors and other values required for the model have been identified, the values must be assessed. It is rare to have representative historical information that can be used without any human intervention; risk analysis models almost invariably involve some element of subjective estimation. It is usually not possible to obtain data from which to determine the uncertainty of all variables in the model, in order to avoid subjective assessments, because:

- data have never been collected in the past,
- data are too expensive to obtain,
- past data are no longer relevant, or decision makers do not believe they are relevant, and/or
- data are sparse.

The lack of data means that subjective estimates must be made regarding the uncertainty of the variables within the model. Subjective assessments will always be at risk of bias. Even if there is no option but to use them, it is prudent to take steps to limit or avoid bias.

If risk events are significant enough to be described individually in a model, the probability of each one occurring will have to be assessed.

Probabilistic-based methods require as inputs a probability distribution for the various performance, schedule, and costs risks. Risk variables are

differentiated based on whether they can take on any value in a range (continuous variables) or whether they can assume only certain distinct values (discrete variables). Whether a risk variable is discrete or continuous, two other considerations are important in defining an input probability: its central tendency and its range or dispersion. The mean and mode of an input variable are two alternative measures of central tendency: the mode is the most likely value across the variable's range; the mean is the value where the variable has a 50 percent chance of taking on a value that is greater and a 50 percent chance of taking a value that is lower.

The mode and the mean of two example continuous distributions are illustrated in the Figure 2 (Molenaar et al., 2010).

Figure 2. Mean and mode in normal and lognormal distributions.

The other key consideration when defining an input variable is its range or dispersion. The common measure of dispersion is the standard deviation which is a measure of the breadth of values that are possible for the variable. Normally, the larger the standard deviation the greater the relative risk. Probability distributions with different distribution method, which means different mean values and different standard deviation values, are illustrated in Figure 3 (Molenaar et al., 2010).

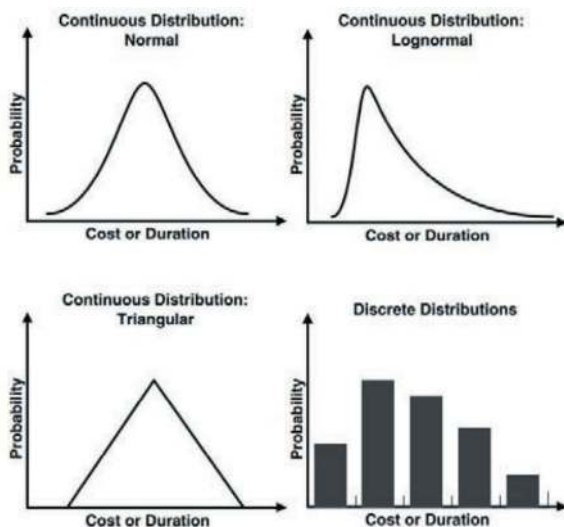

Figure 3. Distributions for risk analysis.

Selecting an appropriate probability distribution is a matter of which distribution is most like the distribution of actual data. For tunnel projects, this is a difficult choice because historical data on unit prices, activity durations, and quantity variations are often difficult to obtain. In cases where insufficient data is available to completely define a probability distribution, one must rely on a subjective assessment of the needed input variables.

Input to Monte Carlo methods requires the user to know and specify probability distribution information; mean, standard deviation, and distribution shape.

4.2.2 Output of risk analysis

Figure 4 (Molenaar et al., 2010) shows typical probability output from a Monte Carlo analysis.

Figure 4. Typical Monte Carlo output for total cost.

The histogram information is useful for understanding the mean and standard deviation of analysis results. The cumulative chart is useful for determining project budgets and contingency values at specific levels of certainty or confidence. In addition to graphically conveying information, Monte Carlo methods produce numerical values for common statistical parameters such as the mean, standard deviation, distribution range, and skewness.

The main output from a Monte Carlo simulation is the s-curve, presenting a cumulative probability distribution of the range of possible values for the parameter being analysed (for example, total project cost, overall duration, end date and so on).

Several elements of useful information can be obtained from the s-curve, including:

- the probability of the project meeting its objectives (taken as the cumulative probability of achieving a given target value, i.e. the 95th percentile as “A” in Figure 4),
- the degree of overall uncertainty in the project parameter, that is standard deviation (derived from the range of possible simulation outputs),
- the predicted “expected value” which would occur on balance if the situation remained unmanaged (taken from the mean value of all possible results, “B” in Figure 4),
- output values corresponding to specific confidence levels (for example, the 95th percentile from the s-curve represents the value for which

we can have 95 per cent confidence of it not being exceeded, “A” in Figure 4).

S-curves can be produced for the overall project, or for interim milestones or specific subprojects, allowing analysis of the components of overall project risk. It is also possible to produce overlaid s-curves, as shown in Figure 4, indicating the cumulative effect of addressing individual risks, showing the relative contribution of planned responses towards overall project risk exposure.

5 APPLICATION OF PROBABILISTIC RISK ANALYSIS

The following is a case history referring to a tunnel construction by double shield TBM. Design is in progress and for reason of confidentiality some data and information will be deliberately simplified. The main frameworks of the project will be presented below.

5.1 Geological context

A double shield TBM is planned for the excavation of a tunnel of length 10,000 m.

The excavation of the tunnel affects the following geological formations: arenaceous formations (A) with the best mechanical characteristics and flysch formations (B) with poorer characteristics. In addition, there are some faults and intense fractures zones (C). The water table is present along the tunnel layout in some sections, also affecting fault zones with maximum heads of 20-30 m.

Table 1 shows the compressive strength, GSI and disturbance values representative of the formations defined above.

Table 1. Geological formations and their parameters.

Formation	σ_c [MPa]	GSI
A	30-35	40±5
B	40-45	24±5
C	30-45	18±5

Double shield TBM is not equipped with systems for pressurising the excavation face and consequently for crossing unstable sections and/or below the water table.

Based on the geotechnical characteristics and the depth of the tunnel, different sections with homogeneous deformation behaviour were identified according to the stability conditions, identified in the diagnosis phase for which three stability classes were defined from the highest (A) to the lowest (C).

Figure 5 Shows the main features of each section identified.

ID	Length [m]	Head [m]	Formation	Stability class	Flow rate [l/s]
1	80	-	B	A	-
2	100	-	C	A	-
3	75	-	B	A	-
4	105	-	C	A	-
5	110	5-10	B	B	<50
6	125	-	C	B	-
7	250	5-10	B	B	<50
8	125	-	C	B	-
9	705	-	B	B	-
10	120	-	C	B	-
11	770	10-20	A	A	<50
12	115	-	C	B	-
13	1300	10-20	A	A	<50
14	125	-	C	C	-
15	1150	-	A	A	-
16	100	-	C	C	-
17	475	-	A	A	-

20	1295	20-30	A	A	>50
21	770	-	B	A	-
22	150	20-30	C	A	>50
23	1300	-	A	A	-
24	200	-	B	B	-

Figure 5. Identification of sections with homogeneous behaviour.

5.2 From qualitative to probabilistic risk analysis

In the qualitative risk analysis for the tunnel, high level risks were identified in relation to:

- 1) water inflow in high permeability context,
- 2) presence of faults/intense fractured areas.

The first one is related to high hydraulic head (up to 20-30 m) in several sections of geological profiles with indications of water inflow and possible unstable behaviour at the excavation face. The second one is related to presence of intense fractured areas with possible face instability also associated with the presence of hydraulic head leading to face instability situations.

Both risks could lead to the possibility of water flows into the excavations even at high pressures potentially jeopardising the regularity of work and safety and the stability of excavations. A quantitative analysis was conducted for risks 1) and 2) above defined for the tunnel.

5.3 Risk identification and probabilistic analysis

In order to probabilistically assess the sources of uncertainty inherent in the realisation of the work, a quantitative probabilistic risk analysis was developed using the Monte Carlo method, evaluating the random distributions of costs and times related to the rock improvement works and the excavation of the tunnel.

As explained before, in the Monte Carlo method, the probability that a given event exceeds a certain threshold is defined. This method is based on the random generation of a series of uncorrelated values as a function of an assigned probability distribution. Once the random parameters have been defined, estimates can be derived through one or more simulations.

For this specific case, the variable input data were defined by means of a triangular distribution, which

is established with the following values: minimum, modal, and maximum value. Since there is only limited sample data, triangular distribution was selected. Then, once the parameters have been defined, several iterations are generated according to the assigned distribution (triangular), calculating the result for each iteration. After that, the process can be repeated several times for performing several simulations; for this specific case, 5 simulations were carried out to confirm the validity of the analysis with an appropriate number of simulations, and 10,000 iterations were considered for each of them. Based on previously developed geological and geomechanical assessments, type rock improvement works were identified to be carried out from inside the TBM by means of holes drilled at the section outline of the shield and at the excavation face in the following sections:

- where diagnostic analyses showed a type C behaviour,
- where the water table exists,
- where there are fault zones.

Rock improvement works were distinguished by providing for the possibility of improving the excavation face and introducing variability in absorption of injections, length of overlap and speed of execution (Tables 2 and 3).

Table 2. Characteristics of rock improvement works.

Rock improvement works	A	B	C
# injections along the section outline	32	32	32
# injections at the excavation face	-	10	10
Absorption of injections [%]	18	20	20
Length of overlaps [m]	16	16	12

Table 3. Characteristics of drainage works.

Drainage works	D
# drainage columns	8
Length of column [m]	30
Spacing [m]	15

Figures 6 and 7 show cross and longitudinal sections related to double shield TBM, where it is possible to view how the improvement and drainage works were designed. Quantities and positions are fictitious with respect to how indicated in tables above, but these figures are useful to understand the configuration of excavation by double shield TBM of this case history including rock improvement works; 1.1 indicates the drainage columns, 1.2 indicates injections along the section outline, and 1.3 indicates injections at the excavation face.

Figure 6. Longitudinal section of TBM.

Figure 7. Cross section of TBM.

With reference to Figure 5, the following sections were defined to be improved:

- sections 14, 16: fault and stability class C zones,
- section 20: zones in the presence of water table with flow rates at the face greater than 50 l/s (high permeability),
- section 22: fault zones and presence of water table with flow rates at the face greater than 50 l/s,
- sections 5, 7, 11, 13: zones in the presence of water table with flow rates at the face less than 50 l/s (medium permeability),
- sections 4, 6, 8, 10, 12, 18: fault zones.

The analyses have led to the definition of 5 type solutions for which a combination of the works (defined above) is indicated, according to the geomechanical and hydrogeological conditions of the sections to be improved (Table 4).

To analyse costs and times in probabilistic terms, input data, representing the sources of greatest uncertainty, were included in the analyses as a triangular probability distribution varying from a minimum to a maximum value, such as:

1. length of sections to be improved (Table 5),
2. percentage of application of type works (Table 6),
3. length of overlaps,

4. percentage of absorption of injections,
5. speed of execution of type works,
6. speed of TBM.

Table 4. Definition of the type solutions.

Type solutions	Scope	Section	Type works
1	Fault and unstable zones	14, 16	B, C
2	Presence of w.t. with $q > 50$ l/s	20	A, B, D
3	Fault zones and w.t. with $q > 50$ l/s	22	B, C, D
4	Presence of w.t. with $q < 50$ l/s	5, 7, 11, 13	D
5	Fault zones	4, 6, 8, 10, 12, 18	A

Table 5. Overall length of sections [m].

Solution	Min	Mode	Max
1	90	225	315
2	518	1295	1813
3	60	150	210
4	972	2430	3402
5	310	775	1085

Table 6. Percentage of application of type works.

Solution	Type works	Min	Mode	Max
1	B	95	80	40
	C	5	20	60
2	A+D	90	60	40
	B+D	5	10	15
3	D	5	30	45
	B+D	95	80	40
4	C+D	5	20	60
	No works	80	60	40
5	D	20	40	60
	No works	95	90	60
5	A	5	10	40

In addition, the speed of TBM was assumed to be different between the post-intervention sections and the healthy rock sections for which no works are planned (Table 7).

Table 7. Speed of TBM in terms of metres per day.

Speed	Min	Mode	Max
Healthy rock	20	28	35
Post-intervention	15	25	30

5.4 Results

By means of a probabilistic analysis it is possible to get the results in terms of costs and time, which depend on fixed and variable parameters. Therefore, the results will be variables, too. Figures 8 and 9 show the variability of TBM + intervention cost. Figures 10 and 11 show the variability of total time taken by the TBM.

Figure 8. TBM + intervention cost – Histogram.

Figure 9. TBM + intervention cost – Ascending cumulative.

Figure 10. Total time – Histogram.

First of all, it is important to understand where the baseline value (mode) lies in relation to the s-curve, both in terms of cost and time, i.e. considering the parameters as if they were all fixed and none of them

Figure 11. Total time – Ascending cumulative.

variable (no probabilistic risk analysis involved). In this case, the TBM + intervention cost would amount to € 214 million, and the total time would be 701 days. Both cost and time are in the respective s-curves in the cumulative probability of about 30%.

To obtain a cumulative probability of 95% the TBM + intervention cost would have to be about € 229 million.

To obtain a cumulative probability of 95% the total time would have to be about 905-910 days.

This means that in order to have a 95% certainty of covering the TBM + intervention cost and total time, an additional about € 15 million (+7%) and about 200 days (+30%) more than would be achieved without the variable parameters must be taken into account.

This simple example highlights the power of probabilistic risk analysis as a tool that can provide stakeholders with useful elements to evaluate the consistency of cost and time forecasts attributed to a project and thus assess the cost and time contingency amount, develop alternative solutions, or radically change project objectives.

Strong financial and improved procurement strategies for the success of the Grand Paris Express

Alexis de Pommerol*

Société du Grand Paris, Saint-Denis, France

ABSTRACT: Société du Grand Paris was created in 2010. It is in charge of financing, designing, building, testing and commissioning the Grand Paris Express. It's a new fully automated transit network of 200 kilometers. This network is 90% underground, includes four new lines and 68 new stations. A specific financial program was set up by Société du Grand Paris in order to finance the €36bn project: it's based on a 100% Green Bond Strategy and has been successfully implemented since 2018. For the second phase of the project delivery, Société du Grand Paris adapted its contractual scheme and chose design-build contracts. Efficient dialog and updated risk allocation lead to a new generation of contracts meeting performances, costs and planning expectations of all stakeholders.

Keywords: Metro, Deep stations, Green Bond, Design-Build

1 GRAND PARIS EXPRESS PROJECT

During the first decade of this century, Public Transport traffic increased very significantly in the French capital region around the city of Paris. The answer to this raising demand was not to be found in new road or car systems. As in many cities around the world, the Paris region was suffering from social divisions as low-income families were concentrated in some territories that did not offer enough accesses to public transport systems. Several projects emerged at the end of the decade, combining urban planning and transport systems. A dialogue of a rare magnitude took place that reached a significant consensus.

In 2010, the French parliament passed the Grand Paris Act and defined the Grand Paris as a urban, social and economic project, based on a new transit system called “Grand Paris Express.” A new entity “Société du Grand Paris” was established by this Grand Paris Act that is in charge of financing, designing, building, testing and commissioning the Grand Paris Express.

Grand Paris Express consists of a new fully automated transit network. It combines an extension of one existing Paris Metro Line, Line 14, and four new lines 15, 16, 17 and 18. From the very beginning, it was clear that a significant part of the new sections would be underground. By the end of the first studies, the preliminary design of the Grand Paris Express confirmed that 90% of the 200 kilometers’ program would be underground, as 63 of the 68 new stations. The program will also include more than 150 access and/or ventilation shafts as well as six new maintenance centers. The average depth of the network is 35 meters with some stations’ platforms at 50 meters under the ground level.

Figure 1. Grand Paris Express network.

2 GEOLOGY AND CONSTRUCTION

While the overall geology of the “Bassin Parisien” was well documented, it was however clear that Société du Grand Paris would require specific additional geotechnical surveys in order to assess the best possible construction methods for the Grand Paris Express.

*Corresponding author: alexis.de-pommerol@societedugrandparis.fr

Figure 2. Grand Paris Express “carothèque” ».

This enabled the creation of the project geological model and of a specific hydrogeological model, following the G1 and G2 requirements of the French NF P 94-500 standards. A total of 9,800 surveys were carried out for the first delivery phase of the project, with an average depth of 45 meters, the deepest exceeding 100 meters. 21,000 samples were analyzed, 2,400 samples were used to perform laboratory tests and more than 2,000 are now stored in the “carothèque”, the geological library of the Grand Paris Express. All the expertise of the Grand Paris Express community is now available for future construction or research in the Paris area.

Figure 3. March 2022, TBM breakthrough at CMF.

The first Grand Paris Express TBM started its run in 2018 and, by 2020, at its peak, the project required the use of 20 TBMs simultaneously. By the end of 2023, more than 100 kilometers had been dug. Mid 2024, first TBM for the second phase of the project delivery (2030-2031) will start digging in the South-Western part of the Paris region.

3 GRAND PARIS EXPRESS FUNDING

Grand Paris Express is a public funded investment. Its first financial source is a dedicated set of additional taxes on specific items such as offices or parking places. These taxes are local which means that only people or companies settled in, working in or visiting the Grand Paris region will contribute to the financing of the Grand Paris Express. In 2022-2023, the total amount collected by these taxes was around €800m. Meanwhile, operations on the Grand Paris Express required a total expense of around €4bn. This was made possible because, according to the Grand Paris act, Société du Grand Paris has also the capability of issuing bonds on the financial markets. Consequently, since 2018, Société du Grand Paris has developed and implemented a strong and efficient strategy that enables the construction of the whole new network in less than 15 years, while it would have probably required more than 50 years if the tax source was the only one available. As of 2030, following global commissioning of the network, construction expenses will be over and the revenue from the taxes will be used to manage and reimburse the total debt of Société du Grand Paris, up to approximately 2074.

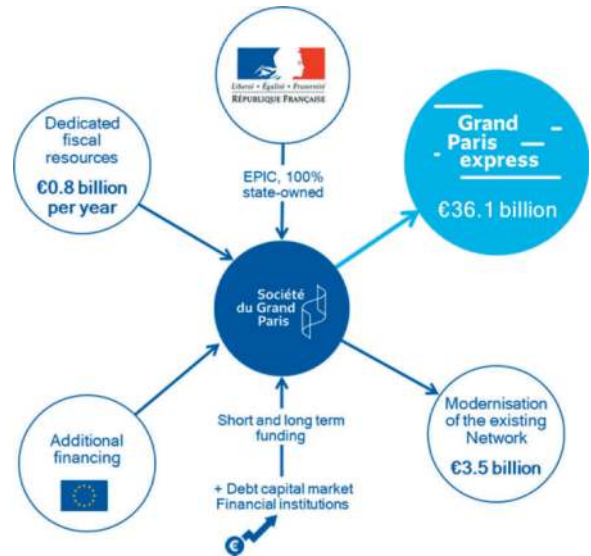

Figure 4. Grand Paris Express funding principles.

Société du Grand Paris was the first global securities issuer to choose a 100% Green financed program through the first international bond program “Green EMTN.” Consequently, Société du Grand Paris reports very precisely on its activities, including specific carbon reports as well as information on the use of excavated materials. Société du Grand Paris’ financial program follows the Green Bonds Principles 2018 standards and are Climate Bond Initiative certified. The initial total CO2 impact of the construction of the Grand Paris Express was 4.4m tons which Société du Grand Paris, following

a complete review with designers and industry, decided to reduce to 3.3m tons in 2021. As early of 2050, the overall impact of Grand Paris Express will be a decrease of 14m tons of CO2. Société du Grand Paris received the 2019 Green Bond of the Year from International Financing Review and the 2020 Green Bond of the Year (supranational, sub-sovereign and agency) from Environmental Finance.

Figure 5. Grand Paris Express debt geography (May 2023).

Construction of the underground sections of the Grand Paris Express results in the excavation of 45m tons of materials. The management of the excavated materials is also key for the appraisal of the project impact. Société du Grand Paris' goal is to reuse 70% of these materials: quarries backfilling or modeling new public areas (parks or public gardens) in the Paris Region. Excavated materials follow strict protocols enabling rigorous and permanent traceability by Société du Grand Paris of their final destination. Water or rail transport is also used for more than 15% of the volumes considered.

Looking at the Grand Paris Express experience, it appears that developing a 100% green financed structure for a transit underground project is possible, considering social and environmental, including decarbonization, management of its construction and future impacts of the network.

4 DESIGN-BUILD CONTRACTING

As a public entity, Société du Grand Paris complies with European and national public procurement regulations that defines scopes of works between employer, designer and contractors, and insists on splitting contracts between design activities and construction activities. In the project first phases, engineering companies carried out the design and supervised construction for the employer, Société du Grand Paris. Interfaces management between the different construction contracts (civil works, tracks, overhead lines, ventilation, power supply, stations' systems...) remains one key issue for the delivery of an efficient transit system. Under this initial scheme,

interfaces management is carried out at engineers' and at employer's level, since several engineering entities can be simultaneously active on one line: civil works and stations, systems, rolling stock, maintenance facilities. On this first phase, systems design was ongoing while infrastructure construction had already started. This situation could lead to change orders as well as costs or delays increase. With the overall progress of the design, a first change in the procurement strategy occurred when tracks and overhead lines were added to a civil works contract that initially include only tunnels, stations and shafts.

Following extensive dialog with the industry (engineering and contractors), Société du Grand Paris adapted its procurement strategy in 2018 for the line 15's second phase. The East and West sections of line 15, around 22 kilometers each, will finalize the loop around Paris by 2030-31 when joining the South section (34 kilometers) that will be commissioned end of 2025. These last sections have been procured through four design-build contracts. These include the design and construction of all the civil works (tunnels, shafts and stations) of the project, tracks, overhead line, power supply, stations' and shafts' systems, ventilation, escalators and lifts. Interfaces between all these systems are therefore within one single hand and enable quick and appropriate adjustment in the project implementation and overall planning. Fire detection, ticketing, access control and passenger information design principles remain at employer's level while their detailed design and implementation are in the contractor's hand. Rolling Stock, signaling, Multi Service Network and Platform Screen Doors are kept under employer's management.

Figure 6. Grand Paris Express first Train run (November 2023).

The procurement process included a two-year-long dialog between bidders and the employer. One critical goal of this dialog was the risk allocation between both parties in order to reduce provisions and, eventually, costs of the contracts. The process duration also enabled 1,200 additional geotechnical surveys to be implemented and analyzed, bringing additional information to the bids' risk evaluation.

Based on these supplementary data, the risk allocation in the contracts was clarified: the number of areas where contractors would be able to call for the owner specific responsibility regarding geological context was consequently reduced, to a maximum of 5. Meanwhile, according to bidders' unformal feedback, the contracts costs were reduced, between 5 and 10%. In 2023, Société du Grand Paris awarded the first two design-build contracts for more than €2.5bn each, the last two design-build contracts are to come into force in Spring 2024.

5 CONCLUSION

An anticipative and voluntarist financial strategy, based on a 100% Green Bond program, has been

implemented by Société du Grand Paris for the Grand Paris Express to benefit from favorable market conditions and reduce exposure to interest rate and liquidity risks. By the end of 2023, more than 70% of the project budget is financed and secured. At this stage, an initial estimate of the theoretical gain (a lower expense) from this strategy exceeds €5 billion.

Confidence provided by this strong financial structure and continuous dialog, in parallel with additional geotechnical surveys, were key for the success of the adapted procurement strategy as Société du Grand Paris chose design-build contracts for the line 15's second phase. The result can be estimated as reduced contract costs, between 5 and 10%, and, overall, meeting major employer's expectations: global costs, planning and performance.

A methodology of risk management to urban tunnels and its application to Bogota subway

J. Esteban Alarcón G.*

Universidad de Antioquia, Colombia

University of Brasilia, Brazil

André Pacheco de Assis

University of Brasilia, Brazil

ABSTRACT: Most of tunnel accidents that happened in the last decades have shown that at least 69% of the accidents were related with uncertainties, although some probabilistic methodologies have appeared as a tentative to include such uncertainties; First Order Second Moment (FOSM), Monte Carlo and others. They have shown themselves as insufficient for making decisions on civil projects. Therefore, Risk Management Methodologies (RMM) have appeared to provide better solutions to such necessities by including both the hazard occurrence probability and its associated costs of potential damages, giving a better tool to the decision-making process. This paper presents a RMM and its application to Line 1 of Bogotá Subway (Colombia). As a part of the methodology, a wide and general mathematical expression has been proposed to calculate the total risk expressed in monetary terms. For the application of the proposed methodology, a data compilation was carried out and a spatial database was constructed with geotechnical data and cadastral information of the surrounding urban area of the Line 1 of Bogotá subway. Subsequently, with the collected data, a geomechanical model was generated and probability distribution functions were defined to design variables. The characterized variables were used as an input of a modified Cam-Clay Model and a Finite Element Modelling (FEM) coupled with a FOSM analysis that was carried out to calculate the probability of exceeding control levels of the design variables. The FEM analysis was carried out in a total of 433 runs to both accomplish the FOSM analysis and cover a selected pilot segment of 4,1 km of the total length of the Line 1 of Bogotá Subway. Finally, by using the formulated expression, the total risk in USD/m² was calculated and the associated map of the study area was built.

Keywords: Risk management methodology, risk analysis urban tunnels, Bogota subway, cost-profit analysis tool

1 INTRODUCTION

This paper presents a Risk Management Methodology (RMM) and its application to Line 1 of Bogotá Subway (Colombia), which is still in concept stage. The methodology incorporates the definition of the Risk Policies, the Qualitative and Quantitative Analysis of the risk and the definition of the Risk Acceptance Criteria, among others. As a part of the methodology, a wide and general mathematical expression has been proposed to calculate the total risk expressed in monetary terms.

For the application of the proposed methodology, a data compilation was carried out and a spatial database was constructed with geotechnical data and cadastral information of the surrounding urban area of the Line 1 of Bogotá Subway. Subsequently, with

the collected data, a geomechanical model was generated and probability distribution functions were defined to design variables.

The characterized variables were used as an input of a modified Cam-Clay Model and a Finite Element Modelling (FEM) coupled with a First Order Second Moment (FOSM) analysis that was carried out to calculate the probability of exceeding control levels of the design variables.

The FEM analysis was carried out in a total of 433 runs to both accomplish the FOSM analysis and cover a selected pilot segment of 4,1 km of the total length of the Line 1 of Bogotá Subway. Finally, by using the formulated expression, the total risk in USD/m² was calculated and the associated map of the study area was built.

2 RISK MANAGEMENT METHODOLOGY (RMM)

Risk Management (RM) is a stochastic design methodology with an associated set of processes, which are complementary to the standard design processes. This additional processes are established in order to: define the risk policy, the risk analysis, the risk-transference mechanism, and to take control measures and supervision of the risks. The procedures and components associated are expanded in this section.

The RMM embraces all stages of a civil project and Figure 1 shows those stages and its relationship.

In Figure 2, it is assumed that conceptualization is a part of the basic design, encompassing all stages before tendering. The tender processes can change

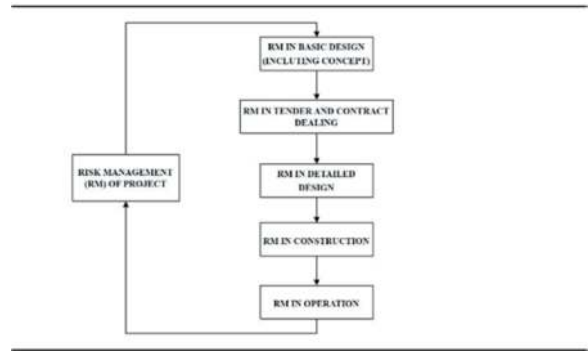

Figure 1. Stages of risk management in a tunnel project.

the position and take place after the detailed design, depending on local tendencies and policies, without affecting substantially the forward discussion.

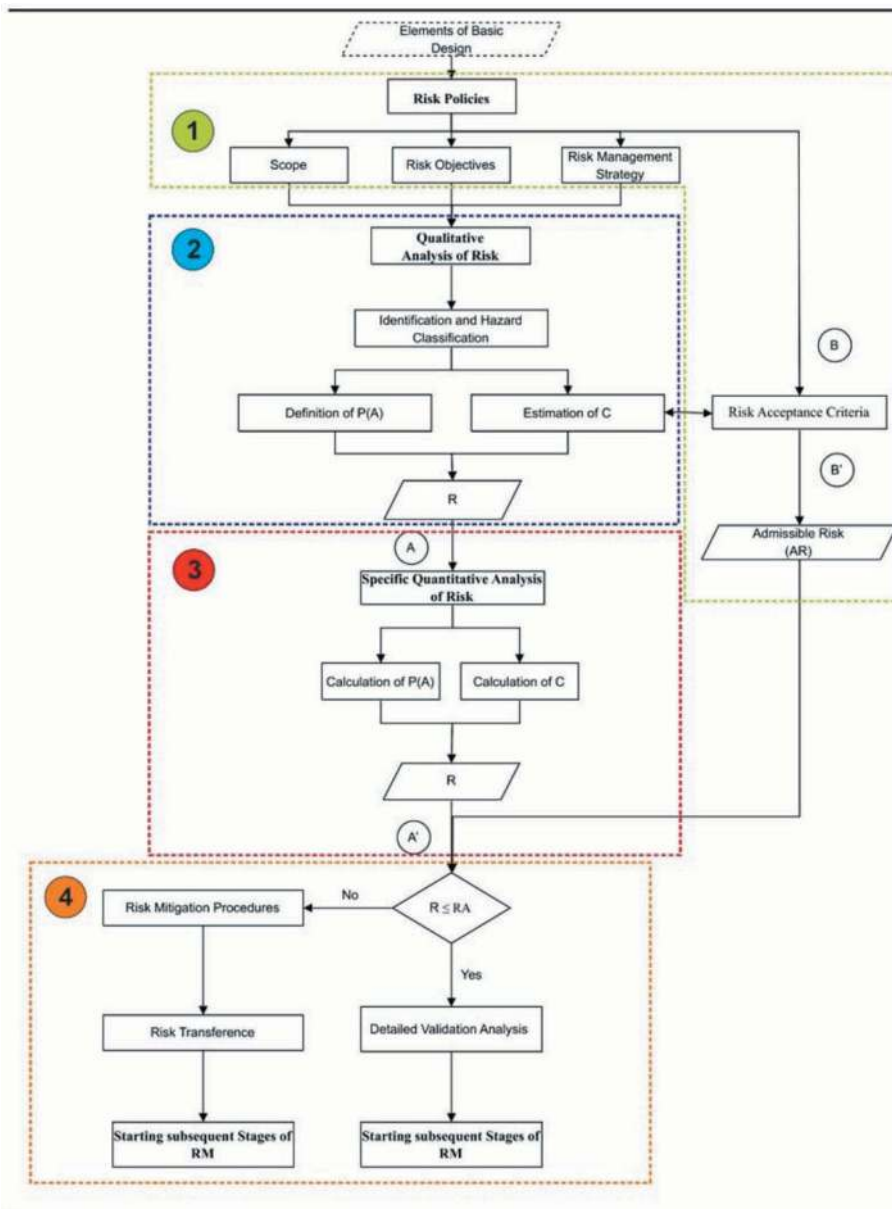

Figure 2. General Risk Management Methodology for a tunnel project in Basic Project Stage.

This paper focuses on the basic design, but, indeed, the methodology can be applied to any design stage or design verification on construction and operation stage no matter the type of civil project. Figure 2 presents the detailed suggested methodology for a RMM in basic design stage.

In Figure 2 four main sets of activities can be seen: risk policies definition; qualitative risk analysis; quantitative risk analysis; and management of the risk.

It is important to highlight that the RM process never ends; it is present in the life span of the tunnel and requires the participation of the owner in all the stages of the project, and the designer, contractor and operator in different stages of it.

The subsequent stages shown in the fourth activity of Figure 2 may be either the tendering and contracting processes or the detailed design, depending on the general requirements of the project and its general configuration.

2.1 Dimensionality of the risk

There are several ways to express Risk mathematically (Sturk et al., 1996; Einstein, 1996; Shahriar et al., 2008; Sousa, 2010). However, the simplest way to express Risk is given by:

$$R = P[H].C \quad (1)$$

Where, R is the Risk, P(H) is the probability of occurrence of the hazard H, and C is the consequence of such occurrences.

Risk Management (RM) is a part of a set of processes named infrastructure management, which belongs to a wider process named territory management. To simplify the decision-making process of territory managers, risk must be expressed in monetary terms as suggested by O'Reilly & Stovin (1996) and Eskesen et al. (2004).

By analyzing Equation 1 and given the dimensionless condition of its first component (P[H]), it is necessary to express the consequence (C) in monetary terms in order to express risk in the same way.

Expressing risk in monetary terms represents a big challenge to risk management's specialists because it implies the attribution of costs, for example, to the indemnification for the loss of human life or other social consequences in which quantifications may be quite difficult and uncommon. Nevertheless, monetary expression of the risk is necessary and investigation and academic debate must be oriented in this regard.

2.2 Acceptability, residual value and risk mitigation

A context without any kind of risk does not exist. The risk that the project owner is prepared to assume is named Admissible Risk (AR) and it must be defined by the owner by a cost-profit analysis

between cost of the mitigation and profits associated with the reduction of the risk.

Nevertheless, some kinds of risks as social and political risks must be analyzed in a wider perspective instead of that cost-profit one. Owner can consider, for example, that certain risks as simply unacceptable.

It is necessary to define AR as a percentage of the cost of the entire project or as an absolute monetary value. For example, 0.5% of the total cost of the project may be recommended as a minimum value of AR.

Risk mitigation process consists on implementing measures in order to reduce risk until the AR level. In civil projects, risk can be reduced by decreasing the P[H] component by improving the design and construction method and/or by controlling the damages, for example, by reinforcing the exposed infrastructure, which implies reducing the probability of occurrence of the consequence. However, due to the nature of some engineering processes, the reduction of the P[H] is not always possible.

Residual Risk (RR) is the remaining total risk after the implementation of mitigation measurements in both design and construction stages. Figure 3 shows a hypothetical relationship between RR, AR, mitigated risks and time of the schedule project before starting operation stage. The shaded area corresponds to the mitigated risk along the time, the dashed line represents the limit given by AR and the area under this line represents the total RR of the project.

2.3 Temporality of the risk

Risks are distributed along the time in association with the schedule of a project. As a general behaviour, total risk decreases over time as individual risks are mitigated or never happen, due its random nature. At the end of the construction stage, the total risk reaches a maximum of RR.

2.4 Risk policy

All elements considered as input of the basic design are considered in the risk policy definition. Owner must define risk policies and it may indicate (Eskesen et al., 2004):

- scope,
- risk objectives, and
- risk management strategy.

Simultaneously, Risk Policy must define the risk acceptance criteria and, thus, the AR. This process is part of the Risk Management and sre useful in Quantitative Risk Analysis (QRA) as an element of comparing and acceptance of risks.

2.5 Risk analysis

Risk Analysis (RA) is the process that consists on the identification and the classification of the main hazards; the calculation of the probabilities of occurrence of hazards; the calculation of the potential

Figure 3. Residual risk, admissible risk and its hypothetical distribution behind the time of the project.

consequences; and of the product between those two components (second and third group of activities in Figure 2).

The Risk Analysis process implies as a first activity the qualitative Risk Analysis (qRA) and as a second activity the Quantitative Risk Analysis (QRA). The qRA is inevitable, but analysts may decide if it is viable to do the QRA, as a function of several conjugated elements, such as, the availability and quality of data; the kind of problem; the scope of the stage of project; and even the knowledgeable expertise of the analysts regarding concepts and tools of RA.

A methodology is called of qualitative or quantitative, depending on the way of determination of the components of Equation 1. A methodology is called of qualitative, when the components $P[H]$ and C are expressed through numerical or adjectival values obtained from the direct specialist inference from his knowledge and practical experience. A methodology is called quantitative when the components of Equation 1 are calculated by engineering and stochastic procedures.

2.5.1 Qualitative Risk Assessment (qRA)

It is advisable to carry out a qRA in design stage, even if it is planned to do the QRA, in order to identify the potential hazards and including all the risk classes defined in risk policies definition. This analysis has the objective of both to identify and to classify the main risks of construction stage and to promote a structured basis to basic project stage decisions. Therefore, the qRA conclusions may define the set of risks, which are analysed into QRA, and, then, will be the input of risk management into tender stage (Eskesen et al., 2004).

The qRA process may be carried out by different methodologies of group working, such as, brain storming, Delphi methodologies (Landeta et al., 2011), among others, either as an isolated methodology or as a combination of many of them.

The main goal of qRA is to obtain a matrix, named risk matrix, which allows identifying the most important risks. A risk may be important either when the consequence is high (from a political,

social, economic, administrative perspective etc.), when the occurrence probability of the associated hazard is high, or when the combination of those aspects is high. The classification of high depends on the definition of the admissible risk given by the owner. Finally, it is important to consider that the whole matter must be filtered by the specialist who must be able to analyse behind the $P(H).C$ product. A further explanation about what the risk matrix is will be carried out ahead.

To sum it up, the Qualitative Risk Analysis must involve:

- the identification and classification of all the likely hazards;
- the qualification of the probabilities of occurrence of all the set of identified hazards;
- the qualification of potential consequences due the occurrence of identified hazards;
- the calculation of risk matrix and the identification of the risks to be analysed into QRA, by its classification.

Hazards must be expressed through design variables and conditions, in order to carry out a good representation of each hazard, for example, angular distortion (β) may be an adequate design variable, in order to analyse the impact of excavation on buildings, in shallow and brown-field tunnel conditions.

Identified hazards and its occurrence probabilities, just as the potential consequences, must be classified according to the level of represented associated risk in order to help decision-taking process (Eskesen et al., 2004). Such components of risk must be estimated and classified separately. Then, product $P(H).C$, i.e., the risk, must be classified, as well. This process is named risk classification process.

Classification system may be established into risk policy process as a part of the establishment of acceptancy risk criteria. Frequency classification of $P(H)$, may be carried out by the identification of number of events into a time unit, a length unit (as a kilometer) or the whole construction period.

Regarding a tunnel project in brown-field conditions and in urban environments, there are five main groups of consequences:

1. Physics:
 - directly on works;
 - on third party infrastructure.
2. Socials:
 - human life lost;
 - psychological and morals, for example, familiar structure rupture due the loss of a family member, and social disaggregation;
 - cultural or symbolic effects, for example, the loss of routines and habits of a society.
3. Environmental.
4. Political or project image behind society.
5. Economical-administrative, such as, work schedule delays.

Table 1 shows an example of frequency classification of P(H) and an example of consequences classification.

As already discussed, the main goal of qRA is risk classification and the identification of the main hazards which can be done through a risk matrix, which is the qualitative representation of Equation 1.

2.5.2 Quantitative Risk Assessment (QRA)

After the identification of the main risks in qualitative-risk analysis process, a quantitative analysis over each of them must be carried out. An individual quantitative risk analysis, named by Eskesen et al. (2004) as specific risk analysis, consists on making accurate the qualitative risk analysis by a stochastic approach, the improvement of the elements and methodologies of design, and a detailed evaluation of consequences.

Statistics allows the designation of a probabilistic distribution to data. For example, to discrete events through Poisson distribution; or to continuous events through a Gaussian, logarithmic, or exponential distributions, between others (Chirioti et al., 2003).

Guglielmetti et al. (2008) highlights probability can be applied to the most of the variables involved in an urban tunnel project such as, geotechnical parameters and construction schedule, among others. Therefore, involved variables in projects, such as, underground characteristics, construction variables, and unpredictable events can be represented by a suitable probability distribution function. It is important taking into account that probability distributions can be determined by statistics procedures or inferred by heuristic processes according to circumstances. Eskesen et al. (2004) describes several heuristic alternatives of analysis if lector is interested in it.

In 1996, Einstein had given a more complete mathematical expression of risk than that of Equation 1. Einstein's expression considered that consequence can be defined as the product of two components: the occurrence probability of consequence, given an event (Hazard) occurrence, and the cost of the consequences, as it is expressed in Equation 2.

$$R = P[H].P[C|H].C \quad (2)$$

Therefore, this can get the uncertainties description by considering each consequence as a stochastic variable, and the designation of a distribution to each variable, instead a deterministic value.

Stochastic components of risk can be obtained, for example, by a Monte Carlo simulation, or approximate probabilistic methods such as First Order Second Moment (FOSM) and Point Estimate Method (Rosenblueth, 1975), between others, in order to determine the statistic parameters of probability density functions.

However, risk demands a wider expression than that of Einstein's. Actually, there are several hazardous events H_i involved in a project. Each of those Hazards involves several kinds of consequences C_j , such as, physic, social, or others, as discussed

previously. Therefore, it is suggested the Equation 3 to total risk, when, total potential consequence is the summation of all the set of consequences C_i of a hazard H_i , times conditional occurrence probability of each consequence, given the occurrence of mentioned hazardous event H_i . Thus, total risk is the summation of the multiplication of the probabilities $P[H_i]$ and their associated total consequence $\sum_i P[C_j|H_i].C_j$ associated to the event H_i .

$$R_{TOT} = \sum_i \left\{ P[H_i] \cdot \sum_j P[C_j|H_i].C_j \right\} \quad (3)$$

Therefore, each hazard H_i will establish an analysis context named Risk Scene (RS). Each RS has an associated risk calculated by the occurrence probability of hazardous event, H_i , and by the set of potential consequences related with. Thus, the total risk can be defined as the sum of the set of risks associated with each RS.

2.6 Decision taking and risk transference

Residual risk must be transferred by a procedure named Risk Transference (RT). This transference process must be controlled by the owner of the project to guarantee the reception of the risk by a technical team in the latter stages, and the implementation of mitigation measurements, progressively, until reaching the admissible risk (AR), as discussed in Section 2.2 and Figure 3.

Therefore, risk transference needs specialist pre-establishing AR into risk policy procedures. Into basic design process, higher risk than AR must be highlighted as important risks and then analysed accurately in detailed design stage, in order to apply the final measures to reduce them until reaching AR.

The transferred risk to tender stage must be under the acceptable risk. In the same way, risks transferred to construction and operation stages must be also under such criteria. On the other hand, the incorporation of new risks higher than AR should not be accepted into tender stage.

During construction stage, mitigation measures consist on controlling and supervising the identified risk; identifying and calculating new risks; and defining its mitigation measurements. Into operation stage, mitigation measures consist on controlling transferred risk from previous stages.

In construction and operation stages, it is important to implement a modern, automatized, fast response, and fast data access, instrumentation system in order to control the risks.

3 APPLICATION CASE

The Line 1 of Bogotá Subway Project was selected as the application case. Regardless of the fact that there have been several basic designs published in the last 40 years and its alignment has changed a number of times, this case-study's methodology

was based on the basic design released in 2010, as depicted in Figure 4 (AMB, 2010).

Feasibility design considers a mechanical excavation methodology by using a Tunnel Boring Machine (TBM) of a 10 m diameter tunnel and a general overburden of 20 m.

Study Area has been defined by considering the requirements of future numerical modeling processes, quality and density of information and the alignment of Bogota Subway established in AMB design.

Geomorphologically, the region is divided in two areas: one flat located in central area and another mountainous in the east and southeast side of the region. The flat area is the densest inhabited area (FOPAE, 2010).

Geologically, the city is located on a sedimentary deposit which is part of the Bogota Savannah. Bogota is bordered to the west by hills formed by several rock formations, such as, sandstones, clays-tones and conglomerates.

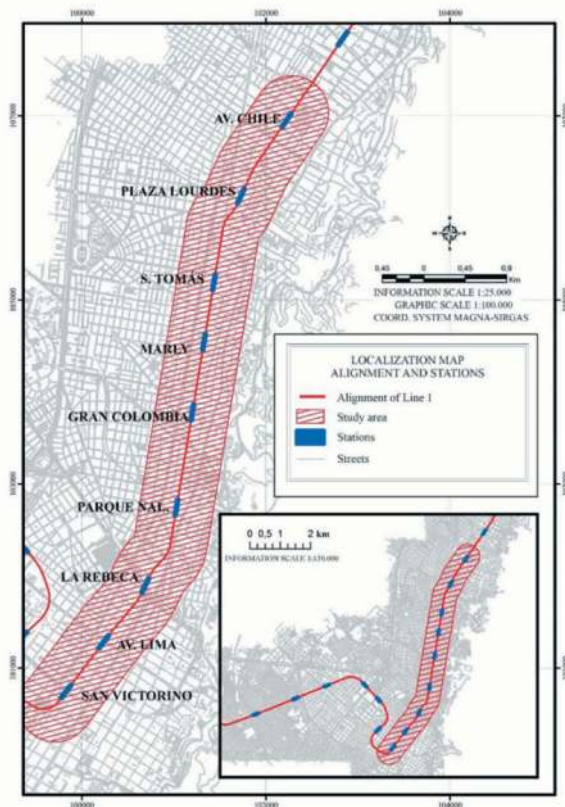

Figure 4. Location of the line 1 of Bogotá Subway (AMB, 2010).

Line 1 of Bogota Subway is planned to be constructed in the transition zone between foothill's materials and aforementioned sedimentary deposits. It is expected higher vertical than horizontal variability and an alternation between fine and large grading materials as a product of different transport-sedimentation processes.

Bogota Subways is going to be constructed mainly downtown, where the urban context is

complex given the different kinds of infrastructures that can be found: historical buildings, large modern constructions, shopping centers, and small commercial and residential buildings.

3.1 Inputs and data base

Data collection to apply risk management on an urban tunnel project must be focused on specific and general elements of:

- The environment: anthropic, biotic and physical (Zuquete & Gandolfi, 2004);
- The socio-economic environment.

For the purpose of this paper, the anthropic environment considers all the elements regarding urban environment while the physical environment considers the whole set of elements of the geo-mechanic environment (sub-superficial physical environment) and the elements of the relief, of the hydric network, among others (superficial physical environment). Socio-economic environment refers to the elements that describe the overall aspects of the economy and society, taken from Gross Domestic Product (GDP) per capita, population density, among others.

In consequence, five main sources of information were consulted:

- Agency for Prevention and Emergencies (FOPAE);
- Colombian Geological Service (SGC/INGEOMINAS);
- Distrital Data Base;
- Bogota aqueduct;
- Bogota Metro Company.

Boreholes were collected by sources and sums up 361 drillings: 214 from the Fopae and 147 from the SGC.

A cartographic database was constructed in order to represent the anthropic, physical and socio-economic environments. In Figure 5 all the aforementioned cartographic elements can be seen.

Figure 5. Elements of the anthropic and physical environment.

Figure 6 shows a constructed geomechanical model of the ground using selected geotechnical drilling and RockWorks software of RockWare in context with the Digital Elevation Model (DEM).

Figure 6. Classified model of subsoil (stratigraphy model) attached to DEM. Vertical enhance: 5X.

3.2 Geotechnical data base and statistical characterization

The geotechnical behavior of the ground was studied using the Finite Element Method (FEM) using Cesar LCPC software V5 t and its constitutive model IMOD18. IMOD18 is a modified Cam-Clay model, but it changes the Cam-Clay elastic law for an isotropic linear elastic model. IMOD18 demand the follow input data (Bourgeois et al., 2012):

A statistic characterization of IMOD18 model's variables was made in order to do a probabilistic analysis of design and technical control variables. A full methodology and procedure presentation of the construction of both the geotechnical database and the statistical characterization of the variables do not concern to this paper.

3.3 Qualitative Risk Assessment (qRA) to Bogotá Subway

A Delphi methodology (Landeta et al, 2011) was carried out in order to do the qualitative analysis. A pool of tunnel specialists were put together and were concerned about situations of instabilities, unexpected displacements and, in those cases, a lack of corrective actions, as well as, a the delay in the installation of the lining.

3.4 Quantitative Risk Assessment (QRA) to Bogotá Subway

3.4.1 Risk scenes, hazards and project variables.

The risk scenes definition was focused on two of the five types of consequences already discussed: physical and social, specifically loss in human life. A quantification of all the other kind of consequences discussed in the previously is a technical challenge, uninvestigated by the scientific community until now, which is beyond this paper's scope.

As defined by Burland and Wroth (1974 and 1977), angular distortion (β) is related to damages in

building and infrastructure, in such a way, distortions greater than 0,002 and 0,007 are related to cracks and minor damage, and structural damages on surrounding buildings, respectively. Mair (2011) highlighted the relationship between the Gaussian Settlement Basin's relative volume (VSr) and the roof failure propagations to the surface, in such a way, a volume upper than 3% can potentially unleash the aforementioned phenomena. Equation 4 shows the mathematical expression of VSr , where $Aexc$ is the sectional tunnel area.

$$VSr = VS/Aexc \quad (4)$$

Given the urban and geological-geotechnical context, for this paper's analysis an excavation method based on a Slurry-TBM by using Ibarra et al. (2013) criteria was chosen.

Additionally, due to all the elements pointed out on Delphi's as part of the qRA, the delay in the installation of the lining is going considered due to a failure if the TBM by a modelling with a typical distension of SEM/NATM excavation method, instead of Slurry-TBM.

In summary, were considered six risk scenes related with six different events:

1. The event of $\beta > 0,002$;
2. The event of $\beta > 0,007$;
3. The event of $VSr > 3\%$;
4. The event of $\beta > 0,002$ due to a delay in the installation of the lining due a failure of the Slurry-TBM;
5. The event of $\beta > 0,007$ due to a delay in the installation of the lining due a failure of the Slurry-TBM;
6. The event of $VSr > 3\%$ due to a delay in the installation of the lining due a failure of the Slurry-TBM;

3.4.2 Numerical modelling

A Finite Element Method (FEM) analysis was carried out in order to do the stress-strain analysis by using the software CESAR-LCPC of IFSTTAR. A state plane of strain was considered.

Into the academic context, only the risks associated to the excavation of the tunnels of study area were analyzed, and specific matters associated with stations' excavation and long-term effects were not considered.

In the context of the Excavation Forces Method programmed in the software CESAR-LCPC, a value of the parameter λ_p (Panet e Guénot, 1982) of 0,1 was defined to the Slurry-TBM standard situation and of 0,67 to the situation of delay of the installation of the lining due to a failure of the TBM situation.

3.4.3 Probabilistic analysis and probability of occurrence of hazards $P[H]$

Four First Order Second Method (FOSM) analysis were carried out: two for VSr and β when λ_p is 0,1 and two for VSr and β when λ_p is 0,67. Input

Variables of CESAR-LCPC using modified Cam-Clay model (IMOD18) were considered as the independent variables, and design variables VSr and β were considered as dependent or response variables

3.4.4 Consequences and $P[C|H]$

Table 1 shows a suggested consequence typology related to each event and its $P[C|H]$ values, as well as, the consequences C, both obtained by heuristic approaching in order to show the applicability of the suggested methodology. Those elements were used to the calculus in the example developed in this paper.

The associated cost of each building placed in the study area has been taken from the public information of the city specifically from a public territory gestor named Catastro Distrital.

For the calculation, a mean value for a unit of length of tunnel was considered, obtained from the aforementioned data. The cost of repairing a human life loss was considered as USD 1.000.000, mean values usually used by airlines to repair that condition in air accidents.

Such calculations were attributed to a spatial location and interpolated in order to construct cartographic continuous information of the aforementioned components of the risk. Allowing both a spatial and cartographic calculation of the risk by maps algebra and a cartographic presentation of this variable.

3.4.5 Individual Risk and Total Risk

By applying the Equation 3 was constructed the map of the risk presented in Figure 7. Each product $P[H_i] \cdot \sum_j P[C_j|H_i] \cdot C_j$ was made using cartographical tools. The Total Risk map with the sum of all the considered risks is the one presented in Figure 7 which shows the urban environment classified according to the zoning of the risk.

3.4.6 Decision taking and risk transference

Identified risks will be transferred to the detailed designer and the owner. A mitigation of risks will consist in both deplete and sophisticate the engineering analysis, as well as, cost-profit balances in order to define which risk must be mitigated and its respective engineering procedures of mitigation.

4 CONCLUSIONS

The best tool to handle uncertainties into a civil project, such as an urban tunnel, is the Risk Management (RM) and must be incorporated into engineering stages.

RM of a large-scale civil project, such as, subway projects involve five steps: RM into basic project (including conceptual step), RM into tender and contract negotiation, RM into detailed project, RM into construction and RM into building operation (Figure 1).

Table 1. Consequence C and probability of occurrence of the consequence $P[C|H]$ given the occurrence of the hazardous event H.

Hazard (H)	Kind of Consequence	P [H C]	Consequence (C)
$\beta > 0,002$	Fissures and minor damage in surrounding buildings	60%	30% of surrounding building cost
$\beta > 0,007$	Fissures and minor damage in the own structure	100%	60% of own building cost
	Structural damage in surrounding buildings	60%	1,5 times of surrounding building cost
	Fatal victims inside affected buildings	20%	Human life lost repairation cost times population density
$VS > 0,03$	Major damage in own structure	100%	Three times of own building cost
	Structural damage in surrounding buildings	60%	1,5 times of surrounding building cost
	Fatal pedestrian victims	50%	Human life lost repairation cost times population density
	Fatal victims inside affected buildings	70%	Human life lost repairation cost times population density

Risk must be expressed in monetary terms in order to use it as a cost/profit tool to civil engineering projects such as urban tunnels, therefore, Risk must be given as a likely costs or likely overrun costs.

By using the formulated both methodology and equation it was possible to calculate the risk, expressed in USD/m², it means in monetary terms, to Bogotá Line 1 subway by using current common projecting and designing information and complementary cartography information common in the most of the city.

The calculation of $P[C|H]$ is one of the most relevant challenges, for the moment and until the development of practical scale engineering formulations, it is possible to use heuristic methodologies, such as, event tree. It is possible assume $P[C|H]$ equal to 1, adopting a conservative perspective of analysis.

To the calculation of $P[C|H]$ to specific soil-structure analysis into a tunnel project is possible to adjust Burd et al. (2000) e Houlshby et al. (1999) work by introducing approximated probabilistic methodologies, however, those approaches can demand a lot of time limiting its use to a whole project.

$P[C|H]$ have a Bayesian nature and such characteristic must be considered. Formulations must be modified by considering aforementioned characteristic.

The use of a reference cost system for contracting underground public works

Eloi Angelo Palma Filho*

DNIT, Brasília-DF, Brazil

Claudio Kazuo Miyazato & Paulo Moreira Neto

ARTERIS, Florianópolis-SC, Brazil

ABSTRACT: The use of reference prices through compositions of unitary prices to contract public road works, within the scope of the federal government in Brazil, began in 1946, in the former National Department of Highways – DNER. As a result of this, in 1992 the Road Costs System – SICRO emerged, which was updated in 2000. In 2017, there was a reform in the System, changing its name to the Referential Costs System, now reaching the Rail and Waterway and bringing, for the first time, references on NATM Tunnels using the classification proposed by Bieniawski and treatment services and consolidation of Underground Works services. Due to its favourable reputation and wide use over decades, SICRO has become the federal reference in the budgeting of public works of transport infrastructure, from which the maximum admissible value for the cost of the enterprise is obtained. However, elements related to underground works have been part of this System for a few years, while other infrastructure elements have already been contemplated there for decades and could be improved by improving their use over time. This article will report on the services contemplated in the Referential Cost System regarding the underground environment, its premises, some evolutions of the first application in a large enterprise and make comments about possible improvements to be made for future uses. As for this practical application, the reference work was the Florianópolis-SC Road Ring, highway BR-101/SC, with construction starting in 2021 of 3 double tunnels totaling 5.4 km and budgeted as US\$116.2 million dollars and completion scheduled for December 2023.

Keywords: Budget, Tunnel, Contractual practices, Reference cost system, NATM

1 THE LEGAL CONTEXT

In the context of public contracts, legal regulations in Brazil date back to the times of the Empire. On May 14, 1862, the Decree no. 2,926 was published, which approved "... the Regulation for the auction of services under the responsibility of the Ministry of Agriculture, Commerce and Public Works" (LIMA, DJALBA, 2014). In this regulation, the rite was presented, which at the time was called "competition" and not bidding, but already required a guarantee from proponents of 20% of the budget value. Furthermore, 10% of the measured value was retained in each measurement, which was returned to the constructor after the end of the work guarantee period (which could vary from 3 months to 2 years).

At the time of the Republic, another Decree¹ established the signing of a contract and the holding of a competition as a condition for committing the expenditure. Subsequently, the term "bidding" is presented in Decree-Law 200/1967, which established Competition, Price Taking and Invitation as procedures. In 1986, has been published a new Decree-Law², with general rules for bidding and contracts at the federal level, incorporating the modalities of Tender and Auction.

In the post-Constitution era of 1988, which established the Union's competence to legislate on the subject for all entities of the Federation, Law no. 8,666/1993 (BRASIL, 1993) which introduced legislation on Public Administration Tenders and Contracts. This includes the possibility of including the maximum contract price, both global and unitary in the bidding process.

1 Decree no. 4,536/1922.

2 Decree-Law no. 2,300/1986.

DOI: 10.1201/9781003495505-476

In 2011, another legal framework aimed at contracting works and services emerged³ (BRAZIL, 2011), which created the Differentiated Public Procurement Regime - RDC. The framework which was originally intended only for projects for the 2014 FIFA World Cup and the 2016 Olympic Games, underwent subsequent expansions in scope, enabling its use in different segments.

In 2013, through another Decree⁴, rules and criteria were established for preparing a reference budget for engineering works and services, executed from the Federal public budget (BRASIL, 2013). In it, the SICRO cost system is tacitly indicated as a reference for defining the maximum value of the contract.

Finally, in 2021, Law no. 14,133, as new legislation applicable to public tenders and contracts, supplanting the then-current Laws no. 8,666/1993 and no. 12,462/2011. This Law reinforces the role of SICRO as a public reference in the contracting of works, stipulating it as the maximum contract value.

2 THE SICRO REFERENCE COST SYSTEM

The National Department of Transport Infrastructure - DNIT is a Federal Authority created in 2001, with multimodal operations (road, railway, waterways and ports), and succeeded the DNER, National Department of Highways, created in 1937, with operations specifically on highways.

The reference cost system has a history of more than 70 (seventy) years, dating back to a time when works were, in most cases, carried out directly by the administration, and not contracted from the supplier market. This history is shown by ALBUQUERQUE FILHO, 2017.

The main history of the DNER and DNIT cost system is presented below:

- 1946 - Implementation of the first DNER price tables;
- 1963 - General price list;
- 1972 - Launch of the Road Cost Composition Manual;
- 1980 - Update of the Road Cost Composition Manual;
- 1992 - Organization of Road Cost Management
- 1992 - Launch of SICRO 1
- 1998 - Revision of the Road Cost Composition Manual;
- 2000 - Launch of SICRO 2;
- 2003 - Publication of the Road Costs Manual;
- 2007 - Start of development of the new Construction Reference Cost System (SICRO)
- 2012 - Recruitment of Getulio Vargas Foundation
- 2017 - Implementation of the new SICRO.

The DNIT Construction Pricing System is made up of technical manuals describing the pricing

methodology, in many cases, with practical examples; description of the composition calculation memory; and payment criteria.

- Volume 12 - Mechanical Team Productions

The Federal Government portal presents a table of services and reference unit prices for each state of the federation.

With this SICRO update in 2017, rail and waterways were incorporated into the system, which already included highway services. Furthermore, the list of services was increased, including, for example, environmental recovery services and Tunnels, whose services can be provided by road or rail.

The methodological concept used by SICRO to obtain the unit reference cost for the execution of a given service considers (DNIT, 2017):

(a) Equipment cycle:

Equipment normally performs operations considered repetitive, that is, it works in cycles. A cycle is understood as the set of actions or movements that the equipment performs from its departure, from a certain position, until its return to a similar position, which marks the beginning of a new cycle.

The time elapsed between two consecutive passes of the equipment is called "cycle duration" or "total cycle time", which determines an interval during which the equipment performs a certain amount of work.

Quantifying the service performed during a cycle and its total duration is essential to determine the hourly production of the equipment, to size and balance the rest of the equipment that forms a patrol, as well as to calculate the production of the patrol itself.

3 Law no. 12,462/2011.

4 Decree no. 7,983/2013.

(b) Production of mechanical teams:

The production of mechanical teams normally corresponds to that of their main equipment or patrol leader, which conditions the performance of the set of equipment, depending on their different capacities and productions.

Determining the production of mechanical teams is a fundamental element for forming the unit costs of services. The unit execution cost is the relationship between the hourly cost of executing a given service and the production calculated in the same unit of time.

One of the most common practices for pricing road tunnels is determining the costs of inputs and losses and the cost per stay of equipment and labor to determine the overall cost of construction. For this purpose, the duration of each construction stage is calculated with the particularities of the project and external constraints (restrictions on blasting times, available resources, etc.) for different combinations of resources multiplied by the cost of operation and maintenance. The distribution of costs by services is usually just for characterizing events within the analytical structure of the project and determining the financial flow.

In this regard, SICRO innovates by proposing an algorithm for the individual calculation of each service until the construction of the overall value of the project.

The contents of the SICRO Transport Infrastructure Cost Manual, Volume 10 – Technical Manuals, were incorporated into the second edition of the Technical Notebooks, whose SICRO reference is the base month of October 2022. (DNIT, 2022)

2.1 Tunnels

SICRO adopts a fictitious tunnel 400 meters long with 4 lanes of cross sections from 20 to 40 m², from 41 to 60 m², from 61 to 90 m² and above 90 m², geotechnical classification proposed by Bieniawski and typical advances of 0.60m to 4.00m depending on the geotechnical classification.

The productivity coefficients for determining the hourly production of equipment and services were determined by theoretical (productivity declared by equipment manufacturers) and empirical methods (field measurement, technical reference and consolidated historical reference).

Productivity reducing multipliers (efficiency factor) were considered in order to represent the various production losses and discontinuities and multiplier factors corresponding to losses in input consumption.

2.1.1 Modelling and example

The referential modelling adopted in the design of the service cost compositions presupposes the execution of the following steps:

- manual installation of electrical systems for tunnel lighting and ventilation;
- drilling holes in the rock mass using an electro-hydraulic jumbo jet;

- manually filling the holes with explosive material using the electro-hydraulic jumbo work platform;
- manual assembly of the detonation circuit;
- rock detonation;
- manual execution of the choco (scalling) with the aid of the electro-hydraulic jumbo work platform;
- slaughter of cuttlefish using an excavator with a hydraulic hammer;
- loading the rock into a dump truck using a tire loader;
- transport of material using a dump truck.

2.1.2 Hourly production and mechanical team

The activity is carried out by the following equipment:

- electro-hydraulic jumbo with 3 arms;
- hydraulic excavator with 1,700 kg hydraulic hammer;
- rock tire loader with a capacity of 2.50 m³;
- rock dump truck with a capacity of 12 m³;
- axial fan;
- generator sets.

The hourly production of services was established using the theoretical method, being defined through the application of the following expression:

$$P = H \times \frac{A}{T_c} \quad (1)$$

Where, P is team production (m³/h); H is excavation depth (m); A is the cross-sectional area of the tunnel (m²); T_c is the cycle time of progress in tunnel excavation (h).

- a) electro-hydraulic jumbo with 3 arms

Hourly production is established by the theoretical method, being defined by applying the following expression:

$$P = 60 \times A \times H \times \frac{F_e}{T_c} \quad (2)$$

Where, P is hourly production (m³/h); A is the excavation area (m²); H is excavation depth (m); F_e is the efficiency factor; T_c is the total cycle time (min).

- b) hydraulic excavator with 1,700 kg hydraulic hammer

Hourly production is established by the theoretical method, being defined by applying the following expression:

$$P = 60 \times A \times H \times T_c \quad (3)$$

Where, P is hourly production (m³/h); A is the excavation area (m²); H is excavation depth (m); T_c is the total cycle time (min).

- c) rock tire loader with a capacity of 2.50 m³

Hourly production is established by the theoretical method, being defined by applying the following expression:

$$P = 60 \times C_{ap} \times F_{ca} \times F_{cv} \times \frac{F_e}{T_c} \quad (4)$$

Where, P is hourly production (m^3/h); C_{ap} is capacity of the tire loader (m^3); F_{ca} is a load factor; F_{cv} is a conversion factor; F_e is the efficiency factor; T_c is the total cycle time (min).

d) rock dump truck

Hourly production is established by the theoretical method, being defined by applying the following expression:

$$P = 60 \times C_{ap} \times F_{ca} \times F_{cv} \times \frac{F_e}{T_c} \quad (5)$$

Where, P is hourly production (m^3/h); C_{ap} is capacity of the tire loader (m^3); F_{ca} is a load factor; F_{cv} is a conversion factor; F_e is the efficiency factor; T_c is the total cycle time (min).

2.1.3 Payment criteria

The measurement of underground excavation services for class I to IV tunnels must be carried out in cubic meters, depending on the volume actually extracted, measured and evaluated in the cut (in natura volume).

2.2 Adjusts already made in the SICRO from its initial application

Based on the studies for reference budgeting for the construction of tunnel works on the Florianopolis-SC Road Ring, on the BR-101/SC highway, notes were made that resulted in adjustments to the SICRO system, for underground activities.

These adjustments can be checked on the DNIT website.

3 THE FIRST APPLICATION OF SICRO IN TUNNEL WORKS

The pioneering application of SICRO for the pricing of underground works tunnel took place for the concession contract resulting from Notice no. 003/2007, for the so-called “Contorno Rodoviário de Florianópolis-SC”, Florianopolis Road Ring project, on the BR-101/SC highway.

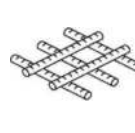

As these works were not foreseen in the original contract, their inclusion will require compensation to the concessionaire, which will be done through an adjustment in the toll rate paid by road users. Thus, there are such interventions as public works, which is why the reference value is defined based on official tables, in this case, SICRO.

3.1 Florianopolis road ring

The Florianopolis Road Ring is a new highway with 50 kilometers of double lanes and an investment of R\$ 3.9 billion or US\$ 780 million dollars (Aug/23) consisting of 6 interchanges, 7 double bridges, 20 uneven crossings and 4 double tunnels with the aim of diverting long-distance traffic from the Greater Florianopolis metropolitan region.

The table below illustrates the large numbers of the enterprise.

Table 1. Project numbers.

Soil Excavation: 9,750,000 m ³	Rock Excavation: 1.655.500 m ³	Asphalt Pavement: 395.400 ton
		
Geodrain: 3,145,000 m	Concrete: 163,160 m ³	Steel Rebars: 9,909 ton
		

The 4 (four) tunnels of the Florianopolis Road Ring total a length of 7,083.90 m, with a platform for 2 lanes of 3.60 m, shoulders of 3.00 m, sidewalks for escape routes with a clear width of 1.20 m, and distributed as shown in figure x below, with tunnel 4 in the central region of the highway and tunnels 1, 2 and 3 concentrated in the southern section.

Figure 1. Road alignment. Source: Miyazato, 2023.

The tunnels were designed and built using the NATM method in which four typical treatment sections were created for classes I to IV (R1, R2, R3 and R4), 2 sections for soils (S1 and S2) class IV and 3 sections for transitions from soil to rock (M1, M2 and M3) using the Bieniawski classification system – RMR as a reference and showed in Table 2.

The extensive geological investigation shows that 2/3 of the length of the tunnels are predominantly in rock and the other segments in sections of soil or in soil/rock transition, as showed in Table 3.

In rock, a typical section had 135m² of excavation (Figure 2), instead in the soil massive, the typical excavation section presented about 160m² (Figure 3).

Table 2. Classes parameters. ANTT, 2018.

SECTION TYPE	CLASS	MASSIVE	RMR
R1	I	Sound Rock	81 a 100
R2	II	Sound Rock	61 a 80
R3	III	Slightly Weathered Rock	41 a 60
R4	IV high	Weathered Rock	31 a 30
M1/M2/M3/ S1/S2	IV low	Soft Weathered Rock/Saprolite	21 a 30
	V	Saprolite/Residual Rock	<20

Table 3. Massive characteristics. ANTT, 2018.

SECTION	TUNNEL 1		TUNNEL 2		TUNNEL 3		TUNNEL 4	
	EXT (m)	%	EXT (m)	%	EXT (m)	%	EXT (m)	%
R1	0.00	69.2	0.00	65.0	0.00	72.5	0.00	84.5

TOTAL	1,960		1,799.2		1,681.4		1,643.3	

Figure 2. Rock typical section. Source: ANTT, 2018.

3.2 Pricing the work

The application of the unit price methodology through the composition of unit prices with the necessary adjustments, the particularities of the Road Ring project brought values to the tunnel budget that are consistent with the historical average prices of the DNIT, as showed in Figure 4.

This represents about US\$ 30 million/km, including all costs (land acquisition, design, excavation, support, pavement and security systems).

Figure 3. Soil typical section. Source: ANTT, 2018.

Figure 4. Tunnel pricing, in BRL R\$/km, 2021 base.

4 TUNNEL COSTS REFERENCES

It is possible to find information regarding tunnel costs in the bibliography, but in order to relate the cost per kilometer related to the extent of the work, as a rule as shown in Figure 5 and Figure 6.

Figure 5. Approximate costs for tunnel excavation and support per tunnel meter according to ground conditions compared with Greek data. Source: Benardos, Paraskevopoulou and Diederichs, 2013.

However, there are no references about cost systems that provide a methodology for calculating the unit costs of underground services in conventional works (sprayed concrete, sequential excavation in soil or rock, rock bolts, steel rebars, lattice girders, etc.).

Figure 6. The effects of tunnel outside diameter on unit costs. Source: HM Treasury, 2010.

In Brazil, there is this national reference, regionalized by state, which must be used in public works contracts, as a reference for the maximum value to be paid by the government, with public resources.

5 CONCLUSIONS

The transparent approach with which the methodology is presented, as well as the courage to incorporate improvements in the system and the national coverage for the reference table of services for underground works, brings to the national market means to mitigate risks in contracts.

This is an attempt to increase the chances of completing projects, guaranteeing investments with lower contractual imbalances and transparency for the government structure.

The continuity in the use of the system, the joint work between the Government, the technical environment, designers and construction companies will certainly bring numerous points of improvement.

It is necessary to always remember that the specificities of underground works must always be captured in the budgeting of the works, otherwise it will not be possible to contract them on the market, for which it is essential to fully understand the SICRO methodology and its openness to adaptation to the particularities of each enterprise.

Moving forward, it is understood that the empirical methods used for productivity must be

studied in more depth and measured, as well as the assumptions and interfaces between the construction stages.

Development of an early contractor involvement selection tool for public owners

Carl Philipp Friedinger*

Bundeswehr University Munich, Neubiberg, Germany

Philip Sander

Bundeswehr University Munich, Neubiberg, Germany

RiskConsult GmbH, Innsbruck, Austria

ABSTRACT: Tunneling projects are complex and large-scale on a regular basis. Consequently, they pose challenges for contractors regarding risk management, cost calculation, and timely execution. These challenges often result in cost and schedule overruns on the part of public-sector owners. An opportunity to remedy these grievances are Innovative Project Delivery (IPD) models. A variation of IPD refers to the early involvement of contractors and suppliers. Early Contractor Involvement (ECI) can take different forms depending on the time of the initiation and the project. The initiation can occur at various points: during the preparation of the project; during the planning phase; and between the planning phase and the construction contract. ECI can influence several aspects positively: improving manufacturing methods; understanding, mitigating, and managing risks; reducing complexity, disputes, and backlog management; cooperation among all stakeholders; on-time execution within budget. This paper aims to identify specific characteristics projects must meet for ECI to be applied successfully. A selection system to determine whether the use of ECI makes sense is developed concerning the requirements of public-sector owners. Firstly, existing and applied forms of ECI are gathered by literature review. Secondly, a qualitative analysis of ECI projects and ECI variations is conducted. Characteristics leading to success or failure are identified by determining the appliance project's success. A selection system for public owners is created to determine whether using ECI is reasonable. Project scale, both financially and in complexity; the application of risk management; timeline; and workforce represent an excerpt of the determined hard characteristics. In comparison, in-house competence and cooperation capability represent soft characteristics. Based on determined characteristics the Contractor Involvement Tool (CIT) is created. The tool helps public owners choose the right variant of ECI for their projects. Therefore, applying the tool to public projects in Germany is the next step.

Keywords: ECI, Integrated Project Delivery, IPD, Project Delivery Model

1 INTRODUCTION

Complex large-scale projects regularly pose challenges to contractors in terms of cost calculation and on-time completion. This in turn leads to cost and schedule overruns on the part of the public owner and the associated negative publicity. One reason for this is the use of traditional project delivery models and unsuitable contracts, both do not meet the special requirements of complex large-scale major projects. Separating mechanisms of these models, coupled with the blinkered pursuit of particular interests, are one reason of the fundamental problem (Breyer et al. 2020). Innovative project management models offer an approach to

counteracting precisely these problems (Becker and Friedinger 2022; Becker and Roman-Müller 2022). Model like the “TIWAG alliance contract”, used for a hydroelectric powerplant in Austria, has had a demonstrably positive effect on the construction time (Friedinger et al. 2023a). Prior to that particular project the German government realised the necessity for a change in project delivery, especially the delivery of major projects. Therefore in 2015 a governmental guideline was published to give public owners a helping hand in project delivery and to establish to use of innovative project delivery models. (Bundesministerium für Verkehr und digitale Infrastruktur 2015). Three years later in 2018 another guideline for

*Corresponding author: carl.friedinger@unibw.de

large-scale projects was published, going into detail even more by describing specific methods and instruments, like “integration of execution competence into the planning phase”, to enable an improved project delivery. (Bundesministerium für Verkehr und digitale Infrastruktur 2018) So, the use of contractor know-how for the definition and optimisation of performance requirements in the early project stages has proven to be a powerful instrument as it also has a positive impact on project management in a spirit of partnership (Sander et al. 2022). Furthermore, changes in early planning phases have a significantly lower impact on costs and execution time than changes in the construction phase, the use of execution competence in early planning phases is particularly useful (CURT 2004). Thereby, helping to avoid costly planning errors and the overlooking of risks can be minimised (Bourn 2007). The involvement of the executing companies in the planning phase is widely called Early Contractor Involvement (ECI) (Mosey 2009; Kinlan and Willems 2023). This form of implementation is already being used successfully in other European countries (Haghsheno 2020). The research questions addressed in this paper are:

1. What types and variations of Early Contractor Involvement are used in the public sector and which variations are suitable for public sector clients in Germany?
2. Which project requirements need to be fulfilled for the successful use of ECI?
3. How can the use of ECIs be promoted to public purchasers in Germany?

2 BACKGROUND AND FRAMEWORK

Traditional project management lacks a common and uniform understanding of the project on the part of both the contractor and the client. This leads to misunderstandings, and risks cannot be identified or dealt with in time (Friedinger et al. 2023b). This is partly due to the strict separation of planning and execution (Haghsheno 2020) as well as due to the common procurement practices. The following is a list of two core problems and the associated scientific theories:

First of all, it is impossible to fully complete the tender documents for complex mega projects for the tendering process. At this time point the planning isn't either complete enough or the planner lacks know-how to fully plan all aspects of the project. This topic is connected to the scientific perception of complexity, which itself is a rather new field of research (Bandte 2007). Simple and even complicated systems are describable, whereas complex systems consist of many elements, connections and multiple layers. To structure the elements, to connect them in the right way and to identify the relationships between the different layers and to build a model and simulate the created system is the simplified aim of this research field (ibid.).

Regarding construction projects this approach can be used to structure the planning process, help to involve contractor know-how at the right time and also involve every other stakeholder on point.

Secondly, there is a fundamental conflict of objectives in the two-party system between client and contractor. Companies carrying out construction work are interested in maximising profits, while clients are only interested in the best possible performance of services within the given framework conditions at minimum cost (Faber 2014). This conflict of objectives is exacerbated by an asymmetry of information in favour of the contractor. Related to the situation in construction projects to the principal-agent theory, the information advantage is always exploited to one's own advantage according to the theory (Nister 2005; Faber 2014). In addition to this theory, the hold-up problem describes a problem scenario that also occurs frequently in the construction industry: when the contract is concluded, the actual motives and motivations of the contracting parties are not known to each other, which can lead to opportunistic behaviour in the ex-post contract phase. Dependencies can be exploited through the “lock-in effect” (Picot et al. 1998).

(Nister 2005) describes the development of trust as a solution to the agency problem. A possible solution might be the involvement of construction companies at an early stage in the planning. Especially for projects classified as complex, this tends to be highly beneficial (Haghsheno 2020). Thereby, the know-how of the construction companies can be used in this way already in the planning phase. However, a fitting procurement method or model is required.

In Germany, the inclusion of execution expertise in the planning phase is discussed within the framework of partnering models (Hauptverband der Deutschen Bauindustrie e. V. 2005). One model, often referred to as a method, that is regularly used successfully in other countries within and outside Europe in order to utilise contractor know-how in the planning phase is “Early Contractor Involvement (Eadie and Graham 2014; Kinlan and Willems 2023). The implementation of an ECI can promote the following aspects: Use of innovative fabrication methods; Understanding, mitigating and managing risks; Reducing complexity, disputes and backlog management; Cooperation of all parties involved; On-time completion within budget (Bourn 2007). ECI can take different forms. It occurs as a contract model, as an element of a project management form or as a form of award (Walker and Lloyd-Walker 2012). In the private construction industry, a form of ECI known as “preconstruction” is already used in Germany (Smart Construction 2023). These circumstances lead to the third theory, decision theory. It was founded in business administration and enables the development of models that are intended to depict the economic effects of a decision in order to facilitate decision-making (Heinen 1972). In relation to this work, the principles of the theory are applied in the linking of decision criteria for a specific ECI variant.

3 EARLY CONTRACTOR INVOLVEMENT

3.1 *History and definition*

Early Contractor Involvement emerged in the 1990s in connection with project alliances. The term Early Contractor Involvement has a slightly different meaning in each country. In the simplest way ECI describes the involvement of construction companies in the early planning phases of a project. In Australia, the focus is in collaboration between client, planners and contractors is on the early project phases. As the project progresses, relationships evolve towards more conventional and traditional models. Whereas in the United Kingdom (UK), the collaborative nature of the relationship is maintained throughout project delivery (Buchal 2014). In both nations, ECI is regularly a two-stage process. Furthermore, ECI can be an element of another project delivery method or established as a stand-alone project delivery model. The term Early Contractor Involvement covers all variants of the involvement of construction companies in the project initiation phase, for example in an advisory capacity, as well as the examination of a complete planning by a construction company right before the execution phase with subsequent execution (Malvik et al. 2021).

Mostly, however, ECI is understood as a two-stage or three-stage procedure. It may start after the building permit has been granted with a minimum planning stage. In the first stage, a construction company is selected according to criteria set by the client. A price for the construction work to be carried out is not requested at this point, but surcharges for general business costs and profit can be used as decision criteria. Likewise, calculation examples, implementation concepts or partnering concepts can be requested and evaluated by the client. After the selection of the construction company, the planning takes place in the second phase. This can be done together with the construction company or by the latter. In the planning phase, the price for the construction work is determined jointly. It is worth noting that the business relationship does not necessarily have to be continued after joint planning. Some literature points out the actual construction as the third a third phase (Becker and Roman-Müller 2022). However, depending on the contractual agreements made at the beginning, the client can also decide against a follow-up order or to end the cooperation (Riemann 2014; Karasek 2021). The term early contractor involvement is hardly used in Germany. It only appears regularly in connection with or as part of innovative project management models such as IPA (Becker and Roman-Müller 2022). The terms “use of contractor know-how” and “inclusion of execution competence in the planning phase”, which are used in partnership models, among others, are also understood to mean the inclusion of contractors in the planning phase in order to make their knowledge available to the client (Girmscheid 2005; Eschenbruch 2008).

Another definition of ECI was provided in 2022 by the Working Group 194 of the World Association for Waterborne Transport Infrastructure. In its guideline the ECI is described as a strategy that differs from project to project, from client to client, from project framework conditions, budget or time horizon, etc. The ECI is thus the project-specific strategy for the waterborne transport infrastructure. The ECI is thus the project-specific strategy for the meaningful involvement of executing companies in an early project phase. The timing, the depth of involvement and the scope of cooperation vary from project to project. The key points of the ECI strategy also form the framework for the design of the applied ECI model (PIANC 2022).

3.2 *Advantages of ECI*

The use of ECI has the potential to generate numerous advantages in and for project management. However, the application of ECI alone does not automatically lead to project success. The advantages and benefits of ECI must be actively worked out. They depend on the commitment of the project participants, their capacities, their organisational structures and, last but not least, their will to achieve the set goals (Wondimu et al. 2016). The mutual benefit and the associated intrinsic motivation to participate in the Early Contractor Involvement can only be generated if the project participants are involved in the project at the right time and are compensated for the provision of know-how [28, 30]. The following aspects, among others, can be positively promoted through the application of early contractor involvement (PIANC 2022):

- Mutual project understanding
- Reduction of complexity
- Reduction of disputes and supplementary management
- Promotion of cooperation and trust between all parties involved
- Reliable information on costs and execution times
- Fair execution within budget
- Use of innovative and sustainable production methods
- Initiation of a risk management system accepted and supported by all parties involved:
 - Mitigate risks
 - Risk sharing instead of risk allocation by the AG
 - Cost transparency

4 METHODOLOGY

Regarding “Early Contractor Involvement” a systematic literature review was conducted to identify the variations as well as the characteristics of these variations. In particular, a search was conducted for studies on Early Contractor Involvement.

Several research strings were established to search for literature in the search engines Scopus, Springer-Link and GoogleScholar. The same search strings were also used on the platforms ResearchGate and Academia.eu. The number of hits was reduced by restricting the search parameters to the field of civil engineering. The actual relevant literature was identified by reviewing the abstracts. By evaluating these collected publications, it was possible to add further thematically relevant literature.

In the course of the literature evaluation, the types and variations of ECI were collected by the analysis of pre-existing studies on ECI. The variations of ECI are subdivided according to when they are implemented in the project. Additionally, the factors and criteria that favour the successful implementation of Early Contractor Involvement are identified. First, these factors are matched with the project properties and then, examined for their feasibility for public clients as they build the base of the selection tool. Based on the results a decision logic is developed and implemented in a new tool. This tool is an software application.

5 FINDINGS

5.1 *Early contractor involvement variations*

(Wondimu et al. 2020) already gives a great overview of the variants by listing 25 different kinds of Early contractor involvement. Within the framework of the systematic literature analysis 15 additional approaches were identified. All together 36 different variants of the early integration of execution competence into a construction project were identified. After identifying that many variants further active research for new forms was stopped.

The variants occur with varying frequency, some were only applied once in practice, others were mentioned several times in the literature. Due to the high implementation effort and the small number of practical implementations as well as the lack of experience reports, the frequency of mention cannot be used for categorisation. However, all identified variants can be differentiated according to time, type, scope and influence of the price on the selection of the contractor. Anyhow, the following list is far from complete as there are still emerging new forms or pre-existing variants under a new name every now and then.

1. Alliance competitive
2. Alliance pure
3. Allowing variant solutions by the bidders during tendering phase
4. Announcing with alternative technical solutions
5. "Bauteam"
6. Construction Management
7. CMR
8. Competitive dialog (CD) procedure
9. Consolation

10. Contractors promote their ideas to the owner in the early phase
11. Cost Led Procurement
12. Design-build contract
13. Design-bid-build contract (DBB)
14. direct contract with front-end phase of projects
15. Framework
16. Front-end partnering process
17. Idea competition
18. Indirect approaches
19. Information meetings
20. Integrated Project Insurance
21. IPD
22. Multiple (dual) TCC/CLP
23. Negotiated procedure
24. Novated design and construction contract
25. Optimization phase after the award
26. Partnering
27. PPP (many sub variations)
28. Public announcement
29. Relational project delivery agreements (RPDAs)
30. Selection based on qualifications and price
31. Selection based on only qualifications
32. Single TCC
33. Supply Chain Collaboration
34. Two-stage TCC/ a tow-stage tender process/ two-stage open book
35. Vladres Model
36. Workshops (with the contractors after design phase but bevor plan approval process starts)

Depending on the ECI model used, an appropriate reimbursement system must be selected for the construction but especially in the case that know-how-transfer from contractor to client takes place. Cost-Plus-Incentive-Fee (CPIF), Cost-Plus-Award-Fee (CPAF), Cost-Plus-Fixed-Fee (CPFF) are suitable reimbursement systems for a joint planning phase. Fixed-Price Prospective Price Redetermination, CPIF, CPAF and CPFF represent a suitable remuneration system for a construction project following early contractor involvement (Becker and Friedinger 2023).

5.2 *Levels of ECI*

Figure 1 illustrates the depth of involvement and the influence of price by distinguishing four levels. Level 1 has the least depth and the smallest scope of cooperation. A construction company is involved in the project planning in an advisory capacity. The public announcement of a major project or participation in the tender process by answering bidders' questions also fall into this category. Price is the main criterion for selecting the contractor in Level 1 (Friedinger and Becker 2023). Level 2 includes models in which selected companies are invited to bid and there is an intensive exchange between the client and the bidder. At this stage, the contractor may already be involved in the design. A functional tender would be assigned to level 2. Level 3 includes those types of ECI where the contractor is selected

in a two-stage procedure and the design is carried out jointly. At level 4, in addition to the execution. In Level 4, the expertise of other key companies in the supply chain is used in addition to the execution expertise of the construction company. From Level 1 to Level 4, the importance of the construction price in the selection of project partners decreases, while at the same time the risk mitigation increases from Level 1 to Level 4.

Figure 1. Level of Involvement based on (PIANC 2022).

5.3 German procurement law

The volume of construction work for which an ECI makes sense is generally above the threshold for a threshold value for a Europe-wide invitation to tender. In this paper, it is assumed that a Europe-wide invitation to tender is also required for the tendering of an ECI. In accordance with § 119 (1) No. 3-7 of the German Act against Restraints of Competition (GWB) five types of procedure are available: the open procedure, the restricted procedure, the negotiation procedure, the competitive dialogue and the innovation partnership. The rules are specified in the VgV and the VOB/A (Breyer et al. 2020).

If an ECI is to be carried out, it must be taken into account when choosing the award procedure that price must not be the sole decision-making criterion. A procedure must be chosen that allows a decision on the basis of other criteria. Therefore, only the competitive dialogue and the negotiated procedure can be considered for an award in the sense of the ECI.

5.4 Variants for German public owners

The 35 identified models were analysed in regards to their usability for Germany Public clients. An important aspect is the compatibility of the variants with German public procurement law.

Apart from a public announcement of a major project, which only aims at arousing the interest of construction companies in a subsequent call for tenders,

there is currently no possibility for public contracting authorities to involve construction companies at level 1 in the planning. Level 2 includes types of project management and tendering such as functional tendering. This is of course available to public clients, but by applying these models, their influence on the planning is lost. Although the execution competence is brought in at an early stage of planning, it is not in the way it is thought of in the common understanding of ECI. The “restricted invitation to tender” of Level 2 can be added to a “competitive tendering procedure followed by a restricted procedure” if the bidders’ proposals for optimisation become part of the invitation to tender. However, an ECI in the true sense is not achieved in this way. Only an implementation of your Level 3 model represents an ECI in the true sense. This is mapped within the framework of innovative project management models such as IPA. These innovative models are currently being tested and evaluated in pilot projects. To include the know-how of key companies of the supply chain in the planning in addition to the execution competence, as described in level 4 of the ECI, is too capacity-binding and complex for public clients at the present time. These ECI variants are used e.g. by private clients in the construction of oil rigs (Laryea and Watermeyer 2016; Wondimu et al. 2018; Wondimu et al. 2020; PIANC 2022).

In principle, several ECI variations are compliant with public procurement law and can be implemented. However, their use requires very good knowledge of public procurement law. Additional some variations are rather easy to implement and only turn out to be a form of ECI on closer inspection like the public announcement, like the public announcement.

5.5 Success factors and criteria

Early Contractor Involvement is not suitable for every project and every client. In 2016 Wondimu identified six factors (Wondimu et al. 2016):

1. The right timing is crucial, contractors need to be involved early enough.
2. The risk transfer to the contractors must be kept at an manageable level.
3. The contractor must be adequately remunerated for the contribution of his execution competence. This is the only way to create an incentive to transfer know-how to the client.
4. Mutual trust, akin to partnering models,
5. The contractor must have the technical qualification to carry out or evaluate the planning
6. The client must have sufficient competence and capacity.

Furthermore, a consensus on fair risk sharing must be fundamentally anchored. Accordingly, an effective, efficient and sustainable risk management, which is developed in the ECI and continued during construction, is essential. The project must also have a certain

complexity and investment volume to justify the increased effort in the planning phase (Rahman and Alhassan 2012; Nibbelink et al. 2017; Narum et al. 2022; PIANC 2022; Rahmani et al. 2022).

6 CONTRACTOR INVOLVEMENT TOOL (CIT)

6.1 Purpose and benefit

The tool provides support for public clients in choosing the adequate form of early contractor involvement for their specific project. It also provides help and additional information for every step to be taken and guides a public client through the complete procurement process.

6.2 Software application

In software development one can choose between either a desktop or a web application. For this research a desktop application was chosen. Implementing a standalone application has the following advantages (Sander 2012):

- It is executed directly by the operating system (without a browser as a “man in the middle”);
- This allows greater complexity with good performance.
- Concentration on a single platform (Windows) that can be used by all users. This is especially true for testing, which does not need to be performed on multiple browsers and operating
- operating systems, which would be very time consuming.
- Possible use of the specific functionality of the operating system and direct cooperation with software packages
- Cooperation with software packages (OFFICE) that run on this system.
- Better availability of GUI elements that can be used to increase usability.
- Connection to a central database is still possible

6.3 Programming language .NET

The .NET Framework is an evolution of the Win32 API, which provides access to all the functions of the of the WINDOWS operating system. NET applications access

NET Framework class libraries (file management, graphics output, data processing, etc.). Plus, all of Microsoft’s popular programming languages (C#, Visual Basic, C++ and F#) can access the .NET Framework (ibid.). To generate an language-independent code the Common Language Specification (CLS) is used. In this code different languages have equal rights and deliver the same result. Being an open standard the CLS enables the porting of other languages to .NET (Kofler and Nebelo 2008) as shown in Figure 2.

Figure 2. Independent CLS (Kofler 2008).

Additionally .NET applications run independently on Windows systems (Sander 2012), which is a major advantage in usability.

6.2 CIT in DigiCon

DigiCon is a software platform developed as part of the “Digital Performance Contracting Center” research project at the University of the Bundeswehr Munich, see Figure 3. The software is still under development. Its aim is to digitally model the mechanisms and processes in public procurement developed in the research project. The Contractor Involvement Tool (CIT) uses the DigiCon platform as a base to model and depict the whole involvement process.

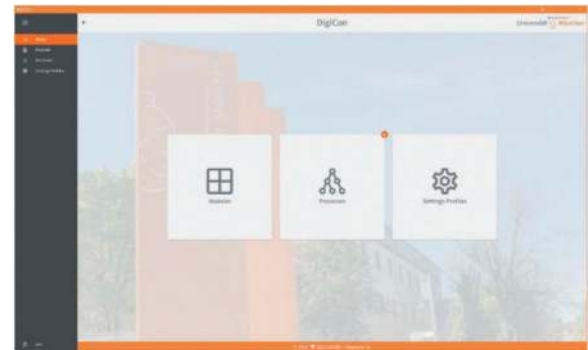

Figure 3. Image of DigiCon platform.

DigiCon enables the use to create modules and connect them in a process as they see fit. It also gives the opportunity to choose the logic when combining different modules, shown in Figure 4.

Figure 4. Module creation in DigiCon.

Regarding this research DigiCon as a platform and CIT in particular models a project enquiry in the first place. The enquiry compares the project specifications and properties with the success factors of ECI. Of particular importance are risk management, the client's own expertise and its own capacities. Depending on the result, CIT proposes several suitable ECI variants to the user. The application process is also shown for each variant and additional detailed information can be called up for each individual process step.

The user is responsible for the final selection of the variant, as CIT is not a management tool but a support tool for project management.

7 SUMMARY AND OUTLOOK

The ECI is only suitable for handling large and complex projects, as it entails considerable additional work in the tendering and planning phases. In addition, the client must provide sufficient competence and resources of his own and sufficiently reward the contribution of the execution competence in order to be able to carry out a project successfully with the ECI. Apart from the simple and straightforward variants, which can only be assigned to the ECI on very close examination, the legal regulations in Germany only allow two award procedures for the implementation of an ECI. Nevertheless, it can be stated that the early involvement of construction companies in the planning phase is possible in principle. The next steps are to finish the development of the DigiCon software-platform.

The selection processes must then be precisely defined and modelled in CIT. As soon as CIT is ready for use, it must be tested in practice by public clients. This will hopefully lead to more ECI projects in Germany, which will generate more data on ECI for public owners. However at this point there is more research required regarding the joint planning in ECI as CIT just shows the way to the joint planning. With regard to the transparent settlement with open-book, the joint calculation, the structure of the joint risk management and the risk allocation during the ECI should be examined and described in detail.

ABSTRACT: The Narragansett Bay Commission (NBC) operates Rhode Island (RI)'s two largest wastewater treatment facilities in the United States of America (USA). In 1992, NBC began a three-phase combined sewer overflow (CSO) program to reduce discharges of CSOs to Narragansett Bay. Phase I and II included a 5,030-meter long, 7.9-meter Inside Diameter (ID) rock tunnel, drop shafts, and pump station in Providence, RI. Phase III includes construction of the 3,535-meter long, 9.1-meter ID, deep rock Pawtucket Tunnel. This paper provides an overview of the Pawtucket Tunnel Design Build Project managing design, quality, and risk from base technical concept through final design into construction; highlighting transition of responsibilities amongst the teams engaged. Some lessons learned from the previous phase affecting the current Phase III Project requirements are discussed. This paper further describes some of the implemented design innovations for the large diameter shaft support, precast segmental tunnel lining including at the tunnel adit openings, and design of the liner pipe for the deep vertical drop and vent shafts. Important design considerations and a couple of critical Alternative Technical Concept (ATCs) during the tender impacting the final project design are presented. Finally, the paper concludes with some of the project construction innovations including the elaborate TBM start-up methodology, installations of the deep vertical shaft liner, and microtunneling for the longest adit using Fiberglass Reinforced Polymer Mortar (FRPM) pipes.

Keywords: Tunnelling, Design-Build, TBM, SEM, Risk allocation

1 PROJECT BACKGROUND

The Narragansett Bay Commission (NBC) embarked on a three-phase CSO control program in 1998, aimed at lowering annual CSO volumes and reducing annual shellfish bed closures in accordance with a 1992 Consent Agreement (CA) with the Rhode Island Department of Environmental Management (RIDEM). Phases I and II of the Program, which focused on the Field Point Service Area in Providence, were completed in 2008 and 2015, respectively. The program succeeded in lowering annual CSO volumes and reducing annual shellfish bed closures to levels that are in keeping with a 1992 CA between NBC and RIDEM.

The third and final phase (i.e., Phase III) is focused primarily within the communities of Pawtucket and

Central Falls. The implementation strategy prioritizes water quality benefits, while also limiting the financial impact on rate payers. The primary elements include the Pawtucket Tunnel and ancillary underground components including a launching shaft, receiving shaft, drop/vent shafts, adit tunnels, and tunnel pump station. The tunnel system provides volume to store all contributing overflows during a storm event up to the three-month storm for subsequent pump out and treatment. The required minimum storage volume to achieve the defined hydraulic criteria (i.e., no overflows for the three-month design storm, and no more than four overflows per year per outfall for typical year storms) is 221.4 million litres (ML).

The Pawtucket Tunnel is a rock tunnel, 35-m to 47-m below the ground surface, located adjacent to

*Corresponding author: irwan.halim@aecom.com

the Seekonk and Blackstone Rivers in Pawtucket, RI. The tunnel is approximately 3,535-m in length with a 9.1-m inside diameter (see Figure 1). The tunnel is mined with a Herrenknecht dual mode (open/EPB) TBM. The machine is fitted with a hard rock cutterhead and a conveyor to extract muck from the face when it is operated in open mode or a screw conveyor when operated in earth pressure balance (EPB) mode. The lining is made of universal double taper rings of seven fibre reinforced segments, thickness 0.36-meter and 2.0-meter in length. Each segment joint both radial and circumferential is fully gasketed to achieve the water tightness criteria.

Figure 1. Pawtucket tunnel alignment.

The geologic history of the bedrock is complex. The rock originates from fluvial deposits, which characteristically are not laterally continuous. Rock types range from conglomerate to coal with sandstone and siltstone as the predominant rock types. Sequential episodes of tectonic deformation have superimposed structural features including folds, faults, and joints. The Pawtucket Tunnel is constructed mainly in the Rhode Island Formation, a Carboniferous-age sedimentary rock comprised of sandstone and siltstone, with lesser amounts of conglomerate, shale, and coaly deposits. Bedrock is moderately folded and faulted. Bedrock is overlain by a thin layer of glacial till and thick layers of glaciofluvial deposits. Glacial deposits are comprised mainly of sand, gravel, and silt, and are overlain by granular fill.

2 PROJECT DELIVERY

Phases I and II were delivered using the traditional design-bid-build method of project delivery. For the Pawtucket Tunnel Project, NBC selected fixed-price design-build to reallocate inherent risks resulting

from the design process, and also to leverage its other benefits to mitigate additional risks:

1. Speed of Delivery – NBC must complete the Pawtucket Tunnel and facilities of the CSO Program in accordance with a consent decree with a regulatory agency. The consent decree includes a milestone date by when the facilities of Phase III must be operational. Design-build allows the procurement of a design-builder prior to final design of the project. It also allows construction to be “fast-tracked” by prioritizing the design of the initial elements of the project such as construction of shafts and starting construction of those elements prior to finishing the design of all elements of the project.
2. Single Point of Accountability – NBC wished to minimize the amount of contractor’s change requests resulting from omissions, unclarity, and gaps in interdisciplinary coordination of the design documents. Contractor’s requests for change based on omissions, unclarity or gaps in coordination in the owner-provided design results in the expenditure of considerable amounts of owner’s time and resources to manage and resolve such requests. Use of design-build relieves the owner of a great deal of involvement in the design change management process.
3. Contractor Involvement in Design Process - Preferences for means and methods of underground construction can vary between contractors. The owner can reduce risk of duplicated design efforts by the contractor related to preferred construction methods by allowing the design-builder to determine the best design to accommodate its means and methods.
4. Price Certainty – As with all capital projects, NBC strongly desired to limit costs for the Pawtucket Tunnel Project to within the contract amount and its contingency. With the exception of differing site conditions, the use of design-build mitigates the risk of cost increases resulting from changes to an owner-provided design.

Although design-build cannot eliminate project risks, it can facilitate the allocation of risk to the party best suited to manage the risk. The assumption of additional risks by the design-builder is likely incorporated in the design-builder’s lump-sum price in the form of a contingency.

3 PROJECT CRITERIA

The Base Technical Concept (BTC) design included preliminary design drawings, Geological Baseline Report (GBR), Geotechnical Data Report (GDR), and Environmental Data Report (EDR). The Design Builder (DB) was responsible to developing final design documents for project elements to comply with project criteria for each of the project elements. The

project elements included bored tunnel, large diameter shafts, suction header, drill and blast adit tunnel, and drop/vent shafts. The design was completed in January 2022 to comply with dates in the CA.

The primary functionality of the tunnel is to provide storage of combined sewage during wet weather events to control CSOs. The project criteria require the tunnel provide a storage capacity of 221.4 ML to store CSO generated during the 3-month design flow. The hydraulic criteria are prescriptive specifying vortex style drop shafts with hydraulic capacity to convey peak flows from the 2-year storm.

Durability criteria requires precast concrete segmental lining, internal components, permanent bolts, and associated inserts to be designed for a minimum of 100-year service life. Design and durability analysis considers pH level, chloride content, sulphates and other contaminants in soil, rock, ground water, and future wastewater. Analysis and testing confirmed exposure conditions for service life modelling.

Other key project criteria for the Pawtucket Tunnel included the following:

- Diameter 9.1-m ID
- Slope 0.001 m/m
- Minimum rock cover of two tunnel diameters.

Maximum allowable groundwater infiltration 3.8 litre per minute (lpm) per 305 m of tunnel and 0.38 lpm at any one segment.

4 PROJECT RISKS MANAGEMENT

NBC identified the top five (5) risks to be worker and public safety; TBM mechanical failure; damage to third party building, structures, or utilities due to ground movement during excavation; delay in production or delivery impacting project schedule and milestone completion, and differing site conditions. The procurement commenced in December 2019 prior to risks/issues associated with COVID, supply chain delays, and macroeconomic inflationary pressures. The risks associated with bored tunnel focused on ground conditions, which were baselined in the GBR for Bidding (or GBR-B): methane, water inflow, low strength rock, and potential fault at northern alignment. The GBR-B identified construction considerations attributed to how predominant types of ground are expected to behave in response to construction.

Pawtucket area coal has the capacity to retain high amounts of methane, but geologic history combined with mining and drilling experience indicates that the actual methane content of coal is low. Methane can be adsorbed on organic surfaces of coal and is released by a reduction in hydrostatic pressure. The potential exists for discharge of methane from carbonaceous rock, so excavations in rock were classified as “potentially gassy.”

Rock mass quality generally improves from south to north. For an excavated diameter of 10.2-m, potential collapse in the crown is indicated for some

of the alignment in poor rock if not supported properly. To mitigate the risk of roof fallout, the project criteria require tunnel excavation with a shielded TBM and concurrent installation of a permanent lining of gasketed precast concrete segments. The single-pass lining approach minimizes groundwater discharge volumes. This approach mitigates problems associated with localized deposits of weak mudstones and coal, such as loss of bearing on gripper pads, and a soft invert.

A potential fault crosses the tunnel alignment under the river at the northern end of the alignment as was inferred from the change of lithologies from the Rhode Island Formation to the Wamsutta Formation. The GBR-B baselined the fault zone conditions for a total width of 37.5-m. To mitigate the risk of excessive inflows while tunnelling under the river, it is expected that probing and grouting ahead would be needed. The baseline conditions were conservative based on the inability to locate the contact between the two formations during the preliminary geotechnical investigation.

Groundwater inflow was an identified risk due to flow rates encountered during construction of the Phase I Providence tunnel. A secondary risk was impact to NBC wastewater treatment facility from elevated loadings of total suspended solids, pH, and impact to sludge production. Efforts to reduce tunnel dewatering flows became important for both points. The GBR-B baselined the main tunnel drive to cross one or more shear zones. Such locations of high fracture density would produce high inflow rates over a short distance of up to 30.5-m. The baseline for localized heavy inflows is set at a sustained inflow rate of up to 492 lpm per 30.5-m of tunnel, to occur at one interval at an unidentified location. It also baselined the tunnel drive to cross a fault zone under the river. As a baseline, sustained inflows of up to 1,514 lpm per 30.5-m of tunnel may occur within the fault zone. The fracture network related to the fault zone is expected to be directly connected to the river.

The process for modification of the GBR-B to the GBR-C was provided through the Tunnel Design-Build Agreement and was proven to be quite effective. In addition to the GBR, the procurement process also established procedures for Alternative Technical Concepts (ATCs) which are design concepts and/or construction methods that offer alternative approaches to completing the project according to the criteria provided in the RFP. This process was enabled through Proprietary Meetings between the Owner, the Program Manager, and the Design-Builder in an effort to allow the Design-Build team to provide innovation and propose alternatives that suit their preferred design and means and methods and reduce risks. The GBR-B produced for the procurement provided all Design-Build teams with the same set of physical baseline conditions to be used in their design and construction planning during their bid. The process

was set up to allow the selected Design-Build team to provide their interpretations of the various baselines expressed in the GBR-B in developing their design and construction approaches, identifying any gaps, and providing any supplemental information gained through additional geotechnical investigations performed by the Design-Build team. The Owner and the Design-Build team then negotiated revisions to the GBR-B to formulate the Geotechnical Baseline Report for Contracting (GBR-C). The GBR-C reflects the joint understanding of NBC and the selected Design-Build Team regarding the interpreted baselines that are consistent with their design approach, equipment and construction means and methods.

The Design-Builder conducted additional investigations from the surface to revise the baseline within the reach in the GBR for Construction (GBR-C). The Design-Builder successfully located the contact zone between the Rhode Island and Wamsutta formations but with no fault detected and no fractured water bearing features. In addition, a probe at the base of the receiving shaft was drilled in December 2022 with two horizontal probes confirming the contact zone: no apparent faulting along the contact between the two formations, two formations appear to be interfingered, and no significant groundwater inflows. The Design-Builder updated the GBR-C accordingly, identifying TBM operation through this zone to be in open mode.

The Design-Build Team developed a list of ATCs that were discussed at the initial proprietary meetings. The ATCs were proposed to reduce costs or risks to the project. During preliminary design, the vertical profile provided two diameters of sound rock cover over the crown in an area of low rock. The horizontal alignment and shaft locations accommodated property acquisition constraints and operational preferences. The Design-Builder submitted a critical alternative technical concept (ATC) to raise the tunnel elevation and reduce its depth by about 7.6 meter, thereby reducing the amount of rock cover which was approved by NBC. Another important ATC proposed was related to adverse ground conditions near the tunnel pump station (TPS) and launch shaft (LS) locations and was designed to reduce both project risk and costs. The proposed ATC was to relocate the launch shaft to the north along the tunnel alignment and shifting it to the east of the existing shaft. In addition, the TPS was to be moved closer to the launch shaft to be in line with the re-aligned tunnel and to shorten the suction header tunnel. This alternative would move these elements away from the highly fractured rock (potential fault zone) as observed in the Owner's geotechnical explorations.

5 TUNNEL LINING DESIGN

A seven-segment universal tapered ring system was adopted as shown in Figure 2. The tunnel lining ring is 0.36m-thick, 9.2m in internal diameter, and 2m in

length, and consists of four (4) regular segments of rectangular geometry, two (2) counter-key segments of right trapezoidal geometry, and one (1) wedge-shaped key segment. All segments will be staggered to avoid creating cruciform joints which could cause leakage and structural distress due to stress concentration. As the key segment cannot always be installed at the tunnel crown, the TBM will need to be able to hold segments in place during ring assembly using an erector and support roller system. The length of the ring was selected by balancing between the constructability factors (ease of transportation, assembly, and ability to negotiate curves) and the utility factors (limiting joint number to reduce leakage and production cost and to increase tunnel advancement rate).

The wedge-shaped key block is often designed as a smaller size piece than other segments because smaller segments are easy to handle. Lately, a large key segment is becoming more accepted in the industry. Our design adopted similar-sized segments. It is advantageous to make all the segments as similar size as possible because of structural and constructability reasons. The longitudinal joints evenly spaced within the ring lead to increased load bearing capacity and reduce ring distortions. The larger key segment also can reduce the size of the regular segments (and therefore the number of longitudinal joints). The segments will not be bolted to each other at the longitudinal joints. This will help increase tunnel advancement rate because some bolting is eliminated. The rings will be connected to each other at the ring joints using fourteen (14) equally spaced dowels. In addition, fourteen (14) pairs of equally spaced shear connectors, i.e., shear bicones with a steel core were specified at the ring joints for centering and shear recovery purposes at the tunnel adit openings.

Figure 2. Tunnel lining geometry.

For waterproofing purposes, all-around ethylene propylene diene monomer (EPDM) compression gasket was used. The compression gasket is anticipated to resist maximum 500 kPa of hydrostatic pressure under the design compression and allowable offset scenario. The typical segments are reinforced by steel fibres. The segment thickness was selected to withstand all short-term and long-term loading cases and

service conditions. To achieve the desired 100-year service life, the selected segment thickness includes sacrificial concrete layer to protect the tunnel lining from concrete degradation due to hydrogen sulfide (H₂S) gas from the CSO water. The tunnel lining was designed where loss of the sacrificial layer does not impact the 100-year structural integrity of the lining system.

To demonstrate the adequacy of the adopted tunnel lining design, the stress and deformation of the tunnel lining were evaluated using two-dimensional (2-D) numerical analyses as shown in Figure 3. Total of five analysis sections were selected as representative of variations in overburden depths and anticipated ground and groundwater conditions. Among the five analysis sections, the section with the presence of intensely fractured soft and weak graphitic shale layer that traverse the tunnel alignment was found to govern the design. The graphitic shale layer is approximately 6-meter-thick sub-horizontal layer imbedded within bedrock. The raising of tunnel vertical alignment by 7.6 m resulted in reduction in lining thickness from 0.38 m to 0.36 m and the deletion of the hybrid reinforced (fibre and rebar) segments requirement for the graphitic shale zone.

The analysis was done in stages to evaluate the lining forces and the deformations under various loading conditions that are expected during the construction and throughout its design life. These include the variation of the anticipated groundwater levels, dewatering of groundwater during construction, and crossing of intensely fractured fault zone. The analysis showed that the tunnel lining will be able to withstand the anticipated loads and meet the ring distortion requirement for all these conditions. A seismic analysis was performed to evaluate the effects of seismic waves vertically propagating perpendicular to the tunnel axis. A transverse racking analysis was performed to quantify the racking deformations and their effects on the tunnel lining.

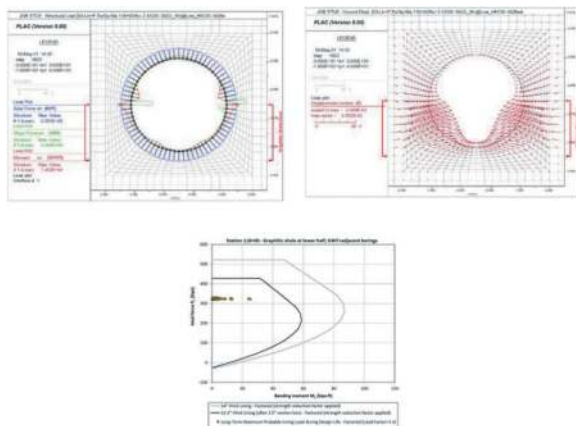

Figure 3. Tunnel lining design verifications.

The segment design was checked against the temporary construction loading scenarios including stripping and handling minimum concrete strength, storage

and transportation, erection and TBM thrust rams pushing against the segments, during backfill and contact grouting, and for the TBM gantry load and segment feeder immediately behind the erector. The segment joint design consisted of checking the circumferential dowel system capacity to hold the segments together during erection and maintain gasket compression to adequately seal off the design hydrostatic pressure.

The Pawtucket tunnel is connected to four drop shafts by tunnel adits along its alignment, three of the adits are shown schematically in the above Figure 4. Two adits are planned to be constructed by sequential excavation methods (SEM) and the third will be constructed by microtunneling.

Figure 4. Adits connecting to the bored tunnel.

The SEM tunnel adits will be constructed from the main tunnel by drill and blast with mining outwards towards the base of the drop shaft structures. The third adit constructed by microtunneling will start from the drop shaft location and be jacked into the main tunnel. The final connection between the main tunnel lining and the adits will be achieved by installing a monolithic cast-in-place (CIP) concrete collar around the segment cuts.

At the adit locations in the tunnel, segments will be cut and removed. At these locations the tunnel requires additional bracing to support the temporary forces due to the tunnel wall opening at these locations. Rather than designing the usual external bracing frame at these locations, the opening will be temporarily supported by modified segment rings installed during tunnel construction these rings have additional reinforcement and shear elements included within the specially designed tunnel segments installed along the four rings immediately adjacent to the opening. While the standard lining design along the alignment is pure steel fiber reinforced concrete (SFRC) with two shear dowels installed at each thrust pad, the specially reinforced segments feature a heavy rebar cage in addition to the SFRC as well as 2 additional high-capacity shear cones per segment ring joint installed in the middle of the thrust pads between the shear dowels. The geometry of the specially reinforced segments is equivalent with that of the typical segments.

A staged Finite Element (FE) model was developed for the structural analysis of the lining and collar at the TBM tunnel-adit locations that

considers all the critical design issues, e.g., The in-situ ground pressures, the temporary and permanent ground water loads, the supporting action (or lack thereof) of friction between rings, and the durability of the lining concrete, and the nonlinearities of all the materials involved. An image of the model is shown in Figure 5 below.

Figure 5. Model of adit connections: a) adit collar; b) isometric view of segmental lining ring.

The structural analysis indicates that, as expected, the most critical case for design is the temporary loading of the segments immediately following the cutting and removal of the lining and before installation of the CIP concrete collar. Specifically, the analysis indicates that the tensile stresses are too high to be carried by steel fibers alone and this resulted in the requirement for additional circumferential rebar reinforcement and shear cones in these special segments.

6 SHAFT DESIGN

Circular secant pile walls were selected as the method of temporary excavation support in soil for the three large diameter shafts, as this method is well suited for the rock depth at each shaft, and due to the need to establish groundwater cut-off. To achieve groundwater cut-off and support lateral soil pressures, secant piles were socketed into unweathered bedrock and designed to have sufficient overlap at depth to form a continuous circular shell, considering installation tolerances. Installation of the secant piles was followed by a pre-excavation grouting program to effectively seal the secant-rock interface. The secant wall design included no internal bracing, allowing for rapid shaft excavation upon completion of the grouting program. In addition, the design excludes the typical ring beam at the bottom of secant piles to save on the final shaft concrete lining thickness in overburden soils.

The analysis model for the temporary secant walls consisted of a circumferential structure of uniform thickness and diameter. Loads to be resisted by the secant walls during excavation included soil and groundwater pressures, as well as localized construction surcharge pressures near the surface. The loading conditions resulted in approximately uniform pressure around the secant wall circumference, increasing with depth. A closed-form solution analysis was used to establish initial dimensions and concrete strength, followed by 3D finite element

analyses with soil structure interaction considering various construction surcharge cases. It was determined that an unreinforced circular secant wall of sufficient thickness to resist the pressures in circumferential compression was a feasible option, eliminating the need for steel core beams and internal bracing. Localized, near-surface bending moments resulting from non-uniform construction surcharge loads are resisted by a cast-in-place reinforce concrete ring beam at the top of the secant pile walls.

The project criteria documents recommended initial rock support in the form of grouted rock dowels and wire mesh reinforced shotcrete. Alternatives were considered during detailed design, including use of fibre reinforcement in lieu of wire mesh, and friction bolts in lieu of grouted dowels. After consideration of alternatives and based on the Design-Builder preference, final design was advanced consistent with the initial support system described in the project criteria documents. Initial rock support demand in the large diameter shafts was analysed using wedge analyses, informed by discontinuity data obtained from borehole televiewer logging, and strength parameters determined from laboratory testing conducted during the initial project subsurface investigation and the supplemental investigation. Additional procedural requirements were included in the design, such as line drilling and excavation by mechanical means only near the top of rock to reduce risk of undermining the secant pile SOE system or damaging the grouted cut-off zone. Below this critical zone, the remainder of each shaft was excavated by drill and blast methods.

Fibre Reinforced Polymer Mortar (FRPM) pipes are used for the final drop and vent shaft liners as shown on the Figure 6 below.

Figure 6. Drop pipe installation.

The important design factors for these pipe systems consisted of:

- Ring wall compression, pipe buckling resistance and minimum pipe flexural stiffness for handling purpose.

- Minimum annular grout thickness and strength to act in combination with the pipe inside the shafts.
- Pipe installation method which includes water filling inside the pipe during lowering into the shaft to compensate for buoyancy and hydrostatic pressure, maximum allowed grout lift height, and minimum grout strength gain before the next lift can be placed.

7 TBM START-UP AND LAUNCH SEQUENCES

The Design-Builders have selected a Herrenknecht hybrid TBM with open/closed EPB mode capabilities which presents the advantage of controlling muck management, minimized maintenance and optimized production time. The TBM delivery was completed at the end of June 2022. The 10.3-meter bore diameter TBM has a 14-meter-long shield and a 91-meter-long back-up, comprised of four gantries to supply power to the shield, and connect the utilities and logistics. The shield is composed of 3 main sections with one active articulation. This will enable it to achieve the minimum required curvature of 305-meter radius. The structure and seals are designed for 500 kPa (5 Bar) of pressure.

The 10.3-meter diameter cutter head is designed for hard rock and protected against wear. It is equipped with sixty-four 0.48m disc cutters for high efficiency and reliability in the anticipated conditions. The machine is fitted with a conveyor belt in open mode and a screw conveyor in EPB mode to move muck from the cutting chamber to the Tunnel muck conveyor that will transport the material to the shaft. The face can be closed in less than 10 minutes if required. The dual mode has a real benefit on the Project because it will significantly reduce the need for probe drilling and pre-grouting that a single open mode TBM would require. The selected TBM is shown in Figure 7.

Figure 7. TBM in Herrenknecht factory in January 2022.

The TBM was launched and operated from the Launch shaft located on the main site at the Southern end of the project. It is of 18.9-meter diameter and

47.2-meter deep, excavated within the soil portion inside an excavation support wall made of secant piles and in the rock using drill-and-blast method. When the shaft excavation reaches the level of the tunnel at a depth of 36.6 m a starter tunnel of 70.1 m long, and a tail tunnel of 18.3 m long were excavated by SEM in two stages, top heading and bench. The remainder of the shaft was then completed after the starter tunnel and tail tunnel were excavated. The bottom of the shaft was backfilled, and a trench was kept below the tunnel invert to install the bottom part of the vertical conveyor as shown in Figure 8.

Figure 8. The launch shaft installation during TBM operation.

The TBM was pre-assembled on surface. The 1,665 tons machine was delivered in 82 packages. The pre-assembly on the surface made it possible to lower larger assembled TBM sections into the shaft weighing up to 375 tons as shown in Figure 9

Figure 9. 375 tons TBM front shield lowered with the 600 tons crawler crane in the launch shaft.

The main site is set-up to provide the necessary logistic support to the TBM operation. A crawler crane of 350 tons capacity handles the

segments and the services inside the launch shaft. There is sufficient space on top of the shaft to store up to 60 rings, more than a week of anticipated TBM production. The TBM muck is transported from the TBM by a chain of conveyors at a rate of 1,250 tons per hour. The muck is lifted in the shaft using a vertical bucket conveyor as depicted in Figure 10.

Figure 10. Muck conveyors system in the tunnel and shaft.

On the surface the muck is dropped by a radial stacker in a stockpile accumulating 15,000 cubic yards, the anticipated average weekly quantity excavated by the TBM. The rest of the surface installation comprises a grout plant, electrical distribution, water treatment plant, offices, material storage and workshop. The main launch site is shown in Figure 11.

Figure 11. Main site aerial picture during TBM assembly.

The TBM is set up in the starter tunnel and launched in the second half of September 2022. To minimize the length of the starter tunnel excavation only three gantries are installed initially, the fourth gantry with non-essential services is lowered in the tunnel once the TBM has advanced. The transport of segments in the tunnel is by two multi service (VMS) vehicles shown in Figure 12 that can hold one full ring made of seven segments and one set of temporary services that will be installed in the tunnel to provide fluids, ventilation, and power to the TBM. Tunnelling was started in September 2022 and due to be completed by the end of 2023.

Figure 12. Vehicle Multi Service (VMS) for the segments transport in tunnel.

The Design-Builder self-performed the tunnel liner segments at a facility approximately 40 kilometres from the launch site. Non steam controlled temperature curing is used with production halted during coldest months of the winter.

8 SEM TUNNEL AND ADIT CONSTRUCTION

The Pawtucket project contains several mined tunnels (i.e., main drive, adits). In contrast to TBM tunnelling, mined tunnelling is performed under open face conditions without the aid of a protective shield. As such, to minimize risk, the Sequential Excavation Method (SEM) is employed using separate support classes depending on the expected rock behaviour. The design build delivery allows for a close interaction between the engineer and contractor during tunnelling. This close interaction allows for efficient adjustment of rock support to ensure that what is installed is both safe and economical.

The largest mined tunnel along the alignment is the starter tunnel. The starter tunnel extends northwards from the launch shaft in the direction of the main tunnel and houses the TBM during launch. To further extend the launching area for the TBM, a shorter tail tunnel has been constructed between the launch shaft and the future pump shaft. In addition to these larger mined tunnels, The Pawtucket tunnel will be connected to four drop shafts by smaller adits along its alignment. The adits are “preceded” by a slightly larger deaeration chamber immediately below the drop shafts. When the water is collected in the drop shafts, it flows first through the deaeration chamber and then into the adit.

The final lining of the starter tunnel will be cast-in-place fibre reinforced concrete cast flush with the inner diameter of the TBM tunnel. Fibre reinforced concrete was selected not only out of economy, but to increase robustness of the lining against corrosion, further minimizing risk that significant damage would occur to the as-built-structure over time. The tail tunnel will be completely backfilled.

The longest adit is excavated from the access shaft to the mainline tunnel by microtunneling to mitigate the geological risks inherent to drill and blast mining initially anticipated in the BTC. The adit is over 305 m in length and crosses under the Seekonk River. Additional ground investigations from the surface

were limited by accesses not granted into private properties. The choice of a confined microtunnel TBM prevent the use of pre-excavation grouting and secure the schedule against geological conditions.

Fibre reinforced polymer mortar (FRPM) jacking pipe is used for the 305-m adit to attain the 100-year durability requirement for the project as well as achiev-

ing pressures needed on the gaskets. The pipe is 2.4-meter in nominal diameter with a pipe wall thickness of 7.6 cm. The pipe joint is a flush bell and spigot joint which has an allowable safe jacking load of about 1,150-ton and a maximum allowable hydrostatic pressure up to 483 kPa. The MTBM will be retrieved from the mainline tunnel as illustrated in Figure 13 below.

Figure 13. MTBM drive and retrieval from the mainline tunnel.

Comprehensive risk management for slurry shield TBM tunneling using fuzzy set theory

Kibeom Kwon*, Minkyu Kang, Hyeontae Park, Yongxun Ma & Hangseok Choi
Korea University, Seoul, Republic of Korea

ABSTRACT: During ground excavation using tunnel boring machines (TBMs), inherent risks stemming from various uncertainties must be addressed. Without effective risk management, construction costs and timelines can significantly overrun, and accidents may occur. However, conventional research approaches have often overlooked uncertainties in expert opinions and TBM tunneling, leading to a limited understanding of risk management outcomes. To address this issue, this study employed the concept of membership degree in fuzzy set theory (FST) to propose a comprehensive risk management model for slurry shield TBM tunneling. The proposed model initially calculated the membership degree for each class concerning impact and probability by comprehensively considering expert opinions. The impact and probability classes with the highest membership degrees were then applied to a risk matrix to determine the risk class. The practical applicability of this model was validated through its application to an actual slurry shield TBM tunneling project. In the risk analysis, the membership degrees of impact and probability were distributed across all classes, with the highest membership degrees being less than half. Notably, these distributions can be comprehensively reflected in the subsequent risk evaluation within the proposed model. All causal combinations related to collapse yielded the risk class of “Significant”, indicating the need for countermeasures that can be implemented depending on the situation. Moreover, the risk class corresponding to ground surface deformation, such as surface settlement and heaving/blow-out, caused by shallow cover depth, was determined to be “Significant”. In conclusion, the proposed model enhances the reliability of risk management, particularly for tunneling projects with significant uncertainties stemming from various causes, including incomplete site characterization and the utilization of various state-of-the-art techniques. This approach contributes to ensuring both safety and efficiency in TBM tunneling.

Keywords: Tunnel boring machine (TBM), Risk management, Fuzzy set theory (FST), Risk matrix

1 INTRODUCTION

The increasing frequency of tunnel construction has become essential in urban areas characterized by high population density and significant traffic congestion costs (Broere, 2016; Kim et al., 2022). Tunnel boring machines (TBMs) have gained widespread utilization in various tunneling projects, primarily due to their eco-friendliness, stability, and constructability (Hyun et al., 2015; Kwon et al., 2022).

Nonetheless, TBM tunneling comes with inherent risks stemming from various uncertainties, including those related to geology-machine interactions. Proactive risk management is essential to prevent overruns of construction costs and time and mitigate potential accidents such as collapse and mud/water inflow.

Risk, defined as the combined value of impact and probability, is conventionally assessed through expert surveys (Eskesen et al., 2004). This approach involves collecting evaluations of impact and probability provided by experts, and then calculating risk based on these assessments.

A risk matrix has been widely applied in practice due to its simple and intuitive characteristics. Several risk management models in tunneling have introduced the use of the risk matrix (Eskesen et al., 2004; Hyun et al., 2015; Chung et al., 2021). However, these conventional models often require each expert to assign a single class for impact and probability evaluations, which can be challenging. Furthermore, these models typically rely solely on the average or modal opinion when aggregating expert

*Corresponding author: kibb5@korea.ac.kr

assessments, which can hinder the appropriate consideration of uncertainties associated with TBM tunneling.

This study proposes a comprehensive risk management model for tunneling by incorporating fuzzy set theory (FST). FST enables the calculation of membership degrees corresponding to various classes of impact and probability. This approach allows each expert's evaluation certainty to be distributed across multiple classes, rather than restricting it to a single fixed class. Consequently, the risk derived from these distributions comprehensively incorporates the entire range of expert opinions.

2 BACKGROUNDS

2.1 Risk matrix

A risk matrix represents a structured methodology employed for evaluating potential risks. This method involves the establishment of a matrix characterized by two fundamental dimensions: impact and probability. Each dimension is divided into discrete classes or levels. The risk class can be determined based on the combination of the evaluated impact and probability classes.

Various forms of risk matrices can be formulated, depending on the criteria used to categorize risk classes. In particular, although the combination of the evaluated impact and probability classes remains consistent, the classification of risk classes can vary for each form of the risk matrix. Figure 1 illustrates the risk matrix adopted in this study.

Risk matrix		Impact class				Risk class
		Very-low	Low	Medium	High	
Probability class	Very-low	I	I	II	III	Negligible (I)
	Low	I	II	II	III	Tolerable (II)
	Medium	II	II	III	IV	Significant (III)
	High	III	III	IV	IV	Intolerable (IV)

Figure 1. Risk matrix adopted in this study.

2.2 Fuzzy set theory

Fuzzy set theory (FST) was introduced as a framework to accommodate the inherent vagueness in human cognition when dealing with uncertain information (Zadeh, 1965). In classical set theory, a set possesses distinct boundaries, as depicted in Figure 2(a). In this framework, an element either unequivocally belongs to the set or does not, allowing for the definition of membership degrees as binary values of either zero (non-member) or one (member).

In contrast, a fuzzy set permits its members to exhibit gradual membership degrees within the interval [0,1]. This characteristic arises from the use of an ambiguous set boundary, as illustrated in Figure 2(b).

Once a fuzzy set A is defined on a universe of discourse with elements denoted by x , a membership

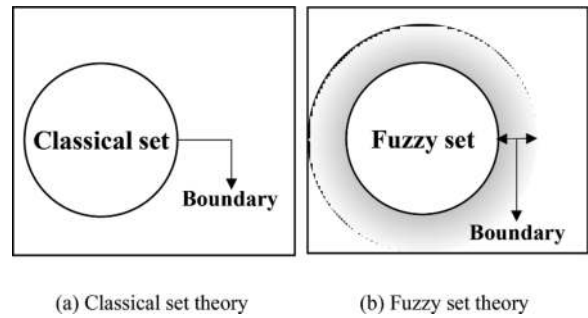

Figure 2. Diagrams of the set boundary.

function can be expressed as $\mu_A(x)$, which takes on values from the interval [0,1] (Wang et al., 2013). Higher values of the membership function correspond to a stronger degree of inclusion of an element within the set.

Various forms of membership functions (e.g., triangular, trapezoidal, and Gaussian membership function) can be employed to represent fuzzy sets, as illustrated in Figure 3. Among these various forms, triangular and trapezoidal functions are frequently preferred due to their straightforward definition, ease of representation, and computational tractability (Thaker and Nagori, 2018).

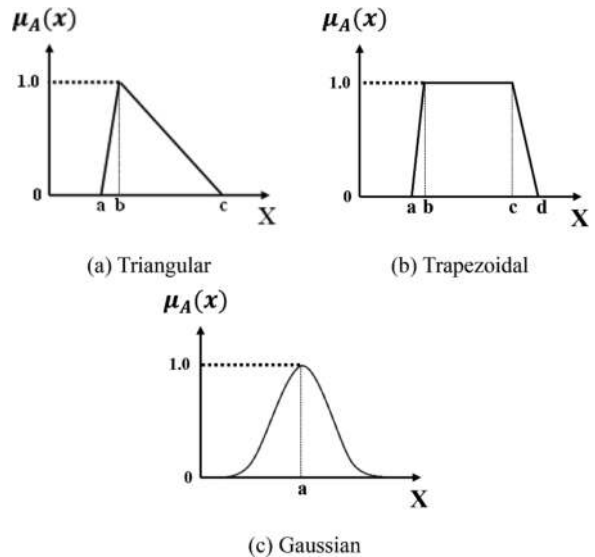

Figure 3. Schematics of the various membership functions.

3 MODEL METHODOLOGY

3.1 Scope

In this study, geological sources were exclusively addressed among various types of potential adverse sources, such as design-related sources (e.g., improper design of the cutter head) and operational sources (e.g., insufficient backfill grout). This selective emphasis on geological sources was driven by their

inevitability during tunnel construction and their notable contribution to documented accidents.

Furthermore, the risk evaluations were conducted for each causal combination (i.e., a one-to-one correspondence between sources and resultant accidents). This approach was chosen to account for the fact that the probability of an accident occurring may vary depending upon the specific causal source (Kwon et al., 2023).

3.2 Risk identification

In the phase of risk identification, the objective was to identify potential sources, accidents, and the causal combinations relevant to a specific tunnel project. Several methodologies for risk identification have been proposed, with the most common approaches involving comprehensive literature reviews and structured expert interviews (Siraj and Fayek, 2019). Furthermore, it is widely acknowledged that the combination of multiple identification methodologies can improve the reliability of the outcomes (Hillson, 2002). Therefore, this study simultaneously employed literature reviews and expert interviews.

3.3 Risk analysis and evaluation

Creating membership functions for each impact and probability class was the initial requirement. In this study, four classes (Very-low [VL], Low [L], Medium [M], and High [H]), two types of membership functions (triangular and trapezoidal), and a total of 12 scores (whole numbers ranging from 1 to 12) were adopted, as illustrated in Figure 4.

Figure 4. Schematics of the utilized membership functions.

It is important to note that each assigned score for both impact and probability corresponded to a specific membership degree within each class. For example, if a score of 3 was given, the membership degrees for each class would be as follows: VL: 2/3, L: 1/3, M: 0, H: 0.

During the risk analysis, each expert was responsible for assessing the impact of each accident and the probability associated with each causal combination. This evaluation involved selecting one of the available 12 scores. It is noteworthy that, in this study, the evaluated impact of an accident

was considered equivalent to the impact of a causal combination containing the same accident. For each impact and probability class, the membership degrees were obtained using Eq. (1), where MD_I and MD_P represent the membership degree of impact and probability, while i, j , and n denote the class, score, and number of expert opinions, respectively.

$$MD_{I,i} = \frac{\sum_{j=1}^{12} C_{I,i,j}}{n}, MD_{P,i} = \frac{\sum_{j=1}^{12} C_{P,i,j}}{n} (i : VL, L, M, H) \quad (1)$$

Risk evaluation determined the risk class based on the evaluation results of impact and probability. In this study, four risk classes were adopted: “Negligible”, “Tolerable”, “Significant”, and “Intolerable”. Each risk class entailed a different level of countermeasure necessity, as summarized in Table 1.

For this study, a new risk matrix was developed based on the adopted impact, probability, and risk classes. In this matrix, impact and probability were considered to contribute equally to the overall risk, leading to the establishment of a symmetric risk matrix. For each causal combination, the impact and probability class with the highest membership degree (i.e., i with the maximum of $MD_{I,i}$ and $MD_{P,i}$ in Eq. 1) were applied to the constructed risk matrix, thereby determining the corresponding risk class. The flow chart illustrating the implementation of the proposed model is presented in Figure 5.

Table 1. Degree of countermeasures required for each risk class.

Risk class	Degree of countermeasures required
Negligible	Countermeasures are unnecessary.
Tolerable	Countermeasures not required but can be applied depending on the situation.
Significant	Countermeasures required but cannot be applied depending on the situation.
Intolerable	Countermeasures must be applied.

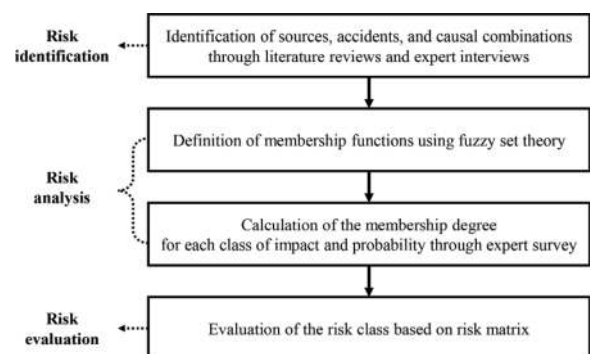

Figure 5. Flow chart of model implementation.

4 RESULTS

4.1 Site description

The proposed model was applied to an under-river tunnel project with a total length of 2.86 km. Excavation of this tunnel was carried out using a slurry shield TBM with an excavation diameter of 14.01 m. The ground types encountered along the tunnel alignment was primarily characterized by weathered, soft, and hard rock. The longitudinal geological profile of this site is presented in Figure 6. The outer and inner diameters of the segment lining were 13.5 m and 12.6 m, respectively.

Figure 6. Longitudinal geological profile of the project site.

4.2 Results of risk identification

Through literature reviews and expert interviews, seven sources and five accidents associated with the target tunneling site were identified, as summarized in Tables 2 and 3.

Table 2. Identified sources at target tunneling site.

No	Name
1	Faults
2	Shallow cover depth
3	Mixed ground
4	Cross-passage
5	Blocky rock mass
6	High water pressure
7	Weathered ground

Table 3. Identified accidents at target tunneling site.

No	Name
1	Collapse
2	Surface settlement
3	Heaving/blow-out
4	Mud/water inflow
5	Cutter head blockage

Table 4. Identified causal combinations at target tunneling site.

Symbol	Causal combination	
	Source	Accident
CC1	Faults	Collapse
CC2	Shallow cover depth	Collapse
CC3	Mixed ground	Collapse
CC4	Cross-passage	Collapse
CC5	Blocky rock mass	Collapse
CC6	High water pressure	Collapse
CC7	Faults	Surface settlement
CC8	Shallow cover depth	Surface settlement
CC9	Mixed ground	Surface settlement
CC10	Cross-passage	Surface settlement
CC11	Blocky rock mass	Surface settlement
CC12	High water pressure	Surface settlement
CC13	Weathered ground	Surface settlement
CC14	Faults	Heaving/blow-out
CC15	Shallow cover depth	Heaving/blow-out
CC16	Faults	Mud/water inflow
CC17	Cross-passage	Mud/water inflow
CC18	High water pressure	Mud/water inflow
CC19	Weathered ground	Mud/water inflow
CC20	Faults	Cutter head blockage
CC21	Mixed ground	Cutter head blockage
CC22	Blocky rock mass	Cutter head blockage

Subsequently, 22 causal combinations considering the potential causal relationships between the seven identified sources and the five accidents were identified, as summarized in Table 4.

4.3 Results of risk analysis and evaluation

A total of 29 experts participated in the survey, and their impact and probability evaluations were compiled. The results of the membership degree for impact and probability classes, derived from these expert evaluations, are summarized in Tables 5 and 6. Using the results from the risk analysis, the risk class for each causal combination was evaluated, as presented in Table 7.

Table 5. Impact results for each accident.

Accident	Membership degree of impact class			
	Very-low	Low	Medium	High
Collapse	0.13	0.18	0.26	0.43
Surface settlement	0.03	0.28	0.46	0.23
Heaving/blow-out	0.09	0.32	0.45	0.14
Mud/water inflow	0.07	0.38	0.41	0.14
Cutter head blockage	0.16	0.36	0.34	0.14

CC22	Low	Low	Tolerable

5 DISCUSSIONS

According to Table 5, most of the identified accidents, except for cutter head blockage, had the highest membership degree in the Medium or High categories. This tendency towards sever impact can be attributed to the specific site conditions under the river. For example, accidents like environmental pollution can have more significant consequences when they occur under a river, and implementing countermeasures becomes more challenging.

Regarding the probability, most causal combinations had the highest membership degree in the Very-low and Low categories, except for CC8 and CC15. However, it's worth noting that in some combinations, there was little difference between the membership degree of the highest probability class and the others. For instance, the membership degree difference between Very-low and Low for CC5 and CC6 was 0.04 and 0.01, respectively. In addition, the difference between Low and Medium classes was less than 0.1 for CC8, CC15, CC16, and CC19.

Furthermore, most of the highest membership degrees presented in Tables 5 and 6 were less than half, and the membership degrees were distributed across all the classes except for CC3, CC5, CC11 in probability evaluation. This distribution cannot be considered in conventional risk management approaches where experts select only one impact and probability class, resulting in narrower results that do not consider this level of uncertainty. These results obtained by the proposed model underscore its superior capability in handling uncertainty.

For eight causal combinations (CC1, CC2, CC3, CC4, CC5, CC6, CC8, and CC15), the risk evaluation yielded a risk class of "Significant" (refer to Table 7). In these cases, implementing countermeasures was advised rather than being deemed obligatory.

Except for CC8 and CC15, the causal combinations with the risk class of "Significant" were related to the collapse accident. These results were made by the application of a conservative risk matrix where at least one of the constituent factors, either impact or probability class, was evaluated as High, leading to the derivation of a risk class of at least "Significant".

The remaining causal combinations designated as the risk class of "Significant" (CC8 and CC15) were related to surface settlement and heaving/blow-out, both induced by the same source, which was shallow cover depth. These findings align with expectations, as ground disturbances near the tunnel can easily extend to the ground surface in hazardous zones characterized by shallow cover depth. This has the potential to cause significant damage not only to the tunnel but also to adjacent structures.

6 CONCLUSIONS

This study proposed a comprehensive risk management model for tunneling that combines fuzzy set theory with the risk matrix. To assess its practical applicability, the proposed model was applied to a real under-river tunnel project that utilized a slurry shield tunnel boring machine.

The majority of the membership degrees for impact and probability, as obtained through expert surveys, were distributed across all classes. This distribution results from the comprehensive risk management approach that accounts for the inherent vagueness in expert opinions.

The proposed model can have a significant impact on risk management, especially for tunneling projects with significant uncertainties arising from inadequate site characterization and the application of various state-of-the-art techniques. In doing so, it contributes to ensuring the safety and efficiency of TBM tunneling.

Mass Rapid Transit Corporation, Kuala Lumpur, Malaysia

ABSTRACT: The recent successful completion of the underground section of the Putrajaya Line, Klang Valley Mass Rapid Transit (KVMRT) project, comprises 13.5km of twin bored tunnel with 10 new underground stations, one existing cross-platform interchange station with the Kajang Line; and various ancillary structures including cripple track siding and crossover box, escape shafts, ventilation shafts and tunnel portal. The tunnel was built using 8 variable density (VD) tunnel boring machines (TBMs) and 4 earth pressure balance (EPB) TBMs. One of the critical tunnel drives required a tunnel launch within the Hospital KL crossover box (HKLX), which is not only sited in Kuala Lumpur's notorious karstic limestone but compounded with extremely complex geological conditions such as steep sided trough infilled with unconsolidated clayey materials and presence of complex solution channel networks. The criticality for an early completion of this crossover box structure has significant impacts on the overall tunnel construction programme. However, the many geotechnical challenges faced since the site establishment, such as ground subsidence during borehole investigation, changes in groundwater levels and possible related building settlement has led to the meticulous task of diagnostic investigation, temporary works design enhancement, development of ground improvement schemes and changes in original construction sequence to mitigate these unique set of anticipated geotechnical risks to allow timely completion of the HKLX crossover box for TBM launching. Extensive risk management process, building impact assessment/protection and instrumentation monitoring particularly to verify the performance of the construction was implemented to ensure the works were to proceed in a safe manner. The project was completed on time without incident to facilitate the tunnel launch in achieving the overall planned programme. The case history clearly demonstrated the importance of the deployment of geotechnical risk management/action plan to overcome unusual geological challenges to be faced by geotechnical engineers.

1 INTRODUCTION

The Putrajaya Line, the second of three planned mass rapid transit rail lines under the Klang Valley Mass Rapid Transit (KVMRT) Project, has been successfully constructed and fully operational on 16 March 2023. The 57.7 km-long alignment covers a span of 13.5 km underground twin tunnels running through the Kuala Lumpur city centre with 10 new underground stations and one existing cross-platform interchange station; and various ancillary structures including cripple track siding and crossover box, escape shafts, ventilation shafts and tunnel portal. Figure 1 shows the underground alignment route map. The running tunnels, measuring 5.8 m internal

diameter with 275 mm thick precast steel fibre reinforced concrete segmental linings, were excavated using 8 variable density (VD) tunnel boring machines (TBMs) and 4 earth pressure balance (EPB) TBMs and was divided into 8 sections of tunnel drive.

The project delivery is in the form of Design and Build (D&B). Geotechnical Information Report (GIR) prepared by the Employer's Consultant, including pre-contract ground investigation data and its inferred geological profiles for the project site area, as well as the risk register developed during the reference design stage, were included and form part of the Contract Documents. Under the prevalent Conditions of Contract, full risk of ground conditions and risk management is borne by the D&B

Figure 1. Location plan of the underground alignment.

Contractor. The Contract further stated it is the Contractor’s responsibility and expense to carry further site investigation and his assessment of ground conditions to fully develop his designs and construction methods for all related activities.

The Hospital KL Crossover/IVS1 (HKLX) is located in between the S14 Hospital KL Station and S15 Raja Uda Station. The HKLX is a two-level multiple track crossover structure, also housing cripple sidings and intervention/ventilation shaft facilities. Besides its operational function, an additional key function of the HKLX box is its use as the ‘shaft’ for the launch of two TBMs from its east end, and the subsequent retrieval of 2 other TBMs at its west end. The criticality for an early completion of the HKLX box structure has significant impacts on the overall tunnel construction programme. However, the chosen site is not only sited in Kuala Lumpur’s notorious karstic limestone but compounded with extremely complex geological conditions such as steep sided trough infilled with unconsolidated clayey materials and presence of complex solution channel networks. The many geotechnical challenges faced since the site establishment, such as ground subsidence during borehole investigation, changes in groundwater levels and possible related building settlement has led to the meticulous task of diagnostic investigation, temporary works design enhancement, development of ground improvement schemes and changes in original construction sequence to mitigate these unique set of anticipated geotechnical risks to allow timely completion of the HKLX box for TBM launching.

This paper presents the detailed examination to establish the geological and hydrogeological model, capturing the geological risks associated with the construction of the HKLX box structure and the various measures adopted to control and minimize the geotechnical risks to an acceptable level. The measures were concluded as effective leading to a safe excavation and successful completion and meeting the overall program.

2 THE SITE AND ORIGINAL DESIGN SCHEME

2.1 Site location and the surrounding context

The Hospital KL Crossover (HKLX) site is located at an existing open car park with a few adjacent

building structures and hospital facilities, which includes hospital’s radicare buildings and offices to the north of HKLX, a power substation in the north-east, Hostel Sejahtera and Hostel Abadi in the south-east and south of HKLX. The hostels are 20-storey high residential quarters for the hospital staff. A river, circa Bonus River, is running along the east boundary. See Figure 2. These structures may be affected by the construction.

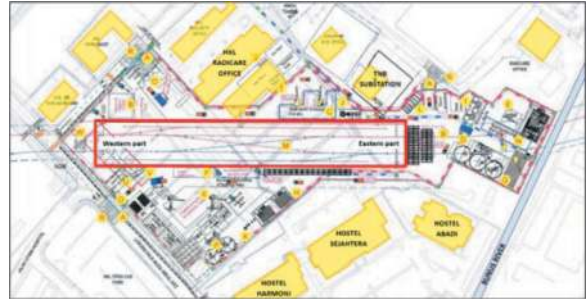

Figure 2. Site context.

Figure 3. Overview of the HKLX site.

The site terrain can be described as flat ground with average level of +34 RLm. The box structure is of approximately 167 m long and 30 m wide and required an excavation of about 20 m below the ground surface. The west end of the box served as a retrieval shaft for the TBMs driven through the Hospital KL station while the other end was for tunnel launching. An overview of the excavation box in relation to the surrounding critical and sensitive buildings is illustrated in Figure 3.

2.2 General geology of the site

According to the geological map of Kuala Lumpur (1993 version), the site is underlain by the Kuala Lumpur Limestone formation. Published geological information (Hutchison & Tan 2009) indicates that the bedrocks belonging to Middle to Upper Silurian Age, which typically comprise locally dolomitised grey and white crystalline limestone and marble that is locally interbedded with phyllite and schist. The Kuala

Lumpur Limestone is weakly metamorphosed and is gently folded in places. Superficial deposits comprise man-made fill and underlain by alluvium (Young and Old Alluvium) and saprolite.

Kuala Lumpur Limestone is well known for its highly erratic karst, which is a distinctive terrain developed on soluble carbonate rock. In accordance with Waltham and Fookes (2003), karst weathering observed in Kuala Lumpur is classified as ‘Extreme Karst kV’ with the associated karst features depicted in Figure 4. Karst features commonly encountered in Kuala Lumpur Limestone include pinnacles alternating with deep troughs, filled and unfilled caves, open and buried sinkholes, open and filled cavities, open and artificially widened vertical discontinuities and limestone floaters, solution channels, overhangs, to name but a few.

Figure 4. Extreme karst topography (after Waltham & Fookes, 2003).

The problems are further exacerbated by the fact that the limestone bedrock in Kuala Lumpur area is often overlain by weak alluvium or mine tailings, which are also commonly affected by dissolution of the underlying carbonate rocks. Tan (2006) discusses the occurrence of very weak collapsed soil zones immediately above the level of the limestone and refers to these as ‘slump zones’. Collapse in soils occurs when either rock caves or other large dissolution features fail under tension or when soil flows into an underlying pre-existing cavity as a result of a change in the groundwater regime. This particular geohazard has significant implications for the formation of sink holes and ground settlement which are considered to represent the greatest risk to the works. The formation of sink holes due to dewatering and construction activities in Kuala Lumpur have been well documented (Tan, 2006).

The nature of this formation is one of the considerable challenges and geotechnical risks for this site. It will be discussed in more detail in the subsequent section with the site-specific data.

2.3 Original design scheme and construction sequences

The HKLX box was originally designed to be constructed using bottom-up construction in an area to the east of the box (Gridline 1 – 6) to enable the TBM launch in accordance with the tunnelling programme,

and semi-top down in the remaining areas. It was planned to excavate within a strutted diaphragm wall. There will be 4 rows of temporary steel struts and the 1.2 m thick diaphragm wall will have a toe level of about 20 m below the final excavation level. Cross-lot diaphragm walls will be installed approximately every 15 m along the excavation. A cross section during excavation is shown in Figure 5.

Figure 5. Original excavation support scheme.

The HKLX box was expected to be constructed within superficial deposits above rockhead and the majority of the diaphragm wall which surround the box will also be founded within the superficial deposits, although the rockhead may locally rise above the toe of the wall. Excavation was anticipated to be in ground conditions comprising a mixture of the following materials: man-made fill, recent alluvium, old alluvium.

3 GEOLOGICAL AND HYDROGEOLOGICAL MODEL

3.1 Geological model

The three-dimensional structure in karst terrains is often very complex especially when the karst is classified as extreme, as is the case in Kuala Lumpur Limestone. A thorough review of all investigative holes undertaken including exploratory boreholes, rock probing records, grouting records were used to assess the ground conditions at the site. Figure 6 shows the locations and extent of the investigative holes while Figure 7 gives a general idea about the interpreted longitudinal geological profile across the site.

The elevation of the first encounter with limestone varies dramatically within the site, ranging from as high as 18.1 m on the north of HKLX box to as deep as 102.5 m within a relatively short distance. This remarkably contrasts indicates the characteristic of the very rugged top of karst. Figure 8 shows the possible extremely variable rockhead over the HKLX box structure.

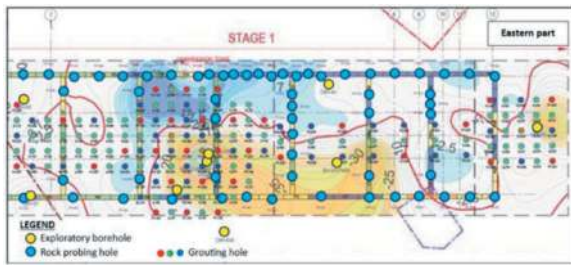

Figure 6. Extent of investigative holes undertaken.

Figure 7. Interpreted longitudinal geological profile.

Figure 8. Interpreted transverse geological profile.

Some boreholes indicated slump zones located beneath the eastern half of the box structure, with the deepest was encountered at BH-UG-PB3AR with SPT value less than 4 blows at depth between 69 m and 96 m from ground level. A three-dimensional model was generated as shown in Figure 9 to have better understanding of the slump zones underlying the HKLX box. However, the dramatic variation of rock-head over short distances suggests that zones of slump materials may be expected to be of limited extent and possibly extending in long narrow zones. These zones are mostly likely to be dictated by the original structure of the limestone which has provided under-drainage and affected its dissolution creating cavities, solution channels, and gullies or ravines between ridges and pinnacles of rock.

On review of available information, the superficial deposits comprise interbedded alluvium that is overlain by man-made fill. The nature of the superficial

Figure 9. 3D subsurface modelling of slump zones.

deposits is also variable both in terms of material type (clay, silt, sand), and density or strength as identified from the results of Standard Penetration Test (SPT). Typically, SPT values fall in the range of 10 to 50 with a small number of results in excess of 50 for tests carried out to a depth of around 40 m to 60 m below ground level. Below this depth the SPT value at some locations falls rapidly to less than 3. The presence of bedding implies that the soils have been transported and deposited. Nevertheless, there was insufficient information available to differentiate between the soils of the Young and Old Alluvium with any degree of accuracy.

3.2 Hydrogeological model

The hydrogeological conditions of the site are generally established based on piezometers and standpipe piezometer installed in the boreholes. The groundwater information obtained during of the boreholes were also assessed carefully. As presented in Figure 10, the measured groundwater levels have been converted into the water pressure at the base of the borehole at the time that the measurement was taken.

Figure 10. Groundwater level monitoring.

The information suggests that there is a perched water table, hydrostatic to +34 RLM in the upper 25 m to 35 m of the soils, with a general water table in the limestone and the soils immediately above the limestone that is hydrostatic to elevation +27 RLM. See Figure 11.

Figure 11. Perched water table condition.

The fact that there appears to be a perched water table at the site indicates that there are relatively lower permeability zones within the upper part of the alluvium, but that the overall mass permeability of the lower part of the alluvium and the limestone is higher (more permeable) than the overlying soils. This has important implications for the design of dewatering system for the HKLX box excavation.

4 GEOTECHNICAL RISKS ASSOCIATED WITH THE CONSTRUCTION

4.1 Ground subsidence caused by borehole drilling

At the onset of site investigation, the boreholes showed soil profiles with generally increasing SPT values with depth and then very low SPT values and reports of drilling rods dropping by several metres. The soils with very low SPT values, in particular which lie beneath firmer soils, were identified as slump material and there was a concern there might be an extensive slump zone underlying the HKLX box with karst limestone beneath.

Not only the identification of slump material, but also records of loss of drilling water, and observations of levels of water in boreholes several metres below the surface are indicators of an underlying drainage system within the limestone which was to be expected. Where soils are dispersive and/or erodible, loss of water from boreholes presents a substantial risk of remobilising flow into the underlying drainage system and of developing a sinkhole.

The first recorded instance of a large ground depression with localised subsidence was when extracting drill rods from borehole BH-UG-PB3A as

shown in Figure 12. That was one of the boreholes where slump zones were identified. The largest localised subsidence occurred during the drilling of grout hole it was centred around a point about 10 m from the borehole. The maximum settlement was estimated at about 1.5 m, forming a conical depression or sinkhole with a diameter of about 27 m. The estimated volume of the depression was 300 m³.

Figure 12. Ground depression occurred during soil investigation.

The presence of karst and slump material has serious implications to the HKLX box structure. This includes not only the design principles due to variable ground support but also the risk of ground subsidence both during construction and subsequent operation. Collapse of slump zone outside the HKLX box will cause undue settlement impacting on the surrounding sensitive structures.

4.2 Unusual ground settlements and building distresses

During the initial earthworks stage, the hostel structure has unexpectedly registered building settlements and movements that breached the predicted design values. There are areas on either side of the eastern half of the HKLX box, adjacent to Hostel Sejahtera, where there has been ongoing and persistent settlement at least since the surface settlement points were installed prior to major site activities. As an instance, the maximum settlement recorded was already 60 mm during diaphragm wall installation. The trend of large settlement and the speed rate of settlement indicates that settlement may have commenced before start of the monitoring, and that only a proportion of the total settlement has been captured by the settlement points.

Correspondingly, building settlement markers indicate that about 10 mm of settlement occurred at nearest corner of Hostel Sejahtera and up to about 2 mm at side of the building away from the excavation which is considered a significant distance from any work on site. While much of the settlement at the nearest point likely reflects that trenching for diaphragm walling, the further point of settlement was likely to be due to consolidation only.

The ongoing settlements of both the ground and adjacent structures was concerning, and the pattern

of settlement was strongly suggestive of being caused by ongoing groundwater drawdown. This situation has the potential to be worse when the full dewatering scheme for the excavation is in progress.

4.3 Seepage/dewatering risks

Most of the standpipes/standpipe piezometers installed at the site have shown a trend of falling water levels since installation, particularly those with any initial reading significantly higher than +27 RLM. The falling water levels in the standpipes are consistent with the standpipes acting as drains, allowing water from the upper, perched water table to drain into the lower aquifer.

Dewatering will be required to lower the water table below the final excavation level and maintain the temporary excavation in dry conditions, therefore preventing base blowout of the alluvial deposits, lowering of groundwater outside the excavation and ensuring the passive pressure support on the diaphragm walls are among the key considerations. From the review of all available data, the possible ground model used for seepage analysis is shown in Figure 13.

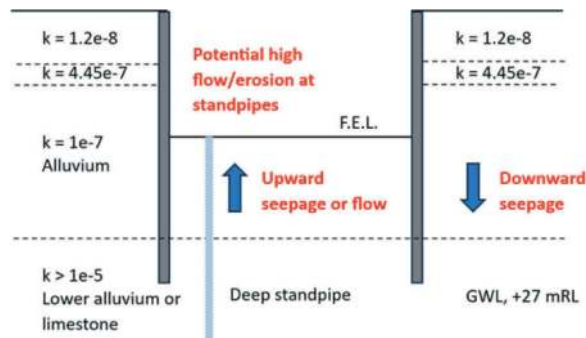

Figure 13. Ground model for seepage analysis.

Based on Figure 13, a number of possible failure mechanisms may occur, such as piping into the base of the excavation due to erosion along the deep standpipes/standpipe piezometers, hydraulic uplift on the base of the upper alluvium exceeding the weight of the upper alluvium in the base of the excavation. If the lower aquifer is deliberately dewatered or is linked to the base of the excavation by the standpipes/standpipe piezometers or wells, then the upper alluvium outside the excavation will be underdrained, potentially leading to further consolidation settlement of the alluvium. On the other hand, significant flow may also occur at steady state conditions through the limestone outside the excavation if preferential high permeability paths, due for example to the presence of cavities, solution channels, and discontinuities in the rock mass, are present within the limestone. Continuous flow through the rock mass from above the limestone outside the excavation may potentially cause loss of fines from the ground overlying cavities with risk of formation of sinkhole if the soil collapses into the cavities.

5 PREVENTIVE AND MITIGATION MEASURES

5.1 Enhancement of temporary works design

The main engineering concept underlying the design of HKLX underground structure is load compensation, i.e. it does not impose any load upon the ground on which it is to be founded that is greater than the load to which that ground is already subjected. The foundation system acquires its resistance from sub-grade reaction below the base slab plus frictional resistance (outer face) of the diaphragm walls against the soil. The toe level of diaphragm wall was determined according to consideration of toe stability rather than vertical load-bearing capacity in order to minimise the potential for disturbance of the slump zone. Resistance to uplift/flotation shall be provided by the diaphragm walls and cross walls shaft friction.

By taking into account the above factors, the mass of the HKLX structure including its foundations was carefully limited such that there is no net increase in effective soil stress at depth. The box structure has been designed to be robust in addressing the known slump zone risks. It was also in a later stage that the temporary works design was further enhanced by introduction of secondary cross walls resulting to higher structural rigidity towards the eastern end of the box to mitigate the adverse risk of damage to the adjacent structures, in particular the Hostel Sejahtera. See Figure 14.

Figure 14. Secondary cross walls added at the eastern portion of the HKLX box.

5.2 Capping and compaction grouting

Prior to excavation, extensive compaction grouting had been performed at pre-determined depths and at targeted risk areas, i.e. within the eastern portion of the HKLX box, to address potential ground collapse and/or migration caused by future development and future progression of the karstic subsurface environment.

The proposed grouting mitigation measure is intended to densify the slump zones and to cap the top of the limestone rock head (if encountered) to prevent collapse/flow of fines into underlying

cavities. The slump zone treatment was based on an observational approach of limiting grout volumes or pumping pressures. The grouting will be terminated once the volume or pressure criteria has been achieved through firstly, delineation of slump zone by primary injection points, followed by secondary injection points then tertiary injection points, as necessary. As shown in Figure 15, the grouting has been concentrated in the area where slump zones have been recorded in the boreholes, and particularly where there were large surface depressions when drilling investigation or grout holes.

Figure 15. Compaction grouting points.

Similar grouting methods were used, largely successfully, to improve soft mine tailings and karstic cavities for the driving of the SMART tunnel (Raju & Yee, 2011). Although carried out at a much shallower level, this prior experience suggests that compaction grouting can have a beneficial effect in terms of improving soft soils in a karstic environment.

5.3 Change of construction sequence

The original planned launching dates were unable to be met due to the unforeseen ground conditions which require a series of ground improvements to be carried out in advance to address the incidents of ground depression/large settlements which happened within the worksite and proximity to the Hostel Sejahtera. In order to avoid further delays to tunnelling program, a proposal was made for new launching arrangement which is from western section of the HKLX box with reduced launch shaft length of 75 m as indicated in Figure 16. This also has beneficial effects as part of settlement mitigation for the eastern section of the box.

Figure 16. New launching arrangements.

By relocating the launch location about 165 m away from the original location, Hostel Sejahtera will be outside the zone of influence of the TBM initial drive.

The western and eastern sections of the box were constructed with differing excavation and construction methodologies. They were separated by a bulkhead wall located at Gridline 6. Splitting the box in this manner allows the eastern section to be built in a semi top-down construction method that will have reduced ground settlements in comparison to a bottom-up construction method.

5.4 Pumping test

As part of a due diligence process, pumping test was conducted prior to bulk excavation at the eastern portion. The primary objectives of pumping test were to evaluate the groundwater regime and the potential adverse impacts that dewatering the excavation may have on adjacent sensitive receivers, in particular Hostel Sejahtera as well as the effectiveness of hydraulic cut-off provided by diaphragm wall. The pumping test was also to help to evaluate whether an impermeable layer and multi-layer aquifer scenario was present.

The pumping test result has eventually verified the presence of a perched water table separated from the sub-artesian aquifer possibly by intermediate low permeability stratum albeit with spatial variance. A degree of vertical hydraulic interconnectivity (drainage paths) has been demonstrated between the upper and lower groundwater regimes. However, the likelihood of significant groundwater drawdown or settlement being induced outside the excavation area during dewatering was anticipated to be limited in view of adequate hydraulic cut-off provided by the diaphragm walls. Besides, the recharge well mitigation measures were already in place and available for immediate activation. Having said that, attention should be given to the potential of encountering high level karstic limestone during excavation and dewatering. The possible presence of preferential flow paths (piping) with the karstic material may potentially adversely impact on the lower aquifer as discussed in section 4.3.

5.5 Control of construction dewatering

To facilitate a dry bulk excavation, a suitable dewatering system was adopted to effectively control groundwater and limit settlements within predicted values. In order to avoid the hydraulic uplift failure when the excavation reached deeper level, additional pressure relief wells and piezometers were installed within the excavation zone of the box, as shown in Figure 17, to release the pore water pressure when required. The tip level of the relief well was defined by assuming the aquitard depth ranges beyond 20 m below the surface. The water pressure was calculated according with the highest piezometer head reading measure from the pumping test results.

Figure 17. Provision of piezometers and pressure relief wells.

As precautionary measure, all the existing boreholes and standpipe/standpipe piezometers were sealed with a grout/bentonite mixture to address and sever a potential groundwater connectivity effect across two aquifers by these devices. The areas disturbed by existing abandoned piles were regouted.

5.6 Other proactive measures

Given the magnitude of ground settlements experienced in the initial stage and the timing requirement for other mitigation measures to be implemented, soakaway holes were installed along the existing box culvert between the hostels and the HKLX site. This was a proactive measure in view of the need to recharge as soon as possible, this passive recharge system will potentially allow a quicker recharge to be achieved, utilising existing stormwater and monsoon runoff flows as water sources. These sources were being channelled into a concrete U-shaped channel and discharged into the Bunus River located to the east of the HKLX site. The soakaway holes were intended to capitalise on the monsoon rainy season in lieu of, and in advance of the active recharge wells being installed around the hostels.

At the same time, recharge wells were installed around at spacing of 20 m to 25 m around the hostels. The purpose of these recharge wells was to actively recharge groundwater levels underneath these structures to at least 1 m below original ground water levels or a minimum 2 m recharge in groundwater levels from the existing observed levels as and when required. Other instrumentation includes standpipes and vibrating wire piezometers, combined inclinometer and extensometers, tilt meters, and building settlement markers were installed as per Figure 18.

6 CONSTRUCTION MONITORING

Similar to other underground construction sites in the project, comprehensive instrumentation and monitoring program was undertaken to provide timely feedback and ensure a safe construction.

The general pattern of ground settlement monitored at the site would be consistent with general consolidation settlement, supplemented by local

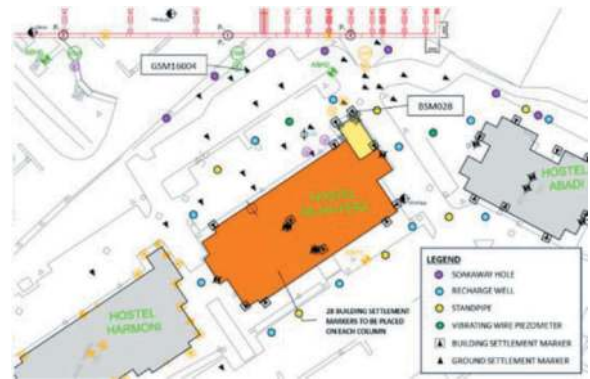

Figure 18. Groundwater recharge system and instrumentation.

settlement due to diaphragm wall installation, and other activities on site such as bulk excavation and dewatering. Figures 19 and 20 respectively illustrate the typical ground settlement and building settlement profiles for the critical area concerned, i.e. surrounding the Hostel Sejahtera. See Figure 18 for the location of the monitoring points.

Figure 19. Ground settlement profile (GSM16004).

The monitoring data showed the majority of the settlement occurred during the initial earthwork stage and when grouting work was carried out. It was thought that this settlement was due to consolidation of the upper strata, due to drainage of the perched water table in the upper strata into the underlying limestone aquifer. Stabilizing trends were observed after completion of diaphragm wall installation, including the cross walls and secondary cross walls.

Figure 20. Building settlement profile (BSM028).

With the mitigation measures implemented and the stability of the ground verified by instrumentation-based performance, the excavation at western portion of the HKLX box proceeded with confidence. Both TBMs were successfully launched from the revised location and bored through the temporary slopes and underside of the plenum slab within the HKLX box before break-through the diaphragm wall. From the monitoring results, the ground and building settlements had stabilized with no appreciable further movements after completion of main basic structures of the HKLX box.

7 CONCLUSION REMARKS

The project site area is underlain by KL Limestone formation, where the rockhead is found to be highly irregular and the presence of network of voids, solution channels, slump zones and floaters. The inherent complex geology with extreme karstic features presents the engineer and the contractor with many unique challenges. Risk management and planning for projects in this challenging environment stemming from a full appreciation of the site history, a comprehensive knowledge of the geological and hydrogeological settings of the site. This would allow an assessment of impacts from the construction method and the consequential risks for the development of a robust risk mitigation strategy. It is necessary to supplement the process by effective implementation of the mitigation strategy and continued monitoring to ensure success.

The challenges of the deep excavation in a karstic environment are predominantly related to groundwater inflow through preferential flow paths due to karstic features resulting in consequential impacts form groundwater lowering, ground settlement and sinkholes. The groundwater lowering could induce a profound effect on the underlying slump zones leading to excessive ground settlement giving rise to damages on the nearby structures and the potential overstressing of the permanent underground railway structure.

This paper presented various robust measures to control and overcome the inherent geological risks present for the project. It is believed that comprehensive grouting cut off in the form of compaction grouting below the excavation base in advance of the excavation serves as the primary and most effective measure to mitigate and minimize groundwater inflow, thus maintain the existing hydrogeological setting as far as practicable. Any pre-existed boreholes and old pile foundations within the site remains a preferential seepage path, the importance

of carrying out grouting to sealing off these features cannot be overstated. To further control the risk of potential heave of the base due to high piezometric water pressure at depth, passive relief well system was installed, if necessary, the passive relief well can be put into action to lower any excessive water pressure to ensure a stable base.

Other risk mitigation measures pertaining to structural aspect include the provision of cross wall below the formation level to achieve a stiffer box structure to cater for unbalance loads and differential movement resulting from the highly heterogenous site conditions. The permanent structure is designed as a floating structure to maintain vertical load balance and avoidance of additional loading onto the underlying slump zone causing undue settlement. The nearby structures have received strengthening and propping to increase their resilience to ground settlement. Extensive instrumentation and an action plan were deployed for this project to allow ongoing assessment of the monitoring results to ensure the performance of the work.

Upon implementation of the robust mitigation measures, the excavation was completed on time and on program. The TBM retrieval and relaunch was successfully completed in accordance with the program. The case history serves as a testimony to demonstrate how good geotechnical understanding, adequate design provision, exceptional construction planning, good construction practice together with a well plan risk mitigation prerequisite can lead the project to ultimate success on time and in a safe manner.

Comparing underground construction risk for urban transportation and hydropower projects – A lender’s technical advisor’s perspective

Andrew Noble*
WSP, Sydney, Australia

ABSTRACT: With the resurgence of pumped storage hydropower as a key enabler for the world’s green energy targets, and with the ever-expanding development of urban tunnels for road and metro transport systems, this paper provides a holistic overview of the key risks related to the underground works for each type of project as viewed from the perspective of the project’s lenders’ technical advisors. Infrastructure across the globe is increasingly heading underground: in urban areas the competition for affordable space forces many new road and rail systems to be in tunnels. Similarly, in remote, large, pumped storage hydropower projects a significant proportion of the scheme is usually located underground but for differing reasons than urban congestion. The categories of types of tunnelling risks in urban transportation projects are similar to those at remote hydropower projects, but the scale and levels of uncertainties associated with those risks can differ widely. For instance, the frequency of drilled geotechnical investigations, and hence the knowledge gained prior to construction, is an order of magnitude larger in the urban shallow transportation tunnel project where typical depths below ground are less than 50m, whereas in large, remote hydropower the average depth may be several hundred metres and the boreholes be spaced significantly further apart. The paper further explores the role of the Lender’s Technical Advisor (LTA) in identifying and mitigating tunnel and underground risks in hydropower projects on behalf of the project lenders. It describes the typical services required to manage the four key phases of: due diligence, pre-financial close, construction financing and operational financing. The paper compares some of the risk management considerations in the planning, design, and construction of tunnels for the conveyance of water versus transportation, from the viewpoint of different stakeholders to the project, but in particular from the project’s lenders, and explores the differences in the typical levels of geotechnical investigation undertaken for these two types of tunnel use.

Keywords: Tunnelling, Risk, Financing, Pumped Hydropower

1 INTRODUCTION

When comparing the pre-construction uncertainties in tunnelling ground conditions between urban transport tunnels and remote pumped hydro project, the uncertainties are much higher in the hydro project. The reasons are many but can be distilled into two key causes: a) the opportunities to undertake cost effective geotechnical exploration at the tunnel depth are better in the shallow depth urban transportation tunnel and b) the urban setting provides a wide range of extremely valuable ‘bonus’ subsurface condition information from previously constructed projects in the locality such as deep foundations for buildings, sewers, deep pipelines, water utility tunnels and rail and metro transportation tunnels. No such bonus information typically exists in remote hydropower projects where the sites are usually greenfield.

Many pumped hydro and hydropower projects have debt funding. In these projects there is usually

a lenders’ technical advisor (LTA) appointed and embedded in that role representing the lenders, are a wide scope of services, encompassing both engineering and environmental and social aspects. Terminology varies between projects and the LTA role is also known as the Independent Engineer, Bankers’ Engineer, Lenders’ Independent Consultant, or Independent Certifier. The entity is selected jointly by the lenders and the project developer (the borrower of the loan from the financiers) but is usually contractually appointed, and the LTA’s services paid, by the developer.

2 WHAT TUNNELS ARE REQUIRED FOR PUMPED HYDRO?

Pumped hydro is increasingly prevalent in countries where wind and solar renewable energy have expanded. The grid requires stability which is

*Corresponding author: andrew.noble@wsp.com

offered by the near instantaneous electrical power when a pumped hydro scheme starts up in generation mode and it can be used to balance the supply when other supply schemes have fluctuating outputs.

The concept is to use a closed system of stored water, of fixed volume (excluding evaporation from the reservoirs), to generate electricity by allowing water to flow by gravity from an upper reservoir to a lower reservoir through tunnels, shafts (or surface penstock pipes) and turbines. The same water is later pumped up from the lower to upper reservoirs through the same waterway facilities to refill the upper storage reservoir.

No two pumped hydro projects are the same and there is no pre-defined template for what features must be included. In terms of the underground works, a focus of this paper, the differences between the underground elements required for a large, pumped hydro and a conventional generation-only hydropower scheme, are small. This is because the pumped hydro still acts as a conventional hydropower scheme while in generation mode, operating almost the same as a conventional generation scheme. In the pumping mode, when water is pumped uphill back through the same tunnels and shafts waterways, conditions are generally similar and so there are very few material differences in the waterways except for possibly the requirement for additional surge chambers and tweaking of junctions to allow efficient water flow in both directions.

A key aim of the designer for pumped storage schemes is to develop as much head (the pressure differential between upper and lower storage reservoirs) over as little horizontal distance as possible, in other words to minimize the L/H ratio. This is principally for economic reasons and means that the tunnel waterways designer needs to understand the economic driver for the optimum layout.

A high proportion of total civil engineering costs will be associated with the tunnels and shafts in a typical pumped hydro scheme because the head is created within the underground works and the storage reservoir embankments/ dams are usually only low to medium height. Whilst not in the same league as large dams they will likely be categorized for dam safety purposes as 'large dams' due to extreme consequences of failure.

The greater the operating head usually means the greater the constructability challenges. Deep shafts usually more than 300m, and up to 1,000m deep, are often required in such schemes and an obvious optimisation is to consider reducing the total waterway length by making a steeply inclined shaft and shortening the lower tunnel length; conceptually this all makes good sense providing that the time and cost and risks are appropriately considered with experienced constructors during the design phase. A vertical raisebore shaft say 500m deep is far more straightforward than an inclined 60-degree shaft of similar depth although there can be significant cost savings in material costs in shortening the overall waterway

lengths especially if the shaft and lower tunnel are to be steel lined, and there are plenty of precedents where the steeply inclined shaft was selected.

3 THE LENDERS' TECHNICAL ADVISOR'S ROLE

The lenders and owner (borrower in this context) will have similar objectives for the project – they each want a successful project delivered safely, on time, and to budget. This is not surprising if we consider that the lenders are effectively the majority owner over the tenure of the loan which is usually 10 to 15 years after the completion of the project.

The LTA represents the lenders across a wide spectrum of technical issues that could arise over the lifetime of their involvement in a project. Flexibility is a key attribute for the LTA, including having the depth of in-house expertise to cope with issues that arise during any of the four key phases of services (due diligence; pre-financial close or 'bankable' stage; construction monitoring; and operations).

The LTA is usually engaged in the pre-financial close stage to undertake a due diligence assessment of the project, once the draft construction contract(s) is available for review, and then continues long after the opening or completion date to monitor the technical and commercial performance of the project.

The lender that engages the LTA is looking for advice on contractual and engineering topics, as well as the growing importance in environmental, social and governance (ESG) matters. With the lenders' reputation at risk if a project fails to follow good ESG practice, the importance of independent monitoring and reporting throughout the construction and operations periods is clear.

The LTA needs to undertake a materiality test for any issues – could it materially impact the lenders' interests? If not, the LTA should not be bringing such issues to the financiers.

4 TYPES OF UNDERGROUND RISKS

4.1 *Overview*

In remote hydro projects which are likely to be located in steep terrain, and possibly sited beneath national parks with restricted access, the available open space for tunnel portal establishment is usually constrained which puts pressure on the environmental management of water management and the siting of adequately sized sedimentation tanks. Achieving a high environmental and sustainability scorecard for the project is important to lenders as most will be committed to supporting projects incorporating ESG good practice and high levels of environmental and social safeguards into their credit approval process. This example is used to provide some balance to the more obvious risk in tunnelling, the ground conditions

uncertainty, which has the potential to dramatically change the time and cost to construct the tunnels.

Lenders will expect the LTA to examine the project in detail to assess that the project will function as planned and produce the revenues needed to meet operating costs and service the debt. Hydropower tunnels earn their position as part of a revenue generating project by delivering water to a generating turbine, whereas a road tunnel earns its payback position through access to vehicles paying toll revenues.

4.2 *Delay in completion*

A major construction delay will likely exceed the cap on the liquidated damages (LDs) for delay applied against the contractor, as beyond those periods, the developer tends to bear most consequential risks (typically the monetary value of caps is 10% of the Contract Price and daily LDs set such that the cap is reached linearly after 6 – 9 months of delay). From general precedents of hydropower tunnels construction in remote locations the lenders may be advised of three broad categories of reasonable expectations of delays:

- 3+ months for a realistic potential delay (statistics show that actually, this is probable)
- 6+ months for the possible delay of an unforeseen event with major consequences
- 12–18 months or more for major unforeseen conditions resulting in an extreme delay (these durations of delay are significant, probably beyond the Sunset Date in the finance agreement and may trigger some form of loan restructure).

The LTA would give an opinion on the probability of occurrence and recommend the level of stress testing to be applied to the borrower's financial model to account for such scenarios.

4.3 *Failure after operations commence*

Tunnelling delays are more likely to occur during construction, leading to a delayed commercial operation date. Unfortunately, however, there are numerous examples of headrace tunnel collapses early in the operational phase which have led to very serious outages in the operational phase and the consequential costs to the owner at this stage are significant. Unlined tunnels, unless located in extremely competent rock, are susceptible to changed conditions at or just beyond the rock inner face, which over time and after subjected to internal water pressure can deteriorate leading to a loss in the self-supporting mechanism.

5 KEY FEATURES OF THE TUNNEL TYPES

5.1 *Urban transportation tunnels*

The dominantly used tunnelling techniques in urban schemes are tunnel boring machines (TBMs) and

roadheader; drill-and-blast excavation is used but is much more rare. TBMs are usually well suited for long transportation tunnels and their abilities to navigate the long radii dictated by functional requirements of alignment/ geometrical grounds for road or rail are not normally onerous for TBMs. The typical long tunnel lengths in major transportation projects justifies their use.

In urban settings the depth below surface is modest; typically less than 50m is the norm in relatively level surface urban terrain, and much shallower at stations in the case of rail schemes.

5.2 *Pumped hydro and hydropower tunnels*

5.2.1 *Types and constraints*

The pumped hydro tunnel designers have more geometrical freedom to suit the functionality of the tunnels and can take advantage of the absence of the tighter geometrical constraints applied to the transport tunnel. However, the hydropower pressure tunnels that may appear to be simplistic because they are usually circular and only carry water, not vehicles and passengers, are subjected to a very different set of operational conditions to urban transport tunnels.

5.2.2 *River diversion tunnels*

River diversion tunnels feature high on the risk assessments of hydropower projects: their function is to have a short operational lifespan, say two to three years (up to three wet seasons), while carrying high velocity silt-laden abrasive river water and probably flood debris through the tunnel. These tunnels are normally on the first stage critical path which is governed by seasonal river flows thus placing increased pressures on the organizational skills of the newly mobilized site team.

Unless the project's dam construction phase can withstand a potential delay equal to the length of a wet season or more, a missed river diversion date will be very costly and so the tunnelling schedule is normally non-negotiable. Given that for many projects the actual contractual commencement date is rarely as planned it is even more important to understand the implications of river diversion scheduling. A major project risk with emerging climate change conditions is the early onset of an annual wet season bringing early floods in the river and the construction team needs to have robust contingencies in place.

The designer needs to understand what range of flows and possible debris or siltation loads could be carried through the tunnel. Flat or large-radius inverts are commonly used because they offer advantages for construction equipment and in times of lower dry season diversion flows the erosion forces from heavy silt loads are better distributed over a wider surface. The long-term durability aspects may be of lesser concern if there is to be no future use of the diversion tunnel, however there is

normally at least part of the tunnel that becomes connected to an outlet or is plugged with a flooded section upstream, thereby requiring that the tunnel still be designed for the full project life.

The main duty however is to withstand the high velocity conveyance of the river diversion flows and to ensure that it has a very robust lining that meets the hydraulic requirements and is not adversely affected by erosion from silt or damage from debris. The diversion tunnel will be subjected to relatively low internal pressures during its diversion phase.

5.2.3 *Main waterway tunnels*

Headrace tunnels carry water towards the turbines in generation mode and will operate at low or high internal pressure depending on their setting level below the upper reservoir. In smaller run-of-river schemes some headrace systems adopt open-channel (non-pressurised) flow and may not even be within a tunnel.

The tailrace tunnels, as defined in a conventional hydropower project or in a pumped hydro in generation mode, return the water back to the river (or lower storage reservoir) after passing through the turbines. They operate at a lower pressure than in the headrace system as the turbine-generators extract the energy from the head for the generation of electricity.

These tunnels will likely be fully lined, normally having a circular profile or at least a D-shape with semi-circular crown, lined either in concrete or steel (not shotcrete, this is ill-advised). The adoption of unlined waterway tunnels is now rare on safety during construction grounds, therefore this paper concentrates on those which are fully lined.

5.2.4 *Access and service tunnels and caverns*

Hydropower schemes that contain headrace tunnels, shafts or caverns will require access tunnels and adits. For schemes with a powerhouse cavern there could be several kilometres of tunnels spiralling down from the surface to cavern level. A modern cavern arrangement requires a complex arrangement of various openings: access/ egress adits, ventilation/ cable tunnels, shafts, surge tunnels, etc. Consideration must therefore be given to flooding of the decline during construction or in the operational stage, permanent dewatering arrangements and provision of fresh air to the decline(s) during maintenance inspections. Fire and life safety aspects including emergency egress provisions are also very important considerations.

5.2.5 *Hydropower tunnel construction methods*

TBMs are well suited to most long headrace and tailrace tunnels, typically justified where the length is at least 500 times the diameter, but they are not suited to the scheme's complex warren of tunnels in the vicinity of powerhouse caverns due to the tunnels' steep grades and tight curves.

In remote areas, the use of drill-and-blast tunnels with multiple headings remains the most common method of excavation. When considering, for example, a 20 km length of transfer tunnel of diameter 7 m, there will be clear advantages and disadvantages for both the TBM and drill-and-blast options. The 7 m diameter sits neatly within the constructability comfort zone for both methods, so the decision comes down to scheduling due to its length, economics, logistics and availability of suitably skilled labour and back-up. A 20 km tunnel is too long to be justified for a single TBM given the likely project time constraints that most projects have, so therefore two or three TBMs might be considered viable to meet the schedule and budget. However, the mobilisation of multiple TBMs to a remote area is a major undertaking. With modern computer-controlled drilling jumbos the progress rates in drill-and-blast are impressive, despite the likely need for multiple access adits to be constructed to service the multiple drill-and-blast headings.

6 KEY COMPARISONS OF THE GEOTECHNICAL INVESTIGATION PROGRAMMES

As shown in (Noble 2023a) the differences in the levels of investigations typically undertaken for the two types of tunnels are far apart. The reasons are numerous, and some key reasons are explained in the next sections which consider a simplified example of a 15km long project; a shallow depth urban rail tunnel, comprising twin tubes, and a large and remote hydropower project spanning 15km overall length of waterway tunnels.

For a not dissimilar cost, both projects might undertake a comparable amount of total subsurface drilling, however the targeted and most relevant data obtained from the very deep holes in the hydro project would be significantly less frequently spaced than in the urban rail project.

Let us consider two similarly sized tunnelling projects:

- An underground railway or Metro within a city. 15km length, twin tunnels of 7m diameter, and seven station boxes, average depth to crown below surface of 40m (so six stretches of tunnels between stations each length 2.5km, ignoring station box lengths)
- An underground high-head hydropower (or pumped storage hydro) project: 15km of waterways length, single waterway comprising headrace tunnel, pressure shaft, pressure tunnel and tailrace tunnel, all 7m diameter, varying depth to crown below surface ranging from 100m to 800m.

The railway tunnel project will have relatively easy and cost-effective access to drill holes closely

spaced along the alignment which when added to the existing data knowledge from the built environment such as other tunnels and buildings with deep foundations, the data bank is very large.

The hydro project must start from almost zero existing first-hand knowledge of the conditions at depth. It is unlikely that any nearby projects would have any data at depth and if there were the extrapolation assumptions would be high; and quite likely for there to be nothing at all already available. To reach a tunnel located 800m below the surface will require a hole of slightly longer than 800m deep to be drilled, to obtain the primary data from within the 35m long primary data zone, hence most of its length is 'secondary' and necessary just to reach that zone.

6.1 *Drilled boreholes for urban transportation*

The urban transportation tunnel, either for road or rail, will be in areas where access is generally easily obtained through special permits to undertake drilling. Access can be challenging but normally very achievable, with good access to back-up support.

The urban rail or road tunnelling project will very likely have access to subsurface geotechnical data at an average of much less than 100m spacing along the tunnel, and in some zones have several boreholes concentrated together. For this comparison between the two types of tunnelling projects, consider there are new boreholes funded by the rail project at feasibility or tender stage at 100m spacing along a 15km alignment starting in a CBD and reaching out to the suburbs. This ignores the additional holes for the stations, some of which might even be in caverns, so this baseline data set for the rail project is a low estimate. The average hole depth will be less than 60m (~40m to crown plus the tunnel D plus the 1.5D below the tunnel), making a total drilled length of 8,625m based on 150 boreholes.

6.2 *Drilled boreholes for pumped hydro and hydropower*

Compare the above example with drilled boreholes for the remote hydro project having just ten boreholes planned over the 15km long scheme ranging in depths from surface to tunnel crown from 100m to 800m. Other holes would be needed for service tunnels used to gain access down to the caverns, however this example just compares the power system waterways as it can be simply envisaged as a comparison with the urban rail tunnel example previously described. Eight holes are for exploration of tunnels and caverns at varying depths and two holes are for shafts.

This programme could yield a total drilled length of 4,425m based on 10 boreholes.

6.3 *Why is there such a difference?*

Again from (Noble, 2023a), boreholes drilled in the geotechnical investigation program are planned to target a primary data zone (PDZ) in the vicinity of the tunnel itself. This is to obtain data directly within the envelope of the proposed tunnel opening size plus immediate influence zones surrounding the tunnel opening. For shallow tunnels in the urban setting typically the PDZ will overlap with the whole of the zone above the tunnel up to the ground surface, as data within that entire zone in an urban setting is considered primary as it needs to be modelled for potential interaction between the proposed tunnel structure and the surrounding existing structures, for example to assess the potential surface or subsurface settlements.

For deep tunnels, typically those for hydropower in the several-hundreds of metres depths, boreholes will also yield secondary data as the hole is drilled from the surface to reach the PDZ. Whilst the secondary data is important for building a geological model, it is considered herein as secondary as it has far less direct influence on the tunnel structure design than that generated from the PDZ information.

The above descriptions of primary and secondary data zones are highly simplified but used here to illustrate one of the key reasons why the amount of primary data obtained for remote and deep hydropower tunnels differs so much from the primary data obtained for urban transportation tunnels. Cost of the boreholes and environmental constraints for access for drilling are major factors, but the depth to simply obtain the critical information from within the PDZ is the underlying reason.

6.4 *Cost comparison and value for the effort*

The comparative cost of the two drilling campaigns is not assessed here, however given the relative ease of undertaking 150 shallow depth urban holes with a total drilled length of 8,625m compared to the challenges of mobilizing workers, equipment and consumables to undertake 10 deep remote holes in mountainous terrain with a total drilled length of 4,425m the overall costs may not be too different. However, the urban project yields a magnitude higher degree of frequency of PDZ information. If the cost was similar, the risks must be significantly higher for uncertainty of ground conditions in the hydropower project.

Another metric such as the number of boreholes per km length of tunnel would be for the above examples:

- The rail project: 10 holes per km
- The hydropower project: 0.67 holes per km.

7 RISK MANAGEMENT ON BEHALF OF THE LENDERS

7.1 Overview

The preceding sections set the scene that there are usually fairly high uncertainties in tunnelling ground conditions, especially in remote hydro tunnels. The LTA has a core role associated with risk management for the underground works, whether at the initial due diligence phase, throughout the construction phase, or into the operational phase.

The project's contractual arrangement will identify where the risk apportionment lies between the owner and contractor(s). A contracts review will be undertaken, and the LTA will liaise with the lenders' legal advisors in the due diligence phase when several advisors will be undertaking separate due diligence assessments – such as technical, legal and insurances.

As covered in (Plummer 2022a), key findings from the analysis which focused on large hydro-power projects in low- and lower-middle income countries suggested that many of the greatest risks associated with large hydropower projects are those that may cause reputational damage to the parties involved, such as social and environmental risks.

7.2 Geotechnical uncertainty

Several key issues must be addressed at the outset of a feasibility study or reference design:

- How many boreholes are sufficient?
- How many boreholes are affordable, and achievable, given access constraints?
- What alignment shall we drill, knowing that alignments may change?
- What can we defer to a later stage and leave to the EPC contractor, and would this be a wise decision to take?

These questions arise in most projects, and it requires experience of what is important to make those decisions, but there must be a minimum level of investigation that needs to be done prior to construction tendering, and prior to obtaining credit approval from the lenders.

It is recommended that a two-stage feasibility study is arranged which allows investigations to be tailored towards the preferred options, but there is no avoiding having to invest in some 'at risk' speculative investigations on which to base initial designs (Plummer, 2022a). This is a risk the developer needs to take. A key message from this is that the developer will end up paying to deal with the geotechnical conditions but will ultimately likely pay less overall if more is spent upfront simply because a civil contractor will add a price for the risk element which outweighs the cost of investigations.

For hydropower projects a significant proportion of the risks is in the tunnelling and underground

works (McWilliams, 2014) (Plummer, 2022a and Plummer, 2022b), mainly due to uncertain ground conditions associated with the fact that it is significantly more costly, difficult and time consuming to obtain the same level of geotechnical exploration for deep and remote hydropower tunnels than would normally be obtained for shallow depth urban transportation tunnels (Noble, 2023a). Contractually this aspect needs to be made clear as to which party takes the risk of changed ground conditions from the conditions known at contract signing, and the lenders are very keen to understand how the downside scenario risk profile would affect the borrower of their loan (Noble, 2018).

7.3 Contractual risk and apportionment for price and time uncertainty

Whichever contractual arrangement is pursued, such as single EPC contract or split contracts, the lenders will look for assurances that the project features are sufficiently developed to be compatible with the contractual mechanism in the construction contract and will look for risk mitigations for cost and time risk such that the borrower is not over exposed. In the case of the tunnelling components of a project this may have a separate contractual mechanism linked to a risk sharing concept, but if this is done the lenders would still want to know the potential downside scenarios for its borrower.

It is reasonable to assume that the differential in pre-construction stage data between the urban transportation tunnel project and the remote hydro project will remain broadly similar throughout all stages of each project. At the initial concept stage, the urban transportation tunnel project will be far ahead of the remote hydro tunnel project in terms of existing knowledge of expected ground conditions, due to the presence of existing city-wide geotechnical data. At best the hydro project will have benefitted from a geological walkover of just the accessible areas, but these are surfaces located several hundreds of metres above the proposed tunnels.

Ultimately the remote hydro tunnels will never match the urban tunnels for metrics on data gathering. Therefore, the contractual mechanisms for tunnelling in the remote hydropower need to be in place for appropriate risk apportionment to deal with the inevitable higher levels of uncertainty than exist in the urban setting. To deal with this there is a growing trend for at least the underground elements of hydropower projects to have a risk sharing mechanism to deal with the inevitable lower levels of certainty in geological conditions.

In large hydropower projects comprising tunnels as well as dams, electro-mechanical works, transmission lines and other supporting infrastructure, the underground works costs may not dominate the entire project cost. However, the unforeseen risks lie mostly here and so a target price type of contract can be developed with only the under-ground works

subjected to such an approach. This gives a better risk apportionment between the employer and the contractor and does make sense given that the owner essentially owns the ground through which the contractor is contracted to excavate.

The relatively new FIDIC form of contract, Conditions of Contract for Underground Works (2019 Emerald Book) is a welcomed new approach which covers risk apportionment of the underground works and is very relevant for use in hydropower. In conjunction with a geotechnical baseline report (GBR), which sets the boundaries of certain geological characteristics as derived from the pre-tender stage site investigation, and thereby sets a trigger level for exceedance, the target price mechanism (TPM) aims to deal with risk apportionment between the owner and the contractor.

8 CONCLUSIONS

The risk profile on the underground works from the lenders' perspective evolves over the life of a hydropower project, from due diligence (pre-financial close) stage, through construction financing and the operation financing, but it does not diminish altogether. Most attention is paid at the pre-financial close phase as this is when the lenders' influence, through the LTA and their other advisors, can impose further risk mitigations if considered necessary.

The LTA role may take a variety of pathways depending on the issues arising on each project. In the author's experience, the major issues are not always of a pure engineering nature, but related to deficiencies in owner's staffing levels, contractor resourcing, scheduling delays or environmental and social aspects.

In urban transportation tunnelling projects, the risks categories are similar to those at remote pumped hydro and hydropower projects, but the scale of those risks due to levels of geotechnical uncertainty can differ widely. The frequency of drilled subsurface geotechnical investigations is an order of magnitude larger in the urban shallow transport tunnel project where typical depths below ground are less than 50m, whereas in large scale and remote hydropower the tunnels may be up to several hundred metres deep. The spacing of drilled holes is therefore significantly further apart in the remote setting. Consequently, the useful data package is far more plentiful in the urban transport project.

For what could be a similar cost in undertaking the two different geotechnical investigation campaigns, the results from the two examples showed that the urban tunnel yielded 4 times the amount of directly targeted PDZ data than the hydropower project, and that PDZ data was distributed 15 times more frequently spaced along the tunnel alignment. This is further evidence that the urban tunnel will have a much lower risk profile for geotechnical uncertainty when compared to the remote hydropower tunnel.

No two transport or hydro projects are the same but there is a compelling argument for the adoption of increased site investigation in the remote hydropower project, together with a compelling case for the adoption of a robust risk sharing contractual mechanism.

ACKNOWLEDGMENTS

Acknowledgements for the insights into this paper are extended to all the project teams and people that I have had the pleasure to work with in the transportation tunnelling and hydropower tunnelling industries worldwide. The experiences and lessons learned formed the basis of what is written.

Underground risk and ESG aspects in pumped hydro and hydropower projects – What worries the lenders?

Andrew Noble*

WSP, Sydney, Australia

ABSTRACT: Large scale pumped hydro and hydropower projects are complex developments and take several years of planning, design, assessment and contracting, followed by at least 4-5 years of construction, to reach the principal goal of generating electricity. Key concerns for lenders over the project lifecycle are the risks which may eventuate on environmental, social and governance (ESG) aspects and risks to the project outturn cost and completion date. The former are reputational issues, and the latter are financial issues. This paper assesses the question: “What worries the lenders?”.

Firstly, dealing with ESG aspects for underground works, these are very wide ranging across the lifecycle of hydro projects. Lenders will typically be involved across four key stages of hydro project development: due diligence phase, pre-financial close (“bankable”) phase, construction phase and operational phase. Each phase brings a different focus with the accumulated lenders’ risk exposure (a blend of financial, technical, stakeholder and a variety of ESG issues), all ebbing and flowing as the project evolves. The paper explores the changing ESG risk landscape from the perspective of the project lenders.

Secondly, the uncertainty on the outturn cost and completion date are key elements of the techno-commercial risk position for the project. Most uncertainties in large, pumped hydro and hydropower projects tend to lie in the tunnelling and underground works and project-wide geotechnical and geological disciplines, as the ability to explore these thoroughly, for various practical, cost limitations or environmental reasons, is very low in most projects (especially when compared with the levels of ground investigation usually undertaken for large transportation tunnels in urban settings). Significant changes in encountered ground conditions, whether for the dams and reservoirs or in the tunnels and caverns, can lead to cost overruns and delayed completion and hence delayed revenue streams. The paper explains why this is so, explores the financial model stress testing to assess such scenarios, and makes some interesting comparisons from the hydro industry with the levels of exploratory investigations undertaken in large transportation tunnels in urban areas.

The paper explores the above risks through the ESG lens, and the ESG impacts and benefits of tunnels and underground solutions in these large projects.

Keywords: Tunnelling, Risk, ESG, Pumped Hydro

1 INTRODUCTION

Large scale pumped hydro and hydropower projects are complex developments and take several years of planning, design, assessment and contracting, followed by at least 4-5 years of construction, to reach the principal goal of generating electricity. Key concerns for lenders over the project lifecycle are the risks which may eventuate on environmental, social and governance (ESG) aspects and risks to the project outturn cost and completion date. The former

are reputational issues, and the latter are financial issues.

The resurgence of pumped hydropower projects in Australia for example, has led to rapid learning curves for developers, most of whom are private entities, and with this the types and scales of development risks across all stakeholders are numerous and large. Coupled with modern and tighter ESG obligations, the pathway is complex. The whole tunnelling industry needs to awaken to tightening ESG requirements across all forms of tunnelling

*Corresponding author: andrew.noble@wsp.com

infrastructure, whether it is for transportation tunnels, water supply, utilities or the expanding field of pumped hydropower.

The uncertainty of the outturn cost and completion date are key risks for the project. The highest uncertainties tend to lie in the tunnelling and underground works, dams, and project-wide geotechnical and geological disciplines, as the ability to explore these thoroughly, for various practical, cost limitations or environmental reasons, is low in most projects. Significant changes in encountered ground conditions, whether for dams and reservoirs or in the tunnels and caverns, can lead to cost overruns and delayed completion and hence delayed revenue streams.

2 KEY ESG ASPECTS

2.1 *Overview of ESG aspects*

The Hydropower Sustainability Assessment Protocol, a product of the International Hydropower Association (IHA) is a tool for assessing projects across a range of social, environmental, technical and economic criteria. It is highly relevant to project developers and to all stakeholders in large hydropower projects which have significant underground works.

Some key ESG risks are presented below.

Environmental risks:

- Flora and fauna impact
- Impacts on water courses, either during construction or over a longer period, from abstraction or water movement and mixing
- Approvals timeline and the risk of having to repeat baseline studies to align with revised engineering approaches.

Social risks:

- Ownership of land.
- Community acceptance.
- The social licence.
- Resettlement or relocation (which are not the same), for example in developing countries.

Governance risks:

- How the project is procured
- What regulatory controls are in place
- Compliance with local and international ESG safeguards guidelines (for example, International Finance Corporation's Performance Standards or the Asian Development Bank's various Safeguards mechanisms).

2.2 *Lenders' credit approval incorporating ESG*

For a project to be successful in bridging the knowledge gap between the feasibility study and the requirements to reach financial close in the most

efficient timeline, the feasibility study needs to be a very good study, have clear and defensible options assessment and to have adequately covered all the topics that lenders will require to have been addressed.

Lenders care about whether the project will generate adequate cash to repay the loan plus a margin against lower performing generation. Foremost these days, lenders care deeply about doing the right thing with regards to ESG matters and are very alert to the potential for reputational damage that will result from improperly planned and implemented projects.

In all of the three main types of hydropower (pumped hydro; conventional generation-only reservoir hydropower; and run-of-river hydropower) and across the range of sizes from mini-hydros at <5MW capacity to the mega projects at >2,000MW, the entirety of environmental and social aspects (being the E and S in ESG) have been assessed for decades. The current spotlight on the environmental and social aspects of ESG is therefore not a new approach at all. However, the equal focus on the governance of projects (the G in ESG) has formalised the entire ESG requirement. This formalisation has elevated the importance of ESG to Boardroom levels for all stakeholders in a project – owners, contractors, consultants, lenders, etc., and it continues to be a key element to be satisfied to obtain the Lenders' credit approval for debt funding to a project.

2.3 *The four phases of lenders' involvement*

Lenders will typically be involved across four key stages of hydro project development: due diligence phase, pre-financial close ("bankable") phase, construction phase and operational phase. Each phase brings a different focus with the accumulated lenders' risk exposure (a blend of financial, technical, stakeholder and a variety of ESG issues), all ebbing and flowing as the project evolves.

3 WHAT TUNNELS ARE REQUIRED FOR PUMPED HYDRO?

Pumped hydro is becoming increasingly prevalent in countries where wind and solar renewable energy have expanded. The grid requires stability which is offered by the near instantaneous electrical power when a pumped hydro scheme starts up in generation mode and it can be used to balance the supply when other supply schemes have fluctuating outputs.

The concept is to use a system of stored water, of fixed volume (excluding evaporation from the reservoirs), to generate electricity by allowing water to flow by gravity from an upper reservoir to a lower reservoir through tunnels, shafts (or surface penstock pipes) and turbines. The same water is later pumped up from the lower to upper reservoirs through the same waterway facilities to refill the upper storage reservoir.

Tunnelling for hydropower projects is a very challenging component of the overall development. In contrast to urban transportation tunnelling where the logistics for access and supply of electrical power, water and other essentials are readily available, hydropower projects are usually in very remote locations with challenging steep terrain and all necessary plant, equipment, spares and materials need to be brought in and the site must function as a self-sufficient unit.

For a large scheme the river diversion tunnel(s) are usually on the initial phase critical path to meet the non-negotiable deadline of river diversion before the onset of the next wet season. A newly formed tunnelling crew, once mobilised to the site for the project, will face the first major learning curve of the project's systems and logistics during this first and critical tunnelling activity. This is a challenge at a time when project systems and procedures are still being developed and fine-tuned.

Power tunnels convey the water to the turbines in the powerhouse and are usually on the critical path for the main works, especially if the scheme comprises a powerhouse located within an underground cavern. A modern cavern arrangement requires a complex arrangement of various openings: access/egress adits, ventilation/cable tunnels, shafts, surge tunnels, etc. All of these underground features have an impact to the ESG aspects of the project as they require rock spoil to be removed, possibly processed, and water managed to permit acceptable deposition. The assessment of the treatment and disposal of tunnel spoil and water is one of the biggest ESG aspects to be assessed for underground works for a large hydro project.

4 THE LENDERS' TECHNICAL ADVISOR'S ROLE

The lenders' technical advisor's (LTA) services and scope are always tailored to the lenders' needs for the particular project and their perceived key areas for concern, but with a largely common underlying terms of reference for most LTA roles. The LTA - also commonly termed the Independent Engineer, Bankers' Engineer or Lenders' Independent Consultant - is selected jointly by the lenders and the project developer (the borrower of the loan) but usually contractually appointed and paid by the developer. However, the LTA's selection process is rarely as straightforward as just described, given that the lenders will tend look for experience, reputation, and quality, whereas the developer will additionally be looking for the most competitive price for those services. In most cases the LTA services also include environmental and social monitoring, which is not always obvious from the term 'technical' in the role title. The increased spotlight on ESG issues has tended to increase these tasks within the typical LTA role.

The lenders and owner (the borrower in this context) will have similar objectives for the project – they each want a successful project delivered safely, on time, and to budget. This is not surprising if we consider that the lenders are effectively the majority owner over the tenure of the loan which is usually 10 to 15 years after the completion of the project.

The LTA represents the lenders across a wide spectrum of technical issues that could arise over the lifetime of their involvement in a project. Flexibility is a key attribute for the LTA, including having the depth of in-house expertise to cope with issues that arise during any of the four key phases of services (due diligence; pre-financial close or 'bankable' stage; construction monitoring; and operations).

The LTA is usually engaged in the pre-financial close stage to undertake a due diligence assessment of the project, once the draft construction contract(s) is available for review, and then continues long after the opening or completion date to monitor the technical and commercial performance of the project.

The lender that engages the LTA is looking for advice on contractual and engineering topics, as well as the growing importance in ESG matters. With the lenders' reputation at risk if a project fails to follow good ESG practice, the importance of independent monitoring and reporting throughout the construction and operations periods is clear.

The LTA needs to undertake a materiality test for any issues – could it materially impact the lenders' interests? If not, the LTA should not be bringing such issues to the financiers.

5 TYPICAL ESG CONSIDERATIONS FOR TUNNELS

5.1 Overview

Tunnels and other underground works may appear to be quite benign to ESG concerns. They will mostly not be visible at all, except for portals and shaft tops, etc. but their construction, and the potential for underground fire during operation, could lead to major ESG issues if not properly addressed at the design stage.

Some examples of ESG elements which need to be addressed are described below.

5.2 Environmental

- Water management: either from groundwater or water used for construction.
- Sediment removal: sediment ponds are required at portals to allow settlement of suspended solids prior to discharge of the water and the removal of the solids.
- Spoil disposal: large volumes normally need to be disposed of in a safe manner. If stockpiled at a remote site, using engineered methods and not

simply tipped to a natural angle of repose of the material.

- Contamination: of groundwater, water bodies or into the environment.
- Spills: of liquids and hazardous materials.
- Noise and disturbances.

5.3 *Social*

- Truck movements: strict monitoring and time of day usage.
- Safety considerations in the communities.
- Worker influx and interactions with community.

5.4 *Governance*

- Contractual requirements
- Conditions Of Approval (COA) linked to the environmental impact assessment
- Ownership and responsibilities for implementing the COAs, i.e. the governance.

6 RISK MANAGEMENT ON BEHALF OF THE LENDERS

6.1 *Overview*

In Project Financing, considerable attention is paid to risk and there are several unique features and risks associated with pumped hydro and hydropower projects that financiers need to be aware of. Lenders will examine the project in detail to assure themselves that the project will function as planned and produce the revenues needed to meet operating expenses and service the debt. The role of the LTA is to identify risks that might influence the viability of the project or affect the borrower's cash flow from the operational revenue and offer strategic advice on how to avoid or mitigate those risks. The lenders expect their technical advisors to point out whether the technology adopted is appropriate and what are the potential or realised items of concern (for instance, the selection of tunnelling methods when faced with a choice between a tunnel boring machine or a drill-and-blast technique).

As mentioned previously, the ultimate objectives of the developer and lender are the same – a successful project that delivers a satisfactory and sustainable financial return. The LTA's duty of care is to the lenders, whose objectives are largely aligned with the developer's.

Delays in completion can be serious events, in particular if the delay period exceeds the cap on the liquidated damages applied to the contractor, as beyond the period when the cap is reached (typically 6–9 months), the developer tends to bear most consequential risks. From general precedents of

hydropower tunnels construction in remote locations the lenders may be advised of three broad categories of reasonable expectations of delays:

- 3 + months for a 'realistic potential delay' (this should be considered as highly likely)
- 6 - 12 months for the possible delay of an unforeseen event with major consequences
- 12 – 24 months or more for major unforeseen conditions resulting in an extreme delay.

Such delays are more likely to occur during construction and would therefore impact the completion date. However, instances of headrace tunnel collapses soon after operations commenced made the international headlines and led to very serious delays in operations. Unlike transportation tunnels where imposed loads on the lining hardly change once the vehicles or trains start using the tunnel, in hydro-power waterway tunnels the internal and external water pressures are the dominant loads. The watering up of the system and then testing for sudden generation 'trips' which impose high transient pressures on the lining, often several years after constructed, is the first real test on the lining. Linings are mentioned here although the situation can be more severe and uncertain in unlined tunnels; observed stable ground during construction may disguise the softening or other change in characteristic of the rock once wetted, and particularly when the tunnel is dewatered and subjected to a rapid build-up of net external pressure.

Delays to tunnelling may lead to delays in wet commissioning of the station, i.e. if the tunnel and underground works are on the critical path (which they usually are) no water can be made available for trial runs until the waterway is fully connected.

When structuring the conditions of the loan and the payback model, the LTA may recommend that the model is stress tested to take account of the likelihood for delays resulting in consequential delays to the owner's ability to generating revenue and to begin to repay the loan.

6.2 *Geotechnical uncertainty*

Several key issues must be addressed at the outset of a feasibility study or reference design, or at whichever design steps are the predecessors to construction contracting:

- How many boreholes are sufficient?
- How many boreholes are affordable, and achievable, given access constraints?
- What alignment shall we drill, knowing that alignments may change?
- What can we defer to a later stage and leave to the EPC contractor, and would this be a wise decision to take?

These questions arise in most projects, and it requires experience of what is important to make

those decisions. But, there must be a minimum level of investigation that needs to be done prior to construction tendering, and prior to obtaining credit approval from the lenders.

It is recommended that a two-stage feasibility study is arranged which allows investigations to be tailored towards the preferred options, but there is no avoiding having to invest in some ‘at risk’ speculative investigations on which to base initial designs (Plummer, 2022a). This is a risk the developer needs to take. A key message from this is that the developer will end up paying to deal with the geotechnical conditions but will ultimately likely pay less overall if more is spent upfront simply because a Civil Works contractor will add a high price for the risk element which far outweighs the cost of investigations.

For hydropower projects a significant proportion of the risks is in the tunnelling and underground works (Plummer, 2022a and Plummer, 2022b), mainly due to uncertain ground conditions associated with the fact that it is significantly more costly, difficult and time consuming to obtain the same level of geotechnical exploration for deep and remote hydropower tunnels than would normally be obtained for shallow depth urban transportation tunnels (supported by the paper, Noble, 2023a). Contractually this aspect needs to be made clear as to which party takes the risk of changed ground conditions from the conditions known at contract signing, and the lenders are very keen to understand how the downside scenario risk profile would affect the borrower of their loan (Noble, 2018).

6.3 *A comparison of the hydropower levels of uncertainty with transport tunnelling*

As shown in (Noble 2023a) and summarised in (Noble 2024), a comparison was made between the differences in the levels of investigations typically undertaken for two similarly priced tunnel projects: an urban shallow depth rail tunnel system, and a remote hydropower with very deep tunnels. It showed that the levels of investigation and the amount of data per length of tunnel explored are far apart.

For a not dissimilar cost, both projects might undertake a comparable amount of total subsurface drilling, however the targeted and most relevant data obtained from the very deep holes in the hydro project would be significantly less frequently spaced than in the urban rail project.

In (Noble 2023a) it considered two similarly sized tunnelling projects:

- An underground railway or Metro within a city. 15km length, twin tunnels of 7m diameter, and seven station boxes, average depth to crown below surface of 40m (so six stretches of tunnels between stations each length 2.5km, ignoring station box lengths)

- An underground high-head hydropower (or pumped storage hydro) project: 15km of waterways length, single waterway comprising headrace tunnel, pressure shaft, pressure tunnel and tailrace tunnel, all 7m diameter, varying depth to crown below surface ranging from 100m to 800m.

The railway tunnel project will have relatively easy and cost-effective access to drill holes closely spaced along the alignment which when added to the existing data knowledge from the built environment such as other tunnels and buildings with deep foundations, the data bank is very large.

The hydro project must start from almost zero existing first-hand knowledge of the conditions at depth. It is unlikely that any nearby projects would have any data at depth and if there were the extrapolation assumptions would be high; and quite likely for there to be nothing at all already available. To reach a tunnel located 800m below the surface will require a hole of slightly longer than 800m deep to be drilled, to obtain the primary data from within the 35m long primary data zone, hence most of its length is ‘secondary’ and necessary just to reach that zone.

The comparative cost of the two drilling campaigns was not assessed, however given the relative ease of undertaking 150 shallow depth urban holes which yielded a total drilled length of 8,625m compared to the challenges of mobilizing workers, equipment and consumables to undertake 10 deep remote holes in mountainous terrain which yielded a total drilled length of 4,425m the overall costs may not be too different. However, the urban project yields a magnitude higher degree of frequency of relevant information in the vicinity of the tunnel itself. If the cost was similar, the risks must be significantly higher for uncertainty of ground conditions in the hydropower project.

Another metric such as the number of boreholes per km length of tunnel would be for the above examples:

- The rail project: 10 holes per km
- The hydropower project: 0.67 holes per km.

7 WHAT MOSTLY CONCERNS THE LENDERS?

7.1 *Overview*

The attempted fast-tracking of pumped hydro development from feasibility stage through to construction presents challenges for the due diligence stage in project finance. If the feasibility study or subsequent early designs have not been as thorough as the lenders may require to satisfy their credit approval processes, or if there are inconsistencies with the environmental impact assessment then delays will occur until the deficiencies are remedied. The lenders’ credit approval process follows strict

requirements within defined boundaries of acceptability, especially on modern ESG issues. Depending on the jurisdiction, a variety of safeguard guidelines will be followed, collectively falling under the umbrella of ESG best practice requirements, and especially for those Equator Principles Financial Institutions.

In the case of Australia, many Australian lenders have not previously loaned to pumped hydro projects and will be wary of the risks. A risk evolution graph from the perspective of the lenders aggregating the perceived risks over the timeline of involvement of the lenders and across five key phases is presented in Figure 1. The five phases are: Development, Bankability, Construction, Defects Liability and Operational.

Figure 1. Pumped hydro project risk trend evolution – a lenders' perspective.

The defects liability period is included in the diagram because it represents a duration, usually 2 years, straight after project completion. At this juncture the debt service starts (loan is being repaid) and any teething problems with the plant are most likely to emerge.

7.2 The greatest perceived risks

As covered in (Plummer 2022a), key findings from the analysis which focused on large hydropower projects in low- and lower-middle income countries suggested that many of the greatest risks associated with large hydropower projects are those that may cause reputational damage to the parties involved, such as social and environmental risks.

7.3 Credit approval

Most lenders have strict requirements to achieve credit approval and if the developer has not understood those from an early stage, i.e., at the feasibility study, there is a likelihood of delays in reaching financial close until the gaps are filled. For environmental and social matters for instance, these assessments can require a very lengthy process of studies that are simply not appropriate for fast-tracking. The gathering of environmental or social baseline data can be at best seasonal but may also be annual or even multi-year, hence a long time is needed.

However, providing the lenders' advisors (typically for legal, technical and insurance aspects) are engaged early enough, then in the road to financial closure there are ways to effectively deal with the actions stemming from the LTA's due diligence so that they are prioritised into various categories to be resolved according to their criticality.

On several projects, large and small, the author has used a three-step categorisation to resolve actions arising from the LTA's due diligence:

Category 1 – to be resolved to the LTA's satisfaction prior to Financial Close (which also means prior to the lenders' timeline for achieving credit or board approval)

Category 2 – to be resolved to the LTA's satisfaction prior to First (or subsequent) Drawdown.

Category 3 – recommended actions to be addressed during Final Design or Project Implementation.

What do the lenders need to know?

Among the key issues that lenders need to know to obtain credit approval, the following items tend to dominate:

- Price certainty of the overall development. This is ranked first but it is by no means a guarantee. Just because a single wrap EPC Contract might appear to be less risky for the borrower in the eyes of the lender, there still remain uncertainties in ground conditions and therefore a better approach is to have a good risk apportionment plan.
- Environmental and Social status and the evolution of risks, i.e. the whole ESG position.
- Contractual arrangements and apportionment of risks between the Borrower and contractor(s).
- Engineer-Procure-Construct (EPC) or split contracts?
- Credentials of main contractors and equipment suppliers – have they recent and relevant experience?
- Implications of performance guarantees not being met.
- Accurate timelines for all steps – pre-financial closure; construction; commissioning and buffer times to establish loan sunset dates.
- Operation and Maintenance (O&M) Agreements – in-house or through a long-term services agreement?
- Planning restrictions.
- Grid interconnection and other local infrastructure (roads, quarries, spoil disposal areas, etc).
- Appropriateness of Owner's organisation, competence of its personnel and operational readiness of the completed facility.
- Power Purchase Agreement.

What does the LTA need to know?

The LTA will be required to opine on most of the above issues plus be informed of the following:

- What is the technology being employed; are there any 'prototype' technologies?

- Dam types, dam break assessments and public perception of new dams.
- Who is constructing it, and how is it being built (e.g. tunnels by TBMs or drill-and-blast)?
- What warranties are being provided?
- Once built, will it operate as planned?
- What is the nature of the Power Purchase Agreement; is it robust and are the lenders' interests protected?
- Can the power be delivered efficiently (i.e. is the transmission infrastructure in place)?
- Are the hydrological studies and energy yield assessments sound?
- Is the technical specification appropriate?
- Are the projected costs reasonable and are appropriate contingencies applied?
- What environmental requirements need to be met and social impact mitigation strategies need to be employed to meet Equator Principles and host country regulations?
- What are the completion risks?
- Is the completed facility going to be operated safely and competently, within the bounds of industry norms and the Power Purchase Agreement?

7.4 *The bankability test*

The concept of a 'bankable' feasibility study differs between stakeholders, but it is clear that such a test needs to assess at least the above aspects. Developers are usually optimistic that the feasibility study is completed to a standard that is acceptable to lenders, however that only becomes clear once the lenders have completed their due diligence reviews. The notion of a 'bankable' feasibility study does not merely mean having satisfactory financial and economic metrics – the project needs to pass other gates to be satisfactory to the lenders and to be 'bankable', most notably the ESG compliance test.

Consequently, in the period approaching financial close it is common for the lenders and its advisors to establish a set of conditions precedent (CPs) that are linked to either the financial close or to subsequent disbursements from the loan. The CPs may cover a range of topics such as commercial, contractual, technical, or environmental/social conditions for which the lenders require more comfort that the critical aspects have been, or can and will be, satisfactorily closed out at a set time (some items are mandatory prior to financial close, and others can be left to later milestones such as first or subsequent drawdowns, which would be known as Conditions Subsequent).

To give further reasoning as to why gaps are often identified in reviews of feasibility studies, the notion of a bankable feasibility study is discussed. It is rare to see feasibility studies that claim in their titles to be bankable, and the term is misleading anyway. With definitions ranging from 'likely to make

money' to 'acceptable to a bank', no feasibility study at the time of submission to the owner can claim to be bankable until it is accepted by a lender and there are several steps to go through before that occurs. The feasibility study should prove a project's technical and economic viability, but not necessarily the bankability; it is the steps that follow which concern the bankability of the project, not the bankability of the feasibility study report itself.

The bank will decide what is bankable – after all, the bank provides the majority of funds and should be considered as the majority owner throughout the tenure of the loan, assuming a typical 70:30 debt:equity ratio. It is therefore not surprising that the objectives of the owner and the lender are generally aligned – each wants a successful project delivered safely on time and to budget.

The summary issues which determine the bankability are:

- Financial metrics
- Contractual terms and conditions
- Technical engineering
- Risks and risk allocation
- Cost estimate accuracy and levels of contingency
- Environmental and Social compliance, e.g. IFC Performance Standards compliance
- Summary: is the project now deemed "ready to lend"?

To be considered bankable by the banks, the risk allocation needs to be firmly understood and be satisfactory to the lenders. If a lender is comfortable with risk allocation provisions, the more likely it will be willing to keep the equity portion to a lower value. So the contract terms and conditions need to be bankable too. This is clearly a topic beyond the typical feasibility study which brings us to conclude that a feasibility study itself could never reach bankable status in its first edition. Lenders will assess the project holistically, but the factors must be appropriate to the bankability test.

8 CONCLUSIONS

The risk profile on the underground works from the lenders' perspective does change over the life of an hydropower project, from due diligence stage, through construction financing and the operation financing, but it does not diminish altogether. Most attention of course is paid at the pre-financial close phase as this is when the lenders' influence, through the LTA, and other advisors, can impose further risk mitigations if considered necessary.

The LTA fulfils a valued role for the lenders in identifying and making recommendations to mitigate the risks to the lenders, across a range of topics. The LTA has a wide remit in operating essentially as the eyes and ears for the lenders but spends the majority of its effort in the initial stages in ensuring that the total contractual package is appropriately apportioned for risk.

It is rare that a feasibility study in itself is considered bankable; it is the project as a whole which earns this status only after the post-feasibility due diligence and third-party assessments are made and the third party declares the bankability from their standpoint. Unless the terms of reference for a feasibility study were developed to address the key issues that are of interest to prospective lenders, then it remains likely that those lenders during their due diligence process will require additional updates in one or more fields. Those supplementary studies are therefore not part of the feasibility study – they instead form part of a post-due diligence phase, or rather more accurately, a pre-financial close phase. In many cases the price for undertaking additional or supplementary studies are not significant, but the consequential cost in terms of delay to the entire project will be significantly higher.

What is important, is to plan the feasibility study from the outset with the next step in mind, in particular the contracting strategy. If the developer is contemplating taking the large step from feasibility to financial close, assuming the EPC contracting model, this can work but the entire feasibility study should be planned with due consideration in advance of what the lenders will be looking for and ensure there are no gaps.

ACKNOWLEDGMENTS

This paper draws from several other technical papers from the author and is based on his global experiences from tunnelling risks for pumped hydro and conventional hydropower. Acknowledgements for the insights into this paper are extended to all the project teams and people that I have had the pleasure

to work with in the tunnelling and hydropower industries worldwide. The experiences and lessons learned from a variety of projects formed the basis of what is written.

ABSTRACT: The multi-subject model of subsea tunnel construction makes information management complex, dynamic, and cross-cutting. At the same time, each department is more willing to keep its own data privacy, and the information exchange and collaboration process across units and departments is relatively vague. This study investigated the work flow of the Jiaozhou Bay Second Submarine Tunnel Project in its construction phase, clarified the functions and responsibilities of the construction unit, survey and design unit, material supplier, supervision unit, etc., and conduct an in-depth study of the current stage of project management. The quality information data in the network uses core technologies such as distributed ledgers, consensus mechanisms, and asymmetric encryption to link multiple subjects of security risk accidents, promote the transparent and efficient flow of information among multiple departments, and provide a basis for the information flow of various organizations to meet the requirements of dynamic risk management during the construction of subsea tunnels can improve the efficiency of risk management and control.

Keywords: subsea tunnel, blockchain technology, risk management

1 INTRODUCTION

With the support of national policies and the growing demands of development, tunnel construction in China is advancing rapidly, and the scale of future development is immeasurable. This also imposes higher requirements on tunnel construction management. Compared to other underground engineering projects, tunnel engineering experiences relatively frequent safety accidents due to the complexity of various uncertainties. These accidents not only result in economic losses for all parties involved but also have significant societal impacts.

The management process of tunnel construction involves multiple stakeholders, including construction units, design units, survey units, supervision units, and others. The construction process encompasses various phases such as construction preparation, portal and adit construction, tunnel

excavation, tunnel lining, waterproofing and drainage, ventilation, and dust control. Information sources during construction are extensive, and information exchange is complex. Additionally, construction conditions can change rapidly, making traditional management methods limited in their effectiveness.

To achieve transparency and precision in risk management during tunnel construction using modern advanced information technology, to reduce the frequency of accidents, and to enable dynamic risk management, is of paramount significance for underwater tunnel construction projects. In response to higher construction requirements and standards and the need to improve traditional management models, various entities are gradually incorporating information technology and continuously updating their standardized management processes.

*Corresponding author: 2210345@tongji.edu.cn

However, the traditional management approach, lacking comprehensive planning, can result in inefficient information flow between modules and underutilization of data mining. Additionally, centralized systems rely on absolute trust in specific authoritative institutions, making it challenging to ensure transparency, equitability, fairness, and verifiability during data flow. In case of data fraud or manipulation, the entire centralized system would lose trust, making accountability after accidents even more difficult.

Blockchain technology is an emerging application pattern that combines distributed data storage, peer-to-peer transmission, consensus mechanisms, encryption algorithms, and other technologies. It possesses the characteristics of immutability and transparency, holding enormous potential in anti-tampering and traceability within information management (Nakamoto, 2009; Yuan et al. 2016). Blockchain's role in promoting data sharing, optimizing business processes, reducing operational costs, enhancing collaborative efficiency, and establishing a trustworthy system was highlighted.

The integration of blockchain technology can enable monitoring and surveillance devices, such as IoT, to connect, allowing for distributed real-time data and information uploads regarding the security of facilities and equipment. This can reduce manual inspections and enhance work efficiency. Furthermore, through data tracing, blockchain can provide a credible level of information input for individuals, facilities, and hazard rectification in the construction management process. It can offer a verifiable, traceable, and tamper-proof information flow and evidence chain for accident processes (Lu, et al., 2020; Cao, et al., 2019).

Hence, there is an urgent need to holistically plan, establish a risk information database for the tunnel construction process, integrate it into the safety risk information mining and analysis process, construct a tunnel informatization platform, and form a new management model based on this, enabling safety control in tunnel construction, thus achieving information, transparency, and quantified control throughout the construction process.

2 FEASIBILITY OF BLOCKCHAIN TECHNOLOGY IN TUNNEL CONSTRUCTION RISK MANAGEMENT

2.1 *Analysis of risk information issues in the tunnel construction process*

During the tunnel construction process, a significant amount of data can be accumulated. However, the multi-stakeholder nature of tunnel construction often leads to relatively vague and (Zhang, et al., 2013; Zhu, et al., 2022). The transparency and immutability of blockchain technology in data transmission have been effectively applied in monitoring data transmission in the construction process (Liu, et al., 2021; Sheng, et al., 2021; Wu ., et al., 2022; Zhong, et al., 2022; Wu, et al., 2022; Wang, et al., 2022).

While ensuring data authenticity, many scholars have proposed integrating blockchain technology with other technologies to expand its application in the construction field (Wu, et al., 2021; Pan, et al., 2022; Yang, et al., 2021). Its application in risk management is relatively less explored, making it necessary to discuss the feasibility of blockchain technology in risk management. A typical block chain including the following key characteristics:

- (1) **Technical Feasibility:** Blockchain technology is a distributed ledger technology that integrates multiple theories and technologies, including asymmetric encryption, P2P networking, smart contracts, and more. Its blockchain structure, with encrypted chained blocks, is used for data verification and storage. P2P technology enables the verification and communication of distributed nodes, while smart contracts allow for automated operations based on complex business logic functions.
- (2) **Traceability:** In the process of transmitting safety information in tunnel construction, safety information primarily exists in the form of signed forms and electronic files, resulting in an inefficient traceability system. However, within each block of a blockchain, there is not only transaction information but also a timestamp (indicating the time of the block's transaction record) and a hash value. All these blocks form a chain-like structure, allowing every block to trace back to the first one. Such a traceability system can provide stakeholders with information about content, source, time, and signatures, serving as the basis for accountability after accidents, enhancing accountability efficiency and capabilities.
- (3) **Authenticity:** Stakeholders in tunnel construction often have motives and behaviors, such as falsifying transaction data, to maximize their interests or avoid accident responsibility. However, the consensus mechanism of blockchain technology requires the approval of all stakeholders for every information change, and transaction content is monitored by all parties, preventing data falsification and improving information authenticity.
- (4) **Distributed:** Storage Many pieces of information in tunnel construction cannot be shared and communicated in real-time among different stakeholders. In a consortium blockchain, each stakeholder has a distributed ledger to store all data, solving the challenge of uneven information distribution. For instance, when an owner initiates a consortium blockchain, other stakeholders join the corresponding chain and complete data and block generation. The survey and design chain records critical safety information or design proposals, the material supply chain records materials supply and testing information, and the monitoring chain records sensor data and approvals.

Considering that tunnel construction risk management involves a large amount of information, a database that can facilitate real-time and transparent information sharing is highly necessary. Blockchain types mainly include public, private, and consortium chains. To ensure that various types of risk information are shared among stakeholders and that information is open and transparent with equal rights and responsibilities, a private chain, which requires specific conditions for information sharing, is not suitable for tunnel construction schedule risk management. Moreover, tunnel construction schedule risk management involves multiple stakeholders, necessitating identity verification for all stakeholders to ensure information security, making it unsuitable for a public chain that is open to all participants. Consequently, the blockchain architecture of a consortium chain is better suited for tunnel construction schedule risk management.

3 ENGINEERING RISK INFORMATION SHARING FRAMEWORK

In the context of tunnel risks, Professor Einstein H. H. from the Massachusetts Institute of Technology (MIT) has long presented valuable theories that provide a theoretical basis for risk analysis in tunnel projects (1974; 1996; Sinfield, & Einstein, 1996). R. Sturk and others applied probability methods and effective statistics in risk analysis to guide highway tunnel projects from the perspectives of reliability and risk (1996). H.M. Tah and V. Carr proposed the five processes of dynamic risk management: risk identification, risk assessment, risk analysis, risk treatment, and outcome monitoring (2001). The application of risk management in tunnel and underground engineering projects in China began relatively late. It wasn't until the early 1990s that Ding Shizhao, an academician of the Chinese Academy of Engineering at Tongji University, explored risk and insurance forms in the Guangzhou Metro Phase I project and the Shanghai Metro Line 1 project. This marked the beginning of research into risk assessment management in China. Huang Hongwei and others suggested that risk assessment typically involves three steps: risk identification, risk estimation, and risk evaluation (2007). These three steps can be improved in terms of information sharing with the help of blockchain technology.

Risk Identification: This involves the process of collecting risk information. Tunnel construction faces numerous risks, such as safety risks like fires, collapses, sudden water inflows, as well as risks related to blasting operations, deformations in surrounding structures, construction organization, and schedule. Each of these risks results from various influencing factors within the risk chain, including factors like inexperienced workers, equipment damage or absence, and inaccurate geological surveys. Based on all possible risks in tunnel

construction and their influencing factors, these can be categorized into four types: personnel information, equipment information, management information, and construction environment information. Each unit can classify and synchronize the corresponding information to the blockchain according to its specific needs during the risk identification process, ensuring the authenticity and reliability of the collected information, and providing a stable and reliable data source for risk assessment.

Risk.

Estimation: This stage involves the processing of risk information. It mainly consists of analyzing the likelihood and estimated losses of risk incidents, building upon the risk identification based on blockchain technology. Reliable information sources enhance the credibility of estimation results. In this process, various methods such as the expert scoring method, the analytic hierarchy process, the fuzzy comprehensive evaluation method, and the fault tree analysis method are widely used. Smart contract technology can perform intelligent calculations of risk levels after scoring, thereby increasing the efficiency of the risk estimation process.

Risk Evaluation: This step includes rating risks, ranking them, and making risk decisions, which is the display layer of risk assessment results. Risk levels are assessed and categorized based on the risk probability, losses, and acceptance criteria as specified in the national standard (GB 50652-2011), "Code for Risk Management in Urban Rail Transit Underground Engineering" (hereinafter referred to as "the national standard"). In this stage, blockchain technology is utilized to showcase the conclusions of risk assessment, the responsible personnel for risk assessment, and the weaker aspects of risk impact factors for tunnel construction management personnel to formulate targeted response measures.

The proposed framework for tunnel construction risk information sharing based on blockchain technology is illustrated in Figure 1 and comprises the following modules:

- **User Module:** This primarily includes various units and departments participating in tunnel construction, such as advanced geological prediction units, survey/design units, construction units, and construction owners. For instance, during the survey and design phase, inaccurate geological surveys may pose a risk, with the responsible units including advanced geological prediction units and survey/design units. The latter are typically information providers, while other units are information reviewers, and there is frequent information exchange between information providers and reviewers.
- **Data Acquisition Module:** This is used for obtaining data for tunnel risk assessment, and the data source depends on the users.
- **Data Storage Module:** The data storage module is connected to the data acquisition module and is

used for storing data relevant to tunnel risk management.

- Data Interaction Module: The data interaction module is connected to the data storage module and facilitates the interaction of tunnel risk management data between PC and web interfaces.
- Data Evaluation Module: This module is linked to the data interaction module and is used for risk level assessment based on the results of data interaction.
- Data Visualization Module: The data visualization module is connected to the data evaluation module and is used to retrieve the results of the data evaluation module and present them in a visual format.

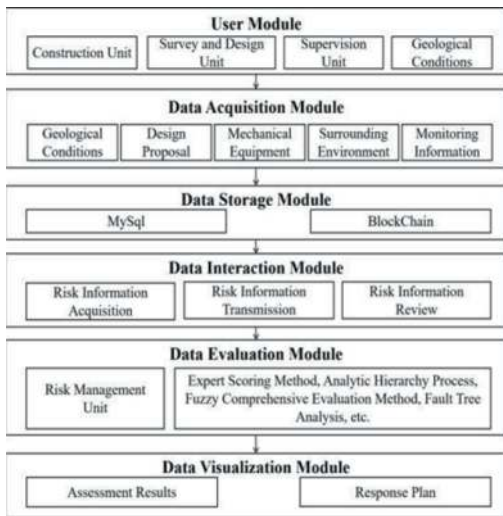

Figure 1. Characteristics of a blockchain-based tunnel construction risk management platform.

4 TYPICAL APPLICATION SCENARIOS

In response to issues such as information sharing and accountability opacity in the risk management process of tunnel fires, a tunnel construction fire risk management platform has been developed based on the Wutong blockchain technology. This platform enables data input, assessment, and user access through a web browser. Leveraging the construction of the second undersea tunnel in Jiaozhou Bay, Qingdao, the construction site of the second undersea tunnel exhibits strong spatial confinement, a high presence of potential combustibles, and challenges in firefighting, posing serious consequences in the event of a fire.

Risk Identification: Taking a specific week in 2023 as an example, the occurrence of unauthorized wiring and the presence of numerous vehicles at the construction site pose significant fire hazards. The possibility of cable wear due to vehicle movement is one of the critical fire hazards for that week. The ongoing installation of geotextiles and waterproof panels involves the use of highly flammable materials such as solid foam and waterproof fabric, representing an

important combustible hazard. The current provision of firefighting equipment at the construction site is deemed sufficient. All construction personnel for the week are certified, and there is no smoking or emergency equipment failure reported.

Risk Estimation and Assessment: Relevant information is reported and described by various departments, and the risk control unit assigns scores ($P \in [0,10]$) to the basic events of the week. A higher score indicates a lower probability of the event occurring, and vice versa. Through the platform's information synchronization and probability calculations, the probability of a fire accident occurring during the week is calculated as 0.28, with a likelihood rating of 1.

Accountability Tracing: Events and incidents with lower scores are traced back to responsible individuals, such as inadequate fire spacing or improper cable laying. Detailed event descriptions can be traced through blockchain hashes to the Wutong chain, as illustrated in Figure 2.

The predictive results from the FRC platform indicate a significant likelihood of a fire occurring in the second undersea tunnel, aligning well with the actual conditions of the week. Therefore, the FRC platform is considered effective in predicting the probability of fire accidents, facilitating the organization of daily fire risk management events and accountability tracing following a fire incident to specific events, departments, and units.

Figure 2. Tunnel construction fire risk management platform.

5 CONCLUSION

Risk management in tunnel engineering is a critical aspect of tunnel construction projects. However, due to issues related to the security and legality of information, achieving high-speed, effective, and transparent information exchange during construction processes has been challenging. Blockchain technology, with its unique capabilities such as immutability and data traceability, offers distinct advantages in the field of information management. Therefore, this paper presents the architecture of a tunnel engineering risk management platform based on blockchain technology.

First, we provided a detailed overview of the advantages of blockchain technology in the realm of

information management. Secondly, we proposed the application of blockchain technology in the context of risk assessment, particularly in the three steps of risk evaluation. We believe that blockchain technology enhances the reliability and transparency of risk identification information, ensures the traceability of risk assessment results, and addresses the limitations of traditional risk assessment methods.

The application of blockchain technology in tunnel engineering risk management holds significant potential. Building upon this architecture, further research and development should be carried out to enable the platform to be piloted in actual engineering projects. This will fill the gaps in the current centralized management architecture and promote more efficient and transparent supervision of tunnel engineering risk management.

Study on the major risk control elements under EPC management mode of rail transit

Zheng Shi

Shanghai Tunnel Engineering & Rail Transit Design and Research Institute, Shanghai, China

Jizheng Huang*

BY Civil Engineering Consulting Co., Ltd., Shanghai, China

Lihong Ding

Shanghai Tunnel Engineering & Rail Transit Design and Research Institute, Shanghai, China

ABSTRACT: In order to explore how to control major risks under EPC (Engineering Purchase Contract) management mode, and ensure the smooth progress and safety of rail transit projects, this paper analysed and summarized the major risk control elements from three aspects: relationship between parties facing risks, organizational structure and management personnel through special research and case analysis. Firstly, the relationship between parties facing risks was sorted out, including the relationship between employer, EPC project team, constructor, supervisor, design unit and the introduced third party for risk control. The cooperation and conflicts of opinions between parties were analysed and solutions were proposed. Then, the management organizational structure for major risks in EPC projects was discussed. Through investigating the management modes of EPC projects both at home and abroad, a “dual control” management organizational structure with centralized control by EPC project teams and inspection control by third party was proposed. Finally, the core elements of rail transit EPC project management talent were studied, including project manager, site management personnel and professional technical personnel of the EPC project team. The results show that the relationship between parties facing risks, the management organizational structure for major risks and management talents are the key elements of major risk control in rail transit projects under EPC management mode. Rationalizing the relationship between parties facing risks, building a reasonable management organizational structure of major risk control, and cultivating excellent management talent can effectively control and respond to major risks of rail transit projects, and ensure the smooth implementation of rail transit projects under EPC management mode.

Keywords: rail transit engineering, EPC mode, risk control, element study

1 INTRODUCTION

In order to address the difficulties faced by the lead design unit in the process of EPC transformation, this explores how to control major risks within the EPC management model. It is necessary to study the essential elements for controlling significant risks in the EPC management model for rail transit. In response to issues such as unclear positioning of responsibilities for the lead design unit in EPC transformation, high associated risks, and insufficient management capabilities as shown by Weifeng Chu (2021), it is essential to streamline the relationships related to ‘risk,’ construct a reasonable organizational framework for managing major risks in EPC projects, and cultivate talented individuals with

the necessary management skills. This is to ensure the smooth implementation of rail transit projects under the EPC management model.

2 CLARIFICATION OF THE RELATIONSHIPS AMONG PARTIES FACING RISKS

The domain of the EPC model is Engineering. Hence, participants in the EPC management model should include the engineering owner, engineering contractor, engineering supervisor, design review entity, third-party safety and quality control, and local government regulatory departments. The engineering contractor comprises project management, design teams, civil construction teams, and system equipment installation

*Corresponding author: yiyanghepan@qq.com

teams. In this model, different parties play different roles and responsibilities to ensure the smooth progress and completion of the project.

2.1 *Engineering owner*

The engineering owner (developer) is responsible for establishing project objectives, requirements, and budgets, overseeing the overall progress of the project. Additionally, they need to assist the engineering contractor in external liaison and communication, purchasing insurance, and jointly hiring a third party for safety and quality management.

Compared to traditional contracting models, in the EPC model, the engineering owner delegates most of the rights to the general contracting unit, with a shallower level of involvement in project management. On the other hand, as the engineering owner only needs to contract with the EPC general contracting unit, usually under a fixed total price contract, in comparison to the traditional contracting model, under the EPC model, the engineering owner can have better control over the total investment as shown by Jinrui Zhang (2016).

2.2 *Engineering contractor*

In China, explicit qualifications for EPC general contracting enterprises have not yet been designed. According to relevant policy documents, as long as there is engineering design or construction qualifications that are commensurate with the scale of the project, it satisfies the qualification requirements to become an engineering general contracting unit. As currently, domestic design and construction are mostly independent units, seeking strong alliances and complementary advantages, a model in which qualified design and construction units form a consortium to undertake EPC general contracting has become mainstream in China.

According to the characteristics of the EPC model, the engineering contractor can also be divided into project management, design, construction, and system installation. Depending on the leading unit of the consortium, the project management may come from the design unit or the construction unit.

The function of project management is to coordinate the design, construction, and system installation teams, ensuring the coherence and consistency of the design plans, and providing technical support. They are responsible for procuring major bulk materials, critical equipment, and services needed for engineering construction, ensuring the efficient operation of the supply chain and timely material supply. The function of the design team is to develop detailed engineering design plans, including technical specifications, construction

drawings, and quantity schedules. The function of the construction team is to carry out construction, coordinate various trades at the construction site, and ensure construction safety, quality, and progress. The function of the system installation team is to execute system installation.

Specifically, for the design unit acting as the leading entity in the EPC general contracting consortium, besides performing well in their role as a design specialist, they also need to carry out the work of project management. However, at this stage, most design units leading the EPC transformation lack construction site management experience, and some do not even have a sound construction quality or safety management organizational structure. Agreements signed by consortium members are often relatively rudimentary (lacking detailed delineation of rights, responsibilities, and benefits). Design and construction units are individually responsible for their respective engineering contents, lacking awareness and management of each other's work. As the leading design unit, mismanagement could lead to potential joint responsibility due to poor management as shown by Yuan Gu (2020).

Therefore, elucidating the relationship between the design and construction units within the consortium is crucial for risk control in EPC general contracting projects. To achieve this goal, the first step should involve selecting suitable and stable consortium partners, signing comprehensive consortium agreements. Subsequently, establishing a complete risk management organizational structure and having sufficient talent to ensure the project's smooth and efficient completion.

2.3 *Supervision entity*

The supervisory entity is commissioned by the engineering owner to oversee the compliance, quality, and progress of design, construction, and installation schemes, ensuring they adhere to relevant legal standards. In the EPC model, the relationship and positioning of the supervisory entity with the engineering owner and engineering contractor have not fundamentally changed.

2.4 *Design review entity*

Similar to traditional contracting models, the design review entity is responsible for reviewing engineering design schemes to ensure they comply with technical specifications and safety requirements.

2.5 *Third-party safety and quality control*

Operating as a third party in the engineering realm, this entity surveys potential safety and quality haz-

ards in engineering, supervises safety measures at construction sites, prevents engineering accidents, and safeguards the safety of workers and the environment. According to the ‘Swiss Cheese Model’ as shown by J. Reason (1990), accidents occur when every person in the accident chain makes an error at some point. The stronger the management capability, the more detailed the control granularity, and the healthier the control levels, the easier it is to prevent common accidents. However, they cannot prevent rare accidents and may even amplify the possibility of rare accidents. Independent professional third parties can offer a new dimension and are the best choice for risk reduction implementation.

Figure 1. Swiss cheese model.

However, the introduction of third-party risk advisory units can be approached in various ways. In numerous rail transit projects without specific

regulations, traditional third-party risk advisory units often face some awkward situations: on one hand, they unavoidably have to point out the shortcomings or even errors of relevant units in specific risk control work; on the other hand, they are commissioned by these units. In past practices, a new approach for introducing third-party risk advisory units has been found. It involves the participation of technical consulting agencies as part of engineering insurance underwriting companies in risk control. This approach both avoids the problems of traditional methods and resolves the inadequacy of technical capabilities within underwriting companies, aligning with the interests of all participating parties.

2.6 Regulatory departments of local government

They are responsible for overseeing the project’s compliance to ensure it aligns with relevant regulations and standards.

The above are general roles and responsibilities of the various parties in the EPC model. The actual situation might differ based on the specific nature of the project and the regulations of the region. In comparison to traditional models, the major changes in role positioning mainly occur between the engineering owner and the design and construction units within the engineering EPC general contracting consortium.

In a rail transit engineering project, all parties need to work closely together, coordinate effectively, while also clarifying their own roles and correctly delineating rights, responsibilities, and benefits to ensure the project’s timely and high-quality completion.

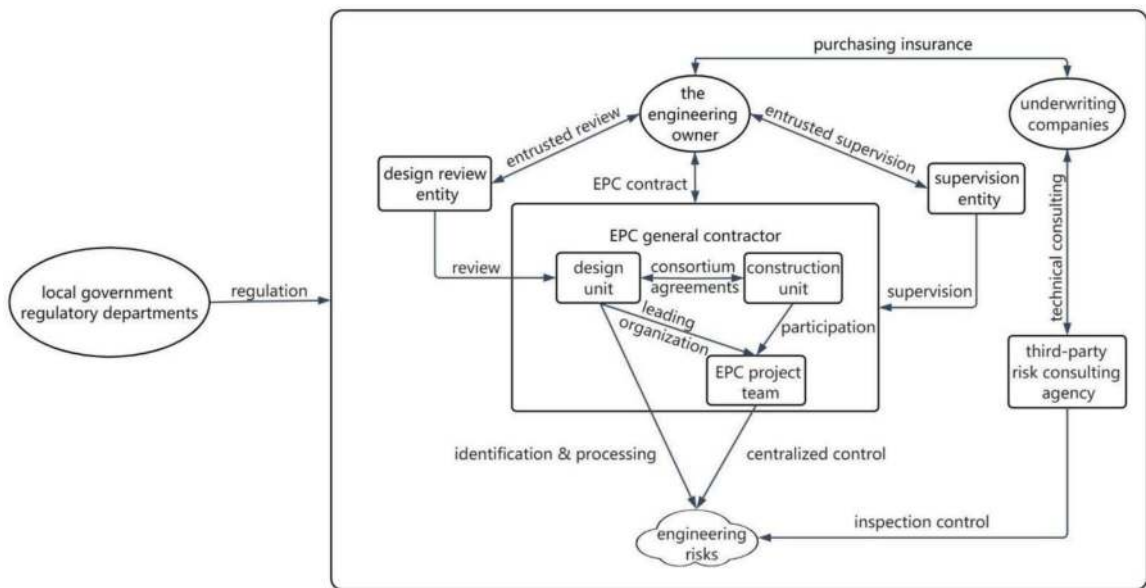

Figure 2. Diagram illustrating the relationships among parties facing risks.

3 RISK MANAGEMENT ORGANIZATIONAL STRUCTURE

3.1 *Risk management organizational structure within the EPC consortium*

According to the analysis in the previous section, the key to controlling risks in railway engineering projects under the EPC model is clarifying the relationship between the design and construction units within the consortium. Therefore, it's essential to establish a comprehensive risk management organizational structure within the EPC consortium to ensure the project can effectively and promptly respond to various risks as shown by Jian Qiang (2011).

3.1.1 *Project senior leadership team*

This includes the project general manager, project executive director, among others, responsible for overall project planning, decision-making, and resource allocation. This team should consist of senior management personnel from various consortium member units, an odd number and not too many in quantity.

3.1.2 *Expert advisory team*

Comprising experts in fields such as law, compliance, engineering technology, risk management, providing professional advice and recommendations to assist in formulating reasonable risk management strategies for the project.

3.1.3 *Risk management committee*

Comprised of the project leadership team, expert advisors, responsible for formulating risk management policies, guiding principles, and reviewing and deciding on significant risks.

3.1.4 *Risk management department*

Responsible for specific risk identification, assessment, control, and monitoring, implementing decisions of the Risk Management Committee. Similar to the project's senior leadership team, the primary personnel of the risk management department should be cross-assigned from various consortium member units. Since the design unit is the lead in the EPC consortium, it's preferable for this department's leadership to be appointed by the design unit. The department should include the following sub-departments or functions:

- (1) Risk Identification and Assessment Team: Identifying various potential project risks, performing qualitative and quantitative assessments, prioritizing risks, and identifying significant risks.
- (2) Risk Control and Planning Team: Developing response measures and contingency plans for each type of risk, ensuring the project progresses smoothly as per the planned schedule.

- (3) Risk Monitoring and Reporting Team: Establishing a risk monitoring system, tracking and monitoring project risks regularly, promptly reporting the status and dynamics of risks to the project's senior management.
- (4) Risk Sub-Teams for Each Project Phase: Establishing sub-teams at different project stages, responsible for assessing and managing potential risks specific to each stage, ensuring comprehensive risk control throughout the project.

3.1.5 *Communication and coordination mechanism*

After establishing the leadership team, the risk management committee, and the risk management department within the EPC consortium based on the above principles, it is possible to manage project risk control effectively. However, significant risk management in railway engineering under the EPC management model still requires extensive collaboration from all members involved. Therefore, it is necessary to establish cross-departmental and cross-functional communication and coordination mechanisms to ensure smooth information flow and resource sharing for swift risk response.

3.1.6 *Training and education department*

Responsible for providing training and education regarding risk management to project team members, enhancing the team's understanding and ability to address risks.

3.1.7 *Risk management tools and technical support team*

Offering technical support such as risk management software, data analysis tools, to assist the team in better identification, assessment, and response to risks. This team can adapt to the trend of digitalized risk management, employing more advanced tools to facilitate effective risk management.

It's important to note that the risk management organizational structure for different projects may need adjustments and optimizations based on the project's scale, nature, and characteristics to suit the actual circumstances.

3.2 *Third-party risk consulting agency*

However, the risk control structure involving various units within the EPC consortium, including the engineering owner, supervisory unit, and others, is insufficient. While centralized control is achieved within the EPC project group, it is necessary to introduce an independent third-party professional organization through the engineering insurance institution to participate in risk control activities, serving as a supplement to the entire risk management system, ensuring that the probability of significant and rare risks occurring is minimized.

After the introduction of third-party risk advisory units into railway engineering projects under the

Figure 3. Organizational structure of risk management within the consortium.

design-led EPC model, they need to engage in risk control through a professional and comprehensive process.

3.2.1 Preliminary preparation

Collaborating with the EPC project team, gather relevant information and perform risk assessment and classification for different engineering aspects of the rail transit project. Based on the results of the risk assessment, engage in thorough communication with the EPC project team to develop a risk management plan and response strategies. The outcomes should be compiled and presented in a preliminary risk assessment report by a third-party agency. Then, organize a risk survey and briefing meeting involving all relevant stakeholders facing the identified risks.

3.2.2 Risk operation tracking

The third-party agency should regularly monitor the project progress. During critical risk-prone periods, pre-selected experts should be communicated with and confirmed by with the EPC project team and engineering insurance agencies.

Prior to the risk survey, prepare a project risk overview and send it for expert review, allowing experts to become familiar with the project in advance.

After the completion of key projects, the third-party agency can conduct a post-assessment of risks. This involves analysing and evaluating the gains and losses of the measures taken by all parties during the significant risk response period, thereby forming effective methods for future similar risk responses.

The third-party agency should also pay attention to the resolution of risk issues and can contact experts for confirmation if there are any special problems

3.2.3 Process risk assessment

At regular intervals (e.g., monthly or quarterly), the third-party agency can summarize and analyse risk issues for similar projects or compare risk issues

across different projects on the same rail line. By analysing and exploring the data, common issues existing in the projects can be identified, facilitating the enhancement of management by the EPC project team and reducing the probability of risk occurrence.

After the completion of key projects, the third-party agency can conduct a post-assessment of risks, analysing and evaluating the gains and losses of the measures taken by all parties during the significant risk response period, thereby forming effective methods for future similar risk responses.

3.2.4 Value-added services

In addition to daily risk management, the third-party agency can organize risk management salons for common technical issues and provide emergency response expert services.

3.2.5 Risk management summary

Upon the completion of rail transit projects, the third-party agency should compile a risk management summary report based on the achievements of comprehensive risk management throughout the entire process, and convene a project risk management summary meeting with relevant parties.

In summary, the combination of a complete risk management organizational structure within the EPC consortium and the involvement of an independent third-party professional organization introduced through the engineering insurance institution constitutes the 'Dual Control Model' of centralized project control and third-party surveillance control.

4 CORE ELEMENTS OF MANAGEMENT TALENTS

Management talents involved in railway engineering EPC projects need to possess a variety of core elements to ensure the smooth and efficient completion of projects. Personnel in the design unit

Figure 4. Framework for risk control services by third-party organizations.

often exhibit strong professional technical capabilities but lack cross-disciplinary comprehensive skills and on-site construction experience. Therefore, the design unit needs to prioritize the cultivation of management talents for railway engineering EPC projects as shown by Xiaodong Zhou (2016). These talents should encompass the following core elements:

4.1 Professional knowledge and skills

Project management talents need to be well-versed in relevant fields of railway engineering, including engineering design, construction technology, procurement processes, etc. They should comprehend the technical requirements and standards of the project to effectively communicate and coordinate with various professional teams.

4.2 Project management skills

Management talents need to master the fundamental principles and methods of project management, including planning, resource allocation, risk management, schedule control, cost management, etc. They should be able to develop detailed project plans and oversee project execution, ensuring timely, high-quality, and cost-effective project completion.

4.3 Communication and coordination abilities

In railway engineering projects, there is a need for external communication with the public and internal coordination involving multiple teams from different professional domains. Therefore, project management talents need to possess excellent communication and coordination abilities to effectively communicate with all stakeholders, resolve issues, manage conflicts, and ensure smooth information flow.

4.4 Risk management

Railway engineering projects face various potential risks, including technical, supply chain, and environmental risks. Project management talents need to identify and assess these risks, formulate corresponding risk response strategies to mitigate their impact on the project.

4.5 Team leadership and management

Management talents need to demonstrate team leadership and management abilities, motivating team members, guiding them in accomplishing their tasks, ensuring team collaboration, and achieving project objectives.

4.6 Problem-solving skills

Throughout project execution, various issues and challenges may arise. Project management talents need to swiftly identify the root causes of problems, find solutions, and take action to resolve issues, ensuring smooth project progress.

4.7 Compliance and legal awareness

Railway engineering projects are often subject to various regulations and provisions. Project management talents need to understand relevant laws and regulations to ensure project compliance within legal frameworks and avoid non-compliance.

4.8 Learning and adaptability

Technologies and methods in the railway sector are continually evolving. Project management talents need to maintain the ability to learn and adapt to keep up with the latest industry trends and best practices.

In summary, management talents for railway engineering EPC projects need to comprehensively consider various factors including technical, management, communication, leadership, and more to ensure the smooth implementation and successful delivery of projects.

5 CONCLUSION

As the leading entity in the EPC, the design unit, for better risk control of railway engineering projects under the EPC management model, needs to streamline the relationships concerning 'risk,' construct a reasonable major risk management organizational structure for the EPC project, and cultivate excellent talents with management capabilities.

5.1 *Clarifying relationships concerning 'risk'*

The key lies in aligning the relationship within the general contracting consortium and the construction units. This involves selecting suitable and stable consortium partners, establishing detailed consortium agreements, and constructing a complete risk management organizational structure. Additionally, choosing a third-party professional institution as a technical advisory body for the engineering insurance underwriting company is crucial for risk control, thereby aligning the relationship between safety and quality control third parties and the project.

5.2 *Structuring a comprehensive risk management framework for EPC projects*

Internally within the EPC consortium, there should be a complete risk management organizational structure consisting of the project's senior leadership team, a risk management committee, a risk management department, communication and coordination

mechanisms, a training and education department, and a risk management tools and technical support team. Based on this, through the engineering underwriting institution, the introduction of an independent third-party professional organization to participate in risk control work serves as a supplement to the overall risk control system, collectively forming a 'dual control model' of centralized project management combined with third-party oversight.

5.3 *Nurturing management-proficient talent*

The design unit needs to emphasize the cultivation of management talents for railway engineering EPC projects, who possess core elements such as professional knowledge and skills, project management skills, communication and coordination abilities, risk management, team leadership and management, problem-solving abilities, compliance and legal awareness, as well as learning and adaptability capabilities.

Tunnel Euralpin Lyon Turin: The design and contract challenges for a modern Alpine base tunnel

Daniele Stocker*

Pini Group, Lugano, Switzerland

Piergiuseppe Gilli

TELT-sas, Torino, Italy

Matteo Falanesca

Pini Group, Lugano, Switzerland

ABSTRACT: The Mont-Cenis base tunnel, part of the TEN-T transport network, is the most important element of the cross-border section linking France to Italy via a 57.5 km rail tunnel. The total excavation length for the construction of the structure is approximately 160 km, 22% of which has already been completed. The tunnel passes through different Alpine geological units with very heterogeneous geological conditions and high overburden, posing particular technical and design challenges. The excavation of the base tunnel will be performed for 75% of the entire length with different types of TBMs chosen on the basis of expected geological risks: Gripper TBMs; Shielded TBMs; Dual-Mode TBMs. Other aspects requiring in-depth design studies concern logistics and the use of excavated materials. On the basis of the agreements adopted by the Inter-Governmental Commission, the work has been divided into 12 main operational sites in order to limit the interfaces among sites and to account for the approval deadlines. The allocation of the main civil works lots has recently been completed. The adopted approach has allowed to maintain a high degree of flexibility in the division of design, construction and supply contracts. This complex project requires thorough design phases, appropriate risk management procedures and the establishment of modern and flexible procurement systems. All these aspects ensure that the economic and time conditions are met, taking into account quality, safety and the environment. Commissioning is planned for 2032.

Keywords: Risk management, Contractual Practices, FIDIC standard, TBM-Tunnelling; High Overburden, Squeezing Conditions

1 INTRODUCTION

As part of the RTE-T transport network, the Mont-Cenis base tunnel (Bufalini et al., 2017; Stocker and Humbert, 2021) is the key element of the cross-border section linking France and Italy via a 57.5 km high-speed rail tunnel (45 km on French territory and 12.5 km on Italian territory). The construction of the Lyon-Turin rail tunnel (Figure 1), connecting the international stations of Saint-Jean-de-Maurienne and Suse with the existing network, will meet regional, national and European challenges. The existing railway lines, built in the 19th century, no longer meet the demand for freight transport (they are too steep, very twisty and do not meet current rail safety standards). The new Lyon-Turin Euralpine Tunnel project is a mixed passenger/freight project that will

overcome the limitations of the current line. For passengers, the project will halve journey times and quadruple capacity. For freight, the Lyon-Turin Euralpine Tunnel will encourage modal shift by making freight transport more efficient and environmentally friendly, and will help to make Alpine road passenger transport safer. The base tunnel consists of two single-track tubes with a centre-to-centre distance of approximately 40 metres, connected by branch tunnels every 333 metres. On the French side, three cut-and-covers (Saint-Martin-La-Porte, La-Praz and Modane) with a total length of about 11 km have already been completed, while on the Italian side, the 7.5 km La Maddalena cut-and-cover has been excavated. Three safety areas are planned along the route (La Praz, Modane, Clarea), connected to the outside by descents. At Modane, the Avrieux shafts will provide

*Corresponding author: Daniele.Stocker@pini.group

ventilation for the future tunnel. Prior to the start of construction, in 2003, the shafts were used to identify the terrain to be encountered during the excavation of the base tunnel and its ancillary structures. During the construction phase, the shafts are used for logistics and ventilation. During the operational phase, in the event of an accident, they will provide access for emergency services and evacuation of victims.

The total excavation length for the construction of the structure is approximately 160 km, 22% of which has been completed (approximately 35 km in total) and 100% of the contracts for the main civil works have already been awarded. Various excavation methods are envisioned, depending on the expected geomechanical conditions, safety and mitigation of environmental impact.

The base tunnel will have a diameter of approximately 10.5 m at the extrados and will be designed to meet safety requirements and to optimise static performance (Figure 2).

The lining along the entire length of the tunnel provides stability during construction and long-term stability for the entire lifetime of the structure (120 years). The final lining is generally unreinforced concrete and is reinforced only in geologically difficult or geometrically complex areas. Water seepage is drained via external drains to a central drain which carries the water out of the tunnel and to the portals.

Figure 1. The Mont Cenis base tunnel.

The bi-national Franco-Italian company TELT is the public-sector promoter responsible for building and managing the cross-border section of the future infrastructure. By 2032, the Lyon-Turin line will take one million lorries off the Alpine roads and reduce greenhouse gas emissions by around 3 million tonnes of CO₂ equivalent per year. The cross-border section

Figure 2. Typical section of the base tunnel.

will cost €8.6 billion. It is currently being financed by the European Union (40%), Italy (35%) and France (25%).

2 MAIN DESIGN CHALLENGES

The unique challenges of the project have required a great deal of investigations over the years and the design of detailed technical solutions. Various excavation methods are examined, depending on the geomechanical conditions, safety and minimisation of environmental impact. The tunnel crosses several alpine geological units with very heterogeneous geological and geotechnical conditions and high overburden up to approx. 2,200 metres, which poses particular technical and design challenges. Other aspects requiring in-depth design studies include surface logistics, underground logistics and the recycling of the excavated muck.

2.1 A difficult geological context

The base tunnel in the cross-border area is located in a very complex geological environment (Humbert, 2015; Monin et al, 2014). This complexity is not only due to the structural aspects, but also to the lithological diversity encountered. In fact, the tunnel is located between the Outer Alps (on the French side) to the west and the Inner Alps (on the Italian side) to the east, separated by the Pennic Front. Figure 3 shows the structural geology of the cross-border area. The geological reference model has been defined along a 4 km corridor along the route and is based on data collected since the 1990s by a series of deep geognostic boreholes along the tunnel axis (to date 357 surveys for a total of 67.7 km of boreholes, 260 km of geophysical surveys), followed by the excavation of the Saint-Martin-La-Porte, La-Praz and Villarodin-Bourget /Modane tunnels (approximately 11 km), the excavation of the La Maddalena reconnaissance tunnel (7.5 km) and detailed studies for the more complex areas (Monin et al. 2014). Ten macro-zones were identified, two of which are located in loose rock and eight in rock. The maximum overburden is approx. 2,200 metres, with around 40% of the alignment characterized by an overburden of more than 1,000 metres.

Particularly critical zones that require special construction methods are:

- The coal-shale formations of the Houiller Productif, a highly compressive formation in which convergences of up to 2 m occurred in the St. Martin del la Porte tunnel adit;
- The quaternary deposits of the Val Cenischia;
- The highly fissured zones in the Piedmont zone, where high water ingress is expected;
- The asbestos formation in the Piedmont zone;
- Tunnelling in fault zones with large overburden.

From a hydrogeological point of view, more critical conditions are expected than in the other

Alpine base tunnels already built or under construction.

In particular, the expected conditions required the design of technical solutions for high water pressures, minimising the impact on surface sources.

Figure 3. Geological profile main tunnel.

2.2 Long and deep tunnel

The design of a long and deep tunnel remains a challenge for engineers today, despite technical and scientific progresses. The complexity of a deep tunnel project lies in the difficulty of anticipating and limiting technical risks from the earliest stages of the project. Given the natural complexity of the geological environment encountered in deep tunnel projects, it is necessary to control the risks and understand the behaviour of the rock mass as well as possible in order to guarantee the safety of personnel and the durability of the structures. The construction of the main tunnel and other underground works will be carried out by alternating several tunnelling methods. Figure 4 summarises the different tunnelling techniques used. As a result, 75% of the tunnel is scheduled to be excavated with TBMs.

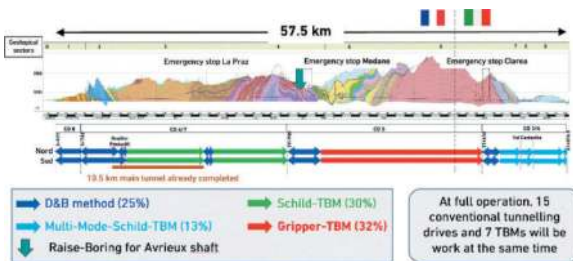

Figure 4. Excavation methods.

The 4 tunnel adits provide access for construction equipment and, at full capacity, 15 D&B headings and 7 tunnel boring machines will be in operation at the same time.

2.3 Logistic aspects to minimise environmental impact

An important aspect of the design is logistics, which must not affect production or safety during the construction phase, all in a very restricted environment.

All the construction sites, both in France and Italy, are designed to minimise external impacts (dust and noise) due to the very sensitive public. The sites are located in the Maurienne and Susa valleys, which

have a restrictive topography, a high density of infrastructures (energy, industrial, transit) and are locally urbanised (Figure 5). Recycling of the excavated muck from the base Tunnel will limit the transport of the spoils and optimise natural resources. Materials with the required characteristics will be used to produce aggregates for concrete, backfill or landscaping. Approximately 50% of the excavated material will be recycled in this way. Materials will be transported mainly electrically, by conveyor belt and by train.

Figure 5. The example of the Saint-Martin-de-la-Porte site.

3 LOTS AND AWARD OF CONTRACTS

The work was divided into operational sites in order to limit the number of interfaces between the various worksites and comply with the government approval deadlines. The system adopted allows considerable flexibility to be maintained in the allocation of design, construction and supply contracts.

In detail, the works are divided into 12 operational worksites (Figure 6):

- 4 lots for Alpine crossings, subdivided by geographical area, 1 in Italy (CO3/4) and 3 in France (CO5, CO6/7, CO8);
- 1 lot for the ventilation shaft in Avrieux (CO5a)
- 2 lots for the recovery of excavated material in Italy (CO10) and France (CO11);
- 1 lot (CO12) for the railway equipment and safety.

A total of 81 tenders are planned and divided in the following:

- 45 tenders for civil engineering works, divided into four tranches (up to €5 million, between €5 and €50 million, between €50 and €500 million and between €500 million and €1.3 billion);
- 36 tenders for engineering services.

The contracts stipulated between TELT and the companies to which the bids are awarded are “framework agreements” of the mixed (single-award) type. The services can be activated by two means:

- purchase orders: for work already perfectly defined in the contract,
- subsequent contracts: for work that requires additional specifications to those in the initial contract.

Subsequent contracts may only relate to:

- the analysis, sorting and classification of excavated materials,
- the removal of excavated materials to disposal sites,
- earthworks for disposal,
- the construction of structures interfacing with CO 12 (equipment).

All contracts are subject to the rules on the fight against mafia infiltration agreed between the French and Italian governments through the contractual regulations validated by the Intergovernmental Commission and ratified by the French and Italian parliaments, which take precedence over national laws.

Figure 6. Operational work sites.

The reference information for the main operating underground sites is provided in Table 1.

Table 1. The main underground construction sites.

Operational site	8	6/7	5	5a	3/4
Estimated value	0,23 bn€	1,43 bn€	1,47 bn€	0,22 bn€	1,2 bn€
Indicative length	3 km	23 km	22 km	4 shafts L=500m	9.4 km
Estimated time	70 months	79 months	73 months	52 months	90 months

4 CONTRACT MANAGEMENT

The risk allocation adopted for the TELT project, follows the principles set out in the recent FIDIC-Emerald-Book (FIDIC, 2019; Marulanda and Neuenschwander, 2019). TELT’s contracts are of the Design-Build type.

The Tender design is developed by the Client together with his Design engineer and completed by technical reports on the construction methods, phases and technologies proposed by the Bidder.

The organization of technical documents for the tender documentation and for the Contract comply with the GT32R3A2 (AFTES, 2020) and are summarized in the Figure 7. Documents similar to the GDR, based on extensive geological investigations and detailed risk analysis techniques, are developed by the Client’s Designer. The Contractor Designer is in

charge of the detailed design (DD) and for construction design (FCD), implementing the proposed construction methods, phases and technologies from the tender phase onwards. The site supervision and detail design check is carried out by the Client together with his nominated Designer.

The contract system is mainly based on:

- 1) the Risk allocation defines the risk type and the owner of the risks;
- 2) a reference Baseline Schedule which is defined in the tender, with contractual unit rates and items/quantities on the basis of the expected geology;
- 3) the time adjustment is recalculated on these bases, according to the effective condition encountered
- 4) some items (installations and equipment) are defined in terms of duration and are therefore activated in case of EoT.

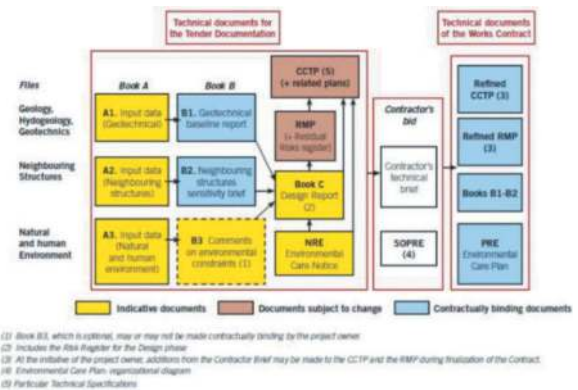

Figure 7. Technical documents for the tender phase according with AFTES GT32.R3A2 (AFTES, 2020).

The contractual time and cost for Excavation, including all necessary support will be adjusted accordingly based on the variations of the physical conditions of the ground encountered within the limits stated in the contractual excavation classes. This adjustment will be performed according to the amounts and production rates stated in the Baseline Schedules in accordance also with FIDIC-Emerald-Book. The contract system included the definition of deadlines, bonuses and contract penalties that could be adjusted on the basis of the effective ground conditions.

The calculation of the estimated construction time is updated periodically for each construction part, usually quarterly.

The construction programme, as shown on the Figure 8, contains the following elements:

- planned construction time: the construction time on which the works contract is based, calculated from the relevant quantities of the bill of quantities at the time the contract is stipulated and the contractor’s performance specifications in the works contract as well as from the planned work interruptions;
- Actual construction time: the construction time actually required;

- Construction time for valuation purposes: this construction time is calculated from the contractual quantities and rates on the basis of the geology actually encountered.

After completion of a construction phase, the contractor's advantage or delay can be determined. In the example of Figure 8, the contractor is behind both the target construction time (green) and the construction time for valuation purposes (blue) after construction month 3.

The backlog of the settlement construction time to the target construction time lies within the client's area of risk (difference green - blue). The backlog of the actual construction time to the settlement construction time is within the contractor's area of risk (difference blue - yellow).

Figure 8. Contractual risk management under normal and exceptional conditions.

Exceptional conditions of execution correspond to situations, not caused by a defect or default of the Contractor, which do not allow the execution of the works subject to the mechanisms of time-adjustment related to the excavations classes fixed in the contract. For the exceptional conditions, the Contractor provides to the Client, within 10 days, all the elements necessary for the assessment of the situation. A Technical Advisory and Mediation Committee (CCMT) may be mobilized by the Client in order to provide an opinion on the effective exceptional nature of the conditions. The entry into exceptional conditions and its date are definitively confirmed by the Client and notified by the

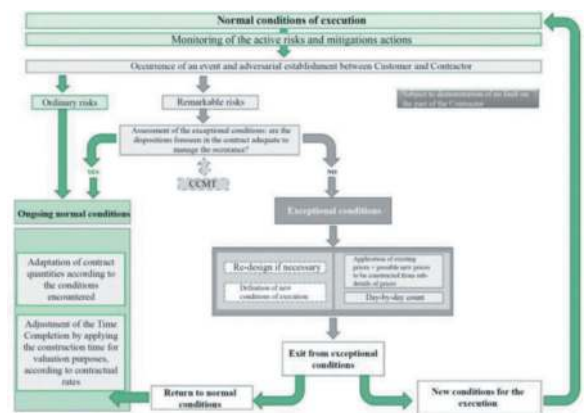

Figure 9. Contractual risk management under normal and exceptional conditions.

Contractor at the latest 4 weeks after. The following flowchart (Figure 9) summarizes the management procedures for normal and exceptional conditions.

Since the main lots are recently awarded or currently in the process of being awarded, there is no direct experience of claims but this possibility seems to be limited only to cases concerning situations not foreseen, and not foreseeable, given the responsibility of the Contractor and its Designer in the development of the DD and FCD.)

5 STATUS OF THE WORKS

In July 2021, all contracts for the entire base tunnel in France were awarded (three lots for a total of 45 km between Saint-Jean-de-Maurienne and the Italian border).

The contracts for the Italian lot (12.5 km between Bussoleno/Susa and the French border) was awarded in August 2023. The international tender for the equipping and technological installations of the tunnel was launched in June 2023. At the end of 2023, the status of the work can be summarised as follows:

- 10 construction sites are operational in France and Italy;
- 35 km, about 22% of the 162 km of tunnels have already been excavated;
- 12 km of the base tunnel have been excavated;
- 10.5 km of the base tunnel between Saint-Martin-la-Porte and La Praz, 9 km of which by Single-shield TBM and 1.5 km by conventional method through the complex formation of Houillier Productif, were completed in April 2022;
- In Saint-Julien-de-Montdenis, the cut-and-cover tunnel, an artificial tunnel that will be the French entrance to the base tunnel, was completed in the autumn of 2021
- In Saint-Jean-de-Maurienne a new temporary multimodal hub station has been in operation since mid-June 2022.
- In Villargondran, consolidation works were carried out on the embankments of the Arc river to protect from floods, as well as to prepare the platform. Work was completed in October 2021.

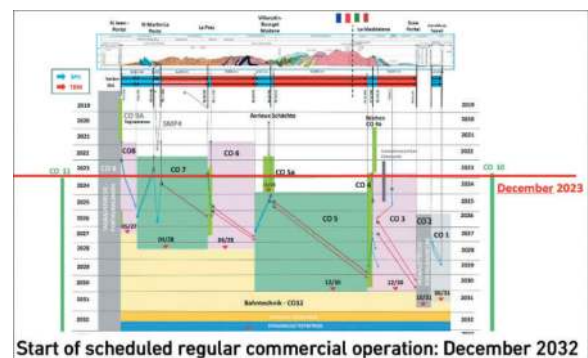

Figure 10. Construction programme.

- In France, the tunnel adit required to start the main construction excavation works were completed: Villarodin-Bourget/Modane (4,000 m, completed in 2007), La Praz (2,480 m, completed in 2009) and Saint-Martin-la-Porte (2,400 m completed in 2010 and 1,800 m completed in 2016)
- In Italy, the Chiomonte exploratory tunnel (Susa Valley, 7,020 m) was completed in 2017.

Overall, more than 2,000 people are currently involved in the construction of this project, including those working in the construction sites and those in services and engineering companies. During the peak of the activities, there will be 4,000 directly hired workers and the same number of people employed in the related supply chain. The following chapters summarize the status of the ongoing work in the base tunnel civil engineering lots.

5.1 Lot CO8 – Base Tunnel Saint-Julien-Montdenis /Saint-Martin-La-Porte

The works for the excavation of the base tunnel access, started in December 2022, continue in the 3 km section between the French entrance portal at Saint Julien Montdenis and towards Saint-Martin-la-Porte.

The operations are taking place on the Villard-Clément platform that previously hosted the work for the cut-and-cover tunnel. Excavation in this section will be carried out using the conventional method, by a combination of hydraulic breaker and explosives. The construction site was set up in December 2021 and during 2022 all the necessary equipment was mobilized and the preliminary work for the underground excavation was performed. The work will be spread over 4 years, and will be followed by the completion of the site, entailing the construction of the portal part of the entrance into the mountain that completes the cut-and-cover tunnel already built and the restoration of the site to its original state. The works are commissioned to the JV headed by IMPLANIA Suisse and composed of IMPLANIA France/NGE/ITINERA/RIZZANI de ECCHER. Currently about 35% of the work is completed. About 420 m of the first tube and 395 m of the second tube are already excavated (Figure 11).

Figure 11. Excavation works in CO8 lot.

5.2 Lot CO6/7 – Base Tunnel Saint-Martin-La-Porte

This construction site for the excavation of the 23 km of the base tunnel between Saint-Martin-la-Porte and Modane proceeds on two work platforms. In total, 43.5 km of tunnels will be excavated, mainly with TBM. Currently about 16% of the work is completed (Figures 12–13). The enlargement of the La Praz tunnel adit for logistic aspects was completed. The excavation of bypass tunnel (currently in progress) will allow the subsequent excavation of the TBM assembly caverns for the two TBM drive through the CO5 lot. In Saint-Martin-la-Porte the technical cavern where the TBM will be assembled is being excavated. The 3 Single-shield TBMs have a diameter of 10.4 metres, 180 metres long and have a total weight of more than 2,000 tonnes with a power of 8,100 kilowatts and 61 cutters.

Figure 12. Excavation works for technical cavern where the first TBM will be assembled.

Figure 13. Excavation works inside the tunnel adit La Praz.

All three shielded TBMs were produced and tested at the Herrenknecht factory in Germany in 2023 (Figure 14).

The first TBM should start excavation by the end of 2024. The works are commissioned to the JV headed by VINCI Construction Grands Projets France and composed of Dodin Campenon Bernard/VINCI Construction France TP Lyon/WeBuild.

Figure 14. Test of the TBM that will be used to excavate the 9 km of the northern tube of the base tunnel, between Saint-Martin-la-Porte and La Praz at the Herrenknecht factory.

5.3 Lot CO5a – Avrieux ventilaton shaft

The construction of the ventilation shafts for the base tunnel is under way. These are four parallel vertical tunnels to be built at an altitude of 1,300 metres. They are very important because they must reach the underground station of Modane (at the foot of the Villarodin/Bourget-Modane slope), 500 metres below, where they will contribute to ventilation and safety. The four parallel shafts with a diameter of 5.2 metres are excavated using Raise Boring Machines, a technology developed in the mining industry specifically for the mechanised excavation of vertical shafts of small diameter. Pilot holes are excavated into the underground caverns at a depth of 500 metres with drilling diameter of 38 cm with admissible tolerance in the vertical 0.46 ‰ or a maximum of 23 cm. Bars are then inserted into the holes, at the ends of the bars the reamers (the heads of the vertical cutters) are mounted, which then go back up and dig the shaft vertically. The excavated material, which falls by gravity, is taken out through the existing tunnel adit. The installation of the rock supports composed of FRC shotcrete and steel ribs for critical section are installed from top to bottom. A final lining of 35 cm in-situ concrete is installed from bottom to top.

The four pilot holes were completed in April 2023. The first shaft was excavated and about 300 m of rock supports are installed. For the second shaft the excavation was completed and the installation of the rock-supports will begin shortly, while boring will start for the third shaft. The safety site tunnels and several technical caverns up to 22 metres in height and 23 metres in width, are also being built underground. They will be used to assemble the TBMs that will then excavate towards Italy. At the end of 2022, the group of companies procured the two tunnel boring machines planned for the excavation of this section. 35% of the works are currently completed.

The works are commissioned to the JV headed by VINCI Construction Grands Projets France and composed of Dodin Campenon Bernard, VINCI Construction France, Webuild e Bergteamet.

Figure 15. Pilot holes and raise borer machine for the excavation of the Avrieux shaft.

Figure 16. Layout of Avrieux shafts.

5.4 Lot CO3-4 – Italian main lot

Preliminary work started in December 2023. In Chiomonte (Susa valley) there is the largest Italian construction site.

The excavation of the niches to facilitate the passage of construction vehicles in the Maddalena 1 tunnel, completed in 2017 (Baldovin et al., 2017), is completed in November 2023. The niches (each 3 m deep and 30 to 40 m long) are constructed every 300-400 m along 7 km. They will transform the tunnel, which was created for exploratory purposes, into an access point for the construction vehicles. In Chiomonte, the construction site for the new junction of the A32 motorway, which will allow the transit of construction vehicles without interfering with the local road traffic is also operational.

Particularly interesting for this lot will be the excavation inside the Cenischia Valley (Figure 17-18). Over a length of around 1 km, the alignment runs through a section with an overburden of approx. 50 m, characterised by the presence of alluvial deposits below the groundwater table with high permeability. The hydraulic pressures are around 5 bar. The alluvial deposits of the Cenischia Valley are classified as sands and gravels with a fine matrix with intercalations and lenses of cohesive material and the possible presence

of larger stones and boulders. The excavation in the quaternary layers and the impossibility of lowering the groundwater level, which is partly due to the built-up area of Venaus, led to the decision to work with a “dual-mode” TBM in this section.

The TBM can be operated both in open mode and in closed mode as a “slurry TBM”. The transition zones with mixed face are critical. The segmental lining is 100% tight in this area, the lining must be designed for the full water pressure because no drainage measures are allowed.

In addition to driving the main tunnels, the construction of several cross-passages between the two tubes as well as technical niches is planned in this section.

The cross-passages and technical niches in the loose rock will be excavated using the freezing method. Outside the excavation area, a ring-shaped shell of frozen ground is created, within which the excavation and stabilisation work is carried out. The excavation work may only take place after completion of the freezing phase, which is considered complete when the frozen shell is closed, i.e. when the minimum thickness of 1.00 m required for the project has been reached at an average core temperature of $\leq -10^{\circ}\text{C}$.

The freezing system may only be deactivated after the final in-situ concrete lining of the cross-passages has been completed.

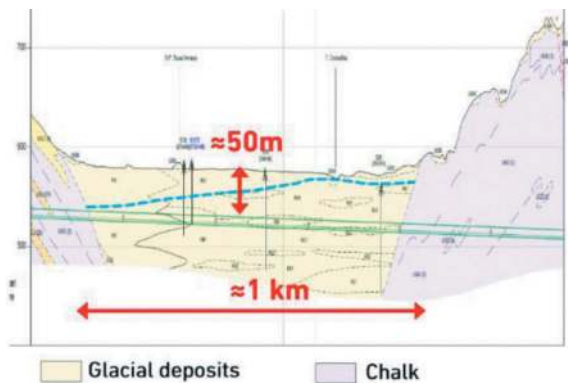

Figure 17. Dual-Mode-TBM excavation inside Cenischia Valley.

Figure 18. Excavation of the bypass using the freezing method.

6 CONCLUSIONS

The following recommendations can be provided based on the experience of the design and execution of the contracts for the construction of this major underground structure characterised by several complex challenges:

Risk management:

- A fair distribution of risks between contractor and client;
- Control of risks in the planning and construction phase with clear mechanisms for activating corrective measures;
- The client’s risk analysis must indicate a possible change in the construction period;
- Control of the interfaces within the lots and among the various construction contracts during all phases of project realization.

Cost management:

- Time-dependent costs must be clearly defined in the bill of quantities;
- A fair allocation of risk between the client and contractor enables quick solutions to be found in the event of changing conditions.

Contractual flexibility:

- Introducing a decision-making tool that can react very quickly to changing conditions;
- Providing the opportunity to implement alternative solutions where appropriate;
- Ensure the consistency and technical quality of the project by rapidly incorporating feedback from experience, using new data acquired during the construction phase to improve the ability to predict the behaviour of the massif and anticipate problems as far as possible, in the interests of efficiency and control of timescales and costs.

Safety and environment:

- Ensuring safety during the construction, operation and maintenance phases;
- Controlling the quality of emissions into the air and aquatic environments, noise pollution for local residents and protecting sensitive environments during the construction and operation phases;
- Managing excavated materials to optimise transport, reuse of materials and use of temporary and permanent disposal sites.
- When the Lyon-Turin line will be operational, over 1 million lorries used for international road transport will no longer be present on alpine roads, thus reducing CO₂ emissions by 3 million tons per year.

Quality of the structure:

- Ensure the durability of the structure for 120 years, taking into account the aggressive nature of the soil and water in certain sections;
- Enable the structure to be operated and maintained with minimum intervention.

ACKNOWLEDGMENTS

The authors would like to thank TELT-sas for the permission to publish the data contained in this paper. The authors would like to thank the S2IP site supervision consortium (Setec, Systra, Italferr, Pini Group) for their support.

Risk limiting in urban tunnel contracts

Harald Wagner*

DHW Consulting Engineers Pte Ltd Bangkok Thailand, Thailand

ABSTRACT: In urban tunnelling, any approach has its limitations in adequately describing the Ground-Structure-Interaction (GSI). Applied approach is of eminent importance in evaluating unforeseeable risks. Tunnel excavation causes disturbance of initial state of stress creating 3-Dimensional-Stress-Regime umbrella like at the tunnel face. Each Simulation of Excavation & Installation of Initial Support shall analyze risks and ground response. Digitisation and engineering based on experience helps to fast-track green underground solutions towards the delivery of UN Sustainable Development Goals (SDG). It helps to limit risks in urban tunnelling and supports contacts with infrastructure industry. Full support is given to “rated criteria” approach at procurement, which has been hailed as a “game changer” for promoting value in procurement. The rated criteria approach underlines the objective of achieving SDG objectives. International procurements shall require use of rated criteria including risk analysis in addition to price as part of bid evaluation.

1 INTRODUCTION

Where municipalities have made decisions for Underground Structures, - taking the example of Mass Transport Systems -, there are positive effects. Living quality for the residents is rising as environmental conditions are improving. Where cost analysis includes environmental effects, land value increase etc., Underground attracts more than Above Ground.

Reasons behind are to be discussed and evaluated as they are manifold. In many cities there are historical reasons.

Beginning of public transport on surface started in the middle of the 19th century, when underground technologies in urban areas have been unknown.

Infrastructure projects are investments for the public. Decisions are made by political representatives of the public. Public Authorities are managed by own staff, supported by external experts. Political/economical responsibilities may change, as decisions are reaching far into the future.

It is expected that from nowadays 15 mega cities with population exceeding 10 million, there will be a total of more than 50 mega cities in the year 2050. As a consequence of this development the amount of underground infrastructure will be multiplied with a factor of 5 to 10. While in the past there has been an opinion that underground structures are expensive, in the future we will see a development whereas

Figure 1. Global megacities (2010/2050).

underground structures will be considered as investment with return to the public, rather than cost.

While underground structures have been considered in the past of being risky due to some spectacular collapses, the underground industry led by the International Tunnelling Association together with the International Tunnel Insurance Group has responded to that development. Risk Management Guidelines became a standard tool in most tunnel design and

*Corresponding author: drhrwagner@yahoo.com

construction contracts. By managing the risk of underground structures, significant improvements resulted in successful projects, leading to the conclusion, that underground structures are equal in risk and chance.

An integral part of tunnelling is data verification by means of in-situ monitoring of design assumptions made regarding the interaction between the ground and initial support. Collapses happen and contractors claim for not reasonably foreseeable. All subsurface physical data described in tender documents are deemed to be foreseeable, and subsurface physical data outside scope of conditions defined in tender documents are deemed to be Unforeseeable.

The contractor shall be deemed to have based proposals for excavation and lining works on the subsurface physical conditions and ground reactions described in the tender documents irrespective of any discrepancy or ambiguity that may be found between such conditions and/or reactions and conditions described in any data made available.

Physical Conditions mean natural physical conditions and reactions of the ground to excavation encountered, having been Unforeseeable and having an adverse effect on the progress increasing cost of execution. It shall be assessed under measurement of excavation and lining works and adjustment of time for completion and contract price. Even under conditions of actual increasing geotechnical observational data, elimination of Unforeseeable Risks per se would lack factual geotechnical uncertainty in underground construction.

In order to ensure uniform style throughout the papers, all the papers have to be prepared strictly according to the instructions set below. Please review this document to learn about the formatting of texts, table and figure captions, references, and the method to include the indexing information. The full paper in MS Word file shall be written in compliance with these instructions (Full paper template). At a later stage, it will be converted into Portable Document Format (PDF).

2 MASS TRANSPORT TUNNELS

The choice of Tunnel Contract Model is determining design, specifications, and drawings to visualize the structure resulting in a sustainable underground building. Tunnel Designer together with his client is deciding about the future success at the very early project stage. He is at same time the manager of the tunnel construction itself. His decision of contract model, standards, and design, assessing the risks, becomes a management tool in construction. This lecture on tunnel contract models, used standards, site organization, and construction management summarizes the state of the art of contracting for both Conventional and mechanized tunnelling.

A detailed description outlines contractual applications, and construction site organization. Fundamental requirements for contracting tunnel works are knowledges of

- Ground condition evaluation/classification, requirements,
- Decision on the use of standards and specifications,
- Design with staged subdivisions, following project/construction,
- Construction Methods suite for plant, equipment, material,
- Risk Management Plan (RMP), Geotech Baseline Report (GBR),
- Flexible Contractual Models for fair remuneration.

With constantly growing underground infrastructure market, demand for proper designed and contracted Underground Works is continuously growing. Today Conventional Tunnelling (CTM) and TBM Tunnelling are both well suited for tunnelling under difficult, complex, and rapidly changing geological and geotechnical conditions.

Minimizing construction cost by models, driving cross section, driving methods, and lining during the design and construction phases are of the essence. During tunnel excavation simultaneous and joint decision by applied contract model must be realized within predetermined limits to manage flexible response to changing ground and ground behavior conditions.

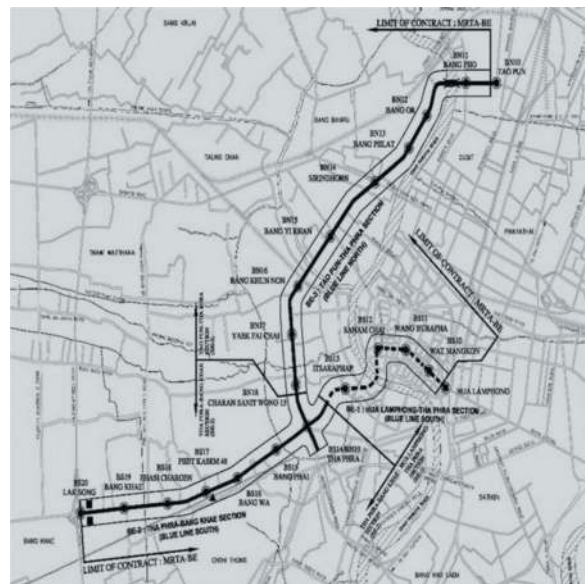

Figure 2. MRTA's blue line extension project in Bangkok (Lay Out).

Tunnels need robust design as well as suitable contract models including suitable standards. Tunnelling needs project specific trained, qualified, and experienced consultants, designers, and contractors. It needs qualified and experienced engineers on site, and qualified and experienced workforce. Contract models shall be able, to cope with changing ground behavior, on base of GBR and RMP. Fair and objective risk management shall be reflected in the contract.

The City of Bangkok has 2 Mass Transport Systems with the Sky Train as an elevated structure dominating the environment of the city where it is built, and the Metro which in the inner urban area is underground, and at the city's Periphery an elevated structure.

Traffic jams in the city and on the roads are daily and omnipresent. Bangkok Municipality's Mass Rapid Transit Authority (MRTA) has therefore decided to invest in further extension of the mass transport infrastructure with the Purple Line having an above ground elevated alignment, and with the Blue Line Extension.

The MRTA Blue Line Extension Project is the 22 km elevated structure with approx. 5 km of Underground Structure. The project is separated into 2 sections, which are Hua Lamphong – Bang Khae section (14 km) and Bang Sue – Tha Phra section (13 km). Hua Lamphong – Bang Khae section contains 7 elevated stations and 4 underground stations. Bang Sue – Tha Phra section contains 10 elevated stations.

The Underground Structure of this project is challenged with complex construction issues around the Old City Area, also known as the Rattanakosin Island. Two underground stations are located inside Rattanakosin Island. These stations need to be constructed using NATM mined methods in order to minimize environmental impact.

Bangkok is a good example but not the only city having both above and underground competing transportation infrastructures. Other examples are the City of Vienna/Austria with U-Bahn (Metro) and S-Bahn (Railway), the City of Hamburg/Germany, New York City/USA et al.

3 URBAN ROAD TUNNELS

Societies worldwide are requesting free mobility, but mobility demands it's toll. Most cities have an urban historical background, and few cities only have, in their core urban structure, streets or roads which are suitable to modern traffic requirements. In fact, most cities have overlapping old fashioned traffic infrastructure with new infrastructure needs and provisions due to increased traffic demand.

Tehran, capital of Islamic Republic of Iran, provides a pioneering example of advanced technical solution in the northern part of the city, in realizing an integrated and intelligent underground urban infrastructure for road traffic and for parking in the alluvial deposits beneath a park.

A total tunnel length of approx. 2 x 3.5 km of unidirectional advanced equipped 3-lane tunnels with complex wide span bi-furcations exceeding 200 m² and lay by areas is under construction using Conventional Tunneling Technology (NATM) in combination with the Iranian Ribbing Method, which has a century long and very successful tradition in the area.

Figure 3. Freedom in underground space use - Bifurcation (Lay Out).

Figure 4. Tehran's urban tunnels (Lay Out).

4 URBAN LORRY TUNNELS

Roads at the beginning of the 21st century and roads one hundred years ago are very different. Traffic in the old days has been fully compatible with living conditions. There was rarely any concern in terms of safety for the neighboring population on the roads under regular traffic conditions. Roads have been used combined, without any hesitation, both for people and for freight traffic.

Roads as a transportation means have reached at the beginning of the 21st century their capacity limits. Serious traffic jams and delays combined with noise, multiple emissions, e.g. carbon dioxide, NOx and fine dust particles, constitute a high risk potential, especially in congested urban area, for urban population, resulting in an increasing demand for separation of people and freight traffic.

Fully automated underground transport concepts can provide freight transport for direct connection between recipient, e.g. department stores in the city centers, and distribution centers located outside the city. In particular in congested urban areas this will serve the distressing of the roads from increasing freight traffic and reduce the environment related problems providing additional surface space.

Due to the use of the underground space this concept offers independence from other traffic infrastructure, traffic jams and unfavorable weather conditions. Transport is managed by computer controlled logistics and is warranting a high freight and destination flexibility.

5 SUMMARY

The world is realizing the shift of economy from rural agrarian to urban service and manufacturing industry. Realisation depends highly on back up infrastructure and energy availability. Requirements are interwoven with developments of underground structures provided by hydro tunnels for energy, metro tunnels for mass transit, road and railway tunnels narrowing communities and underground space development along stressed city centers.

The choice of contracting method and evaluation of tunnel behaviour means balancing the interaction between project owner and contractor, as well as between equipment and ground. For designers guided by FIDIC's Emerald Book, it means production of specs and drawings to visualize a structure which results as a tunnel. The tunnel designers are becoming managers of tunnel contracting including many of its risks, as the choice of contracting and design becomes a management tool in construction.

The paper focuses on principles of tunnel contracting for future Infrastructure and for contract management by design, summarizes state of the art for both conventional (NATM) and mechanized (TBM) tunnelling. Details are provided in regard to Infrastructure and innovative BIM (Building Information Method) technologies, the Choice of Tunnel Contracting, Principles of CTM Tunnelling, Principles of TBM Tunnelling, Monitoring for CTM and TBM Tunnelling, CTM Tunnelling in Soft Ground & Hard Rock.

Issues focus on Underground contracting including claim management, Hydro Tunnelling, Flood-water Control Tunnels, design stages, contractual applications, and construction organization. The ultimate Goal are recommendations for a contract management system and model contract agreement to contribute to accelerated design and construction free of arbitration and disputes.

6 CONCLUSIONS

For Underground Infrastructures in the future a Paradigma Change is to be expected.

As Underground solutions are going to become more attractive, more economic and more safe, even odd surface space is going to receive increased attraction for developers and in consequence will rise in value due to achievements in underground technology.

The lesser above ground infrastructures will require land and space, and the more quality standards of environment will continue to be forced by law, and better life quality is going to be realized.

Underground space use will offer the only sustainable alternative for further development and expansion of living and working.

Within the frame of mega projects, hydro tunnels are going to prevail against open canals. Mass Transport Tunnels are expanding in mega cities with breathtaking progress rates.

Shanghai is giving an example of constructing up to 50 km completed metro sections per year, the majority of which are both mined and open cut tunnels, over the past 15 years.

Freight Tunnels are offering sustainable underground solutions for traffic and transportation problems in urban areas, in separating freight traffic from individual traffic such contributing to the minimization of required storage space of retailers in the cities and to the life quality of the fast increasing global urban population.

The Underground Industry is responding with a clear and positive answer to the question "Why not Underground". It is responding and addressed to sustainable development of a global society.

Underground Infrastructure is growing continuously in the future, providing interesting new challenges for young engineers who are best educated and trained in their profession.

ACKNOWLEDGMENTS

Creative collaboration is spanning decades with ITA International Tunnelling and Underground Space Association's long term Secretary General Claude Berenguer and Executive Director Olivier Villon.

Beyond collaboration with TWB The World Bank, IDB Interamerican Development Bank, ADB Asia Development Bank, and IFC International Finance Corporation, successful collaboration in design and construction has been performed.

Major stake holders of Underground Infrastructures to be acknowledged and highly appreciated are Pravin Karki c/o TWB The World Bank Washington/DC, Julio Lemaitre c/o IFC International Finance Corporation Washington/DC,

Jose Luis Irigoyen c/o IDB Interamerican Development Bank Washington/DC, Vivien Castro Wooldridge c/o ADB Asian Development Bank, Manila/Philippines.
