3 BELGIAN OR TRADITIONAL MADRID METHOD

This method is widely used in the construction of metro tunnels in Madrid, as it adapts well to the nature of the

ground and due to the high level of safety that is achieved during excavation as the size of the open front is minimised at all times. A disadvantage is that the excavation has to be carried out by manual means, and the number of skilled workers that it requires given that performances of some 40 m per month are usually obtained with three shifts made up of 12 workers per shift, therefore several fronts must be opened in order to meet reasonable works execution times. The above is true for the coarse and fine sands found in a large part of Madrid's terrain. However, the ground crossed by the tunnel for the Line 3 Extension to El Casar belongs to the tertiary basin of Madrid, where very compact clays are present with gypsum and even gypsum rock which provide very unfavourable excavation conditions for the work with this construction methodology as very low performance is achieved due to the ground hardness that must be dig with jackhammers.

The excavations are carried out in four phases that are executed successively:

Heading or excavation of the vault.

Figure 11. Phase 1 traditional madrid method.

The excavation starts with a small gallery in the crown, called the top heading, of the order of 1 metre in width and 2.5 metres in length that is continuously shored up with underpinned timber boards to stabilize the excavation. The excavation of the front then continues by laterally widening the gallery with passes of a similar size, so that the alteration of the ground is minimal in each pass. When the complete width is excavated, formwork is put in place and the tunnel vault is concreted.

Figure 12. Construction sequence.

Given the aforesaid adverse conditions for excavation in ground formed by compact clays or directly in gypsum rock, an adaptation of the Traditional Madrid Method was proposed involving extending the length of pass from 2.5 to 3 m and avoiding

shoring, taking advantage of the fact that the ground remained stable with discontinuous support.

With this method, as fewer props are required, the front can be accessed with small machinery but that has better performance than the manual method, thus achieving a certain improvement in the cycle time.

Figure 13. Heading front with a combination of manual means and small machinery.

Central area bench excavation.

The lower central part of the excavation is excavated several rings behind the completed inverted

Figure 15. Bench excavation and transition ramp to the heading front.

vault (at some 15 to 20 m from the front) in such a way that the mass concrete vault is not undercut. Due to the size of the chamber to be excavated and the height to the roof, a backhoe is used.

Side walls (Hastiales).

Figure 16. Phase 3 traditional madrid method.

After the bench excavation, the side walls are executed in a staggered way. The length of the side wall pass is 2.5 m (3 m), identical to that of a heading pass, but offset by 1.25 (1.5m) and without excavating facing passes so that an inverted vault ring is never completely undercut, and it is always supported either on unexcavated ground or on a previously executed side wall.

Figure 17. Excavation of a wall trench.

Invert.

Figure 18. Phase 4 traditional madrid method.

Finally, invert of the tunnel is excavated and concreted, which closes the structural ring which makes up the complete section. Usually, it is executed in sections of some 20 m in length in order to complete the work at weekends.

Figure 19. Refining the excavation of the inverted vault bed assist with a stencil.

As a complement to the excavation and construction of the lining-support, slurry is injected into the backfill in order to close possible gaps between the concrete lining and the ground, whether caused by the loss of temporary shoring of the excavation or because an air bubble was trapped during concreting.

4 MADRID SEQUENTIAL EXCAVATION METHOD

The compactness of the materials excavated in the mined tunnel for the extension of the Madrid L3 to El Casar, made up of compact clays with gypsum in variable proportions and gypsums with hard clays over a large part of its layout, has complicated the construction by the Traditional Madrid Method due to the hardness of the materials whose excavation by the applicable means (pneumatic jackhammers or low-power machines due to space limitations) does not provide reasonable performance making it impractical to complete the tunnel within a reasonable timeframe. Consequently, an excavation method was proposed whose excavation front would have a larger opening

Figure 20. Section type of madrid sequential method.

and thus provide the opportunity to use excavation machinery of sufficient power to break up the front material more effectively and would allow an excavation rate compatible with the works schedule.

The excavation procedure for this work has been called the “Madrid Sequential Method” (MSM) in reference to similar excavation systems based on the construction of a flexible support by the application of a certain thickness of concrete sprayed on the excavation contour (together with other reinforcement elements). These types of procedures are not usual in urban environments given the greater deformability that the support allows and lower stability of the excavation front when they are used in soils. Nevertheless, it is considered that the tunnel layout, away from buildings, and the nature of the ground, which is not rocky and has high compactnesses and resistances, allows this procedure to be used without detriment to the safety level or affecting nearby structures.

The elements that make up the support in the MSM are:

- Sprayed concrete, HP-30/F/12/IIa+Qc.
- Polypropylene reinforcement fibre of the sprayed concrete dosed at 3 kg/m³.
- Trusses with HEB 140 profile spaced at 1 m.
- Front sealing with sprayed concrete for protection against the weather at weekends or during prolonged stoppages.

Figure 21. Elements of support.

The section is excavated in a single phase, the complete section except the lower part of the invert, with a 1 m pass (it has been checked that the open front is almost completely stable).

When the excavation is finished, a 6 cm layer of sprayed concrete reinforced with polypropylene fibre is wet-gunned by a robot. Then, a truss is put in place against the sealing formed from an HEB-140 profile that will be embedded in another layer of sprayed fibre-reinforced concrete of 19 cm thickness. So that the truss is not forced into the base of the excavated ground when it comes under load, it is supported on metal base plates. The next pass starts when the above process is complete.

Figure 22. Excavation the complete section.

problem. Thus, a convergence reading section is put in place every 20 m to collect data every day at the start in order to verify the slowing down of the deformation and the stabilisation of the excavation.

Ilustración 1: Esquema de colocación de cinta extensométrica entre dos pernos

Figure 27. Tape extensometer.

At the end of the week, the inverted vault section corresponding to the previously executed support is concreted, thus closing the structural ring.

Although deformations of the supports are monitored in all the other methods, in the MSM it is essential to carry out an exhaustive monitoring of the closing of the excavation and the support by means of convergences, because, as the support is more flexible, it will deform until it reaches equilibrium with the ground pressure. In the case of there being heterogeneity in the ground not considered in the calculation, this would be shown in the increase of deformation above that envisaged, and the support can be suitably reinforced to solve a possible

Figure 28. Convergence section.

Figure 29. Convergence reading.

Example of convergence graph showing a trend towards stabilization of measurement.

Figure 30. Example of convergence graph with a trend toward stabilisation of the measurements.

The performances obtained are 3 to 4 passes per day and front with support work at 24 hours per day from Monday to Friday and concreting of the inverted vault at the weekend, which equates to monthly progress of around 50 m per front. The support and inverted vault described allow a stable excavation in itself.

Nevertheless, a non-structural HM-30 mass concrete lining is constructed (but also strong and, therefore, redundant) which will smooth the irregularity of the sprayed concrete surface, thus matching the finish of the rest of the tunnel, without complicating hanging systems for the energy conduits and tunnel installations. It will be constructed by means of a moving formwork carriage in 10 to 15 m sections as soon as there is sufficient distance with respect to the front and its interior contour will be coincident with that of the tunnel support constructed by the Traditional Madrid Method.

Deformation failure characteristics and control measures of shallow loess tunnel of water-rich stratum: A case study

Kunjie Tang* & Junling Qiu

School of Highway, Chang'an University, China

ABSTRACT: With the acceleration of tunnel construction, it is inevitable to cross the collapsible loess region. The engineering properties of loess are very poor in the water-rich environment. Additionally, if the buried depth is shallow, the load bearing capacity is further weakened, which can increase the difficulty of tunnel construction. Therefore, this paper provides a case study on the Pangwan Tunnel based on a geological survey, numerical simulation, and on-site monitoring. The failure characteristics of the studied area under the original support scheme are analyzed in detail, and the extreme deformation mechanism is discussed combining the geological conditions and surrounding rock properties. The results show that there are five main reasons resulting in the extreme deformation of the Pangwan Tunnel, which are: abundant groundwater, low strength of surrounding rock, disintegration of loess after water immersion, depth of tunnel is shallow. Then, the corresponding countermeasures are proposed, which are advance drainage, large arch foot and foot-lock bolt, sealing tunnel face and grouting timely, as well as advance pipe shed and small pipe grouting. Finally, from the feedbacks of field application results, extreme deformation of the Pangwan Tunnel is effectively controlled. This work can provide some helpful guidance for similar projects.

1 INTRODUCTION

In recent years, China experienced a fast expansion of its highway network. As the network advances to the northwestern part of China, it is inevitable for some highway routes to pass through China's Loess Plateau (Qiu et al., 2020a). Because of the unique structure and complex engineering properties of loess, the diversity of engineering problems is unprecedented during construction of loess tunnel (Qiu et al., 2018). Especially, tunnel is built in water-rich loess stratum, surrounding rock strength decreases rapidly, and it's going to be silted with poor stability after excavation, that in-turn results in extreme deformation of surrounding rock and by extension damage the supporting structure. For example, during the Shangge Village tunnel (Hong et al., 2021a) passes the soft-plastic loess stratum, distresses including falling blocks and a deformed steel arch were observed during tunnel construction (Figure 1a). Meanwhile, seepage water is observed on the tunneling face and water catchments in the middle and lower benches (Figure 1b). Currently, Pangwan Tunnel is a key project in the Loess Plateau of

China, which connects Fu-Yin Highway and Qinglan Highway. It is different from other loess tunnels in that the Pangwan Tunnel inevitably passes through the water-rich loess stratum due to restricted route schemes. Entrance of the tunnel is extremely disadvantageous due to geological conditions and brings great difficulties and challenges to construction.

Extreme deformation of loess tunnels is always a puzzling problem, which causes safety issues and decreases construction quality. Aiming at this problem, many scholars have conducted research. Xue et al. used the Delphi-extension model to study the deformation characteristics in loess ground. Influencing factors on deformation were analyzed through mining statistical data by rough set (Xue et al., 2018). Taking the loess tunnel with large section of Lanzhou-Chongqing Railway as the research object, Hu et al. found that the vault subsidence weakened slowly, while the side wall horizontal displacement weakened quickly, and the horizontal convergence was generally less than the vault subsidence. Meanwhile they suggested that the appropriate reserved length of core soil is $2R/3$ (R is the tunnel conversion radius), which can

*Corresponding author: tangkunjie@chd.edu.cn

effectively control the longitudinal deformation of surrounding rock (Hu et al., 2012). Zhao et al. systematically summarized the engineering problems of HSR tunnels constructed in loess ground. They found that the displacement of the tunnel in loess ground was highly relevant to the engineering properties of loess (Zhao et al., 2018). Based on Dayoushan loess tunnel, Lai et al. proposed that the final deformation of the tunnel can be predicted by exponential function through field test and research and gave the reserved deformation of vault and side wall respectively (Lai et al., 2015).

Figure 1. Distresses during tunnel construction (a: Falling block, b: Water accumulation at the tunnel toes).

Moreover, as the engineering properties of loess are greatly affected by water environment, more research results have shown that the tunnel can occur severe deformation during construction in water-rich loess (Qiu et al., 2020b; Weng et al., 2019, 2021). Li et al. carried out large-scale field immersion tests on loess ground with an existing tunnel. The results show that surface water could infiltrate into the invert arch of the tunnel, causing extreme deformation of loess near tunnel arch crown (Li et al., 2019). Cui et al. investigated the deformation characteristics of surrounding rock under different loess states and proposed the reasonable reserved deformation amount of tunnel under different loess states (Cui et al., 2021). Hong et al. studied deformation characteristics of soft-plastic loess tunnel by carrying out a series of in situ measurements and numerical simulations (Hong et al., 2021a, 2021b). The results indicated that when the tunnel is totally embedded in the soft-plastic loess, the radial displacement values above the wall waists undergo dominant deformation, while the radial displacement of wall feet is smaller. To control surrounding rock deformation, they proposed to use advanced drainage in combination with advanced small pipe grouting.

Although some exceedingly valuable experience and lessons of tunnelling in loess stratum have been documented in the literature, there have been limited studies focused on shallow water-rich loess tunnel. Due to the lack of experience and awareness, serious

engineering accidents occurs during construction, which seriously endangers the safety of construction personnel and tunnel construction equipment (Jefferson et al., 2004; Derbyshire et al., 2011). To further explore the deformation characteristics of shallow water-rich loess tunnel, taking Pangwan Tunnel as a case study, this paper records the deformation process of surrounding rock through on-site monitoring, analyzes the mechanism of extreme deformation, and put forward corresponding countermeasures. The results are found to be effective based on the analysis for the on-site monitoring, which can guide in the construction of the Pangwan Tunnel. Additionally, the results of the paper create a value-set of references for similar projects.

2 PANGWAN TUNNEL OVERVIEW

2.1 Project description

Pangwan Tunnel is a key control project in the connection line between Fu-Yin Highway and Qinglan Highway. It is located in Xiji County, Guyuan City, which is in the Loess Plateau of Ningxia Region, as shown in Figure 2. A design structure of two unidirectional bores and four lanes, a construction clearance width of 13.36 m, a construction clearance height of 10.76 m and a speed of 80 km/h are adopted by Pangwan Tunnel. The lengths of the left and right lines are 1558 m and 1605 m respectively, the maximum burial depths are 169 m and 157 m respectively. The surrounding rock above class V accounts for more than 75.3%. The tunnel entrance is located on the gentle slope of the valley, with a topographic gradient of about 2°.

Figure 2. Tunnel location.

2.2 Geological conditions

Pangwan Tunnel is located in the central area of loess plateau, rugged terrain, ravines and soil are collapsible loess. The geological structure of the tunnel region belongs to the fold area of the Kunlun Qinling geosyncline. The northeast tunnel region is the corridor transition zone (Liupanshan complex anticline), and the southwest region is the Geosyncline Caledonian fold belt. The elevation of the ridge ranges from 1960 m to 2140 m, and the relative elevation difference is about

180 m. It declines from south to north, and the topography undulates greatly. The tunnel entrance with a topographic gradient of about 2°. Pangwan Tunnel geological conditions are shown in Figure 3.

Figure 3. Pangwan tunnel geological conditions.

According to the engineering geological survey and drilling, the surrounding rock of the study area (ZK63+540 ~ ZK63+590) is mainly composed of loess-like silty clay and loess, with underlying sandy mudstone. The physical and mechanical parameters of surrounding rock are shown in Table 1.

3 DEFORMATION FAILURE CHARACTERISTICS AND MECHANISM

3.1 On-site monitoring

Because the entrance section of Pangwan Tunnel (ZK63+540 ~ ZK63+590) is V class surrounding rock, the stability is poor. Therefore, this section is selected as research section and carried out on-site monitoring. A test section is arranged every 5m and the test contents include tunnel vault subsidence and horizontal convergence. The test data are selected when the measuring points reading remain stable. The layout of measuring points is shown in Figure 4.

3.2 Results analysis

Typical sections ZK63+571 and ZK63+577 of the left line are selected for analysis, and the typical time-displacement curves of the surrounding rock are shown in Figure 5.

The maximum vault subsidence of ZK63 + 571 and ZK63 + 577 sections are 263.8 mm and 253.2 mm respectively, and the maximum horizontal convergence are 108 mm and 81.6 mm. Extreme

Figure 4. Layout of deformation measurement.

deformation occurs during construction of shallow water-rich loess tunnel. Additionally, in some seriously deformed areas, initial support damage or even large-scale collapse occurs during the on-site monitoring.

In ZK63+571 section, extreme deformation occurs in the vault within 1-5 days after excavation. After the excavation of the upper step, the vault subsidence reaches 85.1 mm, achieving 32.3% deformation. The horizontal convergence reaches 30 mm, achieving 27.8% deformation. When the lower step excavation is completed, the vault subsidence reaches 191.8mm, achieving 72.7% deformation; and the horizontal convergence reaches 74.5 mm, achieving 68.9% deformation. After the inverted arch is poured, the vault subsidence and horizontal convergence reach 254.1 mm and 99.6 mm, achieving 96.3% and 92.2% of the deformation, respectively.

In addition, it can be seen from Figure 5 that the deformation trend of surrounding rock in the two selected sections is almost the same, and the two typical sections show three stages of rapid deformation development, continuous deformation development and stable deformation. (1) Rapid development stage of deformation: the tunnel is in the initial stage of excavation, the surrounding rock is disturbed, and the stress of surrounding rock is released. The initial support may be delayed, so the deformation rate and deformation amount of surrounding rock increase continuously, and the maximum deformation rate

Table 1. Surrounding rock physical and mechanical parameters.

Surrounding rock type	Density $\gamma(kN/m^3)$	Poisson ratio μ	Friction angle $\varphi(^{\circ})$	Elastic modulus $E(MPa)$	Cohesion $k(kPa)$
Loess-like silty clay	18.5	0.32	25	8.5	28
Loess	18.7	0.35	20	9	30
Sandy mudstone	25×10^3	0.38	32	1.36×10^3	447

occurs at this stage. Therefore, advance support should be strengthened at this stage to improve the strength of surrounding rock. (2) Sustainable development stage: the subsidence and convergence rate of surrounding rock decrease obviously due to the effect of initial support and the formation of plastic zone. However, the vault subsidence and horizontal convergence continue to increase, so the disturbance of surrounding rock should be reduced as much as possible to realize the deformation stability of surrounding rock. (3) Deformation stability stage: the inverted arch of the tunnel is completed, which increases the support reaction and enhances the stability of the tunnel. The deformation rate is very small and the tunnel deformation tends to be stable.

Figure 5. The time-displacement curves of surrounding rock.

3.3 Deformation and failure characteristics

3.3.1 Extreme deformation

From the monitoring results, the surrounding rock shows extreme deformation. The maximum vault subsidence of ZK63+571 and ZK63+577 sections are determined to be 263.8 mm and 253.2 mm, with maximum horizontal convergence of 108 and 81.6 mm, respectively.

3.3.2 Fast deformation rate

The deformation rate of Pangwan Tunnel initial support is large, and the subsidence rate of the vault increases suddenly in two stages. (1) Rapid deformation occurs within 1-5 days after excavation, and the maximum deformation rate of ZK63+571 section vault reaches 30.18 mm/d. (2) During the excavation of the middle step stage, due to more water at the arch foot of the upper step, the loess disintegrated under water immersion, which can cause the loess at arch foot seriously soften and the bearing capacity decrease sharply. Meanwhile, the excavation of the middle step causes the increase of the subsidence rate of the vault. The maximum deformation rate of ZK63+577 section at this stage reach 26.2 mm/d, far exceeding the stability standard stipulated by The New Austrian Tunneling Method (the deformation rate is less than 0.2 mm/d), and the support system is difficult to stabilize.

3.3.3 Ground cracks

As shown in Figure 6 (a), cracks appear on the ground. Affected by the construction method and stratum, after the excavation of ZK63 + 540 ~ ZK63 + 590 section, cracks of different degrees appear on the ground. The width of the cracks is 8 ~ 20 mm, and the distance between the two cracks is 23 ~ 32 m.

3.3.4 Varied failure types

According to tunnel monitoring data and site conditions, the tunnel surrounding rock deformation area damage is more serious. Affected by the water-rich environment, the stability of loess is very poor. When excavating the upper step to the vicinity of ZK63+566 section, the steel frame is ready to be arranged, cracks suddenly appear on the initial spray surface of the lower step, about 1.5 cm wide. Subsequently, cracks also appear on the initial spray surface above the middle step, about 2 cm wide, and several cracks appear at the position above the upper step. The soil above and in front of the excavation surface collapses suddenly (Figure 6 (b)).

The initial support structure suffers great damage after the collapse. A large range of cracks appear on the vault and side wall (Figure 6 (c) and (d)), with a maximum width of 0.5 cm. Meanwhile, the sprayed concrete around falls off and some I-steel arches are exposed.

In the process of tunnel excavation, the tunnel face seepage and serious accumulation water at arch foot, making the surrounding rock flow plastic. The loess at the arch foot softens seriously, and the bearing capacity decreases sharply, leading to the arch foot failure and the severe vault subsidence. The steel arch of the vault seriously intrudes into the secondary lining boundary (Figure 6 (e)).

Figure 6. Deformation characteristics of tunnel surrounding rock (a: ground cracking, b: partial collapse, c: circumferential crack, d: vertical crack, e: vault subsidence).

3.4 Extreme deformation mechanism

According to the geological conditions and surrounding rock properties, it is concluded that the main reasons for the deformation and failure of the Pangwan Tunnel are as follows:

3.4.1 Low strength of surrounding rock

The surrounding rock strength of Pangwan Tunnel is low, and the surrounding rock above class V accounts for more than 75%. Joint fissures are developed relatively. Meanwhile, the groundwater is enriched in the ZK63+540 ~ ZK63+590 sections, with high water content. Through laboratory tests, pressure-deformation curve tests of loess soil samples with different moisture content are carried out (Figure 7). As shown in Figure 7, the deformation coefficient (ratio of compression to soil sample height) increases gradually with the increase of water content, which will reduce the strength of surrounding rock, produce extreme deformation as well as bring many difficulties to construction.

Figure 7. Pressure-deformation curve of loess samples.

3.4.2 Abundant groundwater

Studies have shown that loess is a metastable sediment with unconsolidated vertical joints (Li et al., 2019; Dušan et al., 2014). Loess behaves like a brittle material with high strength when dry, while after it is immersed in water, the bonding materials of loess break up, and the strength decreases dramatically (Graziani et al., 2012; Houston et al., 1988; He et al., 2020).

Both surface underground water is abundant in the entrance section of tunnel (Figure 8). The water-rich section of the tunnel is at the boundary between silty clay and mudstone. Due to the development of joints, coupled with the strong permeability of clay, mudstone permeability is poor, so that groundwater accumulates here. The maximum water content of loess-like silty clay in ZK63+540~ZK63+590 sections is 31.3%, average water content is 23%~25%. The liquid limit index of the soil samples reaches 1.24 partially, presenting fluid plastic state, and the average is 0.86, presenting soft plastic state.

Figure 8. Inverted arch water accumulation and tunnel face seepage water.

3.4.3 Disintegration

The disintegration of loess is one of the main factors causing extreme deformation. The strength and mechanical properties of loess are especially affected by water (Xu et al., 2020; Sun et al., 2021). In the water-rich environment, the collapsibility of loess is relatively weak, mainly manifested as disintegration (Zhang et al., 2015). Under the action of water, the change of matric suction in loess makes water infiltrate into soil rapidly through pores, and then increases pore water pressure, promoting the chemical dissolution reaction between mineral cement and water in loess particles (Wang et al., 2019; Li et al., 2019). Moreover, the matric suction of soil decreases with the increase of water content, which weakens the interconnecting force between soil particles and reduces the strength of soil. Disintegration occurs when the bonding strength between soil particles is insufficient. Because of the disintegration of loess, the self-stability of surrounding rock decreases greatly after excavation, and engineering diseases such as vault collapse frequently occur. The process of loess disintegration is shown in Figure 9.

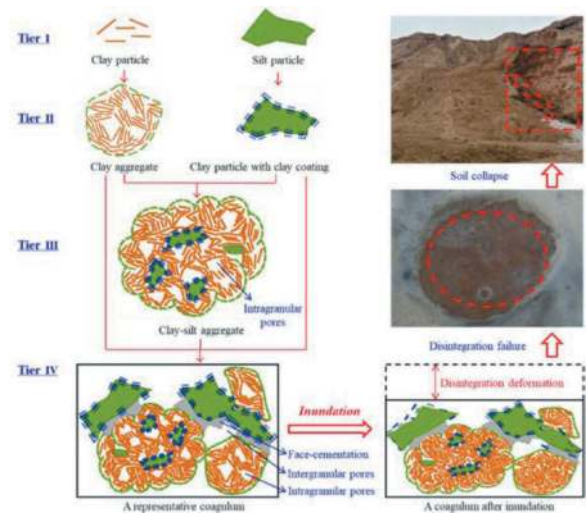

Figure 9. Conceptual model of loess disintegration mechanism.

3.4.4 Shallow buried depth

Affected by the excavation disturbance, the surrounding rock pressure appears redistribution. Due to stress release and excavation of soil, stress concentration area and stress unbalance area are formed in the vault,

and gradually spread from the inner strata to the ground (Shao et al., 2021). The wedge shape with sliding tendency is gradually formed in the shallow stratum, having the trend of sliding towards the inside tunnel face. Failure surface is formed when the tensile stress or shear stress of the sliding surface exceeds the shear strength of the soil. The whole wedge collapses along the sliding face and forms obvious longitudinal cracks on the ground.

In addition, the surrounding rock pressure at the top of shallow loess tunnel is mainly vertical pressure, and the lateral pressure is very small (Soranzo et al., 2015; Liu et al., 2020). With the tunnel expansion, the stress state of loose zone soil and the weight of overlying soil will change. When advance reinforcement or initial support system cannot maintain the coordinated deformation and balance, forming bearing arch is difficult. The soil sinks rapidly along the middle line of the tunnel, which intensifies the development of ground cracks. The formation mechanism of ground cracks is shown in Figure 10.

Figure 10. Formation mechanism of ground cracks.

4 COUNTERMEASURES FOR DEFORMATION FAILURE

4.1 Countermeasures

When the tunnel is constructed in shallow water-rich loess stratum, it is easy to cause the initial support failure, the tunnel face instability and the vault collapse due to the low strength of the surrounding rock. This not only affects the project progress and construction quality, but also causes a great threat to the safety of construction personnel (Lai et al., 2018; Wang et al., 2021). Therefore, it is very important to control the extreme deformation of shallow water-rich loess stratum for tunnel construction. Through the analysis of various conditions, the probability of extreme deformation of surrounding rock increases when the overall stiffness of initial support is not enough, the construction of invert and lining are not timely, as well as the construction methods are improper. Aiming at the extreme deformation characteristics of tunnel in shallow water-rich loess stratum, the construction countermeasures are put forward as follows.

4.1.1 Advance drainage

After excavation of soft plastic loess, water seepage occurs on the tunnel face, and a catchment area is formed at the bottom of the side wall. The permeation

of water causes the transformation of the loess from soft plastic state to flow plastic state. The softening and strength reduction of soil caused by water migration are the main reasons for extreme deformation, so drainage measures should be taken. Hong et al. adopted a combination of advance drainage and small pipe grouting to lower the groundwater level below the excavation contour, transforming the surrounding rock from soft plastic state to hard plastic state (Hong et al., 2021a). The deformation of surrounding rock is reduced and the construction of tunnel is guaranteed.

According to the excavation method characteristics, a temporary drainage ditch is set at the corner of each step, as shown in Figure 11 (a). Drain water from side wall and tunnel face timely to prevent water accumulation at the base, side wall and arch foot.

4.1.2 Large arch foot and foot-lock bolt

When the tunnel is constructed by step method, the subsidence of vault can be effectively controlled by expanding the arch foot in soft surrounding rock (Li et al., 2012). For the case of large subsidence of Pangwan Tunnel vault, the way of enlarging arch foot at the junction of upper and lower steps is adopted, as shown in Figure 11 (d). The enlarged arch foot is beneficial to reduce the support subsidence caused by the soaked-softening soil of the arch foot. Furthermore, it plays an important role in supporting the vault structure during the middle step excavation. The loess at the arch foot presents flow plastic state under water immersion. If the accumulated water is not drained away in time, the bearing capacity will drop sharply. Therefore, the drainage of accumulated water needs to be completed before erecting the arch frame.

Additionally, 4~6 m long $\Phi 89$ large foot-lock bolts are applied to the arch waist and arch feet for reinforcement (Figure 11 (b) and (c)). U-shaped steel bars are used to weld the anchor pipes to stabilize surrounding rock deformation.

4.1.3 Sealing tunnel face and grouting timely

After the tunnel face is exposed to air for 1~1.5 h in water-rich section, the water drips along the tunnel face, which is easy to form accumulated water at the foot of the wall and arch foot. In this process, the tunnel face is sealed as early as possible. 3~5 cm concrete should be sprayed immediately after the excavation of the arc guide pit (Figure 11 (e)) to prevent soil stripping caused by long-term exposure and water seepage in the tunnel face. In addition, the information about tunnel collapse can be obtained by observing whether there are cracks on the concrete surface.

According to the laboratory test results, the tunnel face of soft plastic loess is drum out type, which is an unstable state. Except for the shotcrete sealing of the tunnel face, the effect of grouting on the tunnel face to control the tunnel face stability is also obvious.

4.1.4 Advance pipe shed and small pipe grouting

Pre-supporting within 120° of the vault, forming a pre-support system with the steel frame, is an

economical and effective support method for large-section loess tunnels (Shin et al., 2008). In the shallow water-rich section of Pangwan Tunnel, long pipe shed and small pipe supplementary grouting are adopted for advance support (Figure 11 (f)). The specific parameter is 12 m Φ 89 long pipe shed, longitudinal interval 6m layout. The length of 5m and the longitudinal spacing of 2 m Φ 42 small grouting pipes are arranged between the long pipe sheds. This Advance support system is suitable for the stratum with unstable tunnel face, especially the water-rich stratum. The long pipe sheds have large stiffness and long support distance as well as the small conduits laid between them can limit the collapse of the soil under the pipe shed.

Figure 11. Site control countermeasures (a: arch foot drainage ditch; b, c: application of foot-lock bolt; d: application of large arch foot; e: seal of tunnel face; f: advance pipe shed and small pipe grouting).

4.2 Verification of the countermeasures

Surrounding rock deformation is an important basis to measure the stability of surrounding rock. Figure 12 shows the time-displacement curves of surrounding rock at the sections ZK63+571 and ZK63+577 after treatment. The maximum horizontal convergence of the two sections is 120.1 mm and 113.2 mm, respectively, and the maximum vault subsidence is 36.5 mm and 32.9 mm, respectively. The maximum deformation rate is 15 mm/d. Moreover, during the excavation of inverted arch, the subsidence rate increases. Before the inverted arch is conducted, the two sections achieve 94.2% and 97.8% deformation respectively. In water-rich loess tunnel, the subsidence can be effectively controlled by sealing the tunnel face and pouring the inverted arch timely after the excavation.

Figure 12. Time-displacement curve of surrounding rock after treatment.

Therefore, after the implementation of countermeasures, the surrounding rock deformation control has achieved good results. Not only the deformation rate of surrounding rock is reduced, but also the total deformation is greatly reduced, which ensures the quality and safety of tunnel construction.

5 CONCLUSIONS

To explore and study the deformation characteristics of shallow water-rich loess tunnel, a case study involving a shallow water-rich loess tunnel is provided and studied in terms of the extreme deformation characteristics, influencing factors and effective countermeasures. The rationality and effectiveness of the countermeasures are verified by tunnel on-site monitoring and numerical simulation. The successful experience of this case can provide a meaningful reference to similar projects in the future, and based on the experience, the following conclusions can be drawn:

- (1) Loess is widely distributed in Nanjun region of Ningxia province. Especially in the shallow water-rich sections, various potential geological disasters may occur during construction. The soft surface formed by the joints in the shallow loess stratum is easy to form ground cracks during the excavation. Coupled with the surrounding rock deterioration caused by groundwater, the strength is significantly reduced, which makes the surrounding rock reach plastic yield, resulting in extreme deformation and even local collapse. The deformation of Pangwan Tunnel is characterized by severe vault subsidence, cracking of initial support, failure of arch foot and partial collapse of surrounding rock. The maximum displacement and deformation speed of the studied tunnel region are 263.8 mm and 30.18 mm/d, respectively.
- (2) The deformation that occurred in the shallow water-rich section is remarkable, as an extreme deformation and rate. The extreme deformation is mainly caused by the abundant groundwater and the loess's special properties after water immersion. Meanwhile, the shallow depth of the tunnel and unreasonable support scheme also plays an important role in intensifying deformation of the surrounding rock.
- (3) The proposed countermeasures mainly include the following: advance drainage; large arch foot and foot-lock bolt; sealing tunnel face and grouting timely; advance pipe shed and small pipe grouting. After conducting the countermeasures, the maximum deformation significantly reduces, which is approximately 45.5% of deformation before treatment. Specifically, the maximum horizontal convergence and vault subsidence are 36.5 mm and 120.1 mm, respectively. The achieved results confirmed that the proposed countermeasures can remarkably decrease the displacement amount as well as the speed of deformation, verifying the effectiveness of the proposed countermeasures based on the geological characteristics.

Impacts of the February 2023 Kahramanmaraş, Turkey earthquakes on outlet works in rock formations

Pelin Uygur, Özgür Öztürk, Erol Dumlu* & Fatih Çalışkan

General Directorate of State Hydraulic Works, Dams and HEPP Department, Ankara, Turkey

ABSTRACT: On February 6, 2023, two earthquakes of moment magnitude (M_w) of 7.7 and 7.6 occurred in Kahramanmaraş-Turkey. The earthquakes had a widespread impact, affecting 11 provinces across Turkey and resulting in the occurrence of numerous aftershocks. In response to these earthquakes, engineering teams under the General Directorate of State Hydraulic Works were mobilized to assess the potential effects on nearly 140 dams. Outlet works are usually constructed in rock formations in State Hydraulic Works' applications for dams. Consequently, seismic loads have historically been overlooked during structural analyses. Post-earthquake inspections revealed minor damages to the outlet works attributed to ground shaking, thus supporting the assumption for seismic loads. This paper aims to provide an overview of the conditions of the inspected structures, the geological characteristics of the sites, and the seismic data collected in the wake of these seismic events.

Keywords: Outlet works, tunnels, conduits, earthquake, case studies

1 INTRODUCTION

On February 6, 2023, two earthquakes of moment magnitude (M_w) of 7.7 and 7.6 occurred in Kahramanmaraş-Turkey. The earthquakes had a widespread impact, affecting 11 provinces across Turkey and resulting in the occurrence of numerous aftershocks. In response to these earthquakes, engineering teams under the General Directorate of State Hydraulic Works were mobilized to assess the potential effects on nearly 140 dams.

This paper focuses on the outlet works of inspected dams, which are underground structures. These subterranean constructions exhibited remarkable resilience during the earthquakes, with minimal to no damage. Consequently, case studies presented were chosen based on the extent of damage observed in the dam bodies.

Underground structures had long been assumed to be sustainable against earthquake effects. Dawding and Rozen (1978) presented 71 cases of rock tunnels and formed relationships between damage levels and peak ground parameters. Although classified damage levels did not account for geological conditions or the presence of lining, they stated that there was no damage in both lined and unlined tunnels up to a surface acceleration of 0.19 g. Owen

and Scholl (1981) collected data from 127 underground structures and introduced deformation modes of tunnels resulting from seismic waves. Hashash et al. (2001) discussed a detailed seismic design approach for underground structures.

Wang et al. (2001) assessed the damage inflicted by Taiwan Chi-Chi Earthquake on mountain tunnels. 57 tunnels, 49 of which are damaged, were investigated, damage patterns were classified, and possible influences of tunnel damage such as earthquake intensity, condition of surrounding ground and seismic capacity of the tunnel were evaluated.

Yashiro et al. (2007) generated a profile of historical damage to mountain tunnels in Japan. They also provided retrofit measures such as additional ground support along with repairing and strengthening of lining.

Li (2011) studied the impacts of Wenchuan earthquake on mountain tunnels. His study explored various factors influencing damage, including epicentral distance, seismic wave propagation direction, fault zones, and the bedrock-overburden contact plane.

Jaramillo (2017) presented several case studies involving rock tunnels constructed using different methods. He highlighted the significance of lining presence and adequate ground support in mitigating tunnel damage.

2 BRIEF DESCRIPTION OF KAHRAMANMARAŞ EARTHQUAKES

Turkey is encircled by two prominent fault zones, which predominantly affect the Anatolian Plate, covering a substantial portion of the country's surface. The North Anatolian Fault (NAF), spanning approximately 1200 km, stretches across the northern region of Turkey, serving as the boundary between the Arabian and Eurasian plates. NAF is notorious for its high seismic activity, having generated major earthquakes with moment magnitudes reaching as high as 7.9. Adjacently, the East Anatolian Fault (EAF), extending 580 km, bridges the gap between the Arabian and Anatolian Plates, connecting to the eastern terminus of the NAF. Together, NAF and EAF accommodate the westward motion of the Anatolian Plate. Both faults are classified as transform faults, characterized by their significant seismic activity.

On February 6, 2023, two major earthquakes occurred in Kahramanmaraş-Turkey within a span of 9 hours. Both seismic events were located along the East Anatolian Fault, exhibiting a left-lateral strike-slip fault mechanism.

At 04:17 (01:17 GMT), an earthquake of Mw 7.7 and focal depth of 8.6 km (AFAD, Disaster, and Emergency Management Presidency) struck Pazarçık Kahramanmaraş-Türkiye, rupturing Narlı, Erkenek, Pazarçık and Amanos fault segments. The earthquake induced nearly 300 km long surface rupture and significant surface displacement up to 7 m. The maximum recorded peak ground acceleration (PGA) attributed to this earthquake was 1.23 g.

Subsequently, a Mw 7.6 earthquake happened at 13:24 (10:24 GMT) at Elbistan-Kahramanmaraş-Türkiye with a focal depth of 7.0 km (AFAD). Çardak and Doğanşehir fault zones were activated, resulting in a total rupture length of 160 km. This earthquake led to substantial surface displacement, reaching up to 8 m, with a maximum recorded PGA of 0.65 g. Figure 1 displays the earthquake epicentre locations and finite faults, sourced from USGS database.

Successive earthquakes impacted 11 cities across Turkey, resulting in a devastating toll. Over 50,000 lives were lost, with an additional 115,000 individuals suffering injuries. Approximately 40,000 buildings collapsed as a result of these events. Furthermore, the earthquakes inflicted damage on infrastructure, and ground failure (liquefaction, landslides, rockfalls etc.) is observed in numerous instances.

3 CASE STUDIES

In this study, the selection of tunnel/conduit cases for outlet works was based on the extent of damage to the dam body. The primary focus of this study is on the outlet works of the most severely damaged dams among the 140 dams examined by the State Hydraulic Works. Figure 2 illustrates the locations of the dam sites featured as case studies in this paper.

Figure 1. Epicenters and finite faults of Kahramanmaraş Earthquakes.

The tunnels and conduits originally served as diversions during the dams' construction phase. However, during the water retention phase, they were converted into outlet works by directing the flow through steel pipes via a plug. During our inspections, it was not possible to access the upstream part of the plug, so our examination was limited to the downstream part of outlet works.

Figure 2. Location of the dam sites.

In the State Hydraulic Works' practice, tunnels are constructed with reinforced concrete lining, support systems are implemented, and both backfill grouting and pressure grouting are carried out. Additionally, these outlet works have a minimum of 25 meters of overburden above them and both the tunnels and conduits are constructed within or on top of rock formations. Furthermore, it is important to note that tunnels presented herein were constructed via drill and blast method, where as cut and cover method was applied for the conduits.

The values of peak ground acceleration (PGA) and peak ground velocity (PGV) obtained from the instrumented stations are sourced from both USGS and AFAD databases. The USGS database is utilized for establishing the contours of PGA and PGV.

3.1 *Sultansuyu Dam*

Sultansuyu Dam is an earthfill embankment dam, operating since 1994 in city of Malatya for irrigation purposes. Dam body has a 53 m hydraulic height and a 60 m structural height. There are two outlet works on each embankment: a conduit on the left abutment and a tunnel on the right.

The circular tunnel has a 4.5 m internal diameter (ID) and 0.5 m lining thickness with 28 m maximum overburden height. Hydraulic section of the conduit is 3.6 m wide horseshoe shape with a modified horseshoe outline and 0.8 m lining thickness. Maximum fill height above the conduit is 22 m.

The bedrock of the dam site is identified as the Beylerderesi Formation, composed of loosely consolidated sandstone-conglomerate-claystone alternation. It is classified as poor rock with an RMR value of 40.

The Elbistan Earthquake (Mw 7.6) had a higher impact on the dam site, with the epicenter located 82 km away and the ruptured fault, 15 km away. The site falls within close proximity to the 0.20 g PGA contour and between PGV contours of 20 cm/s and 50 cm/s. The nearest monitoring station, situated 7.4 km away, recorded a PGA of 0.476 g and a PGV of 35 cm/s during the earthquake. Reservoir elevation at the time of the event was 8 meters below the dam crest.

Subsequent inspections carried out after the earthquake revealed the presence of cracks along the dam crest, extending a total length of 400 m and reaching depths of 2.5 to 3.0 m (Figure 3). Outlet works also sustained some slight damage as minor cracks (Figure 4). Detailed studies are carried out in order to rehabilitate the dam body and appurtenant structures.

Figure 3. Cracks along the dam crest.

Figure 4. Minor cracks observed in the lining.

3.2 *Arıklıkış Dam*

Arıklıkış Dam has been operating since 1998 in the city of Osmaniye for irrigation purposes. It is a homogeneous earthfill embankment dam and its hydraulic height and structural height are 24.50 m and 32.50 m, respectively. Active conservation capacity of the reservoir is 1.67 hm³.

Outlet works are carried out via a reinforced concrete coated steel pipe with an ID 0.6 m and a 0.3 m lining thickness. Maximum fill height above the conduit is 20 m.

Geologically, the site is situated on tertiary-aged flysch composed of claystone-siltstone-sandstone-sandy limestone-marn alternations, which reach the surface on both abutments. 18 m thick alluvium is found on the riverbed.

Pazarlık Earthquake had a higher impact on the dam site, which is 14,5 km away from the ruptured fault and 45 km away from the epicenter. The site is positioned between the PGA contours of 0.20 g and 0.50 g and the PGV contours ranging from 20 cm/s to 50 cm/sec. The nearest station, situated 20 km away from the site, recorded a PGA of 0.715 g and a PGV of 119.2 cm/sec during the event.

Subsequent assessments following the earthquakes revealed wide-span splits along the dam crest (Figure 5), and openings in the upstream riprap parallel to the dam axis (Figure 6). Additionally, there was an elevation loss at the crest and horizontal movement toward the upstream.

As the conduit is full of water and located beneath the dam body, the structural condition could not be directly observed. However, the water conveyance capacity remains stable, and no outflow has been detected at the upstream part of the energy dissipator. These findings provide positive indications that there is no risk of collapse or breakage in the pipe.

3.3 *Gömükan Dam*

Gömükan Dam and Irrigation Project comprises Gömükan Dam, two main water conveyance lines,

Figure 5. Wide-span splits along the dam crest.

Figure 6. Openings in the upstream riprap.

and an irrigation network. The project's water transport infrastructure includes a 3080 m long open channel conveyance line that commences downstream of the dam and connects with a 2400 m long conveyance tunnel.

Gömükan Dam is being constructed as a concrete face rockfill dam with a 73.70 m hydraulic height. Diversion is carried out through a 260 m long circular tunnel, followed by a 225 m long conduit. Both of these structures feature an inner diameter of 3.50 m and are equipped with a 0.35 m thick reinforced concrete liner. The conduit initiates downstream of the dam body and has 2.0 meters of backfill above it. The tunnel, on the other hand, exhibits a maximum overburden height of 53 meters.

The conveyance tunnel is also under construction. At the time of the earthquakes, excavation works and installation of ground support were being executed. The tunnel is designed with an ID of 3.00 m, a -0.35 m thick reinforced concrete liner, and a maximum overburden height of 100 meters.

The geological composition at the dam site is characterized by sediments of igneous rocks within the ophiolite complex. Bedrock is mainly limestone and serpentinite blocks together with siliceous shale, with marn bands composed of sanstone, conglomerate, and claystone alternations. The geological classification for the tunnel indicates that it is situated in a weak rock environment, with an RMR value of 30. The conveyance tunnel is also surrounded by the ophiolite complex, featuring similar properties.

Pazarçık Earthquake had a higher impact on the project components. Given the proximity of the dam site and the conveyance tunnel, both were subjected to a similar range of ground motion parameters. The distances from the dam site to the epicenter and ruptured fault are 120 km and 11.5 km, respectively. The dam site falls within the PGA contours of 0.20 g to 0.50 g and PGV contours ranging from 20 cm/s to 50 cm/s. The nearest station, located 17 km away from the site, recorded a PGA of 0.477 g and a PGV of 45.5 cm/sec during the event.

Subsequent to the earthquakes, the diversion facilities of the dam continued to operate without any signs of damage. On the other hand, conveyance tunnel has suffered damages such as disintegration of shotcrete and wiremesh (Figure 7), deformed steel ribs on the side wall (Figure 8), rockfalls at the not yet supported sections (Figure 9), and heave of the bottom shotcrete support (Figure 10).

3.4 Tahtaköprü Dam

Tahtaköprü Dam, which has been in operation since 1975, is situated in the city of Hatay, Turkey, and is designed for irrigation purposes. The project was recently revised, and dam crest elevation was raised by 9 m in order to expand irrigation areas and generate hydroelectric power. It is an earthfill embankment dam with a hydraulic height of 44.50 m and an active conservation capacity of 327 hm³. There is a diversion tunnel, which was also used in the

Figure 7. Disintegration of shotcrete and wiremesh.

Figure 8. Deformed steel ribs on the side wall.

Figure 9. Rockfalls.

Figure 10. Heave of the bottom shotcrete support.

retrofit, with an internal diameter (ID) of 4.0 m and a lining thickness of 0.35 m. Outlet works are carried out by a 3.2 m ID reinforced concrete coated steel pipe with a 1.0 m thick lining. Maximum fill height above the conduit is approximately 30 m and overburden height above the tunnel reaches up to 45 m.

Bed rock formation on the site primarily consists of peridotite, with a few meters of mildly weathered zone on the surface but hard and intact on deeper levels.

Ground motion parameters and spatial properties for Pazarcık Earthquake (Mw 7.7) are presented here since there are no records available for Elbistan Earthquake (Mw 7.6) at the nearest station, which is 0.12 km away from the dam. Additionally, distances from epicenter and ruptured fault of the Pazarcık Earthquake are significantly shorter, with an epicentral distance of 50 kilometers and a distance from the ruptured fault to the dam of 11.5 kilometers. Dam site is located between peak ground acceleration (PGA) contours of 0.20 g and 0.50 g, peak ground velocity (PGV) is more than 50 cm/sec. Maximum PGA and PGV reported at the nearest station are 0.26 g and 60 cm/sec respectively.

At the time of the event, reservoir storage was about 18% of the active storage. No damage has been observed for the dam and appurtenant structures due to Pazarcık Earthquake. In addition to the good quality of the foundation for the conduit and surrounding rock for the tunnel, it should be noted that the retrofit project included a reevaluation of the dynamic response of the dam. This reassessment led to the adoption of a maximum design earthquake (MDE) with a PGA of 0.44 g for the design process.

3.5 Yarseli Dam

Yarseli Dam, located in southern Turkey on the Beyazçay River, was constructed for irrigation and was completed between 1985 and 1989. Dam body stands at a height of 42 m and impounds up to 55 million m³ of water. A diversion conduit with an ID of 2.80 m was constructed beneath the dam under an overburden thickness of 28 m.

Our technical team conducted an inspection of this dam, which is closer to the Pazarcık- Earthquake, compared to the Elbistan Earthquake. Closest distance to the ruptured fault is 16.5 km. PGA reported from the nearest station, located 11 km away from the dam site, is measured at 0.544 g with a PGV of 53.5 cm/s. The dam is situated between PGA contours of 0.20 g and 0.50 g, with PGV exceeding 50 cm/sec.

Following the occurrence of these two significant earthquakes, a thorough inspection of the dam revealed the presence of two primary cracks on the crest, with depths varying between 0.6 and 1.25 m and widths ranging from 0.02 to 0.15 m (Figure 11).

Meanwhile, the inspection included the conduit, which was subjected to ground shaking. There were only minor cracks in the conduit lining constructed beneath the dam.

Figure 11. Primary cracks on the crest.

3.6 Reyhanlı Dam

Reyhanlı Dam, with a height of 25.20 m, is designed as a clay core zoned dam for irrigation and flood control in the city of Hatay, Turkey. Remarkably, it holds the record for the longest crest in the country, stretching over an impressive 9.3 km. The dam's reservoir is replenished with redirected floodwaters from the Karasu and Afrin Rivers during the winter season. The construction of this significant dam was successfully completed on a silty clay foundation between 2018 and 2019, despite the geological constraints. As part of this project, two conduits were engineered, featuring an inner diameter of 3.50 m and a 1.00 m lining, all situated under an overburden depth of 23.5 m.

Regarding seismic considerations, Reyhanlı Dam is situated 105 km away from the epicenter of Pazarcık Earthquake, with a proximity of only 29.5 km to the ruptured fault. In contrast, Elbistan Earthquake had a lesser impact on the dam due to its greater distance from the dam site, which is 192 km from the epicenter to the site. PGA and PGV, recorded at the nearest station which is 11.4 km away, were measured 0.226 g and 29.1 cm/s, respectively. Dam site is situated between PGA contours of 0.20 g and 0.50 g and PGV contours of 20 cm/s and 50 cm/s.

Our team has observed that there were deep cracks on the dam crest, some of which extend to a depth of 1.8 m and a subsidence of up to 0.5 m (Figure 12).

Furthermore, there were cracks ranging from 1 to 1.5 cm at the joints of the conduit within this project (Figure 13). Disruption and cracks were also noted in the penstock support concrete (Figure 14). Detailed studies are being conducted for the rehabilitation of the dam body and its associated structures.

Figure 12 . Deep cracks on the dam crest.

Figure 13. Cracks in the lining of the conduit.

3.7 Kartalkaya Dam

The Kartalkaya Dam, constructed between 1965 and 1972 on the Aksu River in Kahramanmaraş serves the purpose of providing irrigation and drinking water. This 56 m high dam is a clay core zoned dam with a water retention capacity of 195 hm³. Furthermore, a tunnel with an inner diameter of 5 m and a lining thickness of 0.40 m was constructed with an overburden of approximately 101.50 m, primarily comprising the geological formations of karker and serpentinite.

In the context of seismic events, the Kartalkaya Dam was situated in relatively close proximity to the fault line that ruptured during the Pazarcık Earthquake, at a distance of approximately 5 km. Since the epicenter of Elbistan Earthquake is further away from the dam site, Kartalkaya Dam experienced a more significant impact from the Pazarcık Earthquake. PGA and PGV recorded at the 11.5 km away nearest station is measured 0.76 g and 104.8 cm/s, respectively. USGS contours confirmed a PGA exceeding 0.50 g and a PGV exceeding 50 cm/s.

Figure 14. Cracks in the penstock support concrete.

According to our team’s inspection reports, the majority of damage cases were concentrated at the crest of the dam body, specifically in the form of cracks and undulations resulting from settlement (Figure 15). Additionally, it is important to note that no damage attributable to earthquakes was observed within the tunnel.

Figure 15. Cracks and openings on the crest of the dam body.

3.8 Kalecik Dam

Kalecik Dam is a clay core rockfill dam, located in Osmaniye, on the Beyazçay River, which is one of the tributaries of the Ceyhan River. It was constructed between 1983 and 1985 for irrigation purposes. The 77 m high dam from the river bed was constructed onto the geology of weathered diabase. The tunnel, with a diameter of 3.00 m and a lining thickness of 0.30 m, was designed to accommodate 95 m of overburden.

Pazarcık Earthquake had a substantial impact on the dam site due to its close proximity to the ruptured fault, being only 18 km, although it was located about 50 km from the epicenter of the earthquake. PGA and PGV recorded at the nearest

Figure 16. Longitudinal cracks and subsidence on the dam crest.

instrumented station, which is situated 21.5 km from the dam site, were measured 0.715 g and 119.2 cm/s, respectively. Furthermore, it’s worth noting that the dam site falls within the range of PGA contours, with values ranging between 0.20 g and 0.50 g, as well as PGV contours, with values ranging from 20 cm/s to 50 cm/s.

Following a comprehensive inspection of the dam, the engineering team observed subsidence of up to 1.5 m and the presence of longitudinal cracks along the crest (Figure 16). However, it’s important to note that there was no damage detected within the tunnel or penstock during this inspection.

4 CONCLUSIONS

In the case studies section, we provide information about the analyzed tunnels/conduits. This includes essential data such as the distance of the tunnels from the epicenter, PGA and PGV contours, PGA and PGV values measured from the nearest station, and the distance to the ruptured faults following two earthquakes. When evaluating the peak acceleration values measured from the nearest stations, we observed a range of low to high acceleration values. Additionally, the distances to the ruptured faults were relatively short in some of the cases.

However, despite these challenging conditions, minimal damage occurred in a few structures, and most of them remained undamaged.

We believe that the absence of damage resulting from ground shaking can be attributed to several factors. These include the fact that the tunnels were lined, appropriate support systems were implemented during the construction phase, they were situated within rock formations, backfill grouting and pressure grouting were applied effectively, and there was sufficient cover thickness above them. Furthermore, it is important to note that outlet works presented here have relatively smaller openings in comparison to highway tunnels.

Research and development support for the construction of the big circle line on the example of the line's intersection with the existing facilities of the Moscow metro

V.V. Viazovoi, R.A. Evtushenko, D.S. Konyukhov & D.S. Petunina*
JSC «Mosinzhproekt», Moscow, Russia

ABSTRACT: In March 2023, the Big Circle Line of the Moscow Metro, the largest project of the Russian metro construction and one of the largest in the world, was fully commissioned. The project envisaged the construction of 28 new stations and the complete reconstruction of 3, the creation of 47 interchanges, including perspective ones, of which 19 were radial lines of the existing underground. A special construction task was to ensure safety of passenger traffic on the existing metro lines. Special measures were developed for each case of intersection or adjunction to the existing underground lines, taking into account the projected impact of construction and installation works, technical condition of facilities, construction methods and engineering and geological conditions at the site. Among the most difficult construction sections were: the interchange at the Sokolniki station of the Sokolnicheskaya line, the very first line of the Moscow Metro, which is a monument of architecture. In order to construct the adjacency of the station under construction to the operating station, soils were consolidated against the walls of the operating station; interchange at Pechatniki station on Lyublinsko-Dmitrovskaya line, a semi-underground station combined with the Nischenka river collector and built in the floodplain of the Moskva River in very difficult geological conditions; Maryina Roshcha station, which is being constructed using a drilling and blasting method directly beneath present Maryina Roscha station on the Lyublinsko-Dmitrovskaya line, one of the deepest stations of the Moscow Metro. The drill and blast tunnelling method was used to accelerate, including directly under the operating station, calculations were made, and the necessary measures were arranged to ensure the safety and comfort of passenger traffic. Given the complexity of the engineering and geological conditions in Moscow and the dense urban development including not only surface facilities but also the existing underground network, the described experience will be interesting for further development of underground space in large metropolitan areas.

Keywords: Tunnelling, TBM, Drill and blast tunnelling method, Metro, Underground space, Geotechnical monitoring

1 INTRODUCTION

In March 2023, the Big Circle Line of the Moscow Metro, the most ambitious Russian metro construction project and one of the largest in the world, was put into full operation.

The project envisaged the construction of 28 new stations built from scratch and 3 completely reconstructed stations, 47 interchanges, including future ones, of which 19 were on the radial lines of the existing metro.

A special task of construction was to ensure the safety of passenger traffic on the existing metro lines. Special measures were developed for each case of crossing or adjoining the existing metro

lines, taking into account the predicted impact of construction, technical condition of the structures, construction methods and engineering and geological conditions of construction.

The construction of the Big Circle Line provided a great and unique experience of construction in the conditions of the existing metro. The following construction sections were among the most challenging:

- a transfer point at Sokolniki station of the Sokolnicheskaya line, the very first line of the Moscow Metro. This station is an architectural monument. A geotechnical monitoring system was organised during the construction of the interchange tunnels. Soil consolidation close to the walls of the existing

*Corresponding author: petuninads@mosinzhproekt.ru

- station was carried out to ensure that the station under construction adjoins the existing station;
- interchange at Pechatniki station of the Lublinsko-Dmitrovskaya line, a semi-subterranean station combined with the Nishenka River collector and built in the floodplain of the Moscow River in very difficult geological conditions. A two-track tunnel was excavated under the existing station, traffic on the existing section was closed, and simultaneously with the excavation, preparations were made for the construction of the interchange hub: repair of the track structure and dismantling of the station cover slabs;
 - Maryina Roshcha station, which is being built using a drilling and blasting method directly under the Lublinsko-Dmitrovskaya line station of the same name – one of the deepest stations of the Moscow Metro. In order to accelerate the works using the above method, calculations were made, and the necessary measures were taken to ensure the safety and comfort of passenger traffic.

Taking into account the complexity of engineering and geological conditions of Moscow and dense urban development, including not only surface facilities, but also the existing underground network, the adopted experience is of interest for the development of underground space of large megacities.

2 CONSTRUCTION OF THE BIG CIRCLE LINE TUNNELS UNDER SOKOLNIKI STATION

Sokolniki station of the Sokolnicheskaya line is one of the first stations of the Moscow Metro – it was from this station that the first underground train with passengers departed on 15 May 1935. The station design is three-bay, columned, shallow. It became a template for the construction of stations of the open method of works (Figure 1).

Figure 1. Construction of sokolniki station – the first station of the first line of the Moscow metro. drawing of 1933.

The station lobby consists of several parts: underground with a ticket office, intermediate and elevated.

The intervening soils are bulk soils represented by tight-plastic loams and sands with loam and clay

interlayers, with construction debris; fine, dusty water-saturated sand with pressure water at the base of the station structure.

The route of the Big Circle Line ran at an angle of about 74° under the structures of Sokolniki station in clay, limestone and marl. The tunnel lining at the crossing section is high-precision precast reinforced concrete, 6 m in diameter. The crossing tunnels were driven by ‘Herrenknecht’ tunnel boring mechanised complexes (TBM).

In the course of the survey works, it was revealed that Sokolniki station has a deformation joint at the section falling within the zone of influence of the construction of the Big Circle Line tunnels, from which water drainage is organised.

Numerical modelling of the possible impact of construction on Sokolniki station was performed, taking into account the technical condition of the station and its lobby, as well as the design and condition of the expansion joint. The possibility of mutually independent displacements of the station structures in the area of the joint location was taken into account. The results of the modelling studies are given in Table 1.

Since such settlement values could lead to the occurrence of ledges in the settlement joint zone, damage to the station waterproofing, changes in the longitudinal profile of the tracks and gradients, which would lead to a violation of the operational reliability of Sokolniki station (Kobidze, Konukhov, 2022), it was closed to train traffic during the construction of the overpass tunnels with the organisation of scientific and technical support of construction, including the following works (Koval et al., 2022; Konukhov, Polyankin, 2019):

1. Development of technological regulations for tunnelling of the tunnels (Mazein et al., 2019), which described the controlled parameters of tunnelling, gave a diagram of bottom face loading pressure along the entire route of the tunnels, including under the existing Sokolniki station; the recommended loading pressure in the vault neck is 1.6 bar, in the flume is 2.3 bar.

Table 1. Results of calculation.

Tunnel structure	Calculated displacements, mm		
	Horizontal	Vertical	Sediment difference*
As a result of tunnelling of the left crossing tunnel			
Sokolniki station of Sokolnicheskaya line	1/2	12/11	1
Sokolniki station lobby (with drilling piles)	2	2	1
As a result of tunnelling of the left and right crossing tunnels			
Sokolniki station of Sokolnicheskaya line	2/4	17/16	1

* Difference between vertical deformations in zone I and II of station tracks (for the platform part of the station).

2. Automated monitoring of the planned height position of Sokolniki station structures with a frequency of 1 every 4 hours (Merkin et al., 2021).
3. Control of rail head height position and rail string difference with a frequency of 2 times a day.
4. Control of the planned height position of the internal structures of Sokolniki station lobby with the frequency of 2 times a day.
5. Visual inspection of technical condition of metro structures.
6. Geodetic observations of day surface deformations along the tunnelling axis.
7. Monitoring and interactive control of driving process parameters (loading pressure, volume of developed soil, injection pressure and volume of plugging solution) based on the results of geotechnical monitoring (Konyukhov, 2022).

The planned speed of tunnelling of the crossing tunnels was 7 rings per day.

Before the TBM entered the zone of influence at Sokolniki station, a technological stop was performed for maintenance and performance testing of the TBM systems to prevent it from stopping under the operating station.

The final deformations of Sokolniki station based on the results of excavation of two tunnels and their comparison with the results of calculations are given in Table 2.

According to the results of the tunnelling, it can be concluded that the tunnelling of the Big Circle Line tunnels did not affect the structures of the existing Sokolniki station.

As a result of the implementation of measures on scientific and technical support of construction and control of tunnelling parameters:

- maximum stabilised precipitation of Sokolniki station structures was 3.6 mm;
- safe, practically sediment-free tunnelling of the Big Circle Line tunnels was ensured at a depth of about 6 m under the existing Sokolniki station – a cultural heritage site of the station of the Sokolnicheskaya line of the Moscow Metro;

Table 2. Station deformations after driving the left and right crossing tunnels and stabilisation of deformations.

Tunnel structure	Calculated		Based on the results of monitoring	
	layout	depth	layout	depth
Sokolniki station of Sokolnicheskaya line	2/4	17/16	1	3,6
Sokolniki station lobby	2	2	-2,3	-4,3

- there was no need to install safety bags and their subsequent dismantling, waterproofing of the

expansion joint, which could have entailed changes in the appearance of the historical monument and an increase in the cost of construction of the facility.

3 CONSTRUCTION OF PECHATNIKI STATION

The existing Pechatniki station of the Lyublinsko-Dmitrovskaya line of the Moscow Metro was built in 1995 using cut and cover method with cast reinforced concrete and prefabricated reinforced concrete structures. The maximum depth from the surface to the station cover is 1.5 m.

The tunnel inspection revealed sections where track subsidence occurred during operation. The recorded amount of subsidence ranged from 15 to 31 mm (Konyukhov et al., 2021).

Intervening ground mass – technogenic sediments, loams and sands mainly of medium coarseness with crumbs and fragments of bricks, concrete, in some places – with wood chips, glass fragments and pieces of metal; consolidated, low and medium degree of water saturation and water-saturated.

The Nishenka River collector, consisting of three prefabricated reinforced concrete pipes with a diameter of 3.5 mm and 6 chambers, runs under the station (Figure 2).

Figure 2. Mutual location of existing development and construction objects (cross-section: 1 – section along the axis of pechatniki station of the lyublinsko-dmitrovskaya line; 2 – the well of the nishenka river; 3 – tunnel of pechatniki station of the big circle line; 4 – the nishenka river collector; 5 – tunnel of pechatniki station of the lyublinsko-dmitrovskaya line.

The foundations of the chambers are monolithic reinforced concrete slabs 380 mm high, depth of embedment from the ground surface 7.0 m. The foundations under the collector pipes are precast reinforced concrete blocks with a depth of 6.5--10.5 m from the surface.

The construction of the tunnel from Pechatniki station to Nagatinsky Zaton station was carried out by a Herrenknecht 10.69 m diameter TBM with active soil loading of the face. Tunnelling of the Big Circle Line tunnels under Pechatniki station was carried out

at a depth of 13.6 m in the following engineering and geological conditions:

- vault part – in Jurassic clays of hard, with semi-hard interlayers;
- middle and lower parts – in Izmailovo limestones of medium strength, with marl and clay interlayers, fractured, interlayers broken to rubble and flour, water-bearing.

Hydrogeological conditions of the territory are characterised by the presence of groundwater of the Nadjursky and Izmailovskiy aquifers.

The assessment of the impact of the construction of the double-track tunnel on the structures of the Pechatniki station of the Lyublinsko-Dmitrovskaya line and on the Nishchenka River collector was carried out, taking into account the technical condition of the station, its structural features and deformations obtained both during operation and as a result of the dewatering operation during the construction of the excavation of the Pechatniki station of the Big Circle Line (Znamenskaya, Zertsalov, 2022).

The calculation was carried out in the software package “Z_Soil” by the finite element method, in the volumetric formulation (Figure 3).

The calculation results are given in Table 3.

The minimum design safety factor for the Pechatniki station structures after the two-track tunnel is 1.15.

Based on the analysis of available materials, the following measures for scientific and technical support and interactive control of driving parameters were proposed (Konyukhov, 2022):

Verification of numerical modelling results (Konyukhov, 2023; Kulikova et al., 2022).

1. Prediction of geotechnical risks (Kulikova et al., 2023; Kulikova, Konyukhov, 2022).
2. Fixing of penetration parameters (loading pressure, volume of developed soil, injection pressure and volume of plugging solution).

Figure 3. Isofields of vertical displacements during the excavation of a double-track tunnel.

3. Organisation of automated monitoring of the planned height position of the Pechatniki station structures with a frequency of once every 3 hours.
4. Geodetic observations of day surface deformations.

Table 3. Results of calculation by mathematical modelling method.

Object	Maximum displacements of station structures, mm		
	vertical	Along station	Across the station
Estimated displacements from tunnelling of the crossing tunnel			
Pechatniki station of the Lublinsko-Dmitrovskaya line	17.0	0	0
Concrete collectors of the Nishchenka River that are 3500 mm in diameter	39.0	-	-

5. Georadiolocation survey of the ground massif in order to detect leaks from the Nishchenka River collector during shield sinking (Churkin et al., 2021).
6. Measurements using radio-wave geo-introspection of interwell space technology (Figure 4) in the intersection zone of active and under-construction tunnelling structures (Istratov et al., 2019; Kuznetsov, 2012).
7. Analysis of monitoring results and interactive control of tunnelling parameters.

In the course of tunnelling, the technological parameters of TBM operation were monitored and compared with the monitoring data. If necessary, real-time adjustments were made to the TBM loading pressure, which made it possible to ensure the maximum actual settlement of the Pechatniki station of 7.4 mm and of the Nishchenka River collector of 4.2 mm (Table 4).

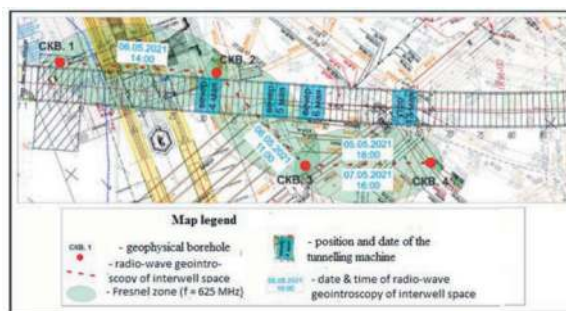

Figure 4. Schematic of measurements using radio-wave geointrospection of interwell space ($f = 625$ kHz).

Table 4. Comparison of calculated and actual settlements of the pechatniki station and the nishchenka river collector.

Tunnel structure	Settlements, mm	
	Calculated	Actual based on monitoring results
Pechatniki station of the Lublinsko-Dmitrovskaya line	17.0	7.4
Nishchenka River collector	39.0	4.2

Measures on scientific and technical support of construction and interactive control of tunnelling parameters allowed:

- monitor changes in the physical condition of the soil mass, technical condition and deformations of the protected structures and make timely decisions to adjust the technological parameters of the TBM operation in real time;
- ensure structural reliability and further safe operation of the existing structures of the Pechatniki station and the Nishenka River collector without additional special construction methods.

4 CONSTRUCTION OF MARYINA ROSHCHA STATION

On 19 June 2010, Maryina Roshcha station was opened on the Lublinsko-Dmitrovskaya line. The station structure is a pylon, three-vaulted, deep-buried station (depth of embedment – about 57.0 m). The station was built by the trenchless method according to the standard design (Figure 5).

Figure 5. General view of maryina roshcha station of lublinsko-dmitrovskaya line.

The station lining is prefabricated cast iron, circular. The outer diameter of the side station tunnels is 8.50 m, the middle station tunnel is 9.50 m. The distance between the tunnel axis is 9.75 m. Pylons are arranged in two rows, distance between pylon axes 10.50 m, pylon width 6.759 m, opening width 3.759 m. The platform width is 19.10 m.

The northern lobby with an escalator tunnel was opened on 24 December 2012. Tunnel construction – reinforced concrete waterproof lining of high-precision blocks with a diameter of 10.6 m.

The construction of the Maryina Roshcha station of the Big Circle Line is of the pylon type with 3.755 m wide openings and 6.759 m wide pylons (Figure 6).

The middle tunnel is constructed with cast iron lining with a diameter of 9.5 metres. The side tunnels are built with cast iron lining with a diameter of 8.5 m. There are 22 openings between the side

tunnel and the middle tunnel. The construction was carried out by a trenchless method through working-cable shafts.

In profile, the station is located at a depth of approximately 73 m from the ground surface; approximately 5 m below the crossing tunnels behind the Maryina Roshcha station of the Lublinsko-Dmitrovskaya line.

Figure 6. General view of the maryina roshcha station of the big circle Line.

The tunnel structures of Maryina Roshcha station of the Big Circle Line are located in stable sediments of Upper Stone Age of the Mescherinsky, Perkhurovsky, Neverovsky, Ratmirovsky and Voskresensky stages, represented by interspersed layers of calcareous, hard clays with marl interlayers; fractured marls of medium strength; fractured limestones of medium strength with interlayers of strong and low-strength marls and clays.

For the construction of the Maryina Roshcha station of the Big Circle Line perpendicular to the existing Maryina Roshcha station, pilot tunnels were constructed using Herrenknecht shield TBM equipped with active soil loading. Tunnel lining at the crossing section is prefabricated from cast iron tubing with a diameter of 6.00 m (Figures 7).

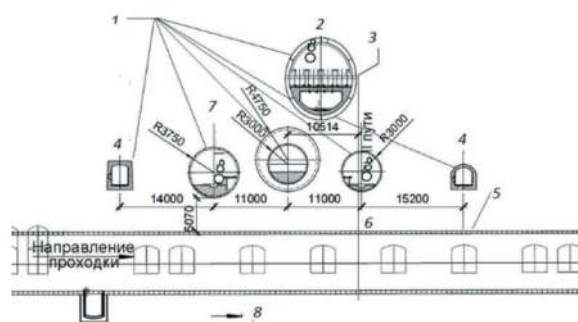

Figure 7. Mutual location of maryina roshcha stations of the big circle line and lublinsko-dmitrovskaya line (longitudinal section): 1 – existing lines; 2 – escalator tunnel centreline; 3 – sheremet'yevskaya station centreline; 4 – cable collector centreline; 5 – line under construction; 6 – track II axis; 7 – track I axis; 8 – tunnelling direction.

In parallel with the construction of the pilot tunnels, construction of the middle station tunnel was started by counter faces. Installation chambers for tunnel lining pavers were built from the approach workings and the station paver was installed.

The project envisaged rock excavation of the station tunnel by drilling and blasting method outside the operating metro zone, under the operating station complex – Brokk type machine. When boring the station tunnels under the operating structures behind the Maryina Roshcha station of the Lublin-Dmitrovskaya line, the project provided for advance grouting of the rock to prevent settlement of its structures in the tunnel vault. After the cement mortar had maturing, the rock was excavated and a sprayed-concrete support was installed.

Construction of the middle station tunnel was stopped while the tunnels under the existing station complex were being driven. The blockage was secured with anchors and sprayed concrete.

After the completion of the middle station tunnel and pilot tunnels, the builders started bulkheading the side pilot tunnels from a diameter of 6.00 m to the design diameter of 8.50 m. The tunnelling was carried out in fractured limestone with hard clay interlayers and uniaxial compressive strength up to 70 MPa. Taking into account the high strength of the rock and the experience of excavation of the middle station tunnel, it was concluded that mining using a Brokk type machine increases the construction time. In order to speed up the works, we switched to the drilling and blasting method in the area of the existing metro structures. At the same time, special measures were developed to ensure safety and comfort of passenger transportations.

The basis for ensuring seismic-safe conditions of works is the limitation of the permissible vibration velocity at the base of the protected object (Verkhovantsev et al., 2019; Vokhmin et al., 2022). For all underground facilities located in the area of blasting operations, including engineering systems of the Maryina Roshcha station, the permissible vibration velocity was assumed to be 30 mm/s.

The seismic permissible masses of instantaneously detonated charges depending on the distance to the structures of the Maryina Roshcha station were analytically calculated. The maximum mass of charges $Q_d = 4.3$ kg is limited based on the impact on surface objects

(construction was carried out at a depth of 61 m) located in the blasting area (Table 5).

The minimum distance from the places of planned drilling and blasting operations during pilot tunnel bulkheading in the technical zone of Maryina Roshcha station to the station structures was 9.0 m, to cable collectors – 6.74 m. The minimum distance from the places of planned drilling and blasting operations in the zone of influence of the station to the station structures was 5.57 m, to cable collectors – 7.5 m.

Then a geotechnical forecast of the impact of the construction of the Maryina Roshcha station of the Big Circle Line on the existing metro structures was made, taking into account the stage of tunnelling. Estimated displacements of the existing structures were obtained, on the basis of which a conclusion on the possibility of construction of the facility was given (Figures 8).

Figure 8. Three-dimensional mathematical model of Maryina Roshcha station construction.

For the entire period of construction of the Maryina Roshcha station of the Big Circle Line, a system of automated monitoring of the operating structures of the Lublin-Dmitrovskaya line was organised (Simutin et al., 2021).

Measurements of the planned and height position of the station structure were carried out at a frequency of once every 4 hours (Table 6).

Results:

1. Thanks to the use of the drilling and blasting method of rock excavation and the counter headway method, the construction time of the side

Table 5. Seismic safe masses of instantaneously detonated charges for bulkheading of station pilot tunnels of the Sheremetevskaya station under construction.

Distance from the explosion site to the structure of Maryina Roshcha station r , m	5.5-7	7-8	8-9	9-10	10-12	12-15	15-17	17-20	20-22	22-25	25 and more
Permissible mass of instantaneously detonated charges Q_d , kg	0.067	0.1	0.15	0.2	0.3	0.5	0.9	1.4	2.2	3.0	4.3

Table 6. Values of predicted and actual vertical displacements of structures of Maryina Roshcha station of the lublinsko-dmitrovskaya line.

Tunnel structure	Main line tunnel construction		Construction of Maryina Roshcha station of the Big Circle Line	
	Design displacements	Actual displacements	Design displacements	Actual displacements
Left side tunnel behind Maryina Roshcha station, track 1	6	-4.5	11.0	-11.1
Right side tunnel behind Maryina Roshcha station, track 2	6	-1.3	11.0	-12.0
Tension chamber of Maryina Roshcha station (north lobby)	3	-2.6	2.0	-7.0
Escalator tunnel (north lobby)	4	-2.6	6.0	-7.0

station and middle tunnels of the Maryina Roshcha station of the Big Circle Line was reduced by 25 %.

2. The developed measures (automated monitoring, calculation of charge mass and minimum safe distance) made it possible to ensure the safety of passenger transportations on the operating metro line without station closure and without other restrictions.

5 CONCLUSIONS

Scientific and technical support during the construction of the Big Circle Line allowed to:

1. develop and validate the analytical method of verification of mathematical modelling results when performing geotechnical calculations;
2. develop a methodology for calculating the coefficient of technological over-excavation of soil when using mechanised tunnelling;
3. monitor changes in the physical state of the soil mass, technical condition and deformations of the protected structures and to make timely decisions on the adjustment of technological parameters of TBM operation in real time mode;
4. develop and introduce into the practice of underground construction modern methods of automated monitoring and interactive control of tunnelling operations parameters;
5. ensure structural reliability and safe operation of the existing structures of the Moscow Metro during the construction of the Big Circle Line without the use of special construction methods;
6. reduce the time and cost of tunnelling works.

The experience gained during the construction of the Big Circle Line of the Moscow Metro will be relevant for further development of the underground space of Moscow and other megacities of the world.

ABSTRACT: The Metropolitan Waterworks Authority involves the construction of several shafts and a tunnel for the Water Transmission Tunnel Project in Bangkok, Thailand. In this project, numerous existing structures are located in close proximity to the underground construction areas. Consequently, these structures are susceptible to potential impacts due to the construction activities, particularly deep excavation of the shafts associated with excessive ground movements. This paper presents the evaluation of effects on the adjacent existing infrastructure resulting from the construction of two shafts with opening sizes of 12 m x 8 m and 10 m x 6 m, and the depth of excavation is around 30 m. A three-dimensional numerical analysis using PLAXIS 3D is carried out to investigate the responses, movements and imposed loads on the structures and piled foundations induced by the excavation in soft ground conditions. Extensive instrumentation and monitoring programs are implemented to observe such movements and to evaluate the serviceability of the existing structures. The monitoring results are in agreement with the analysis results and the construction has been successfully completed.

Keywords: Deep excavation, Impact assessment, Existing structures, Instrumentation

1 INTRODUCTION

The continuous expansion in the Bangkok metropolitan area has resulted in a rapid increase in demand for facilities. The 9th Master Plan Improvement Project of the Metropolitan Waterworks Authority (MWA) has been proposed to improve the efficiency of water supply distribution. The alignment of the project starts from the Mahasawat water treatment plant to the Samrong water pumping station, which is divided into four contracts.

According to the G-TN-9D project, the alignment of the tunnel commences from the Bangmod pumping station to the Samrong pumping station, covering a distance of about 13.4 km as shown in Figure 1. Seven shafts are proposed for construction, consisting of two rectangular diaphragm wall shafts, two octagonal diaphragm wall shafts and three circular sink caisson shafts. These shafts are utilized as the driving and receiving points for the Tunnel Boring Machine (TBM) at an approximate depth of 27.0 m below the ground surface.

Due to space constraints, shafts have to be excavated in close proximity to existing major structures. Typically, the construction of underground structures can result in soil displacements, leading to potential damage to nearby structures as depicted in Figure 2. Therefore, it is crucial to evaluate the possible impacts prior to the commencement of the construction. Figure 3 presents the relative positions between shafts (9D-1 and 9D-2) and the existing expressway viaducts. Preventive measures and risk mitigation strategies to reduce the effects are considered prior to the construction. A jet grout partition wall is proposed as a protection measure.

This paper focuses on the mitigation measure and the assessment of impacts on the existing viaduct adjacent to shaft construction by using 3D finite element analysis. The adjacent foundations are comprehensively evaluated in terms of foundation movements, pile structural capacity and pile geotechnical capacity due to the construction of both shafts. The comparison between computed foundation movements and the monitoring results is also discussed.

2 PROJECT DESCRIPTION

2.1 Shaft 9D1 & 9D2

Construction shaft 9D-1 exhibits a rectangular design, with internal dimensions measuring 8.0 m x 12.0 m. Similarly, shaft 9D-2 also follows

a rectangular layout with internal dimensions of 6.0 m x 10.0 m. These shafts are constructed using a top-down method with a 1.2 m thick diaphragm wall. The toe of the diaphragm wall extends to approximately 57 m from the ground surface.

The internal structure of shaft 9D-1 comprises reinforced concrete walers. These walers have a cross-sectional size of 1.0 m x 1.2 m for the upper two levels (waler-1 and waler-2), and a cross-sectional size of 1.0 m x 2.0 m for the lower two levels (waler-3 and waler-4). The base slab has a thickness of 2 m.

The internal structure of shaft 9D-2 also features reinforced concrete ring beams, with a cross-sectional size of 1.2 m x 1.2 m for the upper two levels (waler-1 and waler-2), and a cross-sectional size of 1.2 m x 1.8 m for the lower two levels (waler-3 and waler-4). The Base Slab in this case also has a thickness of 2.0 m.

These components structurally act as a support system within the shaft during construction. The Base Slab of both shafts is situated at a depth of approximately 32 meters below the ground surface as shown in Figure 4.

2.2 Existing viaduct structures

Three adjacent foundations supporting the Kanchanaphisek outer ring road are considered in a detailed evaluation. The distance between viaduct No. MLP-46-1R and MLP-46-2R and Shaft 9D-1 are 11.8 m and 10.9 m, respectively. Similarly, viaduct No. MLP-46-2R and MLP-46-3R have clearances of 12.7 m and 13.9 m from shaft 9D-2. They are supported by several bored piles with a diameter of 1.20 m, and the pile top level at 50 m below ground surface. The ultimate load of 1150 tons is considered for each pile.

Figure 3. Site Location of Shaft 9D-1 and 9D-2 and adjacent structures.

2.3 Geological condition

The geological condition of Bangkok is relatively uniform throughout the area. It is typically composed of fill material being approximately 0.5 to 2.0 m thick, soft clay layer generally ranges from the ground surface to a depth of 10.0 to 15.0 m. A medium stiff clay layer with a thickness of 1.0 to 3.0 is situated under the soft clay layer. Underlying the medium clay, a stiff clay layer can be found with a thickness varying from 5.0 to 15.0 m. Below the stiff clay layer, a thick layer medium dense to very dense first sand layer is located. The piezometric pressure head during construction is located around 13.0 m below the ground surface.

Figure 4. Cross-sections of shafts 9D-1 and 9D-2.

3 CONSTRUCTION OVERVIEW

According to the top-down construction sequences, the typical stages for excavation and construction of shafts 9D-1 and 9D-2 are represented in Figure 5, which are briefly outlined in the following sequence:

- The construction of shafts commences by excavation and casting of a 50 m-long diaphragm wall around the shaft boundary. Since the piezometric pressure in sand layer is high (approximately 230 kPa) at base slab level and may be susceptible to hydraulic uplift failure (upheaval) during excavation, therefore, TAM blanket grout is designed to create a watertight barrier at bottom of the earth retaining structure system to gain more counterweight with groundwater pressure. Moreover, joint grout within the sand layer is applied to ensure the ground water control during the excavation.

- Jet grout partition wall is constructed around the pile foundation of the existing viaduct to minimize the impacts due to the construction of shaft 9D-1 and shaft 9D-2.
- Jet grout blocks for TBM launching and receiving from both shafts are concurrently constructed. It is essential to complete jet grouting prior to commencing the top-down excavation.
- The top-down construction method is subsequently utilized, involving a sequential excavation of soil inside the shaft area associated with the internal structure installation. It begins with the excavation of the 1st floor to a certain depth and the installation of a temporary support structure. The excavation continues to construct reinforced concrete permanent walers.
- Before reaching the final excavation level, the 2nd temporary bracing is installed due to the large span between waler-4 and the base slab.
- Final excavation is executed for base slab construction at approximately 34.0 m below the ground surface.
- The 2nd temporary bracing is removed after the completion of base slab casting to facilitate the subsequent tunnel excavation.

4 IMPACT ASSESSMENT

4.1 Numerical model

To address construction-related challenges and assess the impact of shaft 9D-1 and 9D-2 excavation on nearby structures, a numerical analysis has been performed by the commercial finite element software PLAXIS. Subsoil condition is referred from the borehole located in the construction site.

A three-dimensional finite element analysis (3D-FEA) is employed to simulate the rectangular shape of the shaft and the relative location of existing piles. The model size is 160 m in length and width. The bottom of the model is extended to 80 m below the ground surface corresponding to the approximated excavation depth of 34 m to ensure that the boundary effect is minimized. For the vertical boundaries, the horizontal movement is restrained. On the other hand, the movements for the bottom boundary are fixed in both horizontal and vertical directions. The mesh generation is intentionally refined in the zones around the considered structural members.

Soils are modelled as linear elastic-perfectly plastic material following the Mohr-Coulomb failure criterion. The correlation between E_u/S_u for Bangkok clay are based on the back-analysis by Phienwej (2008), Teparaksa et al. (1999), and Phienwej & Gan (2003). Likitlersuang et al. (2013) points out that the proposed correlation can be successfully used to simulate the ground movement due to the underground station excavation of the Bangkok MRT projects. Sand stiffness was estimated by using empirical correlations with the SPT-N value proposed by Stroud (1989). The FE model and parameters used in the analysis are presented in Figure 6 and Table 1, respectively.

Figure 5. Shaft top-down construction.

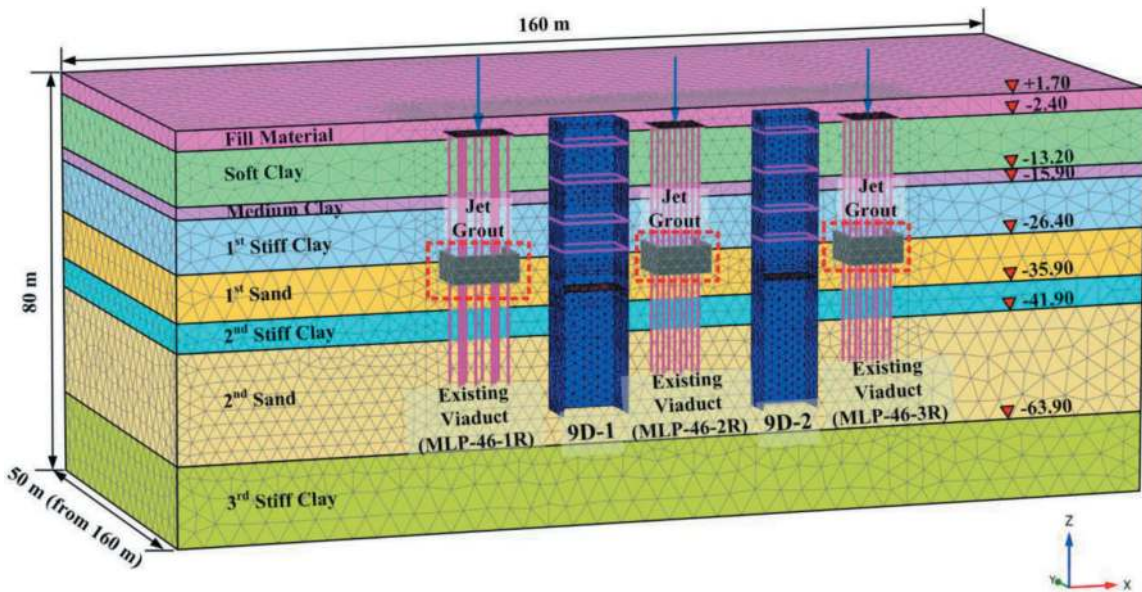

Figure 6. 3D-Finite element mesh for impact assessment analysis.

4.2 Criteria for impact assessment

Three important aspects are adopted to evaluate the possible impacts on the existing structures induced by ground movements during the deep excavation are as follows:

4.2.1 Tolerable movements

To maintain the serviceability of the existing viaduct, settlement shall be limited to under 15 mm, while the foundation tilting shall be lower than 1:500 according to the suggestion by the Building Construction Authority (BCA, 2021). The criterion for lateral

Table 1. Geotechnical parameters.

Soil Type	Elevation (MSL)		γ (kN/m ³)	SPT-N (Blow/ft)	S_u (kPa)	ϕ (Deg.)	E' (kPa)	K_o
	Top	Bottom						
Fill	1.7	-2.4	16.0	-	25	0	10,400	0.60
Soft Clay	-2.4	-13.2	16.0	-	20	0	8,300	0.75
Medium Clay	-13.2	-15.9	17.0	-	40	0	25,000	0.71
1 st Very Stiff Clay	-15.9	-21.9	20.0	26	170	0	141,600	0.68
2 nd Very Stiff Clay	-21.9	-26.4	20.0	20	150	0	125,000	0.68
1 st Dense Sand	-26.4	-30.9	21.0	55	-	38	110,000	0.43
2 nd Dense Sand	-30.9	-35.9	21.0	10	-	43	200,000	0.43
3 rd Very Stiff Clay	-35.9	-41.9	20.0	23	130	0	108,300	0.68
Very Dense Sand	-41.9	-63.9	21.0	100	-	38	200,000	0.41
Hard Clay	-63.9	-80.0	20.0	73	280	0	233,300	0.64

where γ is soil unit weight, S_u is undrained shear strength, ϕ is friction angle, E' is elastic modulus, and K_o is coefficient of horizontal earth pressure.

foundation displacement and the angular distortion follows the recommendation of AASTHO Standard Specification for Highway Bridges (2002). The lateral movement is limited to under 25 mm, while the angular distortion shall be lower than 1:250.

4.2.2 Pile structural capacity

The additional structural forces induced along the adjacent piles shall be investigated so that the actual pile reinforcement can withstand the effect of nearby excavation. The moment-axial force interaction diagram in accordance with BS-8110 is used as a pile structural capacity.

4.2.3 Pile geotechnical capacity

The soil movement according to the deep excavation generally induced negative skin friction on the adjacent, which has a consequence on the axial force distribution along the pile. The mobilized negative skin friction will increase the compressive axial force in the pile (or tension in some cases). Therefore, the effect of this phenomenon will be verified if the available positive skin friction and the end bearing of the piles are sufficient to withstand the superstructure working load.

5 INSTRUMENTATION AND MONITORING

The geotechnical instrumentations are installed to observe the occurring ground movements as the construction control of excavation. The employed instrumentations as shown in Figure 7 including:

- The inclinometers installed in the diaphragm wall (INC) are used to measure the inclination of the diaphragm wall (D-wall) relative to a vertical plane.
- The inclinometers combined with extensometers (IEX) are used to monitor the movements of soil in response to changes in vertical and horizontal directions.
- Surface settlement points are used to measure and control soil movement in a vertical direction. The

- control values are determined based on the surface settlement near the excavation areas.
- Vibrating Wire Piezometers are used to monitor pore water pressure in soils. The control value of piezometers is set in accordance with the design piezometric profile.

Additional instrumentations are installed at the existing structures to ensure the safety and serviceability of the viaducts during the construction, as shown in Figure 7. The control values are typically set based on the allowable movements and distortion that have no adverse impacts on the existing structures. The Trigger – AAA values (Alert, Alarm and Action) of each instrumentation type are given in Table 2. Description of these devices are given below:

- Structural settlement points are used to measure the vertical movement of the existing viaduct near the excavation zone during construction.
- Tilt meters are used to measure the tilt of flyovers relative to one or two axial planes.
- Target prisms are used to measure the structural movements relative to 3 axes: vertical, horizontal, and in-plane axis, which can provide a more comprehensive understanding of the overall movements of the structure.

Table 2. AAA-Level for the Existing Structure.

Movement	AAA-Level			
	Max 100%	Action 90%	Alert 80%	Alarm 70%
Vertical Movement	15 mm	13.5 mm	12 mm	10.5 mm
Horizontal Movement	25 mm	23 mm	20 mm	17 mm
Distortion	1:1,000	1:1,100	1:1,250	1:1,400
Foundation Tilting	1:500	1:550	1:625	1:700

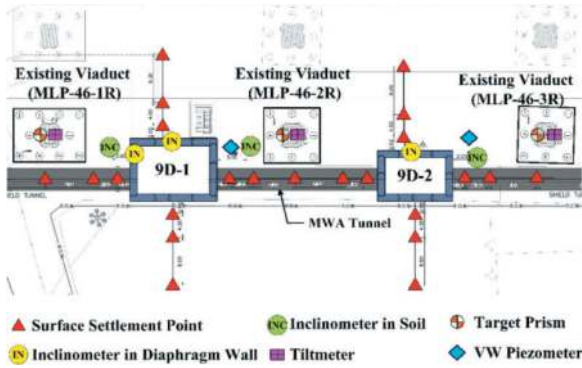

Figure 7. Instrumentation program for Shaft 9D-1 and 9D-2.

6 MONITORING RESULTS AND COMPARISONS

Figure 8 represents the corresponding lateral movements of INC monitoring in diaphragm walls and soil during construction compared to the computed results from the FE modelling. Note that, for the monitoring data, the results of only the final step (after removing the temporary steel bracing) are presented. In general, the shapes of lateral movement along the depth from the FE analysis agree well with the monitoring data, although the predicted values are smaller (particularly the INC in diaphragm wall 9D-2). This is probably due to the reason that a conservative evaluation concept has been considered.

The movements of the three adjacent piers (No. MLP-46-1R, MLP-46-2R, and MLP-46-3R) around the excavation area measured by the target prisms are depicted in Figure 9 together with the predicted results from FEA. As predicted by the computed results, insignificant settlement as well as the lateral movement of adjacent piers are presented by monitoring results. As illustrated in the figure, the maximum viaduct settlement of 2.0 mm is monitored during the

shaft construction can be detected. Hence, the computed angular distortion and foundation tilting are 1:20,000 and 1:23,000, respectively. The maximum lateral foundation movement ranges between 1.0 to 3.5 mm. The observed pier movements are lower than the limiting value recommended by AASHTO (2002) and BCA (2021). Therefore, the monitoring results confirm the safety and structural stability of the excavation and existing structure, as evaluated in the impact assessment prior to the construction.

7 PILE IMPACT ASSESSMENT

Additional evaluations of the structural and geotechnical capacity of the pile were also performed. According to the comparison provided in Section 6, the 3D-FEA can be used to evaluate the effects of shaft 9D-1 and 9D-2 construction on the piles. The additional axial forces and bending moments along adjacent piles are computed and thus compared to available capacity according to the BS-8110 as illustrated in Figure 10. The values of all piles in each foundation are plotted by considering every construction stage. As the excavation process proceeds, the induced bending moments and axial forces change compared to the beginning stage. The predicted axial force-moment values in the piles represented the small change compared to the initial condition according to the relative location near the shaft corner. Moreover, the axial force-moment are enclosed within the interaction diagram, indicating that these piles have adequate structural capacity to withstand the nearby deep excavation activities.

8 CONCLUSION

This paper presents the responses of the existing viaducts in accordance with the ground movement during

Figure 8. Comparison between monitoring and computed results of Diaphragm wall movement and lateral soil movement.

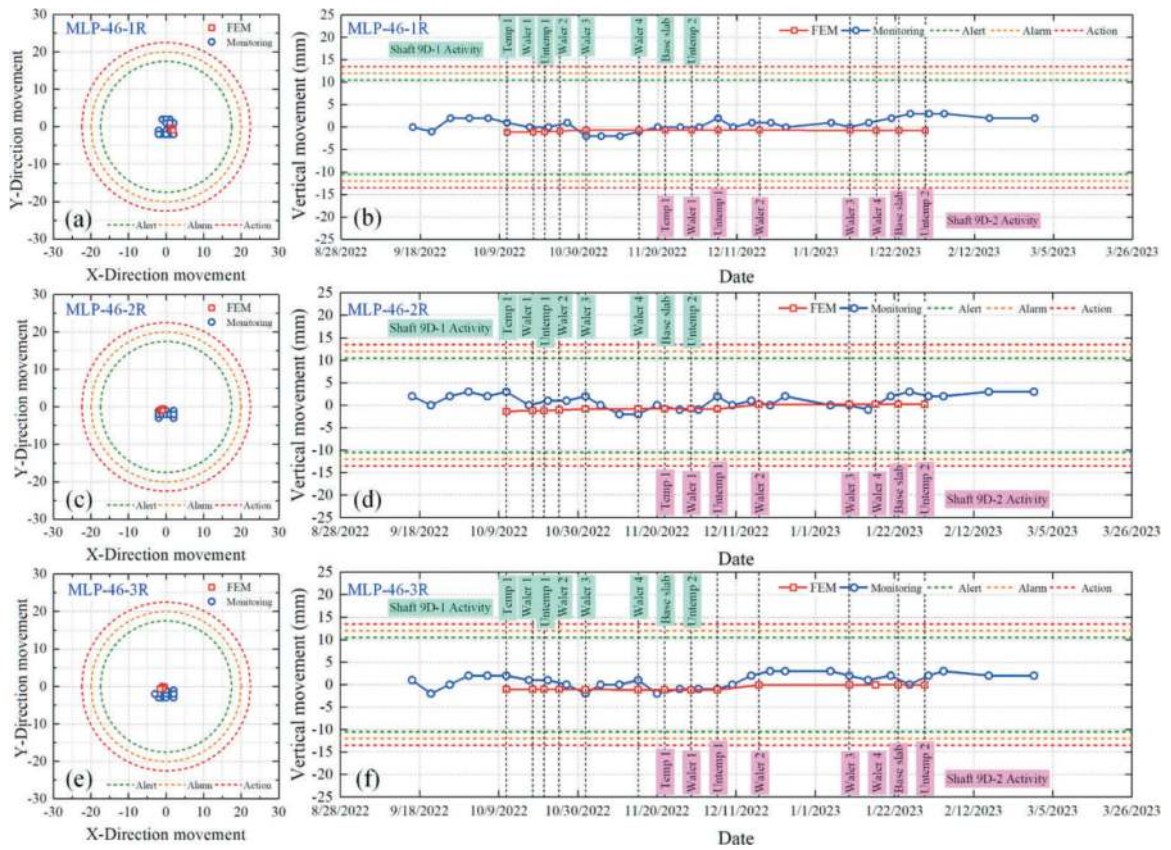

Figure 9. Comparison between monitoring and computed movements of adjacent viaducts.

Figure 10. Development of axial force and bending moment in adjacent piles compared to available capacity.

the top-down construction of shafts in the 9th Master Plan Improvement Project of the Metropolitan Waterworks Authority (MWA). The impact assessment of the excavation of shafts 9D-1 and 9D-2 according to the G-TN-9D project on the Kanchanaphisek outer ring road viaduct is carried out. The results of the field measurement and three-dimensional finite element analysis are represented and discussed. According to this study, the following conclusions can be drawn:

1. The three-dimensional finite element analysis indicates that the impact of ground movement due to top-down excavation of shafts 9D-1 and shaft 9D-2 on the adjacent viaduct is acceptable in terms of viaduct movement, pile structural capacity and pile geotechnical capacity.
2. The predicted diaphragm wall movement and the lateral soil movement are consistently aligned with the measuring data. Moreover, the monitored vertical movement, horizontal movement and tilting of viaducts during the excavation are compatible with the finite element results. According to the criteria proposed by AASHTO (2002) and BCA (2021), their movements consistently remained within acceptable criteria, guaranteeing the safety and structural stability of the existing structure.
3. The computed results from three-dimensional numerical analysis reasonably agree well with the

field monitoring results. This reveals a suitability and practicality for adoption in future projects.

Investigation of vibration patterns generated during rock cutting tests

Ugur Ates, Hanifi Copur* & Aydin Shaterpour-Mamaghani

Istanbul Technical University, Istanbul, Turkey

ABSTRACT: Tunnel boring machines (TBMs) are essential for infrastructure projects and they should be operated in accordance with the geological conditions. Thus, swiftly recognizing and adapting to geological changes plays a critical role for the excavation. In that aspect, vibrations generated during excavation by TBMs have been analysed for ground identification in various studies. However, those measurements are often complicated by numerous influencing factors and noise sources, which make it challenging to isolate the specific effects of rock cutting on vibrations. Due to this reason, there is a need for a better understanding of vibrations created during the rock cutting process under controlled environment. With this aim, laboratory rock cutting tests are realized by a full-scale linear rock cutting machine equipped with a 17-inch disc cutter and accelerometers on three different rock samples with uniaxial compressive strength values ranging from 21 to 82 MPa. Peak, root mean square (RMS), and interval RMS accelerations are calculated from the recorded vibration data and the relations between vibrations, cutting performance parameters, cutting geometry, and mechanical properties of rocks are analysed. The results reveal that there is a relationship between cutting forces (especially average and peak normal force), rock mechanical and mineralogical properties, cutting configuration and vibrations. In general, it is possible to say that the vibrations increase as penetration and rock strength increase.

Keywords: Vibration, Disc cutter, Rock mechanical properties, Full-scale linear rock cutting machine

1 INTRODUCTION

Understanding geological conditions during TBM excavation is crucial for project's success. However, most of the contractors rely on the geological data provided to them during the tendering stage or start the projects by performing additional geological surveys which can be considered as inadequate in general. During the excavation of tunnels, the best way to understand geological conditions is to check excavation face. However, continuous TBM excavation makes face inspections challenging and most of contractors are reluctant to stop excavation for face inspections unless it's deemed necessary, or forced by the contract. Another tool for understanding geological conditions ahead is probe drilling, which is generally not applied for the previously mentioned reasons. Therefore, monitoring muck and TBM operational data becomes essential, even though these methods may be interpreted inaccurately.

Vibrations generated during excavation operations, can provide valuable insights into geological conditions without the need for frequent face inspections. Several authors equipped TBMs with accelerometers and investigated vibration changes during excavation.

Those accelerometers were either installed on the cutterhead (Shanahan, 2010; Huang et al., 2018; Wu et al., 2021) or behind the cutterhead (Walter et al., 2012; Walter, 2013; Mooney et al., 2014; Buckley, 2015; Hunt and Frank, 2021; Liu et al., 2021, 2022). Despite significant attention to TBM vibrations, the complexity of these machines and the multitude of factors influencing vibrations highlight the need for further comprehensive research conducted in a controlled laboratory environment.

To understand forces and vibrations generated during rock cutting several authors studied this topic. One of these researches was realized by Samuel & Seow (1984). Strain gauges were placed on the shafts of the disc cutters of a 4.1 m diameter TBM and force components acting on a disc cutter were investigated. Later, Gertsch (1993) conducted a detailed study on this area using a 17" constant cross section (CCS) disc cutter. This investigation involved frequency analyses of the forces, and it was carried out using a full-scale linear cutting machine (FLCM). Notably, these research used strain gauges rather than accelerometers to explore vibrations, which differentiates it from subsequent studies in the field. Huo et al. (2015) took a different approach by

*Corresponding author: copurh@itu.edu.tr

developing a dynamic multi-degree-of-freedom model for disc cutters. This model aimed to provide a deeper insight into the vibration characteristics and the transmission of loads within the cutters. Yang et al. (2020) performed laboratory tests using a Multi-Mode Boring Test System and investigated vibration characteristics of the cutterhead in soft-hard mixed strata.

In contrast to previous studies, Ates et al. (2019, 2022, 2023) and Ates and Copur (2023) conducted comprehensive and continuous measurements and analyses of TBM vibrations across multiple earth pressure balance (EPB) TBMs in three projects totaling 6 km. It was found that there was a relationship between geological conditions, TBM operational and performance parameters, and vibrations.

Three different rock block samples from a metro project site and a quarry are obtained in this study; then, full-scale linear cutting tests are performed by using a 17-inch diameter CCS disc cutter with varying line spacings and penetrations. The experimental setup includes load cells for tool force measurements and accelerometers for vibration measurements. Following the rock cutting tests, the acquired vibration data, comprising peak acceleration, root mean square (RMS) acceleration and interval RMS acceleration are correlated with cutting geometry (line spacing and penetration), cutting performance parameters (peak and mean normal, rolling and side forces, specific energy, and coarseness index), and mechanical properties of the rocks.

2 TESTING EQUIPMENT AND METHODOLOGY

A full-scale linear cutting machine (FLCM) utilized during this study, which is located at the Mining Engineering Department laboratory of Istanbul Technical University. Full-scale linear rock cutting test is widely acknowledged as one of the most reliable, cost-effective, and established methods for the selection, design, and prediction/optimization of mechanical miners' excavation performance. This approach minimizes uncertainties inherent in empirical methods and index tests (Bilgin et al., 2013). These tests involve measuring the forces acting on a cutter while it cuts a large block of rock sample encased in a sample box. The detailed information regarding FLCM is readily available in the literature (Bilgin et al., 2013; Copur et al., 2017). The machine incorporates a strain-gauge based load cell to measure the cutting tool forces. Additionally, five accelerometers, comprising both piezoelectric and MEMS types, are fixed to the various positions on the machine. They simultaneously measure and record vibrations occurring in conjunction with the cutting tool forces during the cutting tests.

A range of triaxial analog accelerometers and analog-to-digital converters are employed throughout the study for measuring/recording the vibrations.

The specifications of the accelerometers are listed on the Table 1. USB-6009 and NI 9230 BNC analog-digital converters from National Instruments are used for digitizing.

Table 1. Specifications of the accelerometers.

Manufacturer	Analog Devices	Analog Devices	PCB Electronics
Model	ADXL354BZ	ADXL356CZ	356A17
Type	MEMS	MEMS	Piezoelectric
Sensitivity (mV/g)	200	20	500
Measurement Range ($\pm g$)	4	40	10
Frequency Range (Hz)	0-1500	0-1500	0.5-3000
Internal Analog LP Filter (Hz)	1500	1500	N/A

The accelerometer placement, their identification numbers used throughout the study, and the directions of the axes are shown in Figure 1.

A specialized data recording software, tailored to the project's needs, is developed and employed for the recording of vibration data. The FLCM force data is obtained by using another dedicated software. The recorded vibration data is analysed in time and frequency domains using custom Matlab scripts and Excel macros are used for processing of vibration data.

After each cut, the length of the cut is measured, the muck is collected, weighed, and sieved. Subsequently, the rock box is laterally shifted by the specified spacing to simulate the actions of multiple cutters on the cutterhead of a mechanical excavator, and the experiment is repeated (Copur et al., 2017).

Figure 1. Locations of the accelerometers.

Single spiral pattern is used during cutting tests, and a constant-cross-section (CCS) disc cutter with a 17" diameter and an 18 mm tip width is used. The cutting speed is set at 12.7 cm/s, and the tests follow surface conditioning procedures as outlined by Copur et al. (2017). The line spacing and penetration configurations used in the tests are given in Table 2.

Table 2. Configuration of cutting tests (experimental matrix).

Formation	Siltstone	Mudstone	Marble (EC)	Marble (DC)
Line Spacing (s) (mm)	Penetration (d) (mm)			
70	5	5	-	-
	7	7	-	-
85	4	4	4	4
	6	6	6	6
	8	8	8	-
	-	10	-	-

The analysis of the collected vibration data involves various time-domain data analysis techniques, which include quantitative statistical methods. The initial phase of the analysis involves evaluating the data through time history graphs that show acceleration data alongside cutting parameters such as normal, rolling, and side forces. During this stage, the video recordings are used to identify the causes of specific vibration and cutting force peaks. Following this initial analysis, root mean square (RMS) and interval RMS accelerations are calculated. It's important to note that, since there are typically at least three cuts performed for each line spacing and penetration setting, the results are averaged to create a representative value for each configuration across all rock samples.

Vibration data is collected in the time domain; however, to gain a more comprehensive understanding of the frequency components of the signals, it can be beneficial to transform the data into the frequency domain. This transformation is achieved through a Fast Fourier Transform (FFT). It's important to note that the analyses show rock cutting generates broadband signals that are challenging to interpret directly in the frequency domain. Despite this, spectrograms and waterfall FFT plots are employed to examine the frequency content of the signals. Spectrograms are graphical representations that depict how acceleration signals vary concerning both time and frequency. They are particularly helpful in identifying the timing of specific activities within the recorded data (Rogers et al., 1997; Hanly, 2016).

3 ROCK SAMPLES

This study utilizes two rock blocks, mudstone from the Pendik Formation and siltstone from the Kurtkoy Formation, both obtained from the Goztepe-Umraniye -Atasehir Metro Line project site. Additionally, a beige marble sample from a quarry is included in the full-scale linear rock cutting tests. These rock samples exhibit various properties and characteristics. It's worth noting that the mudstone and siltstone samples had bedding planes, whereas the beige marble

sample did not. The cutting direction is parallel to the bedding planes for mudstone and 45° angled for siltstone, as illustrated in Figure 2. The photos of the samples are shown on Figure 3.

Figure 2. Bedding planes (a for siltstone and b for mudstone).

Pendik Formation (Mudstone): The rock sample is from the Pendik Formation's Kartal Member. The formation shows intercalation of micaceous shales, mudstones, and siltstones with rare micaceous sandstone of 5-10 cm thickness and bioclastic limestone (thickness of 5 - 10 cm to 40 - 50 cm) at various ratios. Frequently, the shales are severely altered/weathered along discontinuities and outcrops (Geodata Engineering S.p.A., 2016). The sample used during the rock-cutting tests belongs to mudstone units.

Kurtkoy Formation (Siltstone): Bakacak Member (Opkb) of the Kurtkoy Formation is dominant in the area where the rock block is obtained, and the lithology is composed of thin to medium bedded, parallel, and cross-laminated siltstone and sandstone. The lower parts show purple to brown colour banding; upwards in the sequence the purple colour becomes dominant and the grain size increases. Arcosic sandstones, conglomerates, and siltstones dominate within the Sureyyapasa Member (Geodata Engineering S.p.A., 2016).

Beige Marble (Sparitic Limestone): The Beige Marble sample was not homogenous in terms of strength and cuttability features. It was observed that one side of the sample was more difficult to cut during the FLCM tests than the other side. Thus, the data is evaluated in two different sections, which are difficult cuttability (DC) and easy cuttability (EC).

To better understand the distinction between the easy and difficult cuttability sections, petrographic analyses are performed on the thin sections. The ratio of intraclasts to pellets is observed to be the most significant difference between the two samples, as the intraclast ratio rises, the rock gets more difficult to cut and requires a greater tool force. It is also observed that the smaller pellet size requires a greater tool force.

Difficult cuttability section (DC): This section is described as "Fossilized Intra Pel Sparite or Fossilized Pel Intra Sparite". It includes sparitic cemented limestone, which consists of intraclasts, pellets (35-40%), and a slight number of fossils. Intraclastic parts are composed of micritic limestone fragments. It is mostly fractured with calcite fillings. Pellet size is between 0.1 and 0.4 mm.

Easy cuttability section (EC): This section is described as "Fossilized Intra Pel Sparite". Sparitic

cemented limestone includes more calcite fillings than the other section (DC). Pellets are larger in size (0.3-0.6 mm) and occupy more space (50%). Intra-clast ratio is lower, while pellet size is bigger compared to difficult cuttability section. It includes a slight number of microfossils. It is mostly fractured with calcite fillings.

Figure 3. Photos of the rock samples (a for mudstone and b for siltstone and c for beige marble).

4 RESULTS OF ROCK CUTTING TESTS

The physical and mechanical properties of the rock samples are summarized in Table 3 and a total of 55 cutting tests were into consideration. As the difficult cuttability section of the beige marble sample had very high cutting forces, only 4 mm and 6 mm penetration values are applied to this section. Due to the limited rock sample size, the tests with 70 mm line spacing are not performed for the beige marble sample.

The rock cutting tests revealed that the difficult cuttability section of the beige marble required higher cutting forces; however, uniaxial compressive strength values for both the easy and difficult cuttability sections were not significantly different from each other. This observation suggests that the petrographic characteristics of the rocks have a substantial influence on their cutting behaviour.

Figure 4 shows that both average normal (a) and average rolling forces (b) increase with increasing penetration, as expected based on rock cutting science. Beige marble's difficult cuttability (DC) section requires a greater average normal force across all penetrations compared to the other rocks, while its easy cuttability (EC) section requires the lowest normal force. However, in contrast to the normal force, it's worth noting that the siltstone sample exhibits the highest average rolling force when the line spacing is 85 mm.

The correlation between specific energy and line spacing to penetration ratio is shown in Figure 4(c). The mudstone and beige marble (EC) exhibit an optimal S_L/p ratio of approximately 11, whilst the siltstone and beige marble (DC) demonstrate an optimal ratio of 14. However, to obtain a more accurate assessment of the optimal S_L/p ratio for the difficult cuttability section of beige marble, it is preferable to include at least one additional data point.

It is imperative to note that the normal force is typically correlated with the uniaxial compressive strength of the rock; however, the findings do not exhibit a similar pattern. Furthermore, the beige marble's difficult cuttability section requires higher tool forces than the easy cuttability section, although it is worth mentioning that the uniaxial compressive strength values of both sections do not display a substantial disparity. These results demonstrate

Table 3. Geomechanical properties of the tested rocks.

	Siltstone (Kurtkoy Formation)	Mudstone (Pendik Formation)	Beige Marble (EC)	Beige Marble (DC)
Density (gr/cm ³)	2.73	2.52	2.68	2.69
Uniaxial Compressive Strength (MPa)	46.50	21.55	81.58	77.57
Indirect Tensile Strength (MPa)	6.94	4.95	5.83	6.51
Static Poisson's Ratio	0.31	0.11	0.19	0.11
Dynamic Poisson's Ratio	0.32	0.08	0.16	N/A
Static Elastic Modulus (GPa)	14.52	4.93	26.34	19.97
Dynamic Elastic Modulus (GPa)	29.38	19.33	17.29	17.03
P-Wave Velocity (m/s)	3903	2744	2695	2517
S-Wave Velocity (m/s)	2022	1850	1672	1784
Schmidt Hammer Hardness (L Type)	32.95	23.11	39.42	41.03
Shore Scleroscope Hardness	53.2	31.2	48.6	52
Brittleness (B1) ¹ (by Hucka and Das, 1974)	6.62	4.35	13.99	11.91
Brittleness (B2) ² (by Andreev, 1995)	0.73	0.62	0.86	0.84

¹ B1 = σ_c/σ_t by Hucka and Das (1974)

² B2 = $(\sigma_c - \sigma_t)/(\sigma_c + \sigma_t)$ by Andreev (1995)

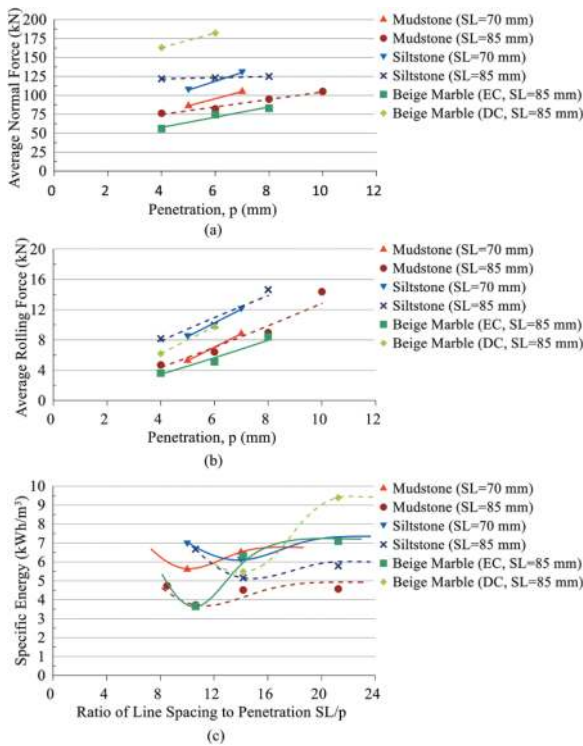

Figure 4. Variations of average normal force (a) and average rolling force (b) with penetration, and specific energy with S_L/p ratio (c).

that the petrographic characteristics of rocks have a significant impact on their cutting properties.

It is imperative to note that the normal force is typically correlated with the uniaxial compressive strength of the rock; however, the findings do not exhibit a similar pattern. The beige marble's difficult cuttability section requires higher tool forces than the easy cuttability section, although the uniaxial compressive strength values of both sections do not display a substantial disparity. These results demonstrate that the petrographic characteristics of rocks have a significant impact on their cutting properties.

5 RELATIONSHIPS BETWEEN CUTTING CONFIGURATION, CUTTING PERFORMANCE AND ACCELERATIONS

Following the investigation of the relationships between penetration, average rolling force, average normal force and interval RMS accelerations it was found that a general trend exists; vibrations tend to increase as these variables increase for all rock types (Figure 5). However, a notable exception is seen with siltstone at a line spacing of 85 mm, where vibrations decrease as the average normal force increases, which could be related with siltstone sample's bedding angle. Even the relationships can be categorized as moderately strong for normal force and weak for rolling force, by taking all data into consideration best fit lines are calculated and,

equations (Equations 1 and 2) are presented for predicting the forces by utilizing the accelerations.

$$FN = 121.78RMS_{int} + 77.24 \quad (R^2 = \cdot 0.53) \quad (1)$$

$$FR = 7.35RMS_{int} + 6.59 \quad (R^2 = \cdot 0.20) \quad (2)$$

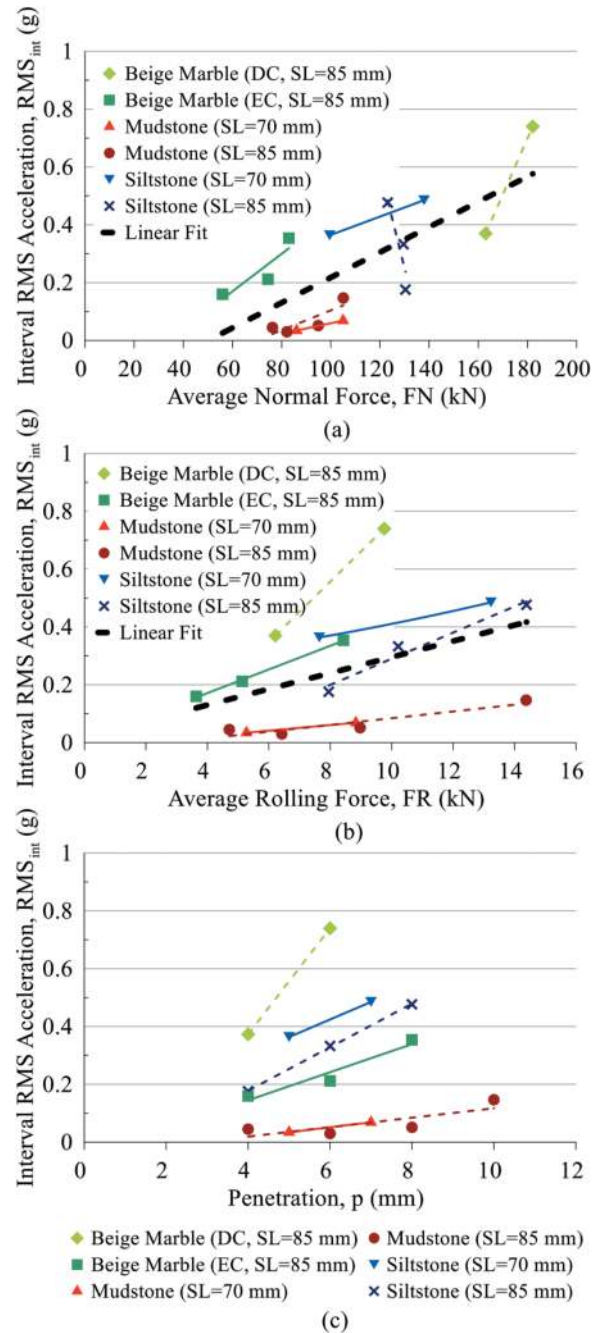

Figure 5. Variation of interval RMS acceleration with average normal force (a), average rolling force (b) and penetration (c).

As the forces also increase with penetration, it is possible to assume that penetration is the major variable affecting the vibrations in terms of cutting parameters.

Figure 6 illustrates the relationships between interval RMS accelerations and peak forces, indicating another clear trend of increased vibrations with higher force values. These relationships can be categorized as strong for peak normal force and moderately strong for peak rolling force. The equations (Equations 3 and 4) are presented to formalize the relationship between interval RMS acceleration and peak normal force, providing a quantitative representation of this correlation.

$$F'N = 171.43RMS_{int} + 133.12 \quad (R^2 = 0.74) \quad (3)$$

$$F'R = 22.58RMS_{int} + 13.04 \quad (R^2 = 0.57) \quad (4)$$

Figure 6. Variation of interval RMS acceleration with peak normal force (a) and peak rolling force (b).

Since the tunnelling machinery needs to withstand constant vibrations, this information is also particularly important and together with the tool force data, can be used during the design stage. If the vibration measurements become an integral part of the FLCM, together with force data, vibration data could also be provided to the related parties during the design stage.

Figure 7 presents the relationship between interval RMS acceleration values and chip size over 25 mm as a percentage of the total, as well as the coarseness index normalized by penetration. The relationships between interval RMS acceleration and coarseness index are not strong thus they are not presented;

however, correlations are clearer for chip size >25 mm (Figure 7a) and coarseness index/penetration ratio. In simpler terms, when larger chips break off from the rock during cutting, it leads to higher tool forces and subsequently, greater vibrations. This observation aligns with video recordings that indicate vibrations occur when significant chips detach from the rock. Additionally, correlations with the coarseness index normalized by penetration are clearer, emphasizing the importance of chip size in understanding vibration dynamics during rock cutting. The relationship between interval RMS and chip size percentage over 25 mm are presented in Equation 5.

$$\begin{aligned} \text{Chip Size (\%)} > 25\text{mm} &= 34.52 RMS_{int} \\ &+ 8.57 \quad (R^2 = 0.32) \quad (5) \end{aligned}$$

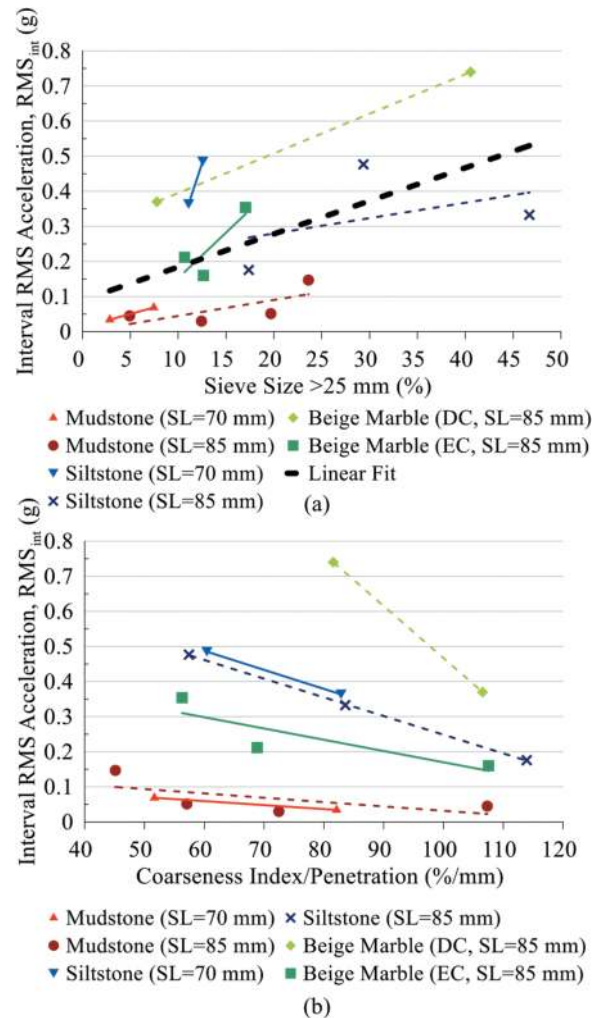

Figure 7. Variation of interval RMS acceleration with sieve size (>25 mm) (a) and coarseness index/penetration (b).

The study reveals that maximum accelerations during rock cutting increase as peak forces rise, and there is a moderately strong correlation between

these values exists. Typically, peak forces occur just before a significant chip breaks off from the rock, resulting in the generation of high-amplitude vibrations during this break-off process. This phenomenon explains the observed moderately strong relationships between peak forces and maximum accelerations, highlighting the influence of cutting forces on vibration amplitudes during rock excavation. Through the conducted analyses, Equations 6 and 7 are derived, which can be used for real-time prediction of peak normal and peak rolling forces by using the real-time measurements of maximum acceleration.

$$F'N = 5.85\text{Max.Acc} + 130.06 \quad (R2 = 0.69) \quad (6)$$

$$F'R = 0.79\text{Max.Acc} + 12.46 \quad (R2 = 0.56) \quad (7)$$

It is also found that maximum acceleration varies with penetration, and a general trend that suggests an increase in maximum acceleration as penetration levels rise. Penetration is considered a crucial parameter in TBM design, along with line spacing. Having knowledge of the maximum vibrations at specific penetration levels can provide valuable insights during the design phase, helping engineers and designers optimize TBM performance and component durability to withstand varying levels of vibration.

6 RELATIONSHIPS BETWEEN ACCELERATIONS AND ROCK STRENGTH

The primary aim of this study is to investigate the influence of rocks' mechanical properties on the vibrations generated during rock cutting. To achieve this, the interval RMS acceleration and maximum acceleration values are compared with the mechanical properties of the rocks. The samples tested at the same line spacing and penetration values are represented together in graph forms to investigate the effect of the rock's geomechanical properties on vibrations. It's important to note that the difficult cuttability section of the beige marble sample was only tested at 85 mm line spacing with varying penetration values of 4 mm and 6 mm (results for 8 mm penetration values are not available for this sample).

The impact of selected mechanical properties on vibration levels is visually presented in Figure 8 for interval RMS accelerations. Due to space constraints the figures showing maximum acceleration values are not presented, however, they follow similar trends. Although the coefficients of determination exhibit a wide range, indicating varying degrees of correlation from low to very strong, a general trend can be observed: as the rock's strength increases, vibrations tend to increase as well.

This trend is noticeable in mechanical properties such as uniaxial compressive strength, Schmidt hammer hardness, Shore scleroscope hardness, indirect tensile strength, dynamic elasticity modulus,

dynamic Poisson's ratio, and brittleness (both B1 and B2, as listed in Table 3). However, static Poisson's ratio and P and S wave velocities do not show clear trends. It's important to emphasize that the strength of these correlations varies across different mechanical properties. For instance, Schmidt hammer hardness demonstrates moderately strong correlations with interval RMS accelerations, while uniaxial compressive strength (UCS) has a lower R^2 value of 0.52 (for SL = 85 mm, p = 4 mm).

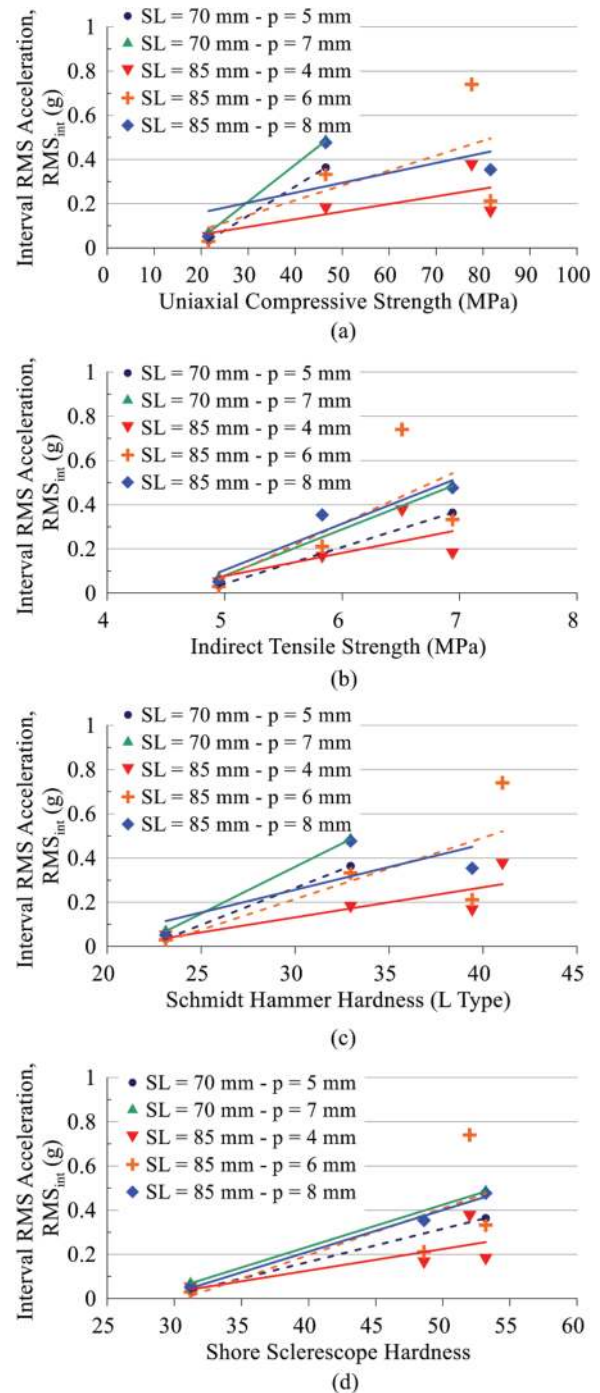

Figure 8. Variations of interval RMS acceleration with uniaxial compressive strength (a), tensile strength (b), Schmidt hammer hardness (c), Shore Scleroscope hardness (d).

Moreover, variations are observed between different penetration levels. Tensile strength and interval RMS accelerations, for example, have R^2 values of 0.49, 0.45, and 0.90 for 4 mm, 6 mm, and 8 mm penetration values, respectively. These findings align with previous studies and site observations, particularly with Ates and Copur (2023). Furthermore, it's worth noting that vibration levels tend to increase with higher penetration values for the same line spacing.

7 CONCLUSIONS

The study highlights the significant influence of cutting configuration, cutting performance parameters, rock mechanical properties, and mineral composition on vibration levels recorded during full-scale linear rock cutting tests. In general, it is observed that vibrations and forces tend to rise with increasing rock strength. Strong correlations are identified between peak normal force, interval RMS and maximum accelerations. As penetration increases, both tool forces and vibration levels increase.

Preliminary equations are provided for real-time prediction of tool forces (average and peak) based on acceleration measurements (both interval RMS and maximum acceleration). As these forces are related with the rock mechanical properties, rock strength can also be predicted during TBM operations, in especially locations where rock samples are difficult to obtain, by using the accelerations if a large database is created.

The analysis reveals that vibration shocks, with accelerations reaching up to 20g, occur after a significant rock chip breaks off, and the magnitude of these shocks is influenced by rock strength and cuttability.

The frequency content of the vibration signal is broadband, and vibrations can decrease as the tool force decreases, indicating stress relief in the rock during chipping.

Understanding expected vibration levels is crucial for TBM and component design, making vibration measurements an important aspect of full-scale linear cutting tests that can provide valuable insights for machine manufacturers.

For future studies, expanding the number of full-scale linear cutting tests would enhance the understanding of the relationships between rock properties, cutting configuration, cutting performance, and vibrations. It is recommended to use accelerometers with a measurement range of at least 20g due to the high amplitude vibrations observed in rock cutting.

ABSTRACT: The objective of this study is to assess the applicability of sodium alginate, a bio-polymer, as an eco-friendly additive for maintaining face stability during the excavation of slurry Tunnel Boring Machine (TBM). The performance of sodium alginate was compared to that of Carboxymethyl Cellulose (CMC), a conventional polymer additive. Performance evaluation included measuring water loss infiltration quantity, filter cake thickness, and viscosity. Both additives were prepared by mixing with bentonite slurry liquid. To investigate the impact of seawater infiltration during excavation, both additives were evaluated under various concentrations of sodium chloride (NaCl) in the slurry liquid. Sodium alginate exhibited water loss quantities and filter cake thickness equivalent to CMC at practical NaCl concentrations. The concentration of NaCl was found to have no significant effect on the performance of either sodium alginate or CMC. The results indicate that sodium alginate has the potential to maintain face stability against seawater infiltration at practical NaCl concentrations. Increasing the quantity of sodium alginate reduces water loss and increases filter cake thickness. Based on the initial assessments conducted in this study, it can be concluded that sodium alginate is a viable and eco-friendly material for preserving face stability.

Keywords: bio-polymer, sodium alginate, eco-friendly, TBM, CMC

1 INTRODUCTION

In recent years, there has been a consistent increase in excavation work within urban areas in South Korea, Singapore, Hong Kong, and other Asian countries as part of infrastructure construction projects, encompassing civil, architectural, and plant development. Particularly, the use of Tunnel Boring Machines (TBMs) has been remarkable growth in urban areas in South Korea. Among the various tasks involved in TBM excavation, ensuring face stability is of utmost importance. In slurry-type TBM tunnelling, stability is typically achieved by utilizing bentonite slurry (Min et al., 2015), often requiring the use of polymer additives to maintain viscosity (Chen et al., 2023).

To address the imperative of reducing carbon emissions, the global construction industry is increasingly focusing on substituting conventional construction materials with eco-friendly alternatives. In slurry TBM excavation, most additives employed to maintain face stability are chemically synthesized polymers (Amorim et al., 2007; Taheri and El-Zein, 2023). However, the use of these materials for natural ground and rock can potentially lead to adverse environmental consequences.

Sodium alginate, derived from brown seaweeds, is an eco-friendly bio-polymer. It possesses notable characteristics, including a high degree of hydrophilicity, the ability to form gels, and biodegradability. This eco-friendly material has been already applied in various industries (Wang et al., 2014; Kaneko et al.,

*Corresponding author: abebae@korea.ac.kr

1998). Specially, sodium alginate has been used in combination with bentonite for the decolorization of basic dyes (Mcyotto et al., 2020). Recently, in the infrastructure sector, sodium alginate's applicability has been explored in soil improvement and purification (Soltani et al., 2021; Liu et al., 2023).

This study investigates the potential of sodium alginate as a replacement for conventional polymer additives in bentonite slurry liquid used for maintaining the face stability during slurry TBM excavation.

2 SODIUM ALGINATE AS BIO-POLYMER

Sodium alginate is a bio-polymer extracted from seaweeds such as kelp and wakame. Notably, its production process results in a significant reduction in carbon emissions, making it an environmentally friendly material. This highly hydrophilic polymer electrolyte easily dissolves in water (Wang et al., 2014). In the food industry, it serves as a stabilizer in dairy products and is employed to enhance adhesiveness and viscosity. The characteristics of sodium alginate are summarized in Table 1.

Table 1. Characteristics of Sodium Alginate.

Variables	Contents
Basic Characteristics	- White to pale yellow in color - Granular in form - Odorless and tasteless - Possessing high absorbent properties
Chemical Form	(C ₆ H ₇ O ₆ Na) _n
pH	6 ~ 8
Viscosity	Barely changes in viscosity in solutions below 80°C
Applications in Industries	- Ice cream stabilizer - Thickener for ketchup and mayonnaise - Microcapsule and drug tables - A film and gel-forming agent

3 METHOD

To evaluate the performance of sodium alginate, three tests were conducted: water loss, filter cake thickness, and viscosity. Figure 1(a) is a filter press tester capable of measuring water loss infiltration volume and filter cake thickness. Figure 1(b) is a viscometer used to determine the viscosity of bentonite slurry liquid with a polymer additive.

These tests were typically conducted on bentonite slurry liquid before activating TBM excavation. Carboxymethyl Cellulose (CMC) was used as a comparative additive, as CMC is commonly employed in slurry TBM operations. Both Sodium Alginate and CMC were mixed with a 30 g/L concentration of bentonite slurry solution, which is

Figure 1. Test Devices.

typical for TBM operations. In excavations affected by seawater, it becomes crucial to assess the impact of sodium chloride (NaCl). Therefore, test solutions were prepared by varying the ionized concentration (IC) from 0 to 0.5 M. Furthermore, the effect of the quantity of sodium alginate was examined by varying it from 0 to 20 g/L. Table 2 summarizes the experimental variables.

Table 2. Experimental Variables.

Variables	Contents	Cases
Additive Types	Sodium Alginate, Carboxymethyl Cellulose	2
Concentration of Bentonite Slurry	30 g/L	1
NaCl Concentration	0, 0.001, 0.005, 0.01, 0.1, 0.5 g/L	6
Quantity of Sodium Alginate	0, 1, 2, 5, 10, 20 g/L	6
Performance Test	Water Loss Infiltration Filter Cake Thickness Yield Stress (Viscosity Test)	3

4 RESULTS

4.1 NaCl concentration effects

Figure 2 presents the results of water loss and filter cake thickness tests concerning NaCl concentration. Sodium alginate was found to yield water loss volume and filter cake thickness equivalent to those obtained using the conventional additive, CMC. This trend remained consistent within the range of zero to 0.1 M of NaCl concentration. This result suggests that sodium alginate has a potential to maintain face stability against practical seawater infiltration during TBM excavation. Note that 0.5 M NaCl concentration is similar to that of seawater.

Figure 2. Filter Press Test as to NaCl Concentrations.

Figure 3 shows yield stress values obtained from the viscosity tests for both sodium alginate and CMC. In the NaCl concentration range of zero to 0.01 M, both sodium alginate and CMC demonstrated consistent yield stress values, although CMC exhibited slightly higher yield stress values than sodium alginate. However, at a NaCl concentration of 0.01 M or higher, both sodium alginate and CMC showed a sharp decrease in yield stress. Notably, at the highest NaCl concentration, sodium alginate exhibited a higher yield stress than CMC.

Figure 3. Yield Stress Corresponding to NaCl Concentrations.

4.2 Sodium alginate quantity effects

Figure 4 presents the results of water loss and filter cake thickness tests in relation to the quantity of

sodium alginate. As the dosage of sodium alginate increased, the water loss volume gradually decreased, and filter cake thickness increased. Note that the application of only 1 g/L of sodium alginate significantly reduced water loss volume. This demonstrates the effectiveness of sodium alginate, a bio-polymer, in maintaining the face stability of slurry TBM.

Figure 4. Filter Press Test with Sodium Alginate Quantity.

5 FINDINGS AND CONCLUSIONS

This study assessed the applicability of sodium alginate, as an eco-friendly bio-polymer, for maintaining face stability during slurry TBM excavation. Performance criteria for face stability were evaluated through filter press and viscosity tests. The findings and conclusion are summarized as follows,

- Sodium alginate demonstrated water loss volume and filter cake thickness equivalent to the conventional additive, CMC.
- In the NaCl concentration range of zero to 0.01 M, both sodium alginate and CMC demonstrated consistent yield stress values. However, at NaCl concentrations of 0.01 M or higher, both sodium alginate and CMC exhibited a sharp decrease in yield stress. Remarkably, at the highest concentration of 0.5 M NaCl, sodium alginate displayed higher yield stress than CMC.
- The test results suggest that sodium alginate has the potential to maintain face stability against sea-water infiltration at practical NaCl concentrations.

- With an increase in the dosage of sodium alginate, water loss volume decreased gradually, while filter cake thickness increased. Note that the application of only 1 g/L of sodium alginate significantly reduced water loss volume.
- Based on the initial assessments conducted in this study, it can be concluded that sodium alginate is a viable and eco-friendly material for maintaining face stability.

More efficient, cost-effective and reliable Slurry Treatment Plants (STPs) for mechanized tunnelling operations in the Asia-Pacific region

Kun Bai*

Herrenknecht (Chengdu) Tunnelling Equipment Co.Ltd., Chengdu, China

Gino Vogt*

Herrenknecht AG, Schwanau, Germany

ABSTRACT: In mechanized tunnelling operations performance, consumption and safety are main factors for jobsites. One of the most important components affecting these factors, especially in slurry TBM operations, are Slurry Treatment Plants (STPs). Inadequately/suboptimally dimensioned and designed STPs create bottlenecks for tunnelling operations and jeopardize time schedules and performance. Inefficiently planned STPs could drastically increase consumption figures such as electrical power, bentonite, water, polymers, etc. Inaccurately selected and treated suspension properties can cause a high-risk potential for the whole project. This paper debates the relevant key parameters for STPs from start to finish of a project and their results in influencing factors from the manufacturer's point of view.

In mechanized tunnelling performance, consumption and safety are main factors for operating jobsites. One of the most important, key components affecting these factors, especially in slurry Tunnel Boring Machine (TBM) operations, are Slurry Treatment Plants (STPs). Inadequately/suboptimally dimensioned and designed STPs which do not follow, for example, a detailed study of the geological baseline report with analysis of the influencing parameters could create bottlenecks for tunnelling operations and jeopardize time schedules and performance targets. Inefficiently planned STPs not adapted to environmental regulations (for example inner city operations) could negatively impact the jobsite surroundings and drastically increase disposal cost and consumption figures such as electrical power, bentonite, water, polymers, etc. Inaccurately selected and treated suspension properties can cause a high-risk potential for the whole project in terms of safety. A reliable process design based on experience is therefore a must for every jobsite to meet overall targets. Based on many years of Asia-Pacific experience, this paper debates the relevant interfaces and key parameters for designing and selecting STPs to operate in a more efficient and cost-effective way by the only global player manufacturing both TBMs and STPs (Herrenknecht). A further focus will be on the development steps of these machines in the history of the APAC region, including latest developments and innovations like data management and automatization.

Keywords: Mechanized Tunnelling, Slurry TBM, STP, Slurry, Treatment Plant, Performance, Efficient Operation, Circular Economy, Greener Tunnels

1 INTRODUCTION

Whenever tunnelling projects are realized with Slurry TBMs or multimode TBMs and therefore include a slurry circuit, Slurry Treatment Plants (STP) are required to remove particles of soil from the slurry suspension and rejuvenate the slurry before it is pumped back to the cutting face of the TBM. It is important the slurry remains in adequate quality ranges to maintain efficient excavation. Slurry treatment has direct influence on the reliability and performance of a slurry tunnelling job. Get the

configuration of the slurry treatment plant wrong, and the TBM may be standing still. Apart from the primary use of STPs, protection of resources, recycling, classification and water treatment are steadily rising in importance all around the globe and therefore increasing the demands in separation units.

The STP in this context describes and stands for the complete setup and scope installed. Consisting mainly of equipment assembly groups such as Separation Plant, Centrifuge, Filter Press, Mixing Plant, Storage Tanks, Belt Conveyor, Slurry Management System, etc.

*Corresponding author: Bai.Kun@herrenknecht.com; Vogt.Gino@herrenknecht.com

The separation process itself could be divided into two main sections, as shown in Figure 1 below, separating the slurry suspension continuously from the by the boring process loaded solid particles in the slurry circuit. The active circuit (or primary separation, numbering 1 to 5 in the left box), consisting of the Separation Plant coarse screen, desanding- and desilting cut stages (dewatering screen combined with hydro cyclones), which are in continuous connection and communication with the Tunnel Boring Machine (TBM) from and to the Slurry Transport System (STS). The passive circuit (or secondary separation, numbering 6 in the right box) operates in a by-pass to the active circuit and consists of ultra-fine particle separation equipment such as a Centrifuge or Filter Press.

Figure 1. Working principle of a separation plant with active and passive circuit.

Following the separation process in detail inside the active circuit, the first stage of separation (coarse screen – numbering 1) can consist alternatively out of a of drum screen (for sticky geologies) or a horizontal shaker screen which take out large particles such as gravel and coarse sand with grain sizes bigger than 3 mm. For taking out even finer particles like fine sand and silt (up to 0.01 mm), two to three sets of hydro cyclones are commonly used in combination with a dewatering screen (numbering 2,3 and 4). Both the coarse screen and dewatering screen material can be classified by the help of a conveyor belt system (5). The secondary stage of separation, also known as fines treatment or passive circuit (6), is able to separate even finer solids as silt and clay particles from the suspension. This is possible with the help of centrifuges or filter presses that can reduce the remaining particles in the suspension to a bare minimum. Deciding for one of these technologies or a combination, several factors must be considered. In general, filter presses are more expensive and require more space on the jobsite due to their lower capacities. On the other side their solid outputs contain less water, which can be desirable in some disposal situations. The centrifuge on the other hand is cheaper, uses up less space, but has a higher level

of residual moisture in the output. To achieve even better results in both secondary treatment technologies, polymers can be added to remove solids in the range of 0 – 0.05 mm.

To be optimally prepared for design and selecting the matching equipment for the specific geological sections of an STP, detailed geotechnical information is required. The results, gathered and evaluated by geological experts, give information about tunnel alignment, soil share distribution, grain size distribution and other soil characteristics.

1.1 Safety factor

Talking about STPs in relation to Safety Factors in tunnelling operations it is all about slurry quality aspects and monitoring and maintaining the rheological conditions in the given target range.

A properly maintained slurry quality/drilling fluid has a direct influence on a stable working face condition in the working chamber of the TBM to achieve a balanced supporting pressure against water and soil pressure as per following Figure 2 which shows the sealing function of the tunnel face by bentonite clay chemistry.

In most cases the suspension used in slurry operated TBMs is a bentonite suspension generated at the job-site surface by mixing bentonite powder with water.

Bentonite is a natural clay mineral from the smectite clay group which has a so-called thixotropic structure to achieve a unique swelling behavior which is used in tunnelling to build up a filter cake and stabilize the working face. In some cases, polymers could also be added to the slurry to achieve particular results (for example against clogging potential, etc.). Besides the stabilization effect, the bentonite slurry is also used as a lubricant and transport medium for the solid loaded suspension via the STS out of the tunnel to the STP for recycling before it is taken back to the TBM.

Figure 2. Stabilization of the working face of the tunnel operation by bentonite.

Key Performance Indicators (KPIs) for the drilling fluid are defined for each project individually based on the geological conditions encountered. The quality of raw bentonite varies a lot worldwide as there is a wide range of products and brands (also prices) on

the market showing different behaviors when mixed. It's therefore essential to undertake consulting and tests upfront with reliable expert companies and suppliers to select matching products. Also, the water quality (pH, temperature, hardness, etc.) used for mixing can have a big influence on the quality of the drilling fluid. Often, soda ash could be of great benefit to waters not in the proper range for bentonite or polymer hydration (such as high hardness values which will retard the process). By adding soda ash the calcium hardness will be treated out and the pH value will increase slightly for better results. For the mixer itself it is important to select equipment with high shear strength. To mix bentonite with water a lot of "power" is required to enable the bentonite particles to react and to ensure optimum swelling behavior. Additionally, the drilling fluid quality will be affected by the constant solid load during the TBM advance. Therefore, KPIs must be monitored and logged during tunnel operations (often several times during one ring) to ensure they stay in the desired safe operation range. Typical main parameters are density (specific weight) to give an indication about solid load/concentration resulting in wear and tear in pipelines and components together as well as the measurement of sand content. Another important parameter is related to viscosity and yield point to check the fluids carrying capacity and resistance to flow. An automated testing system as well as data management systems to monitor the parameters and warn the operator in case risks for the process should appear (settlements, etc.). Here, the selection of the right cut components inside the separation plant is essential to treat the incoming solid loaded slurry as well as possible and transfer it back with a quality as close as possible to that of fresh bentonite slurry. The quality delta between incoming and outgoing slurry shows the efficiency of the process and thus also has influence on the slurry lifetime.

1.2 Performance factor

What starts with the detailed TBM type selection should also be transferred to the STS and STP. Only when considered as one system with clear interface and communication definitions will the system display its full capability. Therefore, it is recommended for each project to specifically tender the STP and its components in all details to match the TBM and tunnelling operation maximum performance and most demanding geological parameters. If not, a lack of performance in operation is predictable.

The following checklist/rules of thumb provide contractors, clients and planners a brief overview of topics to consider with regard to STP selection so that plants are properly sized for performance:

- Size the STP for the fastest anticipated TBM advance rate.
- Size the STP based on maximum volumetric and solid flow rates that can be produced by the TBM and then add 10-20 percent redundancy to allow for the wear and inefficiency of mechanical equipment.

- Size all components to maximum flow rates that can be anticipated by pumps being used in the slurry circuit. Then build in 10-20 percent redundancy to allow for slurry inconsistency and wear and tear on cyclones and pump parts. Keep in mind that pump and hydrocyclone cut points are rated on water and "brand new" efficiency curves. Rates begin to drop quickly when wear occurs.
- Adjust components of the STP to meet the needs of anticipated geotechnical data. If you are anticipating mostly sands and gravels, you should concentrate your efforts on the primary screens, dewatering screens in combination with the hydrocyclones (desanding).
- If the geotechnical data indicates a large amount of clay with high plasticity (Thewes-Hollmann analysis), then your efforts should be geared to clay removal equipment.
- In geological sections where data indicates high amounts of fines (below 0.025 microns), your focus should be on a density regulation system (DRS/ third cyclone stage) and also on the Centrifuges/ Filter Press systems. The more times a solids particle is circulated through the system, the smaller the particle will become and the more expensive it is to remove.

For contractors, consulting STP experts via experienced suppliers or independent consultants is highly recommended due to their training, experience and expertise to alleviate many of the challenges before they have a chance to occur. In many cases these should be utilized prior to the bidding process.

1.3 Cost factor

Planning billion-dollar projects in a desired range of costs is a huge challenge itself but making some profits an even bigger one. Therefore, it is essential to know the influencing parameters on costs for an STP.

The biggest factor is not, as perhaps expected, the selected equipment but operation costs, therefore having to be as transparent as possible to identify savings.

Starting the cycle with the equipment cost, the factors for safety and performance stated in the previous chapters should be taken into account the most. As delays or slowdowns of the project due to poor performance and safety cost tens of thousands of dollars for every day the project schedule must be extended. Often contractors even have a contract which pays them supplements when the project is finished earlier than planned. An investment in properly adapted and highly efficient components with great availability is often beneficial in the long run. Also, decisions like not selecting in the first investment components matching the maximum values could cause problems and higher costs later if short notice add-ons must be purchased. Changes on the jobsite instead of already considering them in the planning/design stage can easily cost 10 times more.

Table 1. Exemplary project cost shares in relation with STPs on an EU jobsite.

Cost Factor	Equipment	Additional Comment
Equipment	25 – 45 %	Ultra-fines content dependent (Centrifuges/Filter Presses are biggest cost factors on site)
Civil Works	< 5 %	Site conditions, design dependent
Transportation	< 5 %	Incoterms, project location, design depending
Assembly	< 5 %	Scope of supply, experience, design dependent
Operation	45 – 55 %	Project location, experience, consumption figures, disposal cost, abrasivity, project duration dependent
Demobilization	< 5 %	Scope of supply, experience, design dependent

In cases where several TBMs start boring from the same launch shaft, STPs can also be combined to avoid redundancies as much as possible and to find savings especially in peripheral equipment like storage tanks, mixing plants, etc.

A common practice also for STPs is having a buy-back option available as contractors try to continuously avoid having their own machine parks. Accordingly, rentals can also be an option. In this case suppliers offer rental services most likely for modular, easily reusable systems. As for TBMs, to avoid cost-intensive surprises on jobsites it is recommended to carry out factory assembly and testing (FAT) in the suppliers' workshop for the main STP components.

The cost factors civil works, transportation, assembly and demobilization are the smallest portion in relation to equipment and operation costs. Still, these factors have high potentials for savings. A big difference in costs can be achieved with the use of modular, container type plants.

Table 2. Exemplary comparison between platform and containerized "mobile" water treatment plant.

	Mobile/Container	Platform
Equipment	120 %	100 %
	Add. Cost in relation to Equipment	
Assembly Personnel	7.5 %	15 %
Civil Works	5 %	10 %
Building/heating/lightning	Included	15 %
Cranes	1 %	2 %
Disassembly	3 %	6 %
TOTAL	136.5 %	148 %

Smaller footprints required on jobsites, improved handling and shipping due to pre-assembled and CSC-certified containers and faster assembly & demobilization thanks to the modularity, fewer parts and no requirement for civil works are the main advantages of using containerized STPs.

The biggest cost block for STPs by far are the operation costs. The following figure shows their approx. share which could vary for each project and circumstances (e.g. power cost, water cost, etc.)

Table 3. Exemplary operation cost for STPs (EU jobsite).

Operation Costs	Equipment	Depending on:
Personnel	5 – 15 %	Project location, setup, experience
Power	10 – 15 %	Project location, setup, design, operation
Bentonite	15 – 25 %	Type, quality, design, geology
Water	< 5 %	Project location, setup, geology dependent
Polymers and other consumers	5 – 10 %	Type, quality, design, geology
Spare parts	5 – 15 %	Scope of supply, geology, maintenance, design
Muck disposal	30 – 55 %	Project location, regulation, reuse options

To operate the STP it is required to have approx. three to four people available per shift including one for operating the active circuit components and communication with the TBM operator, a second one with mechanical skills to maintain the equipment and do routine inspections and a third one to operate the passive and secondary equipment. Additionally, it is recommended to have an electrician with PLC skills on call in case an electrical issue should occur.

On the electrical power side, installed kW (approx. 900-1200 kW for a standard metro TBM size STP), operation time and the final demand factor multiplied by local kWh cost define this block. Here the focus should be on efficient high-level components based on the latest electrical standards and a coordinated interface operation in advance, by-pass and ring building time between TBM, STS and STP.

Bentonite costs are usually the second highest in operation. As bentonite is indispensable for the safety aspect of most tunnelling operations it can generally not be avoided in tunnel construction, ultimately depending on the geo conditions and ground stability. The goal for contractors should be efficient utilization of this good in best relation to the set KPIs. High quality bentonites, for example, often show better thixotropic behaviors and therefore require much less kg per m³. Lower cut points maintain and extend the slurry lifetime and therefore less bentonite must be replaced. Also, reusing already excess "waste" bentonite slurry in some projects can

be an option to lower costs e.g., to prepare high-density (HD) bentonite slurries. Finally, bentonite costs are also highly linked to the geological section the TBM is mining in. In a more stable clay section, for example, less bentonite would be required than in a relatively unstable full sand layer section.

Depending on the jobsite location it might be advantageous to integrate a water treatment system to save costs for fresh water, wastewater and for the possibility of reusing recycled water.

Polymers and all related possible add-on products like lime, iron³, flocculants, etc. for the passive circuit equipment's efficient operation are a minor but not-to-be-forgotten cost indicator. As for bentonite, higher qualities often pay off in the long run. Training operators and regular maintenance are another hint how costs could be controlled.

For smooth operation, spare and wear parts play a key role especially in highly abrasive ground conditions which will influence slurry contacted parts. In close relation to regular maintenance shifts, properly installed spare parts could protect contractors from unplanned financial impacts. The relatively small share shown in Table 3 could increase dramatically if not controlled from the beginning. In case required job-stopper parts are not available on site or need a long delivery period, a loss of availability and overall project schedule impact is possible. It is therefore recommended to plan spare parts early enough to have the most important ones on site with the project ready to bore.

Finally, the biggest share of costs in operation in most projects is the muck disposal handling (restrictions, regulations vary worldwide). It is therefore a key element in early planning stages to have it settled even before the equipment is selected. The focus should be on how to control volumes coming out of the tunnel and what to do with it. Regarding volume, controlling water content is the key to success. Reducing the water content and with it the volume of muck coming from the STP can save hundreds of thousands or even millions of dollars within the total project duration, as disposal companies charge per tonne or m³. Nowadays in this context it is also predictable that what was declared as waste for a long period is now becoming a scarce resource which should be recycled as much as possible. Sustainability is a global trend. Classification and processing of different grain sizes should therefore be a target for modern and state-of-the-art STPs. Gravel and sand are scarce and expensive products in the construction sector so contractors may have good chances of selling their products to third parties to change a declared cost block to an income sector. The ultimate goal is to reuse those resources directly on the jobsites for example in shaft installation, segments or land filling.

2 FOCUS REGION ASIA-PACIFIC (APAC)

For the development and increase in importance of STPs the Asia-Pacific region has always played a key

role. Simply because of its enormous size and due to the fact that ground and project conditions as well requirements in this area require slurry TBM operations more often than in others, the number of STPs used in this region is higher than anywhere else. As a result, contractors have acquired vast experience and transferred this knowledge to tender specifications also addressing new requirements and innovations.

Singapore, as one example, has been one of the hot spots in tunnelling globally in the past two to three decades. The DTSS2 project in particular, which had breakthrough of the last TBMs a couple of months ago, set new milestones in technology especially in data management (e.g. Excavation Management System "EMS") and innovations (e.g. Density Regulation System "DRS").

3 TRENDS AND INNOVATION

With the growing demands and requirements in separation technology, in recent years innovations have also been driven focusing on data management and automation. Another focus topic is how to reduce impacts such as noise and vibration on the jobsite surroundings and people living close by in particular in inner city operations.

Herrenknecht is moving these innovations forward as required by customers. Three example technologies deserve mention here:

3.1 *Density Regulation System (DRS)*

The Density Regulation System (DRS) was a development arising from Singapore DTSS2 requirements to increase the efficiency and cut point of the basic Separation Plant (as per Figure 1 numbering 1-4) in fine geological sections. Its function starts where standard components like screen machines and first plus second cyclone stage cannot cut off any more particles.

In principle it works with a third, ultra-fine cyclone to cut off particles in a range below 25 to 10 microns. By doing that the lifetime extends/ quality of the suspension increases and the discharge process will be delayed as long as possible. This reduction of volume to be exchanged per ring/day ultimately helps reduce the quantity of secondary fines treatment equipment such as Centrifuge or Filter Press. The second benefit and advantage created by the DRS is tackling the fact that Centrifuge or Filter press are not working perfectly efficiently (capacity and dryness of disposal) if the density/ solid content in the inflow is not constant and high. Target >1.2 kg/l. The DRS increases and controls this high, constant density level by means of the mechanical principle of the cyclone (dynamic thickener) and therefore further reduces the number of units required.

Advantages at a glance:

- Increase of fines treatment capacity due to thickened slurry

Figure 3. DRS (4'' Hydrocyclone) working range in geological section.

- Lower operation costs due to longer slurry lifetime (bentonite savings, water, polymer savings)
- Less fines treatment equipment needed thanks to additional cut point (third cyclone stage)
- Less water content of muck due to increase of solids content
- Modular design & easily expandable

3.2 Noise and Vibration Canceling System (NVCS)

The next development arose from projects in Australia (Perth/Melbourne), mainly inner-city operations. Noise and vibrations caused by jobsite operations are becoming more and more problematic as the jobsite surroundings and people living close by suffer as a result of long duration noise impacts. It is therefore imperative to find optimizations and develop solutions to reduce this negative impact. The Noise and Vibration Canceling System (NVCS) tackles this problem. By means of phase-shifting (PSS) technology, which is also used in the latest headphones to cancel surrounding noise, the low frequencies caused mainly by the screen machine/shaker technology of Separation Plants is optimized as even at a distance they can cause rattling and noise e.g., to windows. The software and hardware used even controls for changes in ground conditions and adapts automatically. A positive side effect of the NVCS is that the overall sound power level L_{wa} of the STP is reduced by approximately 10 dB.

Figure 4. Working principle of NVCS using PSS method.

3.3 HK.connected data management system

The last innovation to be mentioned addresses the need to make data from more and more sensors installed in the machinery visible and used for further processes. With the new Herrenknecht.Connected customer portal, Herrenknecht tunnelling technology users can get digital performance reports and worldwide insight into the operators' cockpit monitors at any time and from any location.

These are, for example, consumption figures to be planned far ahead or efficiency and performance of the components to be supervised from the engineers' main offices to find optimization potentials.

The data management system allows digitalization of the overall jobsite processes in a user friendly and modern way.

All sensors and equipment provided by Herrenknecht can be integrated into the system by .ON modules like STP.ON which are stored in a web cloud and finally displayed by accessing using an internet browser. Customers can access a project license for their fleets and e.g. generate customized reports, check the live visualization of the TBM and STP or supervise functions using pre-set performance dashboards.

Figure 5. HK.Connected Overview And Interplay.

4 SUMMARY/CONCLUSION

Many clients, planners and even contractors underestimate the role of a Slurry Treatment Plant in the overall slurry operated tunnelling process in regard to safety, performance and costs. Increasingly stringent environmental regulations mean that the output of STPs is becoming more important than ever for sustainability. Challenging ground conditions, increasing regulations, tighter schedules and performance growth will increase and influence demands on STPs. So, there is a high chance that in future they won't be last minute thoughts anymore for some projects as their output is becoming more and more relevant in terms of the circular economy and greener projects. Latest developments for efficiency increases, surroundings impact and also data management underline the focus on this crucial part of a tunnelling project.

In conclusion, the functions of a properly designed and versatile STP are an absolute necessity to complete tunnelling projects successfully, on time and within budget. A properly selected STP while knowing the driving facts in terms of safety, performance and cost will save time and money and allow the contractor to concentrate on the front tunnelling process, instead of dealing with adverse slurry parameters and cost-intensive interfaces. Knowing that state-of-the-art developments and innovations such as autonomous functions, data visualization and management also help customers modernize jobsite management with Slurry Treatment Plants (STPs).

An evaluation of using different excavation methods related to specific geologic conditions in the Istanbul area

Cemal Balci* & Nuh Bilgin

Faculty of Mines Mining Engineering Department, Istanbul Technical University, Istanbul, Turkey

ABSTRACT: Mechanical excavation with tunnel boring machines is the most widely used excavation method in Metro tunnels in Istanbul. However, drilling and blasting, impact hammers, and roadheaders are also used in some cases, especially in metro station tunnels (platform tunnels). It is strongly emphasized that the prediction of the performance of the tunnelling machine plays an important role in the time scheduling for job termination and in the economy of tunnelling projects. In the past, the accumulated data in Istanbul Metro Tunnel drives served as a sound basis to model the performance prediction models of the excavation machines. This study gives a unique opportunity to compare; TBM's, impact hammers, and roadheaders performances with conventional drilling and blasting methods in a selected Metro Project. Although blasting in urban areas is restricted due to vibrations and difficulties in the transport of blasting agents, in extreme conditions its use becomes a necessity. Roadheader is proven to be more efficient than impact hammer in terms of machine utilization time and production rate. However, high pick consumption makes it a necessity to use impact hammers in similar conditions. An attempt is made to modify the equation used in the past to predict the net breaking rate of impact hammers and it is proved that a reduction factor in the breaking rate taking into account the thickness of the dykes improved the validity of the proposed model. One important point emerging from this paper is that the dip and strike of the joints of 45° in the direction of cutting of the roadheaders are found to be in favor of the cutting rate of roadheaders given higher values than predicted performance values. The dip and strike of the joints having an angle of 45° in favor of the cutting direction improves the net cutting rate of roadheaders.

Keywords: TBM, Roadheader, Impact hammer, Drill and blast

1 INTRODUCTION

In a metro project which is planned to be executed in complex geology like in Istanbul, it is inevitable to use different excavation methods in the same project. The main tunnels are usually excavated with EPB-TBMs. As seen in Table 1, in the last 5 metro projects of 194,121 m in length, 156,127 m of tunnels were excavated with EPB-TBM's, Station tunnels or crosscuts of 37,994 m were excavated with conventional methods such as drill and blast methods, impact hammers or roadheaders as in Kozyatagi-Kadıköy Metro project.

Table 1 clearly shows that conventional tunnelling methods are inevitable parts of mechanized tunnelling, since there is always room for conventional tunnelling in a metro project planned to be realized with TBMs, due to the short length of crosscuts and station (platform) tunnels. Before the introduction of TBMs in Istanbul in Moda and Baltalimani tunnels, the main excavation methods were with impact hammers and roadheaders leading to the accumulation of data and

Table 1. The length of tunnels excavated with conventional tunnelling and with TBMs in 5 recently terminated metro projects in Istanbul.

Metro Project Tunnels	Tunnels with conventional methods (m)	TBM tunnels (m)	Total (m)
Gayrettepe New Airport	8,368	68,282	76,650
Halkalı Airport	6,961	55,617	62,578
Bakırköy Kirazlı	4,820	12,100	16,920

development of performance prediction models of these machines. Over time, the uniaxial compressive strength of andesite dykes surpassed 200 MPa necessitating the use of explosives. Therefore, tunnel project planners or practicing engineers who are responsible for the proper and economic excavation of the project

*Corresponding author: cemalb@itu.edu.tr

should be aware of the difficulties which may be encountered when driving tunnels in complex geology and the use of performance prediction models for the proper time scheduling of the projects.

This paper is written with to introduce the readers understanding the performance of TBMs, roadheaders, impact hammers, and drill and blast tunnelling methods within the same geology of Goztepe Station of Kozyatagi-Kadiköy Metro Project and compare their performances. This paper includes the results of a reevaluated and enlarged paper already published, Ocak and Bilgin, 2010.

2 KOZYATAĞI-KADIKÖY METRO PROJECT, THE GEOLOGY AND GEOMECHANICAL PROPERTIES OF THE FORMATIONS

The geological cross-section of the studied area is given in Figure 1.

Figure 1. Geological cross-section of the metro line between Kadıköy and Kozyatağı stations, Ocak and Bilgin (2010).

The project is a part of Kadıköy-Kartal Metro line having a length of 8800 m, starting from Kozyatağı to Kadıköy. Sedimentary rocks are mainly found in the area. Tunnels between Kozyatagi-Kadiköy are excavated generally in the Trakya and Kartal formations. Trakya formation of carboniferous age consists of interbedded sandstone, siltstone, claystone, and mudstone. Diabase and andesite dykes having some 10 m in thickness are frequently encountered. In the east of the tunnel alignment, Kartal formation of Devonian age is found. Kartal formation consists of fine-grained, laminated, fractured, and interbedded siltstone, limestone, sandstone and shale. Water ingress is common in both Kartal and Trakya formations. Many faults dykes and geological discontinuities exist in the area. The rock material in the contact zone between dykes and the main rock is highly weathered. The overburden varies between 20

and 45 m, and the distance between twin tunnels is around 32 m. The geotechnical properties of the two rock formations show a wide range of variance which are summarized in Table 2.

The number of joint sets per meter occurring along the length of the tunnel can be classified as class 3 (one joint set plus random) and the number of discontinuities per meter changes between 15 and 20. In Figure 1, Kadıköy, Ayrılık Çeşme, Acıbadem, Unalan, Göztepe, Yenisahra, and Kozyatağı stations and associated tunnels are excavated with conventional tunnelling methods. Kadıköy, Göztepe and Kozyatağı stations (Zones A, B, and C) are the studied areas of the conventional tunnelling, drill and blast, impact hammers and roadheaders, Ocak and Bilgin (2009). As seen in this Figure 1 conventional tunnelling methods are used in Trakya Formation having interrelated, siltstone, mudstone, and sandst

one bands, and Kartal formation having shale and limestone layers.

Table 2. The geotechnical data of the formations.

Formation	γ kN/m ³	C kPa	σ_c MPa (+/- sd)	RQD +/-sd
Kartal	26.4	142	34.3 (+/-21.5)	48.5 (+/-11)
Trakya (W1-W2)	26.5	139	50.2 (+/-38.1)	20.3 (+/20)
Tuzla	26.4	210	58.0 (+/-12.3)	N/A
Baltalimanı	26.5	238	62.8 (+/-13.1)	N/A

γ is density, C is cohesion, σ_c is the compressive strength

3 TBM, ROADHEADER, AND IMPACT HAMMER USED IN THE PROJECT

3.1 TBM used in the metro the project

Two identical Herrenknecht TBM's were chosen for Line 1 and Line 2, these machines can work in open and closed modes. The general view of the TBM's is seen in Figure 2, and technical data is given in Table 3.

Table 3. Main characteristics of the TBM.

Machine diameter	6.75 m
Rotational speed	1.65- 5.5 rpm
Number of cutters	28
Cutterhead power	4X315 kW
Cutterhead torque 1	5,200 kNm at 1.6 rpm
Cutterhead torque 2	1,515 kNm at 5.5 rpm
Maximum Thrust	42,575 kN at 350 bar
Opening ratio	%35

In the beginning, TBMs worked without a screw conveyor. Big blocks were coming from the face causing a lot of problems such as clogging the

cutterhead. The mean advance rate was 3 m/day at the beginning of the operation and this value increased up to 7 m/day after the modification of the cutterhead. However, it is interesting to note that the daily advance rate increased to 10.5 m (day) after installing a screw conveyor within the TBM chamber and passing to Earth Pressure Balance (EPB) mode. In the meantime in different tunnels in Istanbul, same remedial works were carried out for Beykoz and Marmaray Tunnels increasing the daily advance rates for those tunnels? to a great extent.

Figure 2. A view of the cutterhead of TBM used.

3.2 Roadheader used in the project

Transverse type roadheader of model WAV 178 Westfalia, was used in the station tunnels of upper and lower bench headings. The view of the machine is given in Figure 3. and the characteristics of the machine are in Table 4.

Figure 3. Transverse type roadheader used in the project.

Table 4. Characteristics of Westfalia WAW 178 model.

Weight, t	75
Cutting power HP/kW	402/300
Max.. excavation area m ²	61
Cutting head diameter, cm	88.8
Cutter type	Conical
Cutting number	82x2=164
Cutting head type	Transverse

3.3 Impact hammer used in the project

Hydraulic Hammers are widely used in tunnelling and several km of tunnels were excavated in Istanbul by hydraulic hammers mounted in excavators. The hammers used in Kozyatağı-Kadıköy metro station tunnels were Atlas Copco MB 170- type hydraulic hammers. All the hammers are the same and have the following characteristics: weight 1.7 t, oil flow rate 130–160 lt/min, working pressure 160–180 bars, impact frequency 320–600 impact/min, impact energy 4170 J. The selection of excavator is important for the success of the operations since the stability of the carrier plays an important role in the efficiency of the system. Volvo EC210B of 7 t, Sumitomo SH200LC OF 9.5 t, and Caterpillar 3066T of 7.5 t in weights were used with attached hammers. A general view of a hydraulic hammer is given in Figure 4.

Figure 4. Schematic view of a hydraulic hammer mounted on an excavator, After Tunçdemir (2007).

4 MAIN FACTORS AFFECTING THE PERFORMANCE OF TUNNELLING MACHINES

TBMs are mainly affected, by the geotechnical characteristics of the ground. Hard rock, soft ground or ground water level will affect the type of the TBMs used: gripper type TBMs, single shield TBMs, double shield TBMs, slurry or EPB TBMs. Weathering degree

of the rock formations, faults, transition zone, and plasticity of the ground affecting clogging of the cutters are among the most important parameters affecting the performance of TBMs. Swelling clays are the main reason of squeezing ground and it is the nightmare of the tunnelers. The main advantages of TBMs are being a continuous excavation system. However, excavation with roadheaders, impact hammers, and drill and blast method are not continuous systems. Due to this fact generally advance rates of tunnelling using these methods are used less frequently than TBMs. If the ground is not favorable, using roof bolts, forepoling, wire mesh, shotcrete and steel arches as seen in Figure 5 will be among the factors decreasing the advance rates.

Figure 5. Cross section of the platform tunnel T1 excavated with roadheader, impact hammer and drill, and blast method, tunnel face has an area of 74 m².

5 THE PERFORMANCE OF TBM

A detailed analysis was carried out to investigate the effect of geotechnical properties on the performance of a TBM. Table 5 is a summary of the results of multiple regression analysis for dependent variables corresponding to 1 bar face pressure. The conclusion emerging from this statistical analysis was that geotechnical factors affecting the instantaneous cutting rate and penetration were the geological strength index as defined by Morinos et al. (2005), Cerchar abrasivity index, and destruction energy as defined by Thuro and Spaun (1996) and Thuro and Plinninger (2003). Thrust index and torque index were predicted best from the product of compressive strength times the Cerchar abrasivity index. Nizamoglu (1978) was the first who noticed this in 1978 during his field studies on Robbins and Wirth TBMs for his Ph.D thesis and he called this product an index of nocivité or index of harmfulness. Plinninger (2010) also noticed that the product of compressive strength times the abrasivity of the rock was a good indicator of drilling performance.

Table 5. The performance prediction equations of the TBM.

$$ICR = 0,896GSI - 37,416CAI + 189,804 \left(\frac{\sigma_c^2}{2E} \right), R2 = 0.84$$

$$p = 0,141 GSI - 5,842 CAI + 29,373 \left(\frac{\sigma_c^2}{2E} \right), R2 = 0.83$$

$$\frac{TF}{p} = 0,1615(\sigma_c \cdot CAI)^2 - 17,668(\sigma_c \cdot CAI) + 737,37, R2 = 0.8$$

$$\frac{TF}{p} = 0,0366(\sigma_c \cdot CAI)^2 - 3,4861(\sigma_c \cdot CAI) + 203,15, R2 = 0.79$$

$$SE = (35,6 \cdot 10^{-3})E - 0,0381(\sigma_c \cdot CAI), R2 = 0.69$$

In the above equations, TF/p is thrust index in kN/(mm/rev), T/p is torque index in kNm/(mm/rev), SE is specific energy in kWh/m³, ICR is the instantaneous cutting rate in m³/h, p is penetration in mm/rev, σ_c is compressive strength in MPa, CAI is Cerchar abrasivity index, E elasticity modulus in MPa, GSI is geological strength index, RQD is rock quality designation, $\sigma_c^2/2E$ is destruction work as defined by Thuro and Spaun (1996) Thuro and Plinninger (2003). A detailed analysis has been carried out using the data of the other projects to justify the validity of the predictor equation given in Table 4. It is hoped to publish the results soon.

Instantaneous cutting rate and penetration rates with machine utilization time are the parameters used to estimate daily advance rates. Machine utilization time is strictly related to job organization, the skill of the TBM operators, and the design of the tunnel operation parameters. A machine utilization time of 45% is a good number justifying the efficiency of the operational parameters used in the mechanized tunnelling

The major criticism of mechanized tunneling with TBMs in Kozyatağı Kadıköy Metro tunnels is that 27% is spent for excavation as seen in Figure, which is too low compared with the other projects. The main reason for this is that the muck is transported with rail system, and the muck is transported from the shaft to the surface with Floxewell vertical band. Sticky muck needed to be cleaned within the flyers plaques, with a ratio of 10% in the overall performance of tunnelling with EPB-TBMs

Figure 6. Overall performance of tunnelling with TBM.

6 THE PERFORMANCE OF TUNNELLING WITH DRILL AND BLAST, ROADHEADERS AND IMPACT HAMMER

Platform tunnels excavated with drill and blast tunnelling method have a cross section area of 74 m² as illustrated in Figure 3. Drill holes were drilled using double boom Atlas Copco Rocket Boomer 282. Fracture characteristics of the rock mass were dictated by the blasting agent as Powergel Magnum 365 and Trimex (with density of 1,20 g/cm³, ideal blasting velocity of 6.437 m/s, and ideal blasting agent of 121.400 atm). The wedge cut, parallel-burn cut methods were used with blasting holes of parallel cuts having diameter of 89 mm and other blast holes of 41 mm in diameter. Nonel Exel MS/LP blasting cabs of 47 different blasting intervals were also used. A pie chart showing the work done in drill and blast tunnelling is given in Figure 7.

Figure 7. Pie chart showing the works done in drill and blast tunneling.

Roadheader and impact hammer used in the project are described in sections 3.2 and 3.3. Pie charts obtained for these machines are given in Figures 8 and 9.

Figure 8. Pie chart obtained when using roadheader.

Machine utilization time is as important as the net cutting/breaking rate in determining the excavation efficiency and economy since daily advance rates are directly related to these factors for a given tunnel section. The performances of mechanical excavators and drilling and blasting methods are summarized in Figures 7, 8, and 9. These figures give a unique

Figure 9. Pie chart obtained when using impact hammers.

opportunity to compare roadheaders, impact hammers, and drilling and blasting methods for a given job. As seen from these figures, machine utilization time for roadheaders is 28.2%, almost twice compared to impact hammers, and time spent for excavation in drilling and blasting is in the same order as the time spent in the excavation by impact hammers with a value of 15.4% (drilling, blast hole charging, blasting and ventilation). Mucking is another factor affecting job duration. In fractured rock formations like Kartal and Trakya formations, sometimes roadheaders excavate the rock in excess of their loading capacities with gathering arms and extra time is necessary to load the muck. The time spent for mucking was 9.8% for roadheader, 13.3% for impact hammers and as high as 29.4% for drilling and blasting methods. It is difficult to control muck size in fractured rock formations with conventional excavation methods, some big muck samples always create transportation problems and due to the disturbed zone, the number of bolts used for a unit length of tunnel is always higher compared to mechanical excavation methods. Time spent for rock bolting in drilling and blasting method is found to be twice as compared to the other excavation methods with a value of 13%.

The following equations 1,2, and 3 were already developed to predict the net production rates of roadheaders and impact hammers. The validity of these equations was tested also for Kozyatağı-Kadıköy Metro tunnels. However, the variety of the igneous dykes in thickness served to develop equation 4. K index which is a function of the thickness of the dykes is given in Table 5. As a statistical test result the field values and predicted values are compared which are summarized in Table 6. The dip and strike of the joints of 45° in the direction of cutting are found to be in favor of the cutting rate of roadheaders given higher values than predicted performance values.

$$ICR = 0.28 \times P \times (0.974)^{RMCI} \quad (1)$$

$$RMCI = \sigma_c \times \left(\frac{RQD}{100} \right)^{\frac{2}{3}} \quad (2)$$

$$IBR = 4,24 \times P \times (RMCI)^{-0.567} \quad (3)$$

$$IBR = Kx4, 24xPx(RMCI)^{-0.567} \quad (4)$$

In the above equations, NBR is the net breaking rate (for impact hammers) in m³/h; Pi is the power output of the impact hammer in HP, it is found by multiplying the oil flow rate by working pressure; RMCI is the rock mass cutability index; UCS the uniaxial compressive strength in MPa; RQD the rock quality designation, %; NCR the net cutting rate (for roadheaders), m³/h; P the cutting power for roadheaders in HP., Bilgin et al. 2018.

Table 6. A guide to estimating reduction factor K used to predict net braking rates of impact hammers related to the related to the thickness of dykes.

The thickness of dykes (cm) (for UCS > 120 MPa)	Reduction factor K for net breaking rate
10-20	0.8-0.90
20-30	0.7-0.8
30-40	0.6-0.7
40-50	0.5-0.6
>50	D&B is recommended

Table 7. The relationship between net field production rate and the predicted production rate for impact hammers and roadheaders.

Impact hammer Equation 1	$y=2.32x-10.02$	$R^2=0.82$
Impact hammer Equation 2	$y=1.98x-12.02$	$R^2=0.63$
Roadheader	$y=3.46x-40.97$	$R^2=0.80$

In this table y is the field value in m³/h; x is the predicted value in m³/h

7 DISCUSSION OF USING TBMS, DRILL AND BLAST, ROADHEADER AND IMPACT HAMMERS

Conclusions will be drawn upon daily advance rates based on a tunnel diameter of 6.75 m as given in Table 8.

Table 8. Production rates obtained in Kozyatağı Kadıköy Metro tunnels with different tunnelling methods.

Method of excavation	Daily advance rate m/day
TBM	10.5
Drill and blast	5.5
Roadheader	6.4
Impact hammer	1.3

Although drill and blast, roadheader and impact hammers were used in the platform tunnels of 74 m²

area, production rates were converted for a tunnel of 6.7 m diameter which is the excavation diameter of the TBM. An advance rate of 10.5 m /day obtained for Kozyatağı Kadıköy is too low. Looking at Figure 4, 17% of overall time is spent for mounting of rails and 10% cleaning of Flexowell (vertical belt). A job organization with belts for muck transport would increase the time spent for excavation from 27% to 40-44% increasing consecutively the daily advance rate.

There is also a possibility of increasing the daily advance rates of impact hammers almost twice by using high-power impact hammers, since as seen from equation (3) net breaking rate of hammers is related to the power of impact hammers. The other alternative is to use impact hammers mounted on carriers having gathering arms eliminating the time spend for mucking.

8 CONCLUSIONS

TBMs are the most widely used in Metro tunnels in Istanbul. However, drilling and blasting, impact hammers, and roadheaders are also used in some cases, especially in metro station tunnels (platform tunnels). In Istanbul in the last 5 metro projects of 194121 m in length, 156127 m of tunnels were excavated with EPB-TBM's, Station tunnels or crosscuts of 37994 m were excavated with drill and blast method, impact hammers or roadheaders as in Kozyatağı-Kadıköy Metro project. In this project daily advance rates for TBM, drill and blast roadheaders and impact hammers were 10.5m, 5.5m, 6.4m, and 1.3m respectively. This paper made a concise criticism on the performance of these tunnelling methods and the modification of the some use of performance prediction models already developed using accumulated data in Istanbul.

Critical issues in selecting conventional and mechanized tunnelling methods, lessons learned from the past

Nuh Bilgin* & Cemal Balci

Faculty of Mines Mining Engineering Department, Istanbul Technical University, Istanbul, Turkey

ABSTRACT: The population is increasing rapidly in urban areas. Parallel to this, the need for a better life will necessitate tunnels for rapid mobility; tunnels to solve energy, water, and sanitation problems, etc. This is reflected in the current worldwide tunnelling market, which is growing fast. In light of these, this paper is prepared to summarize the basic requirements of conventional and mechanized tunnelling methods in a comparative way and to give several examples from the past to make it clear to understand the problems encountered while applying these two tunnelling methods. The incorrect choice between the two methods may lead to tunnel construction lasting several years more than expected and the cost may be 3 or 4 times higher than originally estimated, as happened in T26 high-speed tunnel in Turkey and Yacambu-Quibor Water Tunnel in Venezuela. First, geotechnical, geological, and environmental factors limiting the selection of the tunnelling methods will be discussed given examples of T26 high-speed tunnel, Uluabat, and Kargı power tunnels from Turkey. The paper will discuss the shortest tunnel ever driven 120 m in length with a 6.2m diameter EPB-TBM within the complex Marmaray Project in Istanbul, emphasizing the big cities' environmental restrictions.

Keywords: Drill and blast, TBM Tunnelling, T26 high speed-tunnel, Uluabat tunnel, Kargı power tunnel

1 INTRODUCTION

There are two tunnelling methods; conventional and mechanized tunnelling. Conventional tunnelling can be defined as the construction of underground openings of with a cyclic construction method consisted of excavation by using the drill and blast method or very basic mechanical excavators, mucking, placement of the primary support elements such as steel arch or wire mesh, soil nails or rock bolts, shotcrete or in situ cast concrete.

The second tunnelling method is generally called mechanized tunnelling with TBM or roadheaders. The basic comparison between both methods is summarized in Table 1.

2 HYBRID METHOD, CONTRIBUTION TO TUNNELLING ECONOMY AND EFFICIENCY

Choosing the most appropriate tunnelling method: drill and blast or TBM or the hybrid approach deliberately using both is discussed in detail by Barton (2012). However, in this section, it is intended to enlarge the

topic by giving two examples from Turkey which contributed to the efficiency and the economy of tunnelling.

Table 1. The comparison of both tunnelling methods.

Parameter	Drill and blast	Roadheader	TBM
Geometry	Any shape	Any shape	Circular
Safety	Low	High	High
Handling of explosives	Risky	Avoided	Avoided
Advance rate	Low	Depends on geology	Depends on geology
Length	Any	Any	A limited length
Flexibility	High	High	Not
Operation	Cyclical	Cyclical	Continuous
Initial investment	Low	Low	High
Overbreak	High	Low	Low
Noise and vibrations	High	Low	Low

2.1 Kaynarca Kadıköy Metro line

The general layout of the Kaynarca Kadıköy Metro line of 26.5 km in two lines is given in Figure 1.

Figure 1. The general layout of the Kaynarca Kadıköy Metro line.

The first part of the project from Kozyatagi to Kadıköy of 8,800 m in length was finished first with 2 EPB-TBMs with a mean daily advance rate of 10.5 m/day. The platform tunnels of this project were opened with drill and blast, impact hammers, and roadheaders. The topic is discussed in detail in a paper titled “A Criticism of Using Different Excavation Methods Related to Specific Geologic Conditions in the Istanbul Area” which was submitted to WTC 2024, by Balci and Bilgin (2024). The second part of the project from Kaynarca to Kozyatagi of 17,700 m in length was rewarded to another construction company than the first one. Due to the limited time to complete the project, the contractor decided to open the twin tunnels of 4.6 km in length from Kartal to Kaynarca by two EPB-TBM of 6.57 m diameter. TBM used is given in Figure 2 and the details of TBM are tabulated in Table 2.

Figure 2. TBM used in Kartal Kaynarca tunnel.

Table 2. Main characteristics of EPB-TBM used in the project.

Machine diameter	6.57 m
Rotational speed	0.0- 5.33 rpm
Number of cutters	32 single, 4 double
Number of rippers	72
Cutterhead power	8x160 kW
Cutterhead torque 1	3663 kNm nominal
Cutterhead torque 2	5018 kNm maximum
Maximum Thrust	42,575 kN at 350 bar
Opening ratio	%35

Eight station shafts existed between Kartal and Kozyatagi enabling 8 faces for drill and blast operations. It was decided to open a 13,100 m tunnel with conventional tunnelling methods, Ozcan (2011), Senol, (2014), Senol et al. (2014a). The tunnel area was highly populated and a special blasting methodology was used to minimize the blasting vibrations as given by Kahrman et al. (2008), Ozer (2008). TBM finished the tunnels of 4,600 m in length with a main daily advance rate of 11.6 m/day. From a tunnel face, a daily advance rate of 2.7 m/day was possible to obtain with the drill and blast method. A planned synchronized hybrid tunnelling method enabled the contractor to finish the project before the scheduled time. Pie charts for the works executed for drill and blast method and TBM operations are given in Figures 3 and 4.

Figure 3. Work distribution in drill and blast, 2.7 m/day per round.

2.2 Kargi project

Another example of hybrid tunnelling project is Kargi hydropower project. As Barton mentions, “There are significant numbers of TBM projects that end up with difficult decisions to be made, namely to complete the projects by drill-and-blast from the other end of the tunnel. The deliberate selection of both TBM and drill-and-blast may often be a simple matter of common sense, giving schedule advantages and cost savings. This is the preliminary level of hybrid tunnelling. Very often, time is lost while waiting for TBM

Figure 4. Work distribution in TBM excavation, mean 11.6 m/day.

delivery and assembly, and great advantages could be gained by selective use of drill-and blast for more than just the standard TBM assembly chamber and starter tunnel”, Barton, 2002a, 2002b, 2016”.

The 7.8 km of the total length of 11.8 km of Kargi tunnel was excavated with a double shield TBM of 9.84 m diameter, and 4 km of the tunnel from the inlet part was opened with NATM. TBM was launched in April 2012. After only a boring of 80 m, TBM became stuck in a section of the collapsed mixed ground face of hard rock and running ground. In the first 2 km of the tunnel, TBM jammed 7 times due to face collapses, and bypass tunnels were required to free the TBM. Continuous probe drilling was carried out for 5 km along the tunnel and an umbrella arch was applied in 9 different areas to stop face collapses excavation of the tunnel ended with success. Drilling and blasting at one end of the tunnel and TBM at the other end was a good alternative for decreasing the job termination time, Bilgin 2016. Figure 5 shows the comparison of advance rates of TBM against advance rates of drill and blast tunnelling through the Beynamaz Volcanites. It can be seen that the drill and blast operations took twenty-three months to complete 4,000 m of tunnel whereas it took less than 8 months for the TBM operations to complete the same length of the tunnel. Based on these production rates it would have taken approximately 32 months for the drill and blast operations to achieve the same production as the TBM achieved in 8 months.

Figure 5. The comparison of TBM and drill and blast method based on cumulative advance and number of months.

3 CHANGING THE TUNNELLING METHODOLOGY AFTER STARTING THE EXCAVATION

3.1 T26 High-speed railway tunnel

The complexity of the geology dictates the tunnelling methodology to be applied. Usually in such cases tunnel excavation starts with a conventional tunnelling method. Sometimes due to swelling of the rock or low Q values, the convergence experiences very high values which force the tunnelling method to be changed to mechanical excavation with TBMs. One example of this is T26 High Speed Railway Tunnel. The excavation started with the conventional tunnelling method in 2010. The tunnel is in the North-East of Turkey. Due to geological problems, shear zones, fault zones, and low RQD values, the daily advance rates were very slow. The tunnel excavation method was changed to mechanical excavation using a 13.7 m diameter single shield TBM at the end of 2011. Karakaya formation is the main formation in tunnelling area between the Pazarcik melange. It contains fault zones in several places. This formation has similarities with Karakaya Formation found in Uluabat Energy Tunnel, which will be discussed in the following paragraph. T26 tunnel is planned to pass through the predominated graphitic schist which includes frequently chlorite schist with a size of some tens of meters and rarely marble shear bodies with a dimension of a few tens of meters, Bilgin 2016. Graphitic schist is moderately weathered to fresh and very weak to weak and is extremely sheared along the foliation surface, which causes extreme loads to the precast segments. Finally, segments started failing on 16.11.2012 and the tunnel collapsed. TBM was buried. After tremendous efforts and remedial works tunnel excavation was decided to be carried out with drill and blast. Figure 6 shows the failure of the segment, and Figure 7 the thin section taken from the wall of the tunnel at Ring 484 (9 o'clock direction).

Figure 6. Failure of a segment in tunnel 26.

Figure 7. Thin section of the graphitic schist from ring no 484, tunnel 26.

3.2 Uluabat power tunnel

Tunnel excavation commenced in 2002 from the portal next to Uluabat Lake, using conventional excavation methods with roof bolts, shotcrete, wire mesh, and steel arches as the primary tunnel support. Tunnelling operations were halted in November 2003 due to extreme roof deformations and floor heaves. Figure 8 shows the closure of the cross-section in the tunnel after a certain time for different stations. After the stoppage of tunnelling operations for about two and half years it was decided to continue the project with an EPB-TBM. During tunnel excavation, the TBM was stuck a total of 18 times. 192 days were spent on TBM rescue operations at different tunnel locations. A general view of the squeezing ground around the TBM shield, in Uluabat Tunnel is shown in Figure 9. The excavation terminated in March 2010, after a series of mitigation factors like injecting bentonite through the shield. It is reported that although the squeezing characteristics of the formations depend on several factors, it is closely related also to Q values, Barton and Bilgin, (2016).

This example shows how important it is to understand the squeezing characteristics of the formations and the mitigation factors to overcome the problems arising. The example is important since it dictates the time scheduling of a tunnelling project, to select the correct tunnelling methods and the mitigation factors to overcome.

Figure 8. The closure of tunnel face area in % in conventional tunneling.

Figure 9. TBM shield and squeezing characteristic graphitic schist.

3.3 Yacambu-Quibor water tunnel in Venezuela

The project began in 1974, but it took 34 years to be completed, for technical, political, and financial reasons. Over those 34 years, the project was stopped and started up again eight times using TBMs, roadheaders, and conventional tunnelling methods. The tunnel, instead of costing \$173 million as originally expected, ended up costing more than \$800 million in current dollars, Ramonet, 2008. The geology consists of sandstone, phyllite, and limestone. The graphitic phyllite has a squeezing characteristic and has compressive strength changing between 15-50 MPa and the estimated GSI value is about 24, (tunnelbuilder.com., 12/08/2008) Graphitic phyllite is a very poor quality rock that causes serious squeezing problems which, without adequate support, results in the closure of the tunnel at an important level. Tectonically deformed graphitic phyllite on the tunnel face is seen in Figure 10. Hook and Guevara (2009).

The readers are invited to to check the similarity of the rock material in Figure 9 and 10.

4 ENVIRONMENTAL CONDITIONS RESTRICTING THE USE OF TBM, ONE OF THE SHORTEST TBM TUNNELS OPENED

The north entrance tunnel of Sirkeci Station is a part of the Marmaray Project/Istanbul as outlined in Figure 11. It has a length of 120 m and it was originally designed to open with a conventional tunnelling method. Detailed geological investigation showed that the conventional tunnelling method was very risky due to bad ground conditions and a low overburden of 20 m. It was decided later to drive the tunnel with an EPB-TBM of 6.2 in diameter, which was the 6th TBM used in the first phase of the project, where 5 TBMs were slurry type. The launch EPB-TBM in the

Figure 11. Marmaray project/Istanbul Sirkeci underground station. The figure is kindly provided by Niyazi Sennazlı.

Figure 12. The portal of the tunnel.

Figure 13. Construction concept of Marmaray tunnel.

north entrance tunnel is shown in Figure 12. The excavation of the tunnel lasted one month without serious surface deformations. The final profile of the north entrance is shown in Figure 13. As far as the authors knowledge this tunnel is the shortest tunnel opened by mechanized tunnelling methods. To understand the construction concept of the Marmaray project, the readers are referred to consult Figure 13.

5 CONCLUSIONS

The incorrect choice between conventional and mechanized tunnelling may lead to tunnel construction lasting several years more than expected and the cost maybe 3 or 4 times higher than originally estimated. First, the contribution of the hybrid method to tunnelling economy and efficiency is discussed given examples of Kargi power tunnel and, Kaynarca - Kadikoy Metro tunnels in Istanbul. In this metro tunnel it was decided to open a 13,100 m tunnel with conventional tunnelling methods. The tunnel area was highly populated and a special blasting methodology was used to minimize the blasting vibrations. TBM finished the tunnels of 4,600 m in length with a main daily advance rate of 11.6 m/day. From a tunnel face, a daily advance rate of 2.7 m/day was possible to obtain with the drill and blast method. A planned synchronized hybrid tunnelling method enabled the contractor to finish the project before the scheduled time. Pie charts for the works executed for drill and blast method and TBM operations are given in Figures 3 and 4. Changing the tunnelling methodology after starting the excavation is another challenge as happened in T26 High-speed railway tunnel and Uluabat Tunnels in Turkey and Yacambu-Quibor Water Tunnel in Venezuela. One of the shortest tunnels of 120 m in length, driven with a EPB-TBM of 6.2 m in diameter EPB-TBM within the complex Marmaray Project in Istanbul, emphasis the big cities' environmental restrictions We hope that the summary of critical issues discussed in this paper in Selecting conventional and mechanized tunnelling methods will help in the future to decision makers of the tunnel designers.

ABSTRACT: In this paper, we present a simulation tool based on the state-based peridynamic theory, developed to model the interaction between cutting discs of a TBM and the ground being excavated. As compared to existing TBM performance prediction models, this computational model allows to consider various heterogeneous and mixed ground conditions, different TBM and disc designs, as well as the direct coupling with wear models. Furthermore, the consequences of wear in terms of partially degraded or damaged discs on the excavation performance can be assessed numerically. The developed model is thoroughly validated using several benchmarks, including indentation tests on sandstone specimens and biaxial strength tests for concrete. The simulation model was further tested by simulating a full-scale LCM (Linear Cutting Machine) test conducted on Colorado Red granite, and the resulting cutting forces at various disc spacings are compared with experimental data. To investigate excavation in mixed ground conditions, which can lead to abnormal tool wear and even failure, an LCM experiment is performed where the cutting disc excavates through a series of rocks with a high contrast in UCS (Uniaxial Compressive Strength). These experiments successfully identify an overshoot in the cutting force as the disc enters the rock domain with a higher UCS which can cause localized damage to the cutting disc. The cutting forces obtained from scaled-down simulations using the developed model for mixed ground excavation scenarios exhibit qualitative agreement with the LCM experiment. Additionally, the simulation model is equipped with an abrasive wear model, which is verified using analytical solutions. This implemented wear model is able to identify the changes in wear rates as the cutting disc excavates through varying rock formations. Finally, the versatility of the simulation model is demonstrated by investigating various aspects of the cutting disc-ground interaction, including the efficiency of excavation with varying disc geometries.

1 INTRODUCTION

Excavation processes involving a Tunnel Boring Machine (TBM) use cutting discs to fracture and excavate rock. These cutting discs are mounted on a rotating cutterhead of the TBM, which is pressed against the tunnel face. As the cutting disc penetrates the rock, the pressure in the contact area between the disc and the rock surface increases and a crushed zone develops (Rostami, 2013). The stresses in this zone continue to increase, leading to the initiation of radial cracks. These cracks grow and coalesce with adjacent cracks until the rock mass is disintegrated (Cho et al., 2010). The interaction between the rock

and a cutting disc can be characterized by three-dimensional reaction forces at the disc. To accurately predict the performance of a TBM, including global thrust and torque requirements, and to design new cutter heads for specific ground geology, it is necessary to estimate the cutting forces for a single disc cutter. In addition, the loads on the disc cutters cause severe wear and damage to the tools. To plan maintenance stops and avoid unexpected TBM stoppages, it is necessary to estimate the working life of cutting tools in a given geology.

The cutting process in hard rock is modeled using the Peridynamics (Silling, 2000), (Butt and Meschke, 2021) continuum formulation. This class

*Corresponding author: sahir.butt@rub.de

of models allow, in contrast to standard continuum mechanics theories, for the modeling of complex fragmentation processes. The reason is, that the stresses are computed from a direct interaction of material point \mathbf{x} , with a set of material points \mathbf{x}' within a volume defined by a cut-off radius δ known as the peridynamic horizon. This notion of direct connectivity between the material points is referred to as a bond. Fracture processes are modelled by irreversibly deleting the bonds between the material points once they reach a critical value. Once a bond fails, it does not further contribute to the internal force calculation. In this study, the critical energy required to break a bond is calibrated using the fracture energy of the rock.

2 ROCK INDENTATION

This section presents the indentation tests performed on a porous sandstone using a blunted tip indenter. The standard ordinary state-based peridynamic simulation model (Silling, 2000), (Silling et al., 2007), (Foster et al., 2011) is extended to consider the additional dissipation due to the pore-collapse phenomenon observed in porous rocks and applied to the indentation test of a sandstone. Qualitative features of indentation are analyzed through Acoustic Emission (AE) data obtained from the experiments performed on Bentheim sandstone (Yang et al., 2022). Quantitatively, the model is validated by comparison of force-penetration and indentation-penetration data obtained in the experiments by the simulation results.

2.1 Consideration of the pore-collapse phenomenon

Ordinary state-based peridynamic model has been thoroughly investigated for the tension-dominated fracture problems, including failure strengths and crack dynamics (Butt and Meschke, 2018), (Butt et al., 2022). However, for cases where the dominant loading is in compression (Butt and Meschke, 2021) and additional nonlinear dissipation phenomena, such as the pore-collapse, are present, the model underpredicts the failure strengths (Butt, 2023). To this end, the standard ordinary state-based peridynamic model (Silling et al., 2007), (Foster et al., 2011) is extended to consider the pore-collapse phenomenon in porous materials.

The mechanical properties and the deformation characteristics of Bentheim sandstone were studied under triaxial loads by Klein et al., 2001. The material parameters for Bentheim sandstone are presented in Table 1. It is a relatively homogeneous porous rock, and these pores collapse under compressive loads leading to stiffening of the material, this effect can be seen by comparing the volumetric strain predicted by a constant bulk modulus with the one obtained in the experiments under hydrostatic compression, as shown in Figure 1. This stiffening under compressive pressure, due to pore-collapse, contributes to a significant increase in the total dissipated energy.

Table 1. Material properties of bentheim sandstone.

Material parameter	Value
Young's modulus (GPa)	9.5
Poisson's ratio	0.18
Density (kg/m ³)	2011
Fracture energy (J/m ²)	10
Porosity (%)	24

Figure 1. Relationship between hydrostatic pressure and volumetric strain from Klein et al., 2001, and a first- and a third-order polynomial fit to the experimental data.

The material stiffening due to pore-collapse is modeled by using the experimental relationship between the hydrostatic compression and volumetric strain (Figure 1) instead of just using a constant Bulk modulus. According to Klein et al., 2001, this relationship has one inflection point leading up to a compressive volumetric strain of 3.0% and after that, this relationship becomes linear again. So, the range of the volumetric strains from 0% to -3.0% is fitted with a third-order polynomial and for compressive volumetric strain greater than 3.0% a linear relationship is adapted. Additionally, these volumetric deformations are assumed to be irreversible, as pore-collapse is an irreversible process.

For the modification of the ordinary state-based linear elastic model, an additive split is defined for the dilatation under compressive deformation as:

$$\theta(\mathbf{x}, t) = \begin{cases} \theta^e(\mathbf{x}, t) & \text{if } \theta(\mathbf{x}, t) > 0 \\ \theta^e(\mathbf{x}, t) + \theta^{pc}(\mathbf{x}, t) & \text{if } \theta(\mathbf{x}, t) < 0 \end{cases} \quad (1)$$

Here $\theta^e(\mathbf{x}, t)$ is the reversible elastic part of the volumetric strain and $\theta^{pc}(\mathbf{x}, t)$ is the irreversible volumetric strain representing the pore-collapse under compression. Pressure $p(\mathbf{x}, t)$ is computed according to:

$$p(\mathbf{x}, t) = \begin{cases} K \theta(\mathbf{x}, t) \\ K_1 + K_2 \theta(\mathbf{x}, t) + K_3 \theta(\mathbf{x}, t)^2 + K_4 \theta(\mathbf{x}, t)^3 \\ K_5 + K_6 \theta(\mathbf{x}, t) \end{cases} \quad (2)$$

For the following different compression regimes, respectively.

$$\begin{cases} \text{if } \theta(\mathbf{x}, t) > 0 \\ \text{if } -0.03 < \theta(\mathbf{x}, t) < 0 \\ \text{if } \theta(\mathbf{x}, t) < -0.03 \end{cases} \quad (3)$$

In Equation 2, K is the Bulk modulus, K_1 , K_2 , K_3 & K_4 are calibrated for a third-order polynomial and K_5 & K_6 are calibrated for a first-order polynomial using the experimental data from Klein et al., 2001, as shown in Figure 1. The applicable range of volumetric strain for the third- and first-order polynomial are shown in Equation 3. For further details regarding the formulation of the state-based peridynamic pore-collapse model, the interested reader is referred to Butt and Meschke, 2023.

2.2 Consideration of material heterogeneity

Materials like rocks and concrete have inherent heterogeneity and random defects that must be accounted for in the model. To address rock heterogeneity in the simulations, strength parameters such as the fracture energy are sampled from a probability distribution. According to the literature (Hudson et al., 1969), Weibull's distribution has been found to well represent the distribution of micro-defects in the rocks. Therefore, the simulations will consider the strength parameters sampled from a Weibull distribution (Weibull, 1951), it is given by:

$$P(\sigma) = \frac{k}{\sigma_0} \left(\frac{\sigma}{\sigma_0} \right)^{k-1} \exp \left[- \left(\frac{\sigma}{\sigma_0} \right)^k \right] \quad (4)$$

Here, σ is the sampled parameter, σ_0 is the mean value of the parameter to be sampled and k is known as the shape parameter. The shape parameter k represents the level of homogeneity of the material, where a larger k represents a more homogeneous material and vice versa (Figure 2). Simulations use a value of $k = 3$ for the shape parameter according to Liu et al., 2018.

The open-source software Peridigm (Parks et al., 2012) was extended to consider the pore-collapse model as well as the distributed strengths in the simulation domain. This extended version of Peridigm is used to carry out the simulations presented in the next section.

2.3 Rock indentation simulations

Numerical and experimental investigations (Yang et al., 2022), (Lindqvist et al., 1984) have shown that the rock fragmentation under indentation involves several progressive deformation mechanisms including the

Figure 2. Weibull distribution for a scale factor 1.0 and various shape parameters k (top).

elastic deformations at an initial loading stage, then the volumetric compaction, plastic deformation, and finally the macro fracture. Thus, it is necessary for a simulation model to be able to reproduce these qualitative features observed in the indentation experiments.

Simulations performed in this study for the indentation tests cover a total of six specimen sizes, with a combination of three diameters 30, 50 and 84 mm and two heights 50 and 100 mm. For validating the current model, we use the experimental data from indentation tests on Bentheim Sandstone reported in (Yang et al., 2022). The temporal evolution of fractures occurring due to the indentation load is presented in Figure 3 for a specimen with 30 mm diameter and 100 mm height. The simulation captures the experimental observation of the successive formation of the crushed zone and the initiation of a central macroscopic tensile fracture splitting the sample in half. Once the tensile stresses at the perimeter of this zone exceed a critical value, a tensile crack is formed which splits the specimen. As this tensile crack propagates, it exceeds a critical crack propagation velocity, at which the crack tip bifurcation takes place and the crack branches (Butt and Meschke, 2018), as shown in the middle column of Figure 3. Finally, the specimen splits into two main and several small fragments (right column of Figure 3).

The indentation pressure resulting from the indentation loads is calculated using:

$$p = \frac{F}{4\sqrt{2R_{ind}d - d^2} \left(a_0 + \frac{d}{\tan\alpha} \right)} \quad (5)$$

Here, F is the indentation load, d is the indentation depth, R_{ind} is the radius of the indenter tip, a_0 denotes the half width of the indenter tip, and α is the angle between the indenter and the specimen surface (here 40°). For further details of the indenter

Figure 3. Temporal evolution (left to right columns) of the fracture process during the indentation test (top row), the associated damaged and cracked regions are filtered out for visualization (bottom row).

geometry, the interested reader is referred to Yang et al., 2022. The indentation force- penetration and the pressure-penetration relationship computed from the simulations are compared with the experimental data in Figure 4. The loading stiffness, the peak load as well as the peak indentation pressure predicted by the simulation are in a good agreement with the experiments.

3 LINEAR CUTTING MACHINE (LCM) TEST

LCM test (Rostami, 1997) was developed at the Colorado School of Mines (CSM) to predict the performance of a single cutting tool. In the LCM experiment, a cutting disc moves along a rock specimen at a known penetration level and tool spacing, and tool-rock interaction is characterized by the reaction forces on the cutting disc. Several cutting lines at a fixed spacing can be performed, which comprise a cutting pass, the cutting forces can then be averaged over these cutting lines. These forces are decomposed into normal, rolling, and side forces

and they are used to predict the global thrust and torque requirements for a TBM.

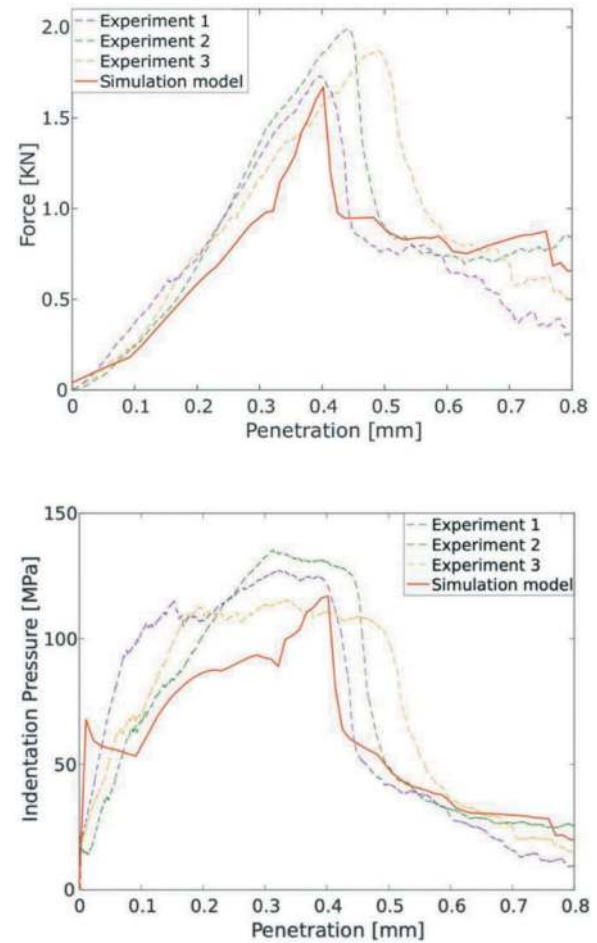

Figure 4. Comparison of the indentation force-penetration (top) and the indentation pressure-penetration (bottom) relationship measured in the experiments and computed from the simulations.

The LCM test is a widely used experimental procedure to predict the performance of a single cutting tool (Gertsch et al., 2007), and it uses cutting tools of the actual size instead of scaled-down versions (Entacher et al., 2014). This method facilitates direct measurement of the cutting forces under controlled process parameters, such as the tool penetration, spacing, and cutting speed. LCM testing is also suitable for validating rock cutting simulation models (Butt and Meschke, 2017, Cho et al., 2013, Labra et al., 2017). LCM-type simulations can be performed to predict the performance of a single cutting disc while varying different process parameters and tool geometries.

3.1 Simulations of the LCM test

This section presents peridynamic simulations of the LCM test carried out on Colorado red granite using an extended version of the open-source software

Peridigm (Parks et al., 2012). The simulations consider both relieved and unrelieved rock cutting cases. Relieved and unrelieved rock cutting modes refer to the stress state present in the rock during the excavation process. In relieved cutting mode, the fractures initiated from the adjacent cutting tools interact with each other and relieve the stress state in the rock, resulting in lower levels of cutting forces. In contrast, in unrelieved cutting mode, the surrounding rock mass is intact and stresses are not relieved, leading to higher forces on the excavation tools.

Table 2. Material properties of colorado red granite.

Material parameter	Value
Young's modulus (GPa)	41
Poisson's ratio	0.234
Density (kg/m ³)	2650
Tensile strength (MPa)	6.78
Compressive strength (MPa)	158

Figure 5. Simulation of the LCM test showing evolving damaged zones just before the third pass of the tool at a spacing of 76 mm and a penetration level of 7 mm.

The simulation model requires an initial calibration according to the pressure-dependent critical-energy model (Butt, 2023), in order to reproduce uniaxial tensile and compressive strengths (UTS and UCS), respectively. It should be noted that Brazilian tensile strength (BTS), commonly used in rock mechanics, can also be used to calibrate G_c , instead of the UTS used here. After calibrating UTS and UCS, simulations of the LCM test for both relieved

and unrelieved cases are performed. The material parameters used for Colorado red granite, as reported in Gertsch et al., 2007, are presented in Table 2. The heterogeneous nature of the rock is considered using randomly distributed strength parameters, as explained in Section 2.2. For further details the interested reader is referred to Butt, 2023.

The simulation setup for LCM test presented here is similar to the one used by Butt, 2023. These simulations can be performed at various tool spacings and tool penetration depths. Simulations are conducted with three cutting disc passes at a fixed penetration and spacing, as shown in Figure 5. The first cutting line is used for rock conditioning to damage the rock and mimic the previous tool pass, as in the LCM test and rock cutting with a hard rock TBM cutterhead. The average cutting forces presented in this section are obtained by averaging the forces over the second and third cutting pass.

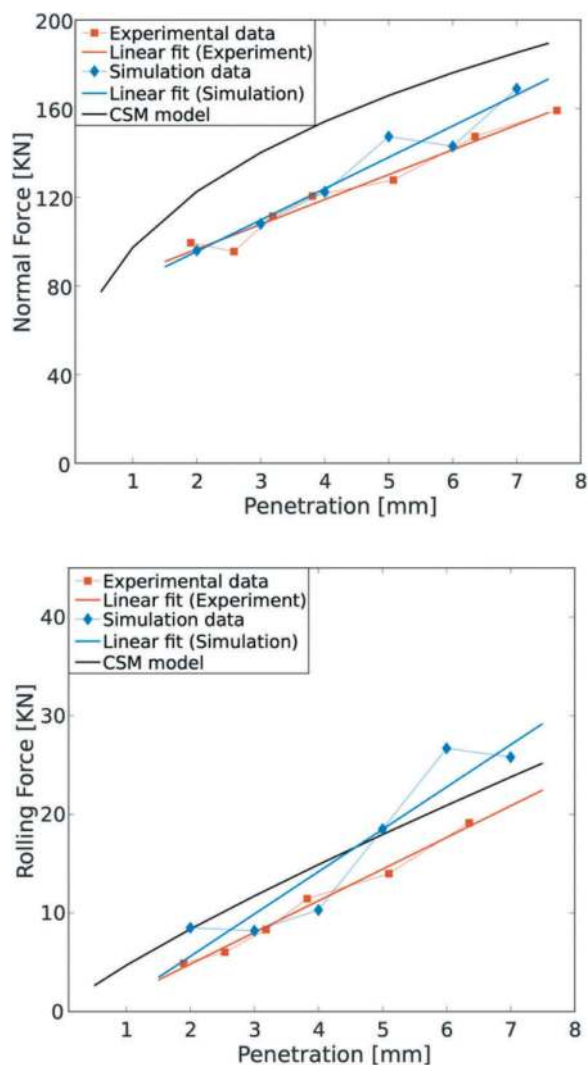

Figure 6. Average normal (top) and rolling (bottom) forces obtained from peridynamic simulations are compared with the CSM model and experimental data for various tool penetration levels and a tool spacing of 76 mm.

Simulation results show that the peridynamic approach can capture the chipping process and cutting forces in rock cutting simulations. For a tool penetration of 7 mm and spacing 76 mm, Figure 5 illustrates that the simulation captured the formation of rock chips between the tool passes. The average cutting forces obtained for a tool spacing of 76 mm at various penetration levels are compared with the CSM model (Rostami, 1997) and experimental data (Gertsch et al., 2007) in Figure 6. The normal cutting forces are in good agreement with the experiment, while the rolling forces are slightly overestimated. As the tool spacing is reduced, the chipping process becomes inefficient, leading to lower cutting forces but also lower excavated rock mass (Butt, 2023).

The average cutting forces obtained from the simulations in this section exhibit significant scatter due to the probabilistic nature of these simulations. As the strength parameters used to model the heterogeneous nature of the rock are randomly sampled from a Weibull distribution (Section 2.2), each simulation has a slightly different spatial distribution of material strength. These differences can result in the observed scatter. Ideally, a multi-simulation approach should be adapted for these cases to find an average solution. However, performing a large number of simulations with such high resolution would require a considerable computational effort and is outside the scope of the current work.

4 MIXED GROUND CONDITIONS

Mixed or heterogeneous ground conditions occur when a tunnel face has two or more layers of rock or soil with significantly different mechanical properties. Mechanized tunneling in such conditions results in highly variable loads on the cutting discs. As the cutting disc moves from soft to hard ground, an excessive load is exerted on the cutting disc at the point of contact with the hard ground layer, as shown in Figure 7. This excessive load contributes to the global torque fluctuation of the TBM and may substantially increase wear rates and cause localized damage to the cutting disc and bearings, leading to unexpected TBM stoppages and delays in the project timeline.

Figure 7. Schematic illustration of the forces acting on a cutting disc at a mixed face tunnel.

4.1 Mixed-ground LCM experiment

The contrast of material properties at the tunnel face is replicated in an LCM experiment with a rock sample constructed using limestone and granite casted in concrete (Butt, 2023). As the cutting disc moves through the various interfaces in the specimen (for e.g. concrete-granite interface) an abrupt change in the cutting forces is measured. Average normal forces obtained from four cutting passes are shown in Figure 8. It can be observed that as the cutting disc moves from concrete into granite (first dotted vertical line in Figure 8), the cutting disc experiences an overloading which can cause abnormal wear as well as localized damage to the cutting disc. In the next subsection, the potential of peridynamic modeling is explored to simulate the rock cutting process in in mixed-ground conditions.

Figure 8. Average cutting forces obtained from four cutting passes in a mixed ground LCM experiment.

4.2 Simulations of mixed-ground LCM test

Mixed ground conditions are simulated in this section using LCM tests where a cutting disc moves from soft soil into a hard rock domain. The simulations used a scaled cutting disc of 56 mm diameter and a rock specimen of $0.2 \times 0.15 \times 0.075$ m, as experimentalists have used such scaled cutting tests to facilitate the experimental setup and the availability of the apparatus in the laboratory (Entacher et al., 2014). Scaled tests were used here due to the large computational expense associated with a full-scale test.

The soil material is modeled using an elastic-plastic Drucker-Prager type plasticity model, and the rock material is modeled using an elastic-brittle constitutive relation. The objective of these analyses is to characterize the impulse load and resulting wear on the cutting disc as it moves through the interface between two materials with significantly different

mechanical properties. Such repeated impulse loads can cause excess vibration in the cutterhead and increased fluctuations in torque and thrust of the TBM, which may ultimately result in premature damage to the cutting disc.

Plastic deformations in the soil and the damage level in the rock obtained from the simulations of the cutting disc moving from soil to rock domain are presented in Figure 9. The reaction forces obtained for two penetration levels (2 mm and 3 mm) are shown in Figure 10. These diagrams show that the normal cutting forces are negligible when the disc cutter is in the soil domain. However, as it reaches the soil-rock interface (cutting length = 0.05 m) and continues to move into the rock domain, the cutting forces show a peak of relatively high cutting forces. As anticipated, the comparison of cutting forces at the two penetration levels in this study shows that the peak cutting force increases proportionally with the tool penetration.

Figure 9. Plastic deformations and damage in hard rock obtained from a peridynamic simulation of a cutting disc working in mixed ground conditions (soft soil to hard rock domain) with a penetration of 3 mm.

An Archard type abrasive wear model (Archard, 1953) has been implemented in the open-source software Peridigm. The simulation model is verified based on a simple sliding test for the abrasive wear. For further details regarding the abrasive wear model, the interested reader is referred to Butt, 2023. The verified model for abrasive wear is utilized in conjunction with the simulations for mixed ground conditions to estimate the abraded volume on the cutting discs and localized wear occurring at the soil-rock interface. Figure 11 (top) displays the accumulated wear on the cutting disc, for a 180° rotation, for two penetration levels at three different stages: in the soil domain (left column), at the soil-rock interface (middle column), and in the rock domain (right column). The figure reveals a significant increase in

accumulated wear on the cutting disc as it progresses into the rock domain. Figure 11 (bottom) presents the total volume loss due to abrasive wear on the cutting disc over the cutting length for both penetration levels. A notable change in wear rate is evident as the cutting disc moves from the soil to the rock domain.

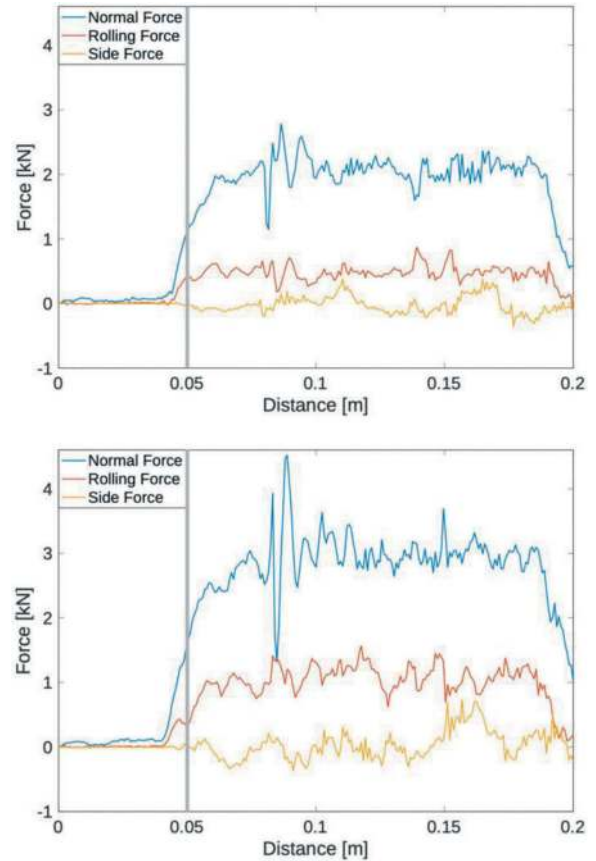

Figure 10. Cutting forces acting on a cutting disc working in mixed ground conditions (soft soil to hard rock domain) obtained from a peridynamic simulation for a penetration level of 2 mm (top) and 3 mm (bottom). The vertical grey line at 0.05 m cutting distance represents the soil-rock interface.

5 CONCLUSIONS

The rock indentation and excavation by means of cutting discs of a TBM has been investigated using an extended peridynamic simulation model. The simulation results for the indentation tests obtained using the extended model were validated through comparison with force-penetration and pressure-penetration data from experiments performed on Bentheim sandstone samples of various sizes. The simulation technique was further validated by simulating LCM tests on granite samples while considering the rock material heterogeneity through random sampling of strength parameters from a Weibull distribution. The cutting forces were found to be in good agreement with the experimental data and the

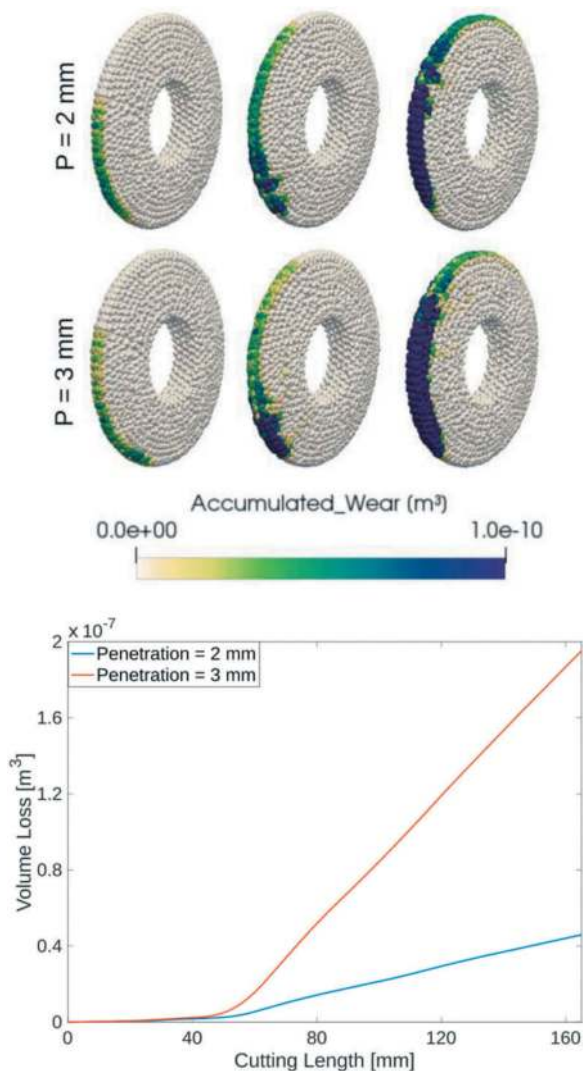

Figure 11. Comparison of the abrasive wear on the cutting disc working in mixed ground conditions (Figure 9 and 10) at two different penetration levels (top). Total volume lost on cutting disc due to abrasive wear over the cutting length (bottom).

CSM model predictions. In addition, the simulation model was used to perform LCM tests for mixed ground conditions where the cutting disc moves from a soil medium, modeled using a Drucker-Prager type plasticity model, to a hard rock medium. An Archard-type wear law was incorporated in the simulation model to simulate abrasive wear of the cutting discs. The mixed ground simulations revealed an abrupt increase in the cutting forces as the disc moves from soil to rock medium, resulting in uneven wear of the cutting disc. These results demonstrated the effectiveness of the proposed method in accurately identifying the cutting forces on the cutting discs working in changing ground conditions. The extended simulation model has a promising potential for modeling the rock excavation process in various scenarios.

Pumice mineral using as a backfill grout injection in TBM excavations

Ufuk Cemali Çalışkan*, Seden Beyhan & Hasan Ergin
Istanbul Technical University, Istanbul, Turkey

ABSTRACT: Shielded full-face tunnel boring machines (TBM) have been used in the mining and construction industry for many years in underground tunnel excavations. There are two important elements of this manufacturing method, which is based on the principle of filling every voids in underground excavations that will meet certain strength values; the first is reinforced concrete structures consisting of precast segments, and the second is backfill injection injected between these segments and the ground cavity. In a tunnel opening in which the excavation-support cycle progresses rapidly, therefore it is desirable to improve the mechanical requirements of the backfill mortar, such as early setting, reaching high early strengths, maximum gap filling, easy pumpability, reducing water permeability into the precast segments, and at an affordable cost. In addition to being an expensive binder, the cement used in backfill mortar also causes CO₂ emissions during its production. All these factors motivate the tunnelling industry to reduce the use of cement in backfill mortar and to seek alternatives. In this direction, the use of different pozzolans as additives to improve the properties of the backfill mortar been examined. In this study, as a pozzolan named pumice was obtained by chemical synthesis from rocks containing high percentage of silica by weight. Cement backfill mortar samples mixed with different proportions of pozzolans at different ratios will be prepared and the optimum pozzolan ratio was be determined by strength tests. With the findings of this research provides to define the suitable pozzolan that's backfill mortar.

Keywords: Tunnelling, TBM, Backfill, Grout, Pozzolan, Pumice

1 INTRODUCTION

The TBM tunneling method is widely used in metro tunnels and infrastructure tunnels due to its high automation, fast construction speed and low impact on ground disturbance (Liu et al., 2018). To increase the stability of the layers and reduce ground settlement, grouting is often used to strengthen the layers for the shield tunnel. The backfill grouting consumption for the shield tunnel is enormous and the development of backfill grouting with high performance, environmentally friendly and low cost features is of great importance and has economic benefits (Ye et al., 2019).

In the TBM tunnel method, since the outer diameter of the machine's cutter head is larger than that of the segment, a ring-shaped gap is formed between the segment and layers after the machine's mattress and shield tail are separated from the segment (Liu et al., 2018). The task of synchronous injection is to fill the annular gap by injecting injections with appropriate early strength and final strength according to the prescribed injection pressure. With backfill injection, the segment can be supported against the surrounding ground pressure, which can effectively reduce ground deformation (Ding et al., 2019).

TBM backfill grouting is the filling of cement, mortar, bentonite or various organic-inorganic chemical substances under pressure into discontinuities in the

rock mass and/or ground voids. By grouting under a certain pressure into the inaccessible gaps and cracks in the foundation;

- The bearing capacity of the foundation is increased,
- Leaks are either completely prevented or minimized,
- Ground settlements are minimized,
- Hydrostatic lifting pressures are prevented.

The backfill injection has to be;

Figure 1. Backfill grouting in TBM tunnelling (gulermak umraniye goztepe metro method of statement).

- Spreads easily around the precast segments,
- Setting times can be easily controlled,

*Corresponding author: caliskanuf@itu.edu.tr

- High durability,
- Low heat of hydration,
- No segregation after mixing,
- Short mixture preparation time,
- Low cost of injection mixture,
- It should not adversely affect health conditions.

A few scientific papers or tunnelling projects have so far reported the use of secondary cementitious materials in two-component grouts. A conference paper from 1950 presented characteristics of grouts formulated with slag cement bentonite and silicate (Florentin and Heriteau, 1950). Sculte- Schrepping and Breintenbucher (2019) demonstrated the interest of using ground granulated blast furnace slag, fly ash, or metakaolin to replace some of the ordinary Portland cement. According to these authors, the higher calcium content of the slag, compared to the other Al-Si materials, allows faster jellification and higher compressive strength. Other recent papers have associated fly ash for eco-friendly two-component grout design (Aboulayt et al., 2020; Song et al., 2020). However, grouts formulated in these studies used a lower water-to-binder ratio and a higher accelerator content than the mix-design presented in this work. One of the rare cases of a tunnelling project using SCMs in its two component grout design is the Warsaw metro. A blended CEM IV/B-P cement, containing between 36 and 55% of natural pozzolan (AFNOR, 2012) was used (Peila et al., 2015).

The aim of this paper is to assess the feasibility of using pumice as a alternative pozzolan for two-component grouting, by presenting the results of an experimental campaign that shows the effect of a partial replacement of Ordinary Portland Cement. It focuses on two main aspects of grout properties that must be managed: fresh state characteristics and compressive strength development.

2 EXPERIMENTAL

A two-part mortar typically consists of two components; Component A, which consists of cement, water, bentonite, and a retarder, and Component B, which usually consists of sodium silicate and water. The function of the retarder in Component A is to

Table 1. Specifications for grout properties, considered as acceptable quality parameters on jobsite.

Property	Criteria
Component A (only)	
Marsh cone flow time	30-45 sec
Bleeding	<3 % at 3h
Components A+B	
Gel time	5-15 seconds
Compressive strength	>0.6 MPa at 24 h
	>0.8 MPa at 7 days
	>1.20 MPa at 28 days

guarantee its workability from blending to transportation and injection into the annular space (Peila et al. 2011). When Component A is mixed with a sodium silicate-based accelerator, the mixture hardens rapidly due to the chemical action of the accelerator. The mixture begins to gel and begins to gain mechanical strength within a few seconds of mixing. The TBM backfill grout specifications listed in Table 1.

2.1 Materials

Pure cement mortars have various performance defects, so they are not used directly in TBM tunnel grouting. Quantitative industrial residues such as fly ash, slag, steel slag and silica fume, special pozzolans such as bentonite, gypsum, clay and metakaolin, chemical additives such as superplasticizers, dispersion resistance agents, setting accelerators, retarding agents, early strength agents, water reducer agents, microexpansion agents and viscosity modifying additives can improve the performance of mortars for shield tunnel (Wang et al. 2018).

Table 2. Typical composition of two-component backfill.

1 m ³			
Content	Weight (kg)	Density (kg/m ³)	Volume (desi)
Cement	320	3150	101,59
Bentonite	30	2700	11,11
Plasticier	3,1	1100	2,91
Water	830	1000	830,00
Accelerator	75	1400	54,29
Total	1258		1000

First, bentonite is added to the water and mixed for 2 minutes. Afterwards, cement and pumice powder are added to the plasticizer mixture and mixed with a mixer for 3 minutes. Some of the material removed from here is taken into a measuring tape and kept waiting for slump testing.

Table 3. Grout design for laboratory (2 desi).

2 desi		
Content	Weight (g)	Volume (desi)
Cement	640	0,2
Bentonite	60	0,02
Plasticier	6	0,01
Water	1660	1,66
Accelerator	150	0,11
Total	2516	2,00

Pumice, a natural mineral source, has very few uses. However, the large amount of pumice stone reserves with high silica content in Turkey allows the use of pumice stone as an alternative to cement. Using pumice stone to improve binder hydration in

recipes by reducing the cement content in the backfill mortar can not only reduce the cost but also provide the opportunity to use more pozzolanic material (pumice). Development and/or promotion of low or inexpensive pumice use will be critical for the acceptance of nanomaterial application in backfill mortar injection technology in underground operations.

The cement industry is responsible for approximately 7% of CO₂ emissions, and it is predicted that this will increase further in the coming years. Since pumice particles have a high surface area, they fill the gaps between solid particles and serve as filler and pozzolan in cementitious materials.

Table 4. Composition of grout with pumice.

Components Unit	Cement		Pumice		Water	
	g	%	g	%	g	%
Cement (100%)	640	25,41	0	0,00	1660	65,90
Cement +Pumice (%90+%10)	576	22,87	64	2,54	1660	65,90
Cement +Pumice (%80+%20)	512	20,33	128	5,08	1660	65,90
Cement +Pumice (%70+%30)	448	17,79	192	7,62	1660	65,90

2.2 Laboratory tests

Marsh cone test

The Marsh cone test [UNI 11152:2005 (Italian Standards 2005) was conducted to evaluate the fluidity and viscosity of the grout before mixing with an accelerator, and this is expressed as the time required by 1,000 mL grout to flow through a standardized cone. The time required for a complete flow should range between 30 and 45 s.

Figure 2. Flowing test with Marsh cone.

Bleeding test

The bleeding test was carried out by leaving an undisturbed grout sample (without accelerator) of 1,000 mL for 3h and measuring the water separation. In the technical literature (Peila et al. 2011), it is usually considered that a good mix should not exceed 3% water separation. The bleeding test was carried out to test the water separation from the grout sample. In case of standstill during a TBM excavation, the water in the grout sample should not separate from the mix.

Figure 3. Bleeding test.

Hardening time evaluation

This hardening time evaluation test was carried out by mixing Component A with 6% of Component B (accelerator) until the grout was no longer workable. This is defined as the hardening time of the two-component mix. The usual hardening time for a two-component grout ranges from 5 to 15 s. Shorter values are avoided because they may lead to choking of the injection pipes, whereas larger values are unwanted because an immediate support is needed by the segmental lining as it exits from the TBM tail.

Figure 4. Gel time evaluation.

Uniaxial compressive strength test

Early strength is required to ensure that the segments can support the loads applied by the TBM back equipment and also to transfer the loads between the segments and the soil. However, testing relatively low 1-hour strengths has proven problematic as there are no directly applicable ASTM standards (Antunes, 2012). In this context, uniaxial compression tests were carried out based on the 1-7-28 day strengths accepted in Turkey.

Figure 5. 5x5x5 cubes with different rates of pumice.

Characterization tests

Before mechanical tests are carried out, characterization experiments must be carried out to reveal the content of the CEM I 42.5 R cement and pumice to be used in the tests. In this context, CEM I 42.5 R type cement and pumice X-Ray Fluorescence (XRF) experiments were carried out in an accredited laboratory.

Figure 6. Pumice and cement samples.

3 RESULTS AND DISCUSSION

In order to determine most suitable bentonite the 4 different brand sample used in the tests. The fresh and hardened test carried out with 320 kg CEM I 42,5 R cement,

830 kg water, 30 kg bentonite, 3,1 kg EUCON NP205 plasticier additive, 75 kg CreteShot NS303 (%6) sodium silicate under the 2.60 w/c ratio. The bentonite which has a lesser bleed ratio chosen for further test process (Table 6).

Table 5. XRF test results.

Compound	CEM I (%)	Pumice (%)
SiO ₂	19,28	72,95

In this study, the physical results of pumice stone, which has reserves in many regions in Turkey, when used in combination with cement in TBM backfill, were examined. Pumice stone powder; it was observed that when added into the Marsh cone, it flowed within 30-45 seconds and showed very similar properties to the cementitious mixture. In addition, when components A and B were mixed (with the addition of 6-10% sodium silicate setting accelerator), it was understood that they gelled in 7-8 seconds and showed almost the same properties as the cementitious mixture. In the slump funnel, which is another physical test, it is understood that the mixture prepared with pumice stone powder collapses at almost the same rate as the mixture prepared with cement, so it does not create a disadvantage.

When we look at the uniaxial compressive strengths, it is understood that when 10% pumice stone powder is used, the uniaxial compressive strengths are the same as cement, but after 20% it starts to decrease. The tests were carried out with 10-20-30% pumice stone powder additive, but these tests should be tried at dosages such as 5-15-25% to better investigate the diffraction point and determine the optimum point. In addition, water permeability

tests of the backfill prepared with pumice stone must be carried out and compared (Table 7-8).

4 CONCLUSIONS AND RECOMMENDATIONS

All tests in this article were performed with CEM I 42.5 R type cement. It will be beneficial to perform tests on cement types such as CEM I 52.5 R and examine the results. The tests performed under different B/A ratio, for TBM backfill grouting the most important requirements for TBM backfilling is that the grout begins to set as soon as possible in order to fill the gap open by the cutter head and reducing possible surface settlements to zero. This help to understand the importance of early strength, so uniaxial compressive strength tests should also carried out for 1-3-6 hour periods with all receipts. Also for the corrosive and high underwater projects its necessary to carry out permeability tests for TBM backfill.

One of the most important issues in creating alternatives in a region is the geographical proximity to the raw material as well as the availability of suitable raw materials. Pumice stone is a raw material with very high reserves in Turkey. It contains up to 75% SiO₂ in its entire state without any physical or chemical treatment.

According to the results obtained from all these results, the use of pumice stone as an alternative raw material to cement at a certain rate is promising in terms of mechanical tests and cost advantage. Pumice is a suitable pozzolanic material due to its lightness, porous structure, high SiO₂ content and amorphous structure and provides a more economical and environmentally friendly concrete production. Although 40% of the world's 18 billion tons of pumice reserves are in Turkey, they are still not used effectively (Gündüz et al., 2005).

Performance analysis of TBM excavation parameters related to small-diameter horizontal and inclined tunnels

Marilena Cardu*, Carmine Todaro, Oveis Farzay, Alfio Di Giovanni & Simone Saltarin
DIATI Politecnico di Torino, Turin, Italy

ABSTRACT: Horizontal, inclined, and vertical ways through the rock are needed for several mining and civil purposes (hydropower, transportation, sewer collector, underground transports), and quite often, in the same project, horizontal, inclined, and vertical ways are necessary. These cases offer a great opportunity for comparing the performance of the excavation systems in similar geological-geomechanical environments. The basic mechanism of rock breakage, either cyclical (Drill and Blast) or continuous (TBM or Raise Borer), is the same for horizontal or inclined ways. In the latter case, the fixed motor option (Raise Borer) tends to be preferred for short, small-diameter, easily accessible top-point cases. As to the Drill and Blast system, it tends to be employed only for horizontal ways or very short inclined ways. In the first part of the paper, a general discussion of the techniques for horizontal, inclined/vertical ways excavation is provided, comparing some real cases of tunnel driving by TBM under the aspect of the machine's average performance. The comparison of the cases makes it possible to draw some prediction criteria applicable to the TBM performance in horizontal and inclined tunnel driving.

Keywords: Tunnelling, TBM, Performance prediction, Inclined tunnel, Horizontal tunnel

1 INTRODUCTION

The use of the TBM for horizontal and inclined ways has become a widespread practice in Italy, both for the excavation of highway and railway tunnels and for the implementation of hydroelectric programs, for new plants and the adaptation of old plants, due to the general policy to transfer underground all the water conducts and powerhouses (Edvardsson & Broch, 2002). The cases examined here pertain to hydropower and water supply plants, and to the ventilation inclines of a large road tunnel, with diameters in the 2.5 to 4.2 m range (at places, subsequently enlarged). Although excavation with TBM potentially has the advantages of safety, respect for the environment, and speed, the cost and difficulty of realising the project, construction, and operation can be considerable (Zhu et al., 2019). It must be recalled that a hydropower tunnel project is far more complex than a road or railway tunnel (Nilsen, 2021). Today, tunnels are usually excavated through TBM, to ensure that construction is completed in a reasonable time; therefore,

predicting TBM performance is a crucial issue and a primary requirement for implementing a tunnel project, both for planning purposes and for selecting the construction method (Graham, 1976; Farmer & Glossop, 1980; Hughes, 1986). Performance prediction for a hard rock TBM can be done in many different ways. The main approaches can be theoretical or empirical, the first being based on cutting force estimation and the other, on field performance. In general, over the past decades, various models and equations have been proposed to estimate the performance of TBM based on the properties of rock and machine, which employ various statistical analysis techniques (Yagiz, 2008; Yagiz et al., 2009; Gong & Zhao, 2009; Hassanpour et al., 2009, 2010, 2011, 2015, 2016; Khademi Hamidi et al., 2010; Farrokh et al., 2012; Delisio et al., 2013; Oraee & Salehi, 2013; Macias et al., 2014; Salimi et al. 2016; Zare Naghadehi & Ramezanzadeh, 2017). In the case under study, the aim is to assess and compare the data collected from tunnel boring machines used in both horizontal and inclined tunnels, identifying the correlations among

*Corresponding author: marilena.cardu@polito.it

the various parameters under consideration, taking into account the specific geological conditions of each project.

2 DATASET OF CASES EXAMINED

The main data of the examined cases are collected in Table 1. To be noticed, letters from A to F are used to recognise cases belonging to the same type of rock type crossed during the excavation: cases A pertain to granitic gneisses, B to limestones, C to calcschists and related, D to extremely hard gneiss-pegmatites, E to sandstone and marls, F to meta-ophiolites and meta-sediments.

Case A₁ refers to two inclined shafts for a pumped storage hydropower plant, subsequently enlarged to 6.4 m by D&B. A₂ is a pedestrian access tunnel, pertaining to the same plant as A₁, and is quoted to provide a comparison with a horizontal tunnel. Tunnel A₂ has been driven by TBM only for a short stretch (less than 2 km) and completed by D&B due to the excessive consumption of the tools and frequent machine failures; B₁ consists of two inclined tunnels for a hydropower plant, driven through comparatively soft limestones, subsequently enlarged to 5.8 m by mechanical excavation; B₂ is a horizontal tunnel driven through dolomitic limestone, harder than case B₁, as a part of an aqueduct; B₃ is an inclined tunnel for a hydropower plant, driven through a dolomitic limestone, whose strength is intermediate between B₁ and B₂; C₁ consists of a couple of inclined tunnels driven for ventilation purposes from a large road tunnel through calcschists, subsequently reamed to 5.8 m, again by TBM; C₂ – C₃ represent two stretches of a hydropower tunnel driven through calcschists (somewhat stronger than C₁); D is an inclined tunnel for a hydropower plant, driven through the most strong and abrasive rocks among the types considered in this report. Excavation by TBM has been discontinued because of a failure, unrelated to the machine. E refers to a horizontal tunnel that is part of a hydropower-plant, while F serves as an inclined tunnel designed for the installation of a pipeline for a hydroelectric power plant.

Apart from cases A₁ and C₁ (the only cases where rolling tools with carbide buttons have been used), machines equipped with standard disc cutters have been used. Table 2 collects the main technical data of the machines used in the excavation works in terms of head diameter (D), maximum stroke (S), maximum thrust (T_{max}), number of tools (N), tool diameter (Φ), head revolution per minute (n), maximum power at the head (P_{max}). In case A₁, roller bits with buttons (RBB) were employed as the selected tools, whereas for cases A₂ and C₁, the TBMs utilized double-disc tools.

The properties of the rocks, as easily predictable, are not uniform along the alignments of the tunnels, and the variability is probably as important as the average strength value in determining the performance of the machines.

In Table 3, information pertaining to the rocks crossed are reported.

The uniaxial compressive strength (C₀) is reported in terms of range and, in brackets, the average reference value (C_{0av}). Furthermore, information concerning the indirect tensile strength (Brazilian test, T₀), the RMR (Rock Mass Rating), and the indicator of the rock abrasivity HK₇₅ (upper quartile of the Knoop micro-hardness distribution) are also provided.

Table 1. General data of the inclined and horizontal tunnel cases examined. D: tunnel diameter; i: tunnel inclination; L₁: tunnel length; L₂: length excavated by TBM; TBM: TBM.

Case	i (°)	D (m)	L ₁ (m)	L ₂ (m)	TBM (%)	Lithotype

Table 3. Geomechanical characteristics of the rocks encountered by tunnels.

Case	C ₀ (C _{0av}) (MPa)	T ₀ (MPa)	RMR (-)	HK ₇₅ (MPa)
A ₁	100-150 (125)	-	-	-
A ₂	70-170 (97)	7-12	70-85	5990
B ₁	15-50 (25)	-	-	-
B ₂	60-180 (70)	5	60-80	1500
B ₃	(40)	2.9	60-85	3600
C ₁	40-60 (50)	-	-	-
C ₂	60-130 (83)	5-7	30-70	6300
-C ₃				
D	90-200 (112)	10-16	60-80	8200
E	49-80 (64)	4-7	-	900-4000
F	75-180 (126)	15	60-90	4300-8300

Unfortunately, the pattern of the information is not complete since, for the same case examined, some data are not available.

Besides numerical information reported in Table 3, further useful details and peculiarities recorded during the excavation by figures involved in the works are hereinafter concisely reported:

A₁: quite uniform rock, with scarce discontinuities;

A₂: rock strength progressively increases from the portal: as explained, the machine gave up after approximately 2 km excavated. A major fault has been crossed, with problems encountered;

B₁: calcarenites, softer, alternate with marls, harder; poor rock, faulted, is crossed in the last 50 m of the tunnels;

B₂: distinctly bedded dolomitic limestone, with marl-clay interlayers;

B₃: thick layers; homogeneous, apart from marl interlayers;

C₁: good rock quality, apart from a jointed rock stretch in the initial part of the layout;

C₂,C₃: problems due to some shear zones crossed; strength quite variable (calcschists, mica-schists and meta-conglomerates alternate along the tunnel);

D: hard gneiss with still harder lenses of pegmatites and amphibolites (machine thrust had to be improved after an initial unsuccessful attempt);

E: fairly regular alternation of homogenous strata of marl and sandstone;

F: schists and serpentinite show a foliated texture, while meta gabbro and metabasite are generally weakly foliated.

3 PERFORMANCE OBSERVED

A very important point in TBM operation, both horizontal and inclined, is thrust. It is seldom possible to exploit the full nominal thrust available from the machine (T_{max} of Table 2) and, consequently, being the thrust linked to the power consumed, to exploit

the full power available (P_{max} of Table 2). The cases are examined under this aspect in Table 4: the values, where available, of T_{max}, of the average actual thrust (T_{av}), of P_{max}, and of the average power consumed considering only the head (P_{av}) are collected. Furthermore, values of thrust per disc (T_D) computed as the ratio between T_{av} and N are also reported.

Table 4. Thrust and power data for the cases examined.

Case	T _{av} (kN)	P _{av} (kW)	T _{av} /T _{max} (%)	P _{av} /P _{max} (%)	T _D (kN / disc)
A ₁	-	340	-	70	-
A ₂	1900	160	64-71	42	112
B ₁	1200	186	28	62	40

C ₂	3960	504	64	84	152
-C ₃					
D	5800	430	72	48	181
E	2390	389	54	70	89
F	5130	-	65	-	143

Table 5 provides information about the progression of the analysed tunnelling works. Specifically, data related to the net penetration rate (NPR), the basic penetration rate (p), the utilisation coefficient (UC), the average daily progression (ADP), the specific energy (Es), and the service life of the tool which is related to the efficiency of the tools (m³ of excavated material per tool) (SL_v).

Referring to the last column of Table 5, it must be noticed that, in most cases, the tunnels are not long enough to provide reliable data regarding the service life of the tool, especially in soft rocks such as limestones: in B₁ - B₃ - C₁ the same discs set installed on the head at the beginning was still serviceable at the end of the work.

In scenario B₂, the parameter is computed based on the number of workdays to calculate the UC. Instead, for scenarios C₂-C₃, the rock reinforcement time is not factored into the calculation.

4 DISCUSSION

The cases examined refer to the use of different machines and, more importantly, in different rocks, which makes it difficult to answer the simple question: how much more difficult is it to drive by TBM an inclined tunnel with respect to a horizontal tunnel? To minimise the disturbance, at least, of the rock factor in comparison, in

Table 5. Parameters related to the progression of the analysed tunnelling works.

Case	NPR (m/h)	p (mm/rev)	UC (-)	ADP (m/d)	E_s (MJ/m ³)	SL_v (m ³ /tool)
A ₁	1.6	2.2	0.24	8.1	115.0	227
A ₂	1.1	1.6	0.31	8.4	97.2	48
B ₁	5.8-6.5	8.5-9.5	0.18	25-28	15.1	-

Figures 1 to 4, some parameters have been selected and plotted against the rock strength indicator C_0 . The choice of selecting the basic penetration rate, the specific energy, the thrust per disc, and the machine utilisation coefficient have been made to provide an easy understanding of the studied topic.

Considering Figure 1, in inclined tunnels, the basic penetration rates consistently fall near or below 4 mm/rev, suggesting that these machines operate at the limit of their boring capacity, apart from an outlier case (Case B₁). In contrast, horizontal tunnels exhibit a wide range of basic penetration rates, spanning from approximately 2 to 9 mm/rev, indicating their capacity to adapt to varying rock strength and geological conditions.

Considering Figure 2, the $E_s - C_0$ trend is similar for inclined and horizontal tunnels, i.e. an increase of C_0 leads to a growth of E_s . The same inferences can be made considering Figure 3; indeed, the correlation T- C_0 shows no differences in trends between inclined and horizontal tunnels.

Considering Figure 4, UC tends to be lower in inclined tunnels with values that never overcome 0.3. Cases examined, however, refer only to inclinations in a 35° – 47° range.

Figure 5 reveals a trade-off between SL_v and E_s . Cases with higher E_s values tend to have lower SL_v , indicating that when more energy is consumed per unit volume of rock, tools tend to have a shorter service life. Conversely, cases with lower E_s values tend to have longer tool service lives. inclined tunnels generally result in lower SL_v values compared to horizontal tunnels. This suggests that tools used in inclined tunnels have a shorter service life, possibly due to increased wear and tear from the more complex excavation process.

Figure 1. Penetration per revolution Vs. rock uniaxial compressive strength. Circles refer to horizontal tunnels, and squares to inclined tunnels.

Figure 2. Specific energy consumption Vs. rock uniaxial compressive strength. Same symbols as in Figure 1.

Figure 3. Thrust per disc Vs. rock uniaxial compressive strength. Same symbols as in Figure 1.

5 CONCLUSION

TBMs have been, and are, used in Italy in several projects. Historically, inclined tunnels are often driven by Drill & Blast, which is probably cheaper but tends to be abandoned. One reason is the scarcity of well-trained workers, but another important reason is the excavation speed, which undoubtedly favours the TBM. In fact, by analysing data presented in Table 1, inclined tunnels have been

Figure 4. Utilisation Coefficient Vs. rock uniaxial compressive strength. Same symbols as in Figure 1.

Figure 5. Service life of the tool Vs. Specific Energy Consumption. Same symbols as in Figure 1.

excavated for a percentage higher than 60 by using the TBM.

The paper mainly refers to the excavation of hydropower tunnels, presenting several cases. It should be clarified that analysing different case histories to summarise inferences generally validly is a hard issue since each machine, even if with similar diameter and similar power, has worked in different rock masses and in different conditions. The choice of select the basic penetration rate, the specific energy, the thrust per disc, and the machine utilisation coefficient have been done in the view to provide in an easy understanding of the studied topic.

Considering the ratio T_{av}/T_{max} , it can be concluded that the machines were quite reasonably exploited in horizontal and inclined excavations to within approximately 60 – 70 % of the capabilities. Exceptions are case B₁ (where the rock was particularly soft) and E (where clay beds were encountered). Considering instead the ratio P_{av}/P_{max} , values range between 40 – 85 %.

Considering Figures 1 to 4, Figures 2 and 3 do not provide useful information regarding the differences between inclined and horizontal tunnels. Indeed, the trends depicted are similar, and the different strengths of the rock dictate the

differences. Instead, Figure 1 and 4 provide interesting detail: the basic penetration rate is lower for inclined tunnels, as well as the utilization coefficient. The rationale behind of this trend can be attributed to the fact that, despite the lower UCS, excavating an inclined tunnel poses greater challenges compared to a horizontal tunnel. Moreover, as highlighted in the study by Chu et al. (2022), it is imperative to assess the longitudinal and circumferential strain as well as stress characteristics specific to inclined TBM tunnels, under given geological and hydrogeological conditions.

Figure 5 reveals that higher energy consumption per unit rock volume results in reduced tool longevity, while inclined tunnels typically lead to shorter service lives for tools, likely due to the added wear and tear in their complex excavation process.

However, it is important to note that TBM performance relies heavily on geological conditions compared to the drill and blast technique. Numerous authors have emphasized the significance of in-situ rock parameters that can potentially influence TBM performance (Nelson et al., 1985; Bruland, 1998; Rostami et al., 2002; Zhang et al., 2003; Hassanpour et al., 2011). Nonetheless, it is worth mentioning that this paper does not take into account two important factors in TBM operations: drillability and the natural state of stress, as some research in this area might suggest (Bilgin et al., 2008; Yin et al., 2014; Ma et al., 2016).

Nonetheless, classification criteria could be implemented using the data collected from this research by combining them with in-situ rock structure parameters, drillability assessments, and abrasivity measurements. This approach would facilitate the implementation of knowledge and the identification of correlations among the various parameters involved in TBM excavation.

Another point is, however, important:

Coming to the cases here presented, the tunnel of case C₁ is served, in addition to the ventilation inclines driven by TBM, by other ventilation inclines, driven by Drill and Blast (Alimak method), practically of the same length. The excavation time by Drill and Blast has been 22 % longer, though considering the machine launching time for the TBM case. Both data are referred to as the pilot hole.

Wear prediction of disc cutter tools during shield tunnelling in composite stratum based on improved deep learning method

Jiaqi Chang*, Dongming Zhang & Hongwei Huang

Department of Geotechnical Engineering, College of Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: As development of underground space, shield tunnels are developing towards large-diameter and long-distance. In upper-soft lower-hard stratum, the disc cutter tools are usually seriously worn, affecting the safety and efficiency of shield tunnel construction. The wear of tools is influenced by geological conditions, construction parameters and structure of cutter head, which is difficult to be predicted because the geological conditions are constantly changing along the longitudinal direction during tunnelling. Deep learning (DP) algorithm is an alternative method that can let the computer to learn from the driver's operation, geological conditions as well as record of tool detection, and try to model the relationship between construction parameters, geological condition and tools' wear. Thus, in this paper, an DP algorithm, Transformer, is improved by principal component analysis, K-means clustering and cutter location coding to predict the wear of cutter tool. Principle component analysis is used to reduce the dimension of input parameters, K-means clustering is used to identify the geological conditions in real time and cutter location coding is used to considering the influence of tool placement on cutter head. A set of parameters for shield tunnelling with geological conditions and tool detection records is extracted from the construction site of a Shenzhen tunnel. In total, 217 pairwise data points are collected and ten-fold cross validation is done. The final predicting errors of tools' wear is 3.3mm which is small compared with the critical wear of 40.0mm. The proposed method is helpful for the prediction of cutter wear in composite stratum.

Keywords: Tunnelling, Tool wear, Upper-soft lower-hard stratum, Transformer

1 INTRODUCTION

Tunnel boring machine, as the main method of tunnel construction, has been widely used because of its high safety, low disturbance to the surrounding environment, fast construction speed, and strong ground adaptability. With the development of tunnel construction in China, shield tunneling is developing in the direction of large diameter, large depth and long distance. Along with this, complex ground conditions such as composite strata, soft upper and hard lower strata bring great challenges to shield construction. As the main tool of shield machine for cutting and crushing strata, the tool is very easy to be severely worn under adverse geological conditions, and if the tool wear cannot be accurately predicted, it will often lead to problems such as damage to the cutter plate, difficulty in shield tunneling, and even affect the safety of shield tunneling. Therefore, it is necessary to predict the wear of shield tunneling tools under complex stratigraphic conditions.

Shield tools can be categorized into rock-breaking disc cutter and soil-cutting tooth, among which the disc cutter tend to wear more seriously and are the focus of scholars' research. In the study of the mechanism of wear, the CSM model of Colorado School

of Mines (Rostami, 1997) and the NTNU model of Norwegian University of Science and Technology (Zare and Bruland, 2013) established the force model of the disc cutter and proposed the abrasive coefficient and abrasion value to predict the life of the disc cutter; Xue et al. (2021) established a discrete elemental model of disc cutter to analyze the rock-breaking process and the wear of the disc cutter; and Wang et al. (2015) analyzed the wear of disc cutter by the change of specific energy of the shield; Su et al. (2020) classified the wear of hob into abrasive wear, adhesive wear, and fatigue wear, in which abrasive wear and adhesive wear are the main causes of tool wear. Kilic et al. (2022) established Convolutional Neural Network models to predict the disc cutter wear based on shield construction parameters to predict the hob wear.

However, most of the above studies are aimed at homogeneous strata, and the rock breaking process of the disc cutter is relatively stable in homogeneous strata, whereas in composite strata, the strata on the face is not uniform, and the disc cutter force mechanism is more complicated, so the studies on the wear of the disc cutter in the upper-soft and lower-hard composite strata are fewer, and most of them

*Corresponding author: 1910278@tongji.edu.cn

are empirical summaries. Yang et al. (2021) modified the tool wear model proposed by Japanese Tunneling Society (JTS) for the heterogeneous grounds by assign different wear coefficients to cutters with different cutter diameters.

Traditional analytical and numerical simulation methods are difficult to analyze the complex interaction between construction parameters, ground conditions and cutter wear. And machine learning algorithms are able to establish complex models by mining the relationship between data, which have been widely used in the prediction of shield tunneling parameters (Huang et al., 2022). Some scholars have also tried to apply machine learning algorithms to tool wear prediction (Kilic et al., 2022; Mahmoodzadeh et al., 2021), but it is still dominated by tool wear prediction in full-section hard rock, and tool wear prediction is very rare for tunnelling process in which soft and hard strata interact with each other.

Therefore, this paper relies on the construction process of a large-diameter slurry pressure balanced shield tunnel in Shenzhen, and establishes an improved deep learning model, taking construction parameters and ground conditions as the input parameters, and cutter wear as output parameters. And with the help of principal component analysis for input parameter dimensionality reduction, and with the help of clustering algorithm for the introduction of artificial experience.

2 ALGORITHMS

2.1 Kmeans clustering method

Kmeans is an unsupervised machine learning method, which cluster a sample set by calculating the Euclidean distance between samples (Wang and Bai, 2016). The basic principle of the algorithm is:

- (a) Randomly select n points from the sample set as clustering centers;
- (b) Calculate the distance l_i from each sample $s_i = \{s_{i1}, s_{i2}, \dots, s_{in}\}$ to each cluster center $c_i = \{c_{i1}, c_{i2}, \dots, c_{in}\}$:

$$l_i = \sqrt{(s_i - c_i)^2} \quad (1)$$

And classify the sample into the category that the closest cluster center belongs to;

- (c) Calculate the geometric center c'_i of each category as the new clustering center:

$$c'_i = \frac{\sum_{l=1}^n s_n}{n} \quad (2)$$

- (d) Repeat step (b), (c) until the change in the position of the clustering center is less than the specified value or the maximum number of iterations is reached.

2.2 Spectral clustering method

Spectral clustering is also an unsupervised machine learning method, based on the principle of graph connectivity optimization. The basic principle of the algorithm is:

- (a) Initialize the weight matrix W and number of clusters n , where W is a $k*k$ matrix, k is the number of input parameters;
- (b) Calculate Diagonal matrix D where d_i is the sum of w_{ij} in W :

$$d_i = \sum_{j=1}^n w_{ij} \quad (3)$$

- (c) Calculate the Laplacian matrix $L=D-W$ and the eigenvectors e_1, \dots, e_n , set $E=[e_1|e_2|\dots|e_k]$;
- (d) For $i = 1, \dots, n$, define X_i the vector given by the i -th row of X ;
- (e) Calculate the eigenvalue, cluster the samples with the positive eigenvalue value in to the same category and repeat the steps until convergence.

Unsupervised clustering methods are able to automatically categorize construction parameters according to their correlations. Existing shield construction research shows that different construction parameter relationships reflect the tool wear: when the advance speed and thrust force are high, the cutter wears at a normal rate; the cutter wears faster when the chamber pressure is high and the total thrust is low; the cutter wears slowly when the total thrust is low, the cutter torque is low and the advance speed is normal. It can be seen that the cutter wear rate is different for different construction parameter relationships. Based on the clustering results of construction parameters in the above two methods, different cutter wear correction coefficients are assigned to different categories of construction categories, and this coefficient is used as an input parameter. The initial value of the correction coefficient is assigned according to the established research results, and the higher value represents the faster wear, the specific value is shown in Table 1.

2.3 Transformer method

Transformer algorithm was proposed by Vaswani et al. (2017), which is mainly used for natural language recognition problems. To apply it to the tool wear problem, its structure is slightly improved, and the structure of the improved Transformer model is shown in Figure 1: the input parameters are combined with the position encoding and fed into the encoder, and the number of encoders is N . Each encoder consists of a self-attention layer and a feed-forward layer and the residuals and regularization operations are immediately followed by each layer. After N encoders the data goes to decoders, the number of decoders is M . Each decoder consists of a self-attention layer, an

Table 1. Relationship between construction parameters and corresponding initial correction coefficients.

	Tool wear rate	Initial correction coefficient
Low thrust Low torque Normal advance speed Low chamber pressure	Normal	1.0
Low thrust Low torque Normal advance speed Low chamber pressure	Normal	1.1
Low thrust Low torque Normal advance speed Low chamber pressure	Fast	2.5
Low thrust Low torque Normal advance speed Low chamber pressure	Faster	3.0

encoding-decoding attention layer and a feed-forward layer, and each layer is also immediately followed by residual and regularization operations. After M decoders the data again goes through the feed forward layer with normalization and finally the predicted value is obtained.

Since different tools are installed on different cutter spokes and the cutting trajectories of neighbouring tools on the same spoke are usually not adjacent to each other, the interaction between tools is a complex spatial problem. The unique self-attention mechanism and position encoding method of Transformer is very suitable for this problem. To consider the position of the tools on the cutter head, the position code is adjusted. The original position code is:

$$PE_{(pos,2i)} = \sin(pos/10000^{2i/d_{model}}) \quad (4)$$

$$PE_{(pos,2i+1)} = \cos(pos/10000^{2i/d_{model}}) \quad (5)$$

where pos means the position of the feature, i.e., the installation radius of the tool. But on the cutterhead as shown in Figure 1, the tools with adjacent installation radius are not on the same spoke. Thus, the position code is adjusted as:

$$PE_{(pos,2i)} = \sin(pos/10000^{(2i+\theta/2\pi*6)/d_{model}}) \quad (6)$$

$$PE_{(pos,2i+1)} = \cos(pos/10000^{(2i+\theta/2\pi*6)/d_{model}}) \quad (7)$$

where θ is the angle between the spoke and the vertical direction. The coefficient of 6 means that there are 6 spokes on the cutterhead. By this adjustment, the position of the tools, including installation radius and angle of spoke, is taken into consideration. The position code after adjustment is shown in Figure 2.

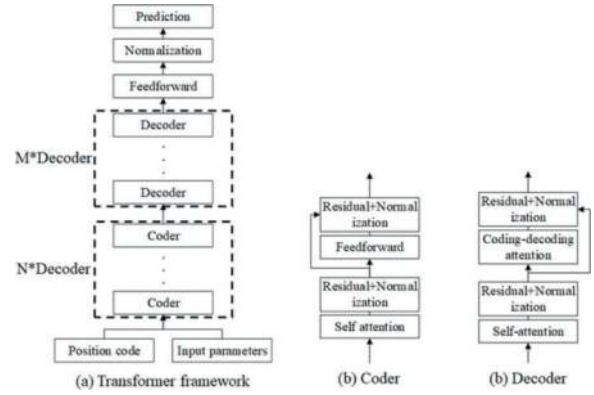

Figure 1. Improved Transformer model for predicting wear of disc tools.

Figure 2. Adjusted position code.

Transformer's positional coding step can consider the positional relationship between the input parameters, and the installation radius of the tool itself, as one of the input parameters, responds to the spatial position of the tools, so it can be used for positional coding to input the positional information of the tools into the model. The self-attention mechanism takes into account the interaction between the input parameters, and assigns a higher attention value to other tools or construction parameters that have a greater influence on one tool, so the Transformer model is well suited for the prediction of tool wear on the cutterhead, which has spatial position information.

2.4 Principle component analysis

The principle component analysis is a popular method for dimension reduction. It projects high-dimensional data to low-dimensional space through linear projection and expect the maximum amount of information, i.e. maximum variance in the low-dimension space, of the data as shown in Figure 3. Since the prediction problem is a high dimension problem, PCA is applied to improving the stability and accuracy of models. The specific procedure for principle component analysis is described in (Huang et al., 2022).

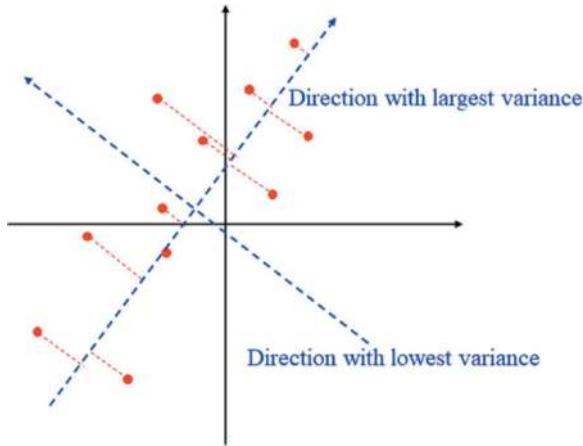

Figure 3. Schemes of principle component analysis.

2.5 Predictive model based on clustering, PCA with Transformer algorithm

The flow of the proposed prediction model based on clustering, PCA with Transformer algorithm is shown in Figure 4. The input parameters include four categories: construction parameters, tool parameters, stratigraphic parameters and wear correction coefficients. The construction parameters include total thrust, cutterhead torque, cutterhead rotation speed, chamber pressure and advance speed, which have obvious influence on the tool wear; the tool parameters include the installation radius of the tool and the cutting distance of the tool; the stratum parameters include the ratio of the area of soft and hard strata on the palisade surface; the wear modification coefficients are obtained by the kmeans clustering algorithm based on the construction parameters, and the initial value of the wear modification coefficients are assigned to the different clustering results. Different initial values of wear correction coefficients are assigned for different clustering results. The output parameter is the normal wear of the tools. The input parameters are fed into the Transformer model for training. The tool wear prediction model is obtained after the accuracy rate reaches the requirement or the maximum number of iterations.

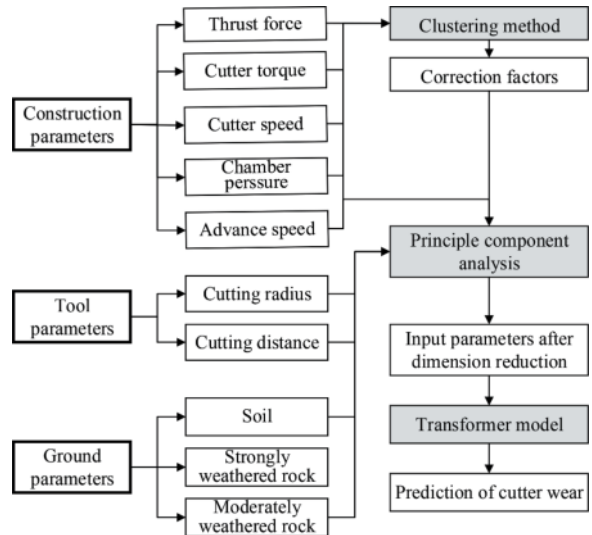

Figure 4. Prediction model based on kmeans clustering and Transformer regression.

3 DATA PREPROCESSING AND STRUCTURING

3.1 Data collection

Cutterhead of the shield machine as shown in Figure 5, the disc cutters are installed on the cutterhead. The installation radius of different disc cutter is different, and the distance crossed when the cutterhead rotates around is different. The larger the installation radius is, the longer the distance crossed when the cutterhead rotates around, and the corresponding wear is also larger. Therefore, the installation radius of the tool is used as an input parameter. In addition, the number of rotations of the cutterhead determines the cumulative cutting distance of the tools, so the number of rotations of the cutterhead is used as an input parameter.

Construction parameters are recorded by control system of shield machine, the construction parameters are recorded every 5 mins. As mentioned in Section 2.5, torque of cutterhead, cutterhead rotation speed, chamber pressure, total thrust, and advance speed are selected for the prediction of tool wear based on the existing research.

Based on the geological survey, the ground condition along the tunnel alignment can be obtained. For disc cutter, the wear is mainly caused by cutting hard rock. And the types of hard rock on the face of tunnel are strongly weathered rocks and moderately weathered rocks. For the same type of rocks, the physical properties are similar. Thus, the area proportion of different stratum on face is selected as the input parameters to reflect the ground condition.

3.2 Data denoising

The record of construction parameters usually contains noise. Thus, 3σ method is applied for the

Figure 5. Shield cutterhead and disc cutter.

denoising of construction parameters. The process of 3σ method is described in (Huang et al., 2022). Then, average of construction parameters during the construction of each ring is calculated for the represent of construction parameters of this ring. The reason for using the average is two-fold. One is that calculating the mean can eliminate some random errors. The other is that the wear of cutters are recorded after the construction of one ring and the data format based on the ring facilitates the data structure of the construction parameters and wear records.

3.3 Data structuring

The cutter wear, cutter radius, ground condition and construction parameters are multisource data. They should be structured to be used for the establishment of deep learning model. Analysing the problem, it can be seen that wear of cutter tools is the focus of this study. Thus, the data are structure based on the record of tool wear. Due to the complexity of tool wear detection, its detection frequency is uncertain. The ring number is selected for the description of the detection range of tool wear. Then, the averages of construction parameters are calculated as:

$$p_{ave} = \frac{1}{Ring_B - Ring_A} \sum_{i=Ring_A}^{Ring_B} p_i \quad (8)$$

where p_{ave} is the average of construction parameters in this wear detection range, $Ring_A$ is the ring number of beginning of the wear detection, $Ring_B$ is the ring number of the end of the wear detection. For example, a cutter is detected in Ring 18, then detected in Ring 50, then for the record detected in Ring 50, $Ring_A$ is 18 and $Ring_B$ is 50. p_i is the

average of construction parameters during the construction process of $Ring_i$.

For ground condition, the area proportion of different stratum is calculated at different ring number based on the geological survey. Then the averages of ground condition in each wear detection range is calculated as shown in formula (7).

For cutter installation radius, the radius of each cutter is shown in Figure 6. There are total 79 cutters on the cutterhead, each cutter has unique installation radius. In data structure, the corresponding installation radius is matched to the corresponding wear record.

Figure 6. Installation radius of each disc cutter.

4 ENGINEERING APPLICATION

4.1 Database for deep learning

During construction, there are total 217 records of wear detection. Based on the method of data structuring, there are finally 217 samples in the database. For each sample, its dimension is 12, containing 5 construction parameters, namely torque of cutterhead, cutterhead rotation speed, chamber pressure, total thrust, and advance speed; 2 tool parameters, namely installation radius and cutting distance; 3 ground conditions, namely proportion of soil, strongly weathered rock and moderately weathered rock; 1 correction coefficient based on the results of clustering and 1 tool wear record. Among them, the construction parameters, tool parameters, ground conditions and correction coefficient are input parameters, tool wear is output parameters.

4.2 Results of clustering

In this research, two clustering methods are applied to cluster the construction parameters. For different categories, the values of construction parameters are different as shown in Figure 7. The black points, representing category 1, have low pushing force, low cutterhead torque and low advance speed, meaning that the wear speed of tools is low. The red points,

representing category 1, have normal pushing force, normal cutterhead torque and normal advance speed, meaning that the wear speed of tools is normal. The green points, representing category 2, have large pushing force, large cutterhead torque but normal advance speed, meaning that the wear speed of tools is fast. The brown points, representing category 4, have normal pushing force but low cutterhead torque and low advance speed, meaning that the wear speed of tools is large. Figure 7 shows the results of spectral clustering. For Kmeans method, the 4 categories have the similar relationship.

Figure 7. Relationship between construction parameters in the Kmeans results.

The stratum on the face include soil, strongly weathered rock and moderately weathered rock. Based on the geological survey report, the area proportion of these three strata along tunnel axis is shown in Figure 8 with the Kmeans results. The black line represents the area of soil on the face. The red represents the area of strongly weathered rock on the face. The blue line represents the area of moderately weathered rock on the face. The black semi-transparent box marks out the region of category 3 of Kmeans result. Similarly, the red box marks category 1, the green box marks category 2 and the brown box marks category 3. In category 3, it is the beginning of the construction and the driver set the construction parameters carefully, so the thrust force, cutterhead torque and advance speed are all low and the wear speed of tools is low. While in category 2 and category 3, the area of hard rock on face increases but the driver does not adjust the construction parameters properly. Thus, the wear speed of tools increases quickly. By assigning different values to different categories of clustering, the artificial experience is introduced into the model, i.e., higher correction coefficients represent higher tool wear rates.

In order to eliminate the influence of unit of the input parameters, a mix-min normalization is applied to the input parameters. The final size of dataset is 217*12. There are total 217 samples in the dataset with 12 features.

4.3 Result of the model

Training of each epoch requires about 0.1s and ultimately 1000 epochs were trained. Since the prediction of tool wear is regression problem the

Figure 8. Area of different strata on tunnel face in longitudinal direction with the results of Kmeans.

evaluation factors are chosen as mean absolute error (MAE), mean squared error (MSE) and goodness of fit (R^2). They are calculated as:

$$MAE = \frac{\sum_{i=1}^{n_{test}} |y_i - y_{pi}|}{n_{test}} \quad (9)$$

$$MSE = \frac{\sqrt{\sum_{i=1}^{n_{test}} (y_i - y_{pi})^2}}{n_{test}} \quad (10)$$

$$R^2 = 1 - \frac{\sum_{i=1}^{n_{test}} (y_i - y_{pi})^2}{\sum_{i=1}^{n_{test}} (y_i - y_{ave})^2} \quad (11)$$

where y_i is the i^{th} true value, y_{pi} is i^{th} prediction value, y_{ave} is the average of true value. The lower values of MAE and MSE mean lower prediction error of model. R^2 ranges from 0 to 1, reflecting the proportion of real information reflected by the model. The closer R^2 to 1, the better the model is.

The tool wear detection results during the construction of this large-diameter slurry pressure balanced shield tunnel are used to validate the model, and the final model prediction results are shown in Figure 9, the the MAE is 3.3 mm, the MSE is 4.3mm and the R^2 is 0.73. In this project, the allowable tool wear of the disc cutter is 40 mm, and therefore the error of 3.3 mm or 4.3mm is acceptable for the complex problem of predicting the tool wear in composite stratum. And the prediction result of the model can provide a reference for the current tool wear, so as to arrange the replacement of tools in time to ensure the construction efficiency and safety.

5 RESULTS

An advanced Transformer method is proposed for the prediction of the tool wear of disc cutter during shield tunnelling in composite stratum. Clustering methods are applied to cluster the construction parameters for the introduction of artificial experience, position code is adjusted to consider the position of the disc cutter on the cutterhead, and

Figure 9. Results of predicting model.

principle analysis is applied for the dimension reduction of the input parameters. The following conclusions are obtained:

- 1) The clustering method can classify the construction parameters based on the relationship between the construction parameters, and the clustering results reflect the construction state of the shield. The wear rate of the tool varies in different construction states, and different correction coefficients are assigned to different construction states by the introduction of wear correction coefficients, so that the influence of the construction state is introduced into the prediction model to help the model accurately predict the wear of the tools.
- 2) Advanced position code is proposed to distinguish different location and relative positional relationship of disc cutters. The closer the cutters are, the more obvious the mutual influence of wear between them.
- 3) Considering the construction parameters, tool parameters, ground parameters and the correction coefficients, as well as optimizing the position code, the proposed Transformer model can predict the wear of disc cutter with the error of only 3.3 mm. The corresponding tool change program can be formulated according to the prediction results during construction.

ABSTRACT: Soil conditioning is used in most earth pressure balanced (EPB) shield tunnelling projects and foam is one of the most used chemical additives. Foam with sufficient stability should have a suitable half-life time to ensure the effectiveness of soil conditioning during segment construction and through the whole process of excavated soil discharge. This study explained the limitations of current half-life time measurement method by introducing the influence of foam expansion ratio (FER) and foam column height. A modified foam half-life time test method is brought up by measuring the drainage of foam column with a certain height. The modified measurement method is specific enough to ensure that comparable results are obtained by scholars and engineers worldwide. It is found that both Cf (foam concentration) and FER play important roles in half-life time and they would influence each other, which can be explained by the surface tension of the foaming agent solution.

Keywords: EPB shield, soil conditioning, foam stability, half-life time, surface tension

1 INTRODUCTION

During EPB shield tunnelling, soil conditioning with foam can be used to reduce the permeability of sand, decrease the clogging potential in clay and increase the workability and compressibility of conditioned soil (Mori et al., 2018; Wang et al., 2020; Thewes and Budach, 2010; Thewes et al., 2012).

The stability of foam is crucial during the soil conditioning in sand, a sufficient foam stability is needed to ensure stable mechanical properties of conditioned soils during the mixing of excavated soil and the discharge of soil at the end of screw conveyor (Peila et al., 2007). The stability of foam can be evaluated by a parameter called half-life time. In shield tunnelling area, the half-life time is defined as the time needed for 80 g foam to lose 40 g weight (EFNARC, 2005). Bezuijen et al. (1999) found that foam can reduce the permeability of conditioned sand by replacing pore water in the sand, and foam could stay stable for over 24 h when mixed with sand. Wu

et al. (2018) indicated that the half-life time of foam is much longer if evaluated by the foam volume loss than the foam weight loss. Wu et al. (2020) analysed the sand grain-foam pictures and performed compression and vane shear tests in 60 minutes after the foam-sand mixture is prepared; they found that foam is stable in the mixture during this period. Zhao et al. (2021) indicated that anti-clay agents could reduce the stability of foam bubbles. El Souwaissi et al. (2023) found that the half-life time measured by foam volume and foam weight loss share the same trend despite the differences in measured values.

It is found in chemistry area that foam stability changes with surface tension which is caused by the concentration change in foaming agent solution. In shield tunnelling area, Sebastiani et al. (2019) performed extensive half-life time tests with various foaming agent products and concentrations, a foaming agent classification system was proposed based on the test results. Wan et al. (2021) and Li et al. (2022) measured the half-life time of foam at various concentrations and found

*Corresponding author: zhongtian.chen@ugent.be

that the half-life time trend to be stable after Cf is higher than 2%. Carigi et al. (2022) found that the stability of foam can be influenced by the concentration of foaming agent solution and the flow rate in the foam generator.

The extensive work about foam stability gives valuable instruction to soil conditioning, yet limited studies take the surface tension of foaming agent solution in consideration. This paper performs half-life time tests and explains the limitations of current measurement methods based on the test results. A modified measurement is brought up to avoid current limitations. The surface tension of foaming agent solution is also measured to further explain the stability of foam.

2 METHODOLOGY AND MATERIAL

A widely used commercial foaming agent is tested in this study and the foaming agent is diluted to desired concentration by tap water. The tested foaming agent is regular type for common use without any other polymer and anti-clogging chemicals.

The foaming agent is first mixed with tap water at rotation speed around 6 rpm to prepare the foaming agent solution. Foam is generated by a small-scale laboratory foam generation device which is introduced in detail in Chen et al. (2022). The flow rate of air and liquid is controlled carefully to provide foam with a precise and stable FER. A foam tester which meets the requirements of EFNARC 2005 is used to test the half-life time of foam, as shown in Figure 1. The test device consists of two acrylic parts, a cylinder and a funnel. Three cylinders are used in this study, the dimensions of these cylinders are shown in Table 1 and the funnel has inner height of 6 cm.

Table 1. Dimensions of test cylinders.

Test cylinder	Inner diameter (cm)	Height (cm)
A	13	10
B	5	20
C	13	30

A hydrophilic membrane with pore size 2 μm is placed between the cylinder and the funnel to separate foam bubbles and drainage. The diameter of foam bubbles with various concentrations at FER 10 is shown in Figure 2, it shows that the pore size 2 μm can separate all foam bubbles. The foam is filled in the test device after the hydrophilic membrane is saturated and installed. The actual FER of the generated foam is checked at the beginning and the end of filling process by measuring the weight of foam in a 70 ml container. It is found that the

Figure 1. The half-life time test device.

actual FER can be controlled at ± 1 around the target FER. The weight of the drainage is recorded at a frequency of 1 Hz after the foam is filled in the container for the half-life test.

Figure 2. The foam bubble diameter at various concentrations.

The surface tension of the foaming agent solution used in this study is tested by the platinum plate method, which has an accuracy of 0.1 mN/m. The platinum plate is cleaned carefully before each test to ensure the accuracy of test results.

Figure 3. The platinum plate method device.

3 TEST RESULTS

3.1 Results following current standard

Half-life time tests are first performed following exactly the requirement of EFNARC (2005). The size of foam half-life time test device used in this section is shown in Table 1. The weight of tested foam is 80 g for all tests in this section, the weight of tested foam and the size of test device both meet the requirement of EFNARC (2005), where the size is regulated as 1 to 2 liters and the foam weight is regulated as 80 g. The concentration of foaming agent in this section is 3%, which is the suggested value by the foaming agent producer.

The test results following current standard are shown in Table 2, it shows that tests performed in the device with 5 cm diameter have longer half-life time (around 900 s) due to the higher foam column height. For tests performed in cylinder with diameter 13 cm, the half-life time measured is much shorter, which is around 385 s. Results show that although tests in Table 1 all follow the EFNARC (2005) standard, the half-life time measured by test cylinders with various diameters are completely different and even not comparable.

Table 2. Test results with different foam height.

Size (cm)	Target FER	Actual FER	Foam height (cm)	Half-life time (s)
D 5, H 20	5	4.7, 5.2, 5.1	20	905, 898, 909
D 13, H 10	5	5.0, 4.9, 5.2	3	380, 386, 389

Half-life time tests of foam with various FERs are performed in the foam test cylinder with diameter of 13 cm, the results are shown in Table 3. It shows that

foam with FER 15 has much longer half-life time (around 1150 s). This is partly due to the higher foam column. The results show that the current standard for foam half-life time measurement is not suitable for the measurement of foam with different FERs, as foam with fixed weight will have different foam height with changing FER. The longer half-life time for foam with higher FER agrees well with the findings of Wu et al. (2018), where it is found that the longer foam column, the longer the half-life time.

Table 3. Test results with different FER.

Size (cm)	Target FER	Actual FER	Foam height (cm)	Half-life time (s)
D 13, H 10	5	5.0, 4.9, 5.2	3	380, 386, 389
D 13, H 10	15	14.7, 15.5, 15.4	9	1152, 1139, 1158

3.2 Drainage curves at various FERs

To further study the influence of FER, half-life time tests are performed in Cylinder C shown in Table 1. The tests with various FERs in this section are performed with a fixed foam column height of 30 cm to avoid the influence of foam column height difference. The drainage history curves are recorded in Figure 4. It shows that the drainage of foam with FER 5.6 starts directly at the beginning of the test, thus reaches the half-life time earlier than foam with higher FER. An obvious zero drainage stage shows for foam with FER 13.5, leading to a longer half-life time. For both FERs the drainage speed decreases after reaching the half-life time. The drainage history curves of Figure 4 show that the half-life time difference in Table 3 is not only influenced by the foam column difference, but also influenced by the permeability of foam

Figure 4. Typical drainage history curves, dash lines represents the half-life time and corresponding drainage weight.

column itself. It is difficult to analyse the permeability difference with current standard, as the influence of foam column height cannot be excluded.

3.3 Half-life time at various concentrations

Half-life time tests of foam with various concentrations are performed by the two test cylinders shown in Figure 1. The FER of tested foam for all tests in this section is 5. The test results in Figure 5 show that the half-life time increases with concentration until reaching a stable value at concentration of 3%. Further concentration increase does not lead to further half-life time increase. Foam with column height 20 cm has longer half-life time, yet the concentration 3% which corresponds to a stabilized high half-life time is not changed.

Figure 5. Half-life time with various concentrations.

3.4 Surface tension with various concentrations

The surface tension of foaming agent solutions with various concentrations is measured to further study the influence of concentration on foam stability. The results in Figure 6 show that the surface tension starts to decrease sharply at concentration 0.001% and reaches a relatively stable value at concentration 0.1%. The surface tension reaches the lowest value at concentration 3%, which corresponds well to the concentration with highest half-life time.

3.5 Proposed new half-life time measurement method

The half-life time test results reported above show that the major flaw of current half-life measurement method is, it that the size of the test device is not described sufficiently specific. Besides, the fixed initial weight regulation of current standard makes it difficult to evaluate the half-life time of foam with various FERs, as foam with various FERs will have different foam column height, it is difficult to tell

Figure 6. Surface tensions at various concentrations.

whether the stability difference is caused by foam column height or the permeability of foam itself. Both limitations are caused by the fact that the foam half-life time will be greatly influenced by the foam column height.

Thus, a modified foam half-life time test method can be proposed. In the new test method, the foam column height at the beginning of the test should be regulated instead of foam weight, while the half-life time is still the time needed for the drainage weight to reach half the initial foam weight.

4 CONCLUSIONS

This paper studies the stability of foam by performing extensive half-life time tests. Test results show that foam half-life time increases with foam column height and FER. Limitation exists in the current foam half-life time measurement method, as the current method did not regulate the size of the test device specific enough and the fixed foam initial weight could lead to various foam column height with changing FER. A modified half-life time measurement method is proposed with a fixed initial foam column height instead of a fixed initial foam weight. It is also found that for foam with FER 5, foam stability decreases with decreasing foaming agent solution concentration when the concentration is lower than 3%. The possible reason for the decreasing foam stability at low concentrations could be that foam has larger surface area than the foaming agent solution, the larger surface area leads to a lower surfactant density, thus decreasing the foam stability.

Automatic excavation system for directional control in shield tunneling using machine learning techniques

Jian Chen*, Hiroki Kamada, Naohiko Takamoto, Hirokazu Sugiyama, Shinya Yamamoto & Tetsuya Aoyama

Shimizu Corporation, Tokyo, Japan

ABSTRACT: In shield tunneling, it is essential to appropriately control shield jacks according to the attitude of a shield machine and geological conditions to follow a planned alignment. However, the quality of the directional control of a shield machine is dependent on the skill of its operator. Here, we develop an automatic excavation system that proposes the optimal method for controlling shield jacks equivalent to the techniques utilized by a skilled operator. The developed automatic excavation system has an algorithm consisting of two steps. In the first step, the necessity of operations of shield jacks is determined to avoid excessive operations. In the second step, the optimal point where the resultant force of shield jacks should be acted upon to control the propulsive direction of a shield machine is predicted. Both steps use the models trained by gradient tree boosting with the operational data related to the actions of skilled operators. Feature variables of these models are the monitoring data referred to operators such as the shield machine's yawing, pitching, rolling, deviation from the planned alignment, and so on. The moving average is also added to feature variables to consider temporal variations. To investigate the feasibility of the algorithm, the models were trained using the data obtained at a shield tunnel site. It was confirmed that the outputs of the models were comparable to experts' operations, comparing the actual operational data with the prediction results of the models. In addition, the shield machine was driven according to the automatic excavation system to validate its performance at the site. The deviation from the planned alignment and the attitude of the shield machine were within the tolerances. The result shows the applicability of the automatic excavation system in real environments. This indicates the future's possibility of self-driving shield machines.

1 INTRODUCTION

Japan's rapidly declining birth rate and aging population will lead to a decline in the labor force, and many industries are predicted to have labor shortages in the future. In particular, the shortage of workers in the construction industry is a serious problem. This also means fewer highly skilled shield operators in the construction industry. Therefore, technological innovations in shield tunneling are expected to reduce labor time and assist inexperienced shield operators.

The quality of shield tunneling depends on the skill of the operator who controls the shield machine. Thus, the shortage of skilled operators leads to the deterioration of the shield tunnel's quality. Self-driving shield machines are effective in ensuring the accuracy and productivity of tunneling, but there have been several challenges in their development. For example, the operations of a screw conveyor for discharging excavated soil and shield jacks for advancing a shield machine were automated using fuzzy

models (Kuwahara et al., 1988). There has also been a study in which the shield jacks to be activated were selected automatically by using monitoring data to estimate the physical properties of the ground and calculate the moment required for excavation (Tateyama et al., 1994). However, these methods did not lead to the full automation of shield machines: differences from ground and construction conditions in various locations meant that it was difficult to predict the proper operations of shield machines.

Recently, techniques of machine learning have attracted attention. It has become possible to build high-performance models easily. The realization of self-driving shield machines is feasible if machine learning techniques are applied to the monitoring data of shield tunneling. It has already been shown that models capable of making judgments equivalent to that of an operator can be constructed using machine learning (Sugiyama et al., 2017, Kubota et al. 2023). These models predict how the rotational speed of a screw conveyor should be set and the optimal point

*Corresponding author: jianchen77@gmail.com

at which the resultant force of shield jacks should be acted upon. To achieve self-driving shield machines, an automatic excavation system for directional control in shield tunneling using machine learning techniques was developed recently.

The automatic excavation system consists of two types of AI systems as core parts: a Digging instruction support AI system (hereinafter referred to as Instruction AI) for planning the excavation instructions and a Jacking operation support AI system (hereinafter referred to as Operation AI) for automatic jacking operation of shield machines.

This study presents the configuration and the applicability of the automatic excavation system. Firstly, the AI models were trained using the data obtained at a shield tunnel site and evaluated for accuracy. It was confirmed that the outputs of the models were comparable to experts' operations, comparing the actual operational data with the prediction results of the models. In addition, the shield machine was driven according to the automatic excavation system to validate its performance at the same site. The deviation from the planned alignment and the attitude of the shield machine were within the tolerances. The result shows the applicability of the excavation system in real environments. This indicates the future possibility of self-driving shield machines for more actual shield tunneling sites.

2 SHIELD TUNNELING METHOD

The upper half of Figure 1 shows an image of the conventional construction cycle in the shield tunneling method. In this method, a tunnel is constructed in day and night shifts. During the short shifts, the position and attitude of the shield machine and the finished shape of the tunnel rings are surveyed, and then the

next construction plan is made based on the surveying results. In the construction plan, digging instructions are created for each ring that is scheduled to be excavated for half a day. The digging instructions include the instruction items for controlling a shield machine and assembling segment rings. A skilled shield operator then manipulates the shield machine with three types of actions: controlling the propulsive direction of the shield machine, making the pressure in the chamber equal to that of the ground, and injecting an additive agent to the chamber and a bulking agent to the tail voids.

Controlling the propulsive direction of a shield machine is the most important task in ensuring the accurate construction of a shield tunnel. The operator must manipulate the shield machine while comparing the instruction values with the values shown on the shield machine's sensors. The instruction values are the shield machine's azimuth direction, its pitch, the extension lengths of the shield jacks' strokes, and so on. It is not easy to manipulate a shield machine to match all the instruction values. When the operator activates only some shield jacks, the force acting on the shield machine is decentered, and the shield machine can veer to follow the planned alignment, so operators need to be skilled at their work.

3 DIGGING INSTRUCTION SUPPORT AI

3.1 Overview

In shield tunneling, tunnels are constructed by combining standard segments and taper-shaped segments for tunnel alignments that include curved sections. In addition, tunnel excavation in curved sections is performed by adjusting the shield jack stroke and using a combination of articulation mechanism and an over-cutting device.

Figure 1. Shield tunnelling by the conventional method and AI-based methods.

The above considerations will be carried out before construction, but as errors will occur between the planned tunnel alignment and the actual measurements during construction, it will be necessary to conduct routine surveying and re-plan the digging instructions. Conventionally, these digging instructions disseminated to operators were calculated through theoretical calculations based on the geometry of the shield machine and the planned alignment.

To perform the above instructions, the Instruction AI searches for the optimal solution using machine learning and genetic algorithms through repeated three-dimensional simulations of segment allocation methods and shield machine tunneling methods, and then proposes the contents of digging instructions.

3.2 Exploration of instruction AI

In proposing the contents of the digging instructions, the Instruction AI will conduct a trial run on the following items.

3.2.1 Segment assignment

In the planning process, multiple types of segments such as straight and taper-shaped segments are provided and assigned along the planning tunnel alignment consisting of straight lines and curves so that the gaps between each segment and the planning alignment fall within a tolerance.

There are two demands in the segment assignment problem. (1) To make the gaps between each segment and the planning alignment fall within the tolerance. (2) To reduce the amount of soil excavated by the shield machine. The former demand is treated as an inequality constraint, and the latter demand is treated as an objective function. Segment assignment was defined as the constrained combinatorial optimization problem.

3.2.2 Searching methods for optimal solutions

The Instruction AI was built as an AI simulation program that combines shield construction experiences and a patented co-evolutionary combinatorial optimization algorithm inspired by evolutionary computation (Kato, et al. 2019).

The instruction AI performs simulated tunneling on a given planned alignment, based on trial conditions set by the AI, such as the digging plan of the shield machine and the allocation plan of segments. The AI scores the results using errors in the tunneling trajectory relative to the tunnel alignment and the degree of interference between the shield machine, segments, and excavated ground as evaluation indices. If the error exceeds the allowable value during the trial, or if there is a possibility of interference between the shield machine and the segment, the trial is terminated at that point and a new simulation is run with the trial conditions re-set. The AI evolves and learns what conditions can be selected to obtain the highest score over a large number of trials, and finally selects the plan that shows the highest score, which

cannot be further improved, as the solution and develops it into a digging instruction plan.

3.2.3 Reduction of impact on surrounding ground

During curved tunneling, a copy cutter is used to expand the excavated cross-section (extra digging) while the shield machine passes through. The larger the excavated cross section, the greater the influence on the surrounding ground, such as loosening of the ground due to stress release.

This AI system can also propose a plan with no excess or deficiency in diameter expansion, thereby reducing the impact on the surrounding ground caused by the shield machine's passage and contributing to the reduction of construction waste volume by minimizing the amount of excavated soil.

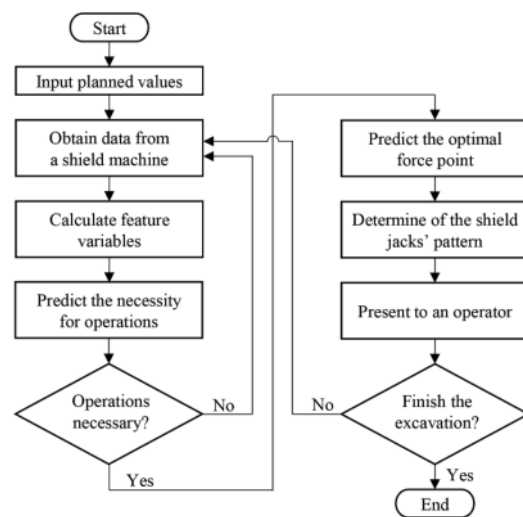

Figure 2. Processing flow executed by the operation AI.

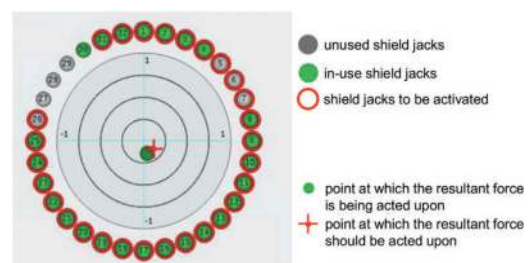

Figure 3. Example of the presented jacking pattern.

4 JACKING OPERATION SUPPORT AI

4.1 Outline

The Operation AI proposes the optimal way to control the shield jacks and to make a shield machine follow a planned alignment. Figure 2 shows the processing flow executed by the Operation AI. In the first step, digging instructions are prepared by the Instruction AI or a supervisor based on the surveying results for the daily excavation. When the shield

machine starts to excavate, the Operation AI obtains data from the shield machine and calculates the feature variables. The necessity for shield jacks' operations is predicted from the feature variables using a machine learning model. When necessary, other machine learning models are used to predict the optimal point at which the resultant force of the shield jacks should be acted upon to control the propulsive direction of the shield. The shield jacks to be activated are selected from the predicted point and presented to an operator, as shown in Figure 3.

4.2 Gradient boosting decision tree

A gradient boosting method (Jerome 2001) is one of the ensemble learning methods. A strong learner is built by combining multiple weak learners. When decision trees are used as weak learners, this method is called a gradient boosting decision tree (GBDT). The GBDT builds a strong learner through the following process. An initial strong learner $F_0(x)$ is given as

$$F_0(x) = f_0(x) \quad (1)$$

where x is a vector of feature variables and $f_0(x)$ is a weak learner of a decision tree. The root-mean-square error E_0 of $F_0(x)$ is calculated as

$$E_0 = \sqrt{(y - F_0(x))^2} \quad (2)$$

where y is a vector of the target values. A weak learner is $f_1(x)$ built with E_0 as the target value and connected to the strong learner:

$$F_1(x) = f_0(x) + f_1(x) \quad (3)$$

When this process is repeated M times, the following strong learner is obtained:

$$F_M(x) = f_0(x) + f_1(x) + \dots + f_M(x) \quad (4)$$

The GBDT can build a high-performance learner by connecting weak learners to reduce the error. In this study, XGBoost, an open-source GBDT library, was used to build the machine learning models.

4.3 Data for machine learning models

Table 1 shows the data for three machine learning models used by the Operation AI. One model predicts the necessity for shield jacks' operations, using F_c as the target variable (F_c -Model). F_c is given as 1 when in-use shield jacks were changed by an operator and as 0 when they were not. The other two models predict the horizontal and vertical coordinates of the point at which the resultant force of shield jacks should be acted upon, using F_x and F_y as the target variables (F_x -Model and F_y -Model). F_x and F_y are calculated from each thrust of the shield jacks. The variables other than F_c , F_x , and F_y are the monitoring data that an operator refers to during the manipulations of a shield machine. These include the information on the shield machine's states and the deviation from the planned values. In addition, the moving averages between 1 and 10 s, 11 and 20 s, 21 and 30 s, and 31 and 60 s are added to feature variables because an operator would consider temporal variations.

4.4 Predicting the necessity for shield jacks' operations

The F_c -Model predicts the necessity for shield jacks' operations to avoid excessive operations. These operations are deemed necessary when a few minutes have passed since the previous instruction of the operation system and when the output of the F_c -Model is more than the threshold.

Table 1. Data for machine learning models.

Variable	Unit	Target	Machine's state	Difference from plan
Binary data of the operator's manipulations (F_c)	-	✓		
Horizontal coordinate of the resultant force point (F_x)	-	✓		
Vertical coordinate of the resultant force point (F_y)	-	✓		
Torque (To)	%		✓	
Velocity (Ve)	mm/min		✓	
Thrust (Tr)	kN		✓	
Face pressure (Fp)	MPa		✓	
Pitch (Pt)	deg		✓	
Roll (Ro)	deg		✓	
Deviation from the planned left-right difference of the extensions of shield jacks' strokes (Dj)	mm			✓
Deviation from the planned azimuth direction (Dd)	deg			✓
Deviation from the planned pitch (Dp)	deg			✓
Horizontal deviation from the planned path (Dh)	mm			✓
Vertical deviation from the planned path (Dv)	mm			✓

Figure 4. Probability distribution by the Fc-model.

Most of the F_c are 0 because an operator controls shield jacks once in several tens of seconds to several hundreds of seconds. If the F_c -Model is built using raw F_c as the target variable, almost all values outputted by the F_c -Model are 0. For this reason, the F_c -Model is trained with weighted data.

The threshold must be set to predict whether the operations of shield jacks are necessary. Figure 4 shows the concept of the probability distribution of the predicted values outputted by the F_c -Model. The numbers of true negatives (TN), false negatives (FN), true positives (TP), and false positives (FP) can be calculated if the threshold is fixed. Here, the threshold is set to minimize the balanced error rate (BER).

$$BER = 0.5 \times \left(\frac{FP}{TN + FP} + \frac{FN}{FN + TP} \right) \quad (5)$$

When the output value of the F_c -Model is larger than the threshold, the operations of shield jacks are necessary.

4.5 Predicting the optimal force point

The optimal point at which the resultant force of shield jacks should be acted upon is predicted by the F_x -Model and F_y -Model. When the operations were predicted to be necessary, these models outputted the horizontal and vertical coordinates of the force point. The F_x -Model and F_y -Model are trained with the data classified as TP and FN in Figure 4. It is considered that more accurate models can be built because only characteristic data that were predicted to require the operations are used.

Furthermore, Operation AI calculates the pattern of shield jacks based on the resultant force point predicted by the machine learning models.

4.6 Ensuring the safety of operation AI

The Operation AI is equipped with a safety function for proper training and good-quality prediction of the aforementioned AI models. This function is divided into two parts, and if all of these are in order, the data is passed to the AI to make predictions.

4.6.1 Input-data check

The Operation AI reads the data to be passed to itself and checks for missing data or data that would be outside the measurement range of the instruments. Depending on how long such a condition persists, the AI determines if it is abnormal or urgent, displays an error, and asks the operator to make a decision.

4.6.2 Unlearned check

The Operation AI verifies if the data is within the training range of the AI model and if it can provide results according to the training results. If the data is not within the learning range, it is determined to be anomalous.

5 ON-SITE IMPLEMENTATION OF THE AUTOMATIC EXCAVATION SYSTEM

5.1 Site description

The shield machine was driven according to the automatic excavation system to validate its performance in a shield tunnel site. The shield tunnel site has a total length of 1,526 m, including two curve sections, which consist of 1 curve with a radius of 30 m, and 1 curve with a radius of 60 m respectively. It was constructed by a shield machine with a diameter of 4.08 m.

5.2 Verification of instruction AI

As a validation of the Instruction AI, a straight alignment composed with 40 rings (R1390 to R1429) was planned. Constraint conditions during planning were set as follows: alignment error within ± 35 mm, tail clearance of 5 mm or more. Under these conditions, AI was able to complete the planning in approximately 5 minutes.

Figure 5 shows the calculated deviation by the Instruction AI from the planned alignment, and Figure 6 shows the calculated tail clearance. It can be said that the planning was successfully completed, as the set constraint conditions were satisfied.

In addition, the digging instruction values by the Instruction AI did not deviate significantly from the instruction values created by the staff, indicating that the Instruction AI was able to plan reasonable instruction values.

5.3 Verification of operation AI

As a validation of Operation AI, an automatic excavation process for the entire 16 rings was conducted for the directional operation of the shield machine. Figure 7 shows the management screen when automatic operation is being performed in the No. 751 ring.

Figure 8 shows the azimuth angle and their instruction values at the end of digging for each ring in the section where automatic excavation was

implemented, and Figure 9 shows the vertical coordinates of the shield machine and their instruction values. These figures indicate that the digging error by the automatic excavation was about ± 0.02 degrees in azimuth and ± 2 mm in vertical coordinates. This indicates that the developed automatic excavation system was able to dig the tunnel without any quality control problems in this verification experiment.

Figure 5. Deviation from the planned alignment.

Figure 6. Tail clearance between the shield and segments.

Figure 7. Management screen of automatic operation.

Figure 8. Azimuth results by automatic operation.

Figure 9. Vertical coordinate results by automatic operation.

6 CONCLUSIONS

This study developed an automatic excavation system for directional control in shield tunneling using machine learning techniques. By presenting how shield jacks operate, the automatic excavation system makes it possible to ensure the quality of shield tunnels in a way that does not depend on the skill of an operator. The following conclusions were derived by evaluating the performance of the machine learning models and the automatic excavation system.

The deviation from the planned alignment and the attitude of the shield machine were within the tolerance levels when the shield machine was driven by the automatic excavation system. No instruction that adversely affected the quality of the tunnel was outputted by the system. The result shows the applicability of the automatic excavation system in real environments.

The automatic excavation was limited to a straight alignment at this time, but shortly, automatic excavation in curved sections, where more frequent jacking operations are required, is planned.

ACKNOWLEDGMENTS

We would like to express our sincere gratitude to all the people involved, including the client, who kindly agreed to allow us to conduct on-site verification in the development of the system.

ABSTRACT: Setting a super-large diameter shield tunnel undercrossing an existing tunnel in upper-soft and lower-hard composite stratum in Southern China as an example, this paper studies the surface settlement and the deformation of the existing tunnel due to the undercrossing construction applying the FEA method. The results of the numerical simulation and the monitoring data indicate the surface settlement and the deformation of the existing tunnel are both within the control standard and the risk level of the undercrossing construction is under control. By setting up test sections, strengthening synchronous grouting, controlling driving posture and construction parameters, strengthening construction monitoring, and so on, the successful undercrossing construction by a super-large diameter shield tunnel through an existing tunnel can be ensured.

Keywords: Super-large diameter shield tunnel, Undercrossing construction, Upper-soft and lower-hard composite stratum, Numerical simulation, Control measures

1 OVERVIEW OF THE PROJECT

In Guangdong Province, southern part of China, there is currently undergoing a north-south-direction underground urban expressway project. The total length of the main road of the project is about 4.77km and the construction of the project consists of surface streets, a cross-line bridge, drilling & blasting (D&B) tunnels, shield tunnels and cut-and-cover tunnels, among which the main line shield tunnel under construction adopts the cross-section design of a single-tube, double-deck, 4-lane dual-carriageway tunnel with urgency parking strips.

The length of the main line shield tunnel is 1.71km and the shield tunnel is connected to the D&B tunnels and one cut-and-cover tunnel at each end. The outer diameter, inner diameter, thickness and width of the segment of the shield tunnel is 15.2m, 13.9m, 0.65m, and 2.0m respectively. To meet the demand of the small radius curve ($R=599.5m$) and to reduce the number of molds needed for segments prefabrication, the universal wedge-shaped segments with the wedge

amount of 80mm is designed for the project. Segments are connected by oblique bolts and erected in the way of stagger jointed erection. And shear pins are installed between segment rings to promote the shear performance of the shield tunnel.

There are many sources of risk alongside the route to the shield tunnel construction, including shield crossing one operational cut-and-cover tunnel, one cut-and-cover tunnel under construction, more than 60 houses and buildings and some drainage and water supply pipelines, etc.

1.1 Overview of the undercrossing construction

The construction of the shield tunnel takes advantage of one super-large diameter slurry-balanced TBM. The excavation diameter is 15.76m. The undercrossing construction during which the shield travelled rightly under the cut-and-cover tunnel that was open to traffic in 2022 took place in March 2023. The floor plan of the undercrossing construction can be seen in Figure 1.

*Corresponding author: 897229441@qq.com

Figure 1. Floor plan of the undercrossing construction.

The construction of the existing tunnel is also part of the project. From what we can see in Figure 2, the existing tunnel is built in the form of a double-hole box culvert with width of 20500mm, floor thickness of 1000mm, roof thickness of 900mm, and tunnel clearance of 5500mm. Cast-in-place piles are applied for the excavation of the deep foundation pit and the waterproof curtain is formed by high-pressure spiral piles. Vertical distance from the shield tunnel to the cast-in-place piles is about 2.6m while to the tunnel floor is about 7.7m, as shown in Figure 3.

Figure 2. Cross section of the existing tunnel.

Figure 3. Cross section of the undercrossing situation.

1.2 Geological condition

From what we can see in Figure 3 and according to the geotechnical investigation report, during the undercrossing construction, the TBM crosses through the upper-soft and lower-hard composite stratum which consists of gravelly clayed soil (④), fully weathered granite (⑤₁) and strongly weathered granite (⑤₂). It is the typical ground in southern China. The description of soil strata can be seen in Table 1.

Table 1. Description of soil strata.

Layer No.	Soil Type	Description
①	plain fill	Cores are slightly compacted.
④	gravelly clayed soil	The liquid index of cores is mainly in the range of 0~0.25 and partly in the range of 0.25~0.75
⑤ ₁	fully weathered granite	Cores are hard soil.
⑤ ₂	strongly weathered granite	Cores are half blocky and half in soil state.
⑤ ₃	moderately weathered granite	Cores are in massive and short strut shape.

2 NUMERICAL SIMULATION

2.1 3D numerical model

To simulate the construction condition of the super-large diameter shield tunnel undercrossing the existing cut-and-cover tunnel in the upper-soft and lower-hard composite stratum, a 3D model for the numerical simulation is built using the software Plaxis 3D, as shown in Figure 4.

Figure 4. 3D numerical model.

The boundary conditions are set as free top surface, normal fixed side surfaces as well as fixed bottom surface. And the number of units and nodes of the model is 149870 and 234728 respectively.

Only gravity is considered in the 3D numerical model.

2.2 Constitutive model and assumptions

To simplify the numerical simulation, the constitutive model and assumptions are considered as follows.

- 1) The soil is isotropic, and the HSS model is chosen for the simulation. Parameters are determined according to the geotechnical investigation report and by applying the calculation method shown by Zhang (2022).
- 2) Since the excavation diameter is larger than the outer diameter of the shield tunnel, there is a gap between tunnel segments and the soil. Considering previous construction experience of the project and similar cases together, the ground loss ratio is taken as 5‰ to simulate the gap.
- 3) Assuming the surrounding rock and soil are relatively stationary during the tunnel excavation process.
- 4) The length of each advance of the TBM is 2m, which is the width of one segment ring.
- 5) The stiffness of the stagger-jointed segment is stable.

2.3 Numerical analysis results

The deformation curve of the cut-and-cover tunnel is shown in Figure 5. The settlement of the tunnel structure is 4.36mm due to the undercrossing construction, which meets the control requirement of no more than 20mm. The settlement of the tunnel floor shows the trend of firstly increasing and then decreasing. Due to the excavation face of the shield approached the existing cut-and-cover tunnel gradually, the disturbance caused to the soils also increased, resulting in the rising of settlement of the tunnel structure. After synchronous grouting as well as compensation grouting came into effect, the tunnel structure was lifted slightly, inducing the settlement value to decrease.

Figure 5. Deformation curve of the cut-and-cover tunnel.

3 ENGINEERING MEASURES

Referring to the case studies (Sun et al, 2022; Wu, 2022; Zhou, 2016; Zhou et al, 2020), following engineering measures are carried out.

3.1 Design measures

- 1) Add the number of grouting holes of the segments for the need of emergency grouting.
- 2) Install shear pins between segment rings to enhance the ability of the tunnel to resist uneven deformation, minimizing disturbance to the soil.

3.2 Construction measures

- 1) Set up trial section before TBM crossing the existing tunnel for better summarizing the construction parameters.
- 2) Check the condition of the cutterhead and the cutting tools in advance to make sure that TBM won't be forced to be in maintenance rightly under the existing tunnel.
- 3) During excavation, strictly control the attitude of TBM and apply reasonable construction parameters to minimize disturbance to the soil and to achieve continuous, balanced, and smooth shield advancing.
- 4) Select appropriate synchronous grouting materials to better control ground settlement and tunnel deformation.
- 5) Improve the quality of segment erection and waterproof work during shield tunnelling.
- 6) Choose grouting materials with short solidification time and grouting to form waterproof rings outside the segment ring at each end of the undercrossing area, thus preventing groundwater from running through to avoid soil erosion, which will otherwise lead to the subsidence of the existing cut-and-cover tunnel.
- 7) Strengthen monitoring of the existing tunnel, ground surface and etc. during undercrossing construction and grouting to control deformation when the monitoring result tells to do so.
- 8) Carry out geological radar survey to detect potential sources of risk, such as strong ground voids, collapses, looseness etc. and grouting to eliminate the risk promptly.

4 CONSTRUCTION MONITORING

4.1 Layout of monitoring points

To ensure the safe and sound passage of TBM, ground deformation and settlement of the cut-and-cover tunnel structure was monitored according to local standard. The layout of the monitoring points for the existing tunnel structure is shown in Figure 6.

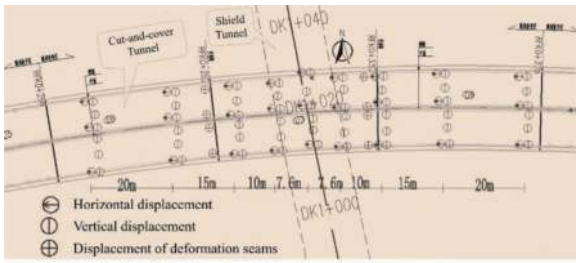

Figure 6. Layout of the monitoring points for the existing tunnel.

4.2 Monitoring data

The shield tunnel travelled under the existing tunnel from the mileage of DK1+004.459 to DK1+045.235. Since the cutterhead of TBM entered the projection area of the existing tunnel on March 2nd, and until the shield tail left on March 8th, it turned out that the undercrossing construction was completed successfully. Monitoring data showed that the maximum surface settlement caused was 1.85mm, and the maximum uplift and settlement of the cut-and-cover tunnel pavement was 3.32mm and 2.87mm respectively. Other monitoring data was also within the range of control requirements.

Besides the construction monitoring, geological radar survey was also carried out with the aim of detecting any underground hazards. According to the report, no hazard was detected after the undercrossing construction.

5 CONCLUSIONS

- 1) According to numerical analysis and monitoring data, ground deformation and settlement of the cut-and-cover tunnel are within the range of control requirements, indicating the undercrossing construction is a total success.
- 2) By setting up trial sections, strengthening synchronous grouting, controlling driving posture, adopting reasonable construction parameters, strengthening monitoring and so on, the risk level of the undercrossing construction can be significantly downgraded.

- 3) Monitoring data is important for shield tunneling. The number of monitoring points and the monitoring frequency should be improved appropriately for the undercrossing construction. Construction parameters should be adjusted timely in the guidance of the monitoring data.
- 4) With the rapid progress of urbanization in China, situations for super-large diameter shield crossing under existing tunnels will be more and more common. Reasonable design and construction plan as well as complete monitoring system is essential to ensure the safety of the undercrossing construction.

Influence of TBM cutter configurations on gravel excavation characteristics revealed by discrete element method

Yi-Fan Chen*, Tai-Tien Wang & Fu-Shu Jeng

National Taiwan University, Chinese Taipei

ABSTRACT: Over the past few decades, as urbanization has progressed, the demand for infrastructure has increased. The shield tunnelling method has been widely applied for underground space development, particularly in urban areas. The tunnel boring machine (TBM) contacts with the geological strata through a process of propelling and rotating. The complex excavation process often leads to severe wear on the cutting tools of the TBM cutterhead, especially in gravel layer, increasing construction costs and project durations significantly. This study establishes a methodology to investigate the influence of cutter configurations on gravel excavation characteristics and to evaluate the cutter wear during tunnel excavation. Numerical simulation using the discrete element method, PFC^{3D} is conducted to mimic the irregular shape and particle size distribution of gravel and their impact on gravel excavation. The effects of different opening ratios, type of cutting tools, and height of cutting tool of the cutterhead on gravel excavation, as well as the mechanism of cutting tool breaking through gravel layer are also examined. The simulation results indicate that cutter bits exhibit a peeling cutting mode, while disc cutters adopt cutting and fragmentation. Simultaneously employing both types of cutting tools on the cutterhead can enhance tunnel excavation efficiency. The method for simulating cutter wear on gravel developed in this paper can provide insights for the analysis and design of shield cutterheads in gravel layer.

Keywords: Shield tunnelling method, TBM, Gravel layer, Cutter wear, Discrete element method, Tunnel excavation

1 INTRODUCTION

In the field of tunnel engineering, the technology and application of the tunnelling method using a tunnel boring machine have matured significantly over the past few decades. Previous researchers have devoted efforts to analysing excavation effects on different common materials such as sand layers, clay layers, and rock layers. In soil tunnelling, the majority of excavation processes involve the use of Earth Pressure Balance (EPB) TBMs, where the cutterhead rotates and advances to excavate. Various cutter tools with tooth-like appearances, including ripper tools and scraper tools, are mounted on the cutterhead. Key factors in sand excavation involve the compression and friction of sand particles. In clay, the crucial factor is the soil's inherent cohesion, which makes cohesive soils challenging to be teared apart and significantly impacts the excavation performance of a TBM. In rock tunnels, the cutterhead configuration differs from that used in soil tunnels, with lower cutterhead opening ratios and primarily circular disc cutters (Fu et al., 2021; Tang et al.,

2022; Jakobsen and Lohne, 2013; Berdal et al., 2018; Zhou and Zhai, 2018; Farrokh, 2021). Previous studies have focused on TBM performance related geological conditions involving small-grained soils and rock layers and their influences fruitfully. Nevertheless, limited study focuses on the mechanical properties of gravel layers and possible impact on TBM tunnelling.

When tunnelling using a TBM, the cutterhead's cutting tools experience significant wear inevitably due to the substantial friction generated during the forward rotation and advancement against the excavation face. Therefore, evaluating cutter tool wear is an important issue. Wen and Huang (2018) mentioned four different wear mechanisms: abrasion wear, adhesion wear, fatigue wear, and corrosive wear. Typically, hard rocks contain quartz minerals, resulting in quartz particles being pressed onto the cutter's surface, causing local plastic deformation of the surface material. Furthermore, the cutting action of the cutter may suffer from material losses in the ground surrounding a TBM. Under high-stress conditions, brittle fractures may occur, leading to wear of cutters of a TBM.

*Corresponding author: a109590065@gmail.com

Currently, there are considerable researches on simulating the mechanical behaviour or failure mechanisms of soil and rock materials using the discrete element method (DEM) such as PFC. For instance, Tian et al. (2018) used PFC^{2D} to simulate direct shear tests on coarse-grained soils. The results showed that the shape of particles significantly affected the mechanical properties of granular materials. Irregular particle shapes increased the peak shear stress ratio, the ultimate shear stress ratio, and the ultimate shear dilation ratio due to interlocking forces between particles. Su and Akcin (2011) employed PFC^{3D} to simulate conical pick cutting of rock to investigate the failure mechanism. In the initial cutting stage, micro-cracks initiated and propagated at the tool tip. As the cutting process continues, the rock occurs normal and shear failure. However, there is currently limited literature on DEM simulation of excavation in gravel layers. Therefore, this paper will utilize numerical analysis tools to explore the influence of cutter configurations on the characteristics of gravel excavation and establish a methodology for cutter wear assessment.

2 NUMERICAL ANALYSIS

PFC^{3D} is used to model the cutter wear during the TBM excavation in gravel. Major considerations regarding numerical model design and related modelling methods are introduced following.

2.1 Numerical model design

Figure 1 shows the numerical model developed in this study. The model consists of a rigid cylindrical container with a diameter of 310 mm and a length of 600 mm. It has an opening at the front, while the sides and rear parts are sealed. Two-thirds of the interior space of cylinder is filled with gravel soil. The base of the cutter tool model consists of a cross-shaped structure with a length of 240 mm. It has four cutter teeth at the front end in the basic case of this study, serving as the primary cutting and peeling tools. These cutters are oriented and have a size of 14 mm.

This study considers the irregular shape of gravel particles in the numerical model. Figure 2 shows a model of gravelly soil with 75% gravel content. In the numerical model, spherical particles are used to simulate the matrix part in a gravel layer with consideration on its grain size composition, while spherical clumps simulate the shape of large grain particles. The grain sizes are divided into two categories based on a 4.75 mm boundary, with smaller sizes representing sand and larger sizes representing gravel for simplification. Figure 3 illustrates the irregularly shaped gravel clumps in the model. Particles with irregular shapes are used to replace circular particles, introducing interlocking forces when particles undergo relative movement due to surface irregularities (Ting et al., 1995; Lu et al., 2017). This approach captures

the characteristics of gravel in numerical simulations, resulting in generated gravel geometries that closely resemble nature.

Figure 1. Geometry of the simulated container.

Figure 2. Gravel layer with 75% gravel content.

Figure 3. Clumps of gravel in the numerical model.

2.2 Numerical model generation

Figure 4 shows the schematic diagram of the wear test. The simulation on excavation process begins by generating two different sizes of balls within a rigid container. Subsequently, a three-dimensional model of gravel is imported. In PFC^{3D}, clumps are used to simulate gravel. Different contact models are then established between various contact particles, following the approach referenced by Hsieh et al. (2008). Three types of contact are defined, including contact between sand particles, contact between sand particles and gravel, and contact between gravel particles, ensuring their equilibrium.

The cutting tools in the numerical model are subjected to both rotational and translational motion conditions, with an angular velocity of 30 rpm and a translational speed of 5 mm/s. Additionally, this study has developed a FISH Function to record the

generation of cracks between clumps and balls within the model. This information, related to fracture patterns and crack propagation, is incorporated into the discrete network to visualize the excavation process in gravel and understanding of related failure mechanisms.

Figure 4. Numerical simulation model of gravel layer.

2.3 Modeling of TBM cutterhead

The design considerations for a shield machine cutterhead involve various factors such as geological conditions, subsurface data, excavation efficiency, and excavation face stability. Figure 5 shows four different cutterhead designs, categorized into four cases. The figure displays the numbering of cutter on the cutterheads for each case. The numbering is carried out counter clockwise from the outer ring to the inner ring, ranging from cutter number 1 to 7.

Afterward, we'll discuss the wear of each numbered cutter.

Case 1 features a cutterhead with four cutter bits, each having a height of 14 mm. In contrast, Case 2 consists of a cutterhead with seven cutter bits, each having a height of 14 mm and arranged in three concentric circles. The purpose of Case 2 is to compare the opening ratio with Case 1.

Case 3 involves a cutterhead with seven cutters, each having a height of 14 mm. Figure 6 shows the geometry of disc cutters used in this study. Unlike Case 2, Case 3 includes the configuration of four disc cutters on the cutterhead. This case aims to investigate whether adjusting the proportion between disc cutters and cutter bits can increase the soil fragmentation capability and further reduce the wear on cutter bits.

In Case 4, the cutting tools are configured at different heights. The outer circle features two disc cutters with a greater height of 26 mm, protruding a distance equivalent to one gravel particle. The middle circle of disc cutters has a height of 20 mm, while the heights of the remaining cutters remain unchanged. This configuration is employed to explore whether the use of high-low cutter height arrangements can enhance soil fragmentation and excavation efficiency or increase the load on higher cutters and lead to more severe wear.

3 RESULTS OF NUMERICAL ANALYSIS

Simulated cutting forces on various cutter bits are used to investigate the wear of cutters, associated with the damage and crack patterns in particles to interpret the excavation characteristics caused by cutters' motion.

Figure 5. The layout of cutters on the cutterhead.

Figure 6. Disc cutters model.

3.1 Analysis of cutter force

In the numerical simulation, the cutting tools excavate the gravel layer by rotating concentrically. During this process, the irregularly shaped and varying-sized gravelly soils are worn down, reflecting frictional characteristics and interlocking effects. As a result, complex interactions of normal force, rolling force, and side force on cutting tools occur. Figure 7 illustrates the schematic representation of the direction of forces applying on the cutting tools. In the figure, θ represents the clockwise rotation angle of the tool. Since the internal coordinate system in PFC remains constant, by recording the forces exerted on the cutting tools in the X, Y, and Z directions during excavation and converting them through angle and quadrant transformation, the F_x , F_y , and F_z forces during the cutting process can be transformed into F_n (normal force), F_r (rolling force), and F_s (side force), as represented by Eq. (1), (2), and (3).

$$F_n = F_x \quad (1)$$

$$F_r = -F_y \cdot \cos \theta - F_z \cdot \sin \theta \quad (2)$$

$$F_s = -F_y \cdot \sin \theta + F_z \cdot \cos \theta \quad (3)$$

Figure 8 shows the forces acting on the cutting tool. The cutting tool penetrates and rotates within the ground, bringing it into contact with the gravel. The cutting tool is affected by frictional properties and the interlocking effects produced by the gravel particles. This necessitates the breaking of bonding between the particles to detach them. Additionally, the non-uniformity in size, shape, hardness of coarse particles, and the presence of potential voids and cavities lead to uneven loading on the tool. Over an extended excavation period, the wear due to friction becomes more pronounced.

Figure 7. Transformation of forces for cutter bits.

Figure 8. Record of cutter bit forces.

3.2 Process of wear test

Figure 9 shows the excavating process of cutter in gravel layer and the resulting failure pattern. When the cutter makes contact with the surface of the gravel, it exerts cutting and twisting forces to dislodge soil particles. In this study, the penetration of a single cutter into a gravel particle is used as a reference.

When the cutting action exceeds the bonding strength of gravel particles, the particles are broken and then removed after subsequent cutter rotating. This also leads to the formation of depressions and protrusions on the cutting surface, creating an irregular surface.

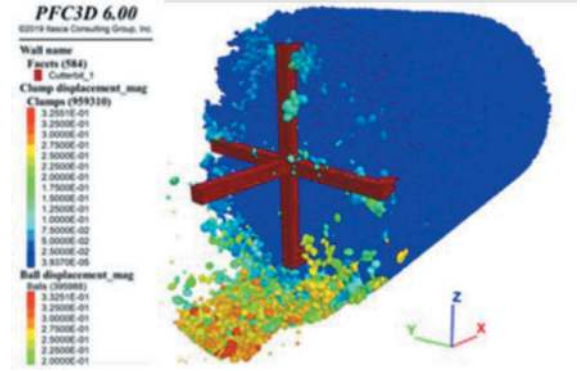

Figure 9. Displacement diagram of gravelly soil.

3.3 Wear index

Wear index is a quantification of the degree of wear. Common indexes include specific energy, work done by friction, cutting forces, weight loss, dimensional changes, and so on. In this study, the concepts of specific energy and frictional energy loss are adopted as indexes of cutter wear during excavation to represent the energy conversion and dissipation of the cutter during the cutting process.

3.3.1 Specific energy

The concept of specific energy was first introduced by Teale (1965). It is commonly used to compare the wear degrees of different materials or tools and evaluate the excavation efficiency. It represents the energy consumed per unit volume. In this study, we simultaneously recorded the relationship between cutting forces, torque, and the volume of cut material during the cutting process in numerical simulation. Eq. (4) represents the calculation formula. The numerator term represents the work done by the cutter, which is the sum of the total cutter moment work (W_m) and the excavation thrust work (W_n). The denominator term calculates the volume of particles removed by the cutter.

$$SE = \frac{\sum W}{V} = \frac{\sum (W_m + W_n)}{V} \quad (4)$$

$$= \frac{\sum_{i=1}^n (\int M_i \cdot d\theta + \int F_{n_i} \cdot dx)}{V}$$

3.3.2 Frictional energy loss

Frictional forces are considered one of the main factors causing tool wear. Thus, the frictional energy loss is a key factor for wear, that is related with the frictional forces between the tool surface and the contact area. The phenomenon of energy dissipation and material loss leads to the conversion of energy into thermal

energy losses and mechanical energy losses. The calculation of frictional energy loss is shown in Eq. (5).

$$W_f = \sum_{i=1}^n \int Fr_i \cdot dl \quad (5)$$

4 DISCUSSIONS

In this section, we will compare and explain the results of the four cases. To evaluate the influence of cutter configurations, including opening ratio, cutter type, and cutter height, based on the perspective of wear indexes.

4.1 Cutterhead opening ratio

Figure 10 shows the distribution of excavation-induced fractures for Case 1 and Case 2. In Case 1, fractures primarily occur along the cutting path of the cutter bits. These fractures are not interconnected, indicating that the excavation face has not undergone overall fragmentation. Therefore, increasing the number of cutter bits in the middle region of the cutterhead achieves overall fragmentation of the excavation face. In Case 2, with the cutter configuration, the number of fractures gradually increases and extends to both sides of the cutting path, forming a sheet-like fracture pattern. Eventually, these fractures connect to each other, resulting in fragmentation of the excavation face.

Figure 10. Fractures at different opening ratios.

4.2 Type of cutters

This paper analyses two types of cutters: cutter bits and disc cutters. Case 2 and Case 3 are designed to analyse the works done on each cutter. Figure 11 shows the distribution of fractures after tunnel excavation in these two cases. The differences in crack positions and quantities between the two cases are not significant. Table 1 summarizes the simulated results of the work done for cutters 1 to 7. For cutter bits 1, 3, 5, and 7, the results indicate that when cutter bits are replaced with disc cutters, thrust, moment

work, and frictional energy loss all decrease. The replacement of some cutter bits with disc cutters reduces the contact area, which increases the pressure on cutter bits. As a result, bits 2, 4, and 6 show slightly higher wear after changing the configuration. However, overall, adjusting the ratio of cutter bits and disc cutters effectively improves excavation efficiency.

Figure 11. Fractures at different type of cutters.

Table 1. Work analysis for Cases 2 and 3.

Cutter No.	Wn (J)		Wm (J)		Wr (J)	
	Case 2	Case 3	Case 2	Case 3	Case 2	Case 3
1	0.35	0.04	5.48	0.85	12.85	1.94
2	0.27	0.42	3.92	8.72	8.14	13.36
3	0.30	0.10	6.32	2.18	16.37	4.70
4	0.59	0.53	8.43	9.70	15.03	18.46
5	0.96	0.33	4.10	2.13	12.04	7.97
6	0.71	0.74	5.14	5.80	18.76	20.72
7	0.74	0.31	2.04	1.20	6.16	4.59

4.3 Height of cutter

The purpose of designing the higher cutter bit is to cut and break the outer circle of the excavation face first, making it the leading cutter. This is expected to reduce the excavation load on the other cutter bits.

Figure 12 shows the crack distribution after excavation for Case 3 and Case 4. It can be observed that Case 4 has a wider and more numerous crack expansion, especially in the outer circle. Table 2 summarizes the results of the work analysis for each cutter. It is found that in Case 4, number 1, 3, and 5 cutters have significantly increased work done and frictional losses. For number 2, 4, 6, and 7 cutters, regardless of being cutter bits or disc cutters, there is a trend of reduced work done and lower frictional energy losses. This phenomenon indicates that the leading cutter bits perform as expected, consuming most of the energy required for excavation and reducing the wear of other cutters.

Figure 12. Fractures at different height of cutters.

Table 2. Work analysis for Cases 3 and 4.

Cutter No.	Wn (J)		Wm (J)		Wr (J)	
	Case 3	Case 4	Case 3	Case 4	Case 3	Case 4
1	0.04	6.16	0.85	57.86	1.94	113.60
2	0.42	0.17	8.72	2.43	13.36	4.89
3	0.10	0.57	2.18	14.97	4.70	45.20
4	0.53	0.35	9.70	4.31	18.46	9.68
5	0.33	0.91	2.13	10.02	7.97	31.83
6	0.74	0.32	5.80	1.60	20.72	4.77
7	0.31	0.24	1.20	0.97	4.59	3.88

4.4 Excavation efficiency

Figure 13 shows the differences mechanism of cutting tool breaking through gravel layer. Tooth-type cutters employ a mechanism of peeling off gravel particles, resulting in a larger crushed area due to the interlocking effects between particles. In contrast, disc-type cutters employ a cutting mechanism, breaking the excavation face by destroying the bonding between particles, with cracks predominantly growing along the cutting path. Figure 14 compares the total number of cracks generated by the four cases. Case 4, utilizing the pre-cutting tool configuration, leads to the highest number of cracks, with the largest expansion area and deepest depth.

Finally, data analysis of the four cutter configurations is presented in Table 3, summarizing the specific energy and frictional energy loss results. As Case 1's cutter configuration was insufficient to complete the cross-section excavation, and the cracks did not interconnect, it was excluded from the analysis concerning the overall fragmentation of the excavation face.

Using specific energy as an index for excavation efficiency evaluation, Case 3 with a mixed configuration of tooth-type and disc-type cutter demonstrates the highest excavation efficiency. This indicates that configuring both tooth-type and disc-type cutter teeth contributes to improved excavation performance. A similar trend is observed when using frictional energy loss as the tool index. Case 3 has the lowest frictional energy loss. Therefore, it is

Figure 13. Differences mechanism of cutting tool breaking through gravel layer.

excavation in the gravel layer. In contrast, Case 4, while reducing the wear of other cutter to some extent, experiences excessively high frictional energy loss overall, making it the cutter configuration with the highest wear among the four cases.

5 CONCLUSIONS

Based on the challenges encountered in tunnel engineering, this study investigated the severe wear issue of cutter in shield tunnelling through gravel layer, as well as the excavation efficiency of different cutter configurations on the cutterhead. A numerical model for cutter wear in gravel layer was developed. Various cutterhead designs were created to simulate tunnel excavation in gravelly soils, investigating the characteristics of different cutter opening ratios, cutter types, and cutter heights. The study yielded the following conclusions:

1. Four different cutterhead configurations were designed to investigate the influence of cutter configuration on excavation efficiency. From a microscopic mechanical perspective, cracks initially form along the cutting path. Subsequently, these cracks extended and increased in number, ultimately connecting with each other and breaking the entire excavation face.
2. The cutter bit breaks the soil by penetrating and cutting, subsequently removing the gravel particles during excavation. In contrast, the disc cutter operates by breaking and crushing. Cutter bits typically generate a significantly larger number of cracks and result in higher frictional energy losses compared to disc cutters.
3. Simultaneously incorporating cutter bits and disc cutters on the cutterhead effectively reduces the overall cutterhead forces, enabling the cutterhead to more efficiently break and remove gravel during excavation. This achieves optimal excavation efficiency while reducing cutter wear.

Research on the application of high-strength burn-free building blocks made from shield muck

Hongshun Chen* & Yongqiang Xiao

Qingdao Qingtie Environmental Protection Technology, Co.,Ltd . Qingdao, China

Bo Chen, An Lin & Xiaowei Liu

Xinde (Shenzhen) Urban Building Environmental Protection Technology, Co.,Ltd, Shenzhen, China

ABSTRACT: A common way to utilize shield muck as a resource is to transform it into building materials products, such as building blocks. However, there is a significant difference in characteristics (such as clay content, composition and so on) between the shield muck and building materials such as sand and stone. The strength grade of building materials products which use shield muck as the main raw materials is usually low, and the dispersion of strength is significant, resulting in a small application scope and insufficient market competitiveness of building materials products made from shield muck, which ultimately affects the consumption of shield muck. In order to solve the problem of low strength grade of building materials products with shield muck as the main raw materials, on the basis of reasonably controlling the particle size and moisture of the raw materials of shield muck and using traditional cement as the cementitious materials, a geopolymer cementitious materials is used in a way of compounding in this study. Alkali and sulfate are used as activators for cementitious materials, besides, a small amount of functional additives are added. While improving the solidification effect of cement, the unique three-dimensional network structure of geopolymer cementitious materials is utilized to further compensate for the shortcomings of cement in solidification of fine clay particles. Thereby the strength of the building blocks is improved. Through the process of ingredient design, raw materials screening, homogeneous mixing, uniform distribution, static pressure forming, and maintenance, the shield muck is transformed into high-strength burn-free building blocks. Its compressive strength can be adjusted within the range of 20-40MPa after 28 days of curing suitable for different market demands, and the production cost can be controlled within a reasonable range, which provide an engineering reference for the resource utilization of different shield muck.

Keywords: shield muck, resource utilization, burn-free building blocks, compressive strength, geopolymer

1 INTRODUCTION

With the rapid development of urban underground space development, the shield tunneling method has been widely used in the construction of rail transit, municipal highways and other projects owing to the advantages of high efficiency, high safety and high degree of mechanization (Xie et al, 2022). At the same time, a large amount of engineering muck will also be generated during shield tunneling construction. Taking subway construction as an example, 55 cities in mainland China have opened rail transit by the end of 2022 with a total operating mileage of 10,287.45 km, of which the subway mileage reaches 8,008.17 km. The subway mileage increased by 798.47 km compared with 2021 and most of them are constructed using shield tunneling technology.

Based on the calculation that the average diameter of shield tunnel is 6.0m and the loose coefficient of the muck is 1.5 (Wei et al, 2023), 33.8643 million m³ of shield muck will be generated in subway construction just in 2022.

Shield muck is generally a flow-plastic soil with high moisture content and low permeability containing clay minerals, foaming agents and polymer modified materials, and its particle size gradation, mineral composition, mechanical properties etc are closely related to the geological conditions and construction methods (Xie et al, 2022). Therefore, the properties of shield muck in different cities and regions vary greatly. At present, most cities in China are faced with the problem of “excavating” more than “filling” and need to “abandon”. However, the land around the city is precious and it is difficult to

*Corresponding author: 1581100245@qq.com

find land for stacking or filling the muck. Therefore, in the era when the whole society is pursuing green and low carbon, resource utilization of the muck is the most expected way out (Wei et al, 2023).

In terms of resource utilization of shield muck, it is a common method to transform shield muck into building materials especially into burn-free building blocks. Guo Aifeng et al prepared a kind of burn-free building blocks using shield muck by pressing (Guo et al, 2023). The compressive strength, water absorption, softening coefficient and frost-resistance of the blocks all meet the MU15 requirements of JC/T 422-2007. However, this product is generally only used for wall materials and is difficult to be used as pavement materials due to the low strength level. Xi Zhiqin et al also prepared a kind of shield muck burn-free building blocks with a compressive strength of 50MPa by pressing, which can be used as pavement materials (Xi et al, 2021). However, the proportion of cementitious materials added especially expensive activators is too high in this method, resulting in low consumption of the muck and high cost of production.

The main purpose of this article is to improve the compressive strength of burn-free building blocks made from shield muck within a reasonable cost and expand the application scope of burn-free building blocks made from shield muck to adapt to different market demands, thereby accelerating the industrialization process of the resource utilization of the shield muck.

2 EXPERIMENTATION

2.1 Materials

2.1.1 Shield muck

The shield muck used for the experimentation was obtained from the naturally air-dried muck generated during shield tunnel construction at a subway station in Qingdao. The basic performance of the shield muck was tested according to JTG 3430-2020. The results of the particle size analysis are shown in Table 1 and Figure 1, and other performance indicators are shown in Table 2. The chemical composition of the shield muck is shown in Table 3.

Table 1. Particle size analysis of the shield muck.

Mesh size / mm	Cumulative percentage retained / %	The mass fraction of particles smaller than a certain particle size / %
0.075	89.6	10.4
0.25	76.8	23.2
0.5	59.9	40.1
1	38.6	61.4
2	22.9	77.1
5	6.4	93.6

Table 2. Physical properties of the shield muck.

Moisture content / %	Liquid limit	Plastic limit	Plasticity Index	Bulk density (kg/m ³)	pH
5.3	40.4	24.9	15.5	1470	7.1

Table 3. Chemical composition of the shield muck.

Chemical composition	Content / %
SiO ₂	72.84
Al ₂ O ₃	13.81
Fe ₂ O ₃	6.93
CaO	1.55
MgO	1.41
Na ₂ O	0.92
K ₂ O	2.54
Total	100

2.1.2 Sand

Common river sand from somewhere in Shandong was selected. The basic properties of the sand are shown in Table 4.

Table 4. Basic properties of the sand.

Fineness modulus	Clay content / %	Bulk density (kg/m ³)
2.8	1.9	1490

2.1.3 Cement

Commercially available PO425 cement was selected. The basic properties of the cement are shown in Table 5.

Table 5. Basic properties of the cement.

Fineness (45 μ m)/%	10
Initial setting time/min	150
Final setting time/min	210
Specific surface area(m ² /kg)	360
Compression strength of 28 days/MPa	50.2
Requirement of normal consistency/%	26

2.1.4 Fly ash

Secondary fly ash from a power plant in Shandong was selected. The basic properties of the fly ash are shown in Table 6 and the chemical composition of the fly ash is shown in Table 7.

Table 6. Basic properties of the fly ash.

Water demand ratio/%	Specific surface area (m ² /kg)	Specific gravity
96	465	2.3

Al ₂ O ₃	32.58
Fe ₂ O ₃	4.6
CaO	4.93
MgO	0.62
Loss on ignition	4.36
others	4.48
Total	100

2.1.5 Water glass

Commercially available liquid water glass was selected. The basic properties of the water glass are shown in Table 8.

Table 8. Basic properties of the water glass.

SiO ₂ Mass fraction/%	Na ₂ O Mass fraction/%	Baume modulus	Degree (20°C)	Density (kg/m ³)
28.21	8.74	3.33	39.6	1340

2.1.6 Sodium hydroxide

Commercially available granular industrial grade solid sodium hydroxide with a purity of 98.5% was selected.

2.1.7 Calcium sulfate hemihydrate

Commercially available industrial grade powdered calcium sulfate hemihydrate was selected, of which the effective content is no less than 60%.

2.1.8 Superplasticizer

Use self-made liquid high-performance polycarboxylate superplasticizer. The basic properties of the superplasticizer are shown in Table 9.

Table 9. Basic properties of the superplasticizer.

Solid content/%	Water reducing rate/%	Density (kg/m ³)	pH
10.56	28	1023	5.1

2.2 Methods

2.2.1 Preparation

Weigh each material separately according to the designed proportion. The design proportions of different burn-free building blocks are shown in the Tables 10 and 11. The liquid materials are sequentially added to 1/3 of the designed total amount of water to dissolve. After dissolution, the solid materials and liquid materials are sequentially added to the star mixer and stirred for 4 minutes. Then the materials are transferred to the wheel mixer and stirred for 1 minute. After that, the materials are transferred to the distributor, distributing the material to the static pressure curing molding machine evenly. The molding pressure is set to 8MPa, and 25 burn-free building blocks are pressed at one time with a dimension of 200mm×100mm×60mm. When the pressing completed, the burn-free building blocks are covered with plastic film. After 24 hours, the burn-free building blocks with intact appearance are picked out and transferred to the standard curing box. The burn-free building blocks are tested and analyzed after curing 28 days at 20°C and relative humidity above 95%.

2.2.2 Test and analysis

Compressive strength test. Take the burn-free building blocks that have been cured for 28 days in the standard curing box out, and wipe the surface of them with a wrung-out wet towel. Use the DYE3000 concrete pressure testing machine to test the compressive strength and control the pressurization rate at 0.4-0.6MPa/s. Test 10 burn-free building blocks for each designed proportion, then take the average value as the 28-day compressive strength under this proportion and list it in the table.

SEM analysis. Take the crushed samples after the compressive strength test of the burn-free building blocks, further break them into small pieces, use absolute ethanol to terminate the hydration reaction,

dry them in a vacuum drying oven at 50°C for 24 hours, and spray gold coating. A Regulus8100 cold field emission scanning electron microscope was used for microscopic morphology analysis.

3 RESULTS AND DISCUSSIONS

3.1 *Compressive strength of burn-free building blocks when cement is used alone as the cementitious material*

Table 10 show the relationship between the compressive strength of the burn-free building blocks and the proportion of cement when the proportion of shield muck is constant and the cementitious material is cement alone. It can be seen that as the amount of cement increase, the 28-day compressive strength of the burn-free building blocks also continues to increase. When cement accounts for 25% of the total solid mass, the 28-day compressive strength of the burn-free building blocks is 34.6MPa. Continuing to increase the proportion of cement, the 28-day compressive strength of the burn-free building blocks does not increase significantly. When cement accounts for 30% of the total solid mass, the 28-day compressive strength of the burn-free building blocks reaches 37.0MPa. However, the high proportion of cement in the burn-free building blocks results in high cost of material, making actual production difficult to achieve.

Table 10. The proportion and the 28-day compressive strength of burn-free building blocks when cement is used alone as cementitious material.

Number	A1	A2	A3	A4	A5
Shield muck/kg	50	50	50	50	50
Sand/kg	38	35	30	25	20
Cement/kg	12	15	20	25	30
Water/kg	10	10	10	10	10
28-day compressive strength/MPa	10.5	16.8	25.9	34.6	37.0

3.2 *Compressive strength of burn-free building blocks when cement is compounded with geopolymer cementitious materials*

Table 11 show the proportion and the 28-day compressive strength of burn-free building blocks when cement is compounded with geopolymer cementitious materials.

Comparing F1 and A3, the 28-day compressive strength of F1 is slightly higher than that of A3, indicating that the addition of fly ash has a certain promoting effect on the strength improvement of burn-free building blocks. This promotion mainly includes three aspects. On the one hand, it is the morphological effect of fly ash (Cai et al, 2018).

The glass bead structure of fly ash can reduce the frictional resistance between cement particles and other particles such as muck and sand, making the cement more uniformly dispersed in the materials and increasing the cement hydration reaction area and reaction degree. on the other hand, it is the micro-aggregate effect of fly ash (Cai et al, 2018). The particles of fly ash are small and can fill the gaps between the mixed materials, increasing the density of the burn-free building blocks. Besides, it is the active effect of fly ash (Cai et al, 2018). Fly ash contains partially active SiO_2 and Al_2O_3 which can further react with $\text{Ca}(\text{OH})_2$ generated by cement hydration and form a certain amount of C-S-H gel, which increase the total amount of the cementitious materials in the burn-free building blocks.

Comparing F2 with F1, the addition of sodium hydroxide increased the 28-day compressive strength of the burn-free building blocks from 27.6MPa to 32.5MPa. Analysis believes that the vitreous structure of fly ash is destroyed in the strong alkali environment provided by sodium hydroxide, releasing more active $[\text{SiO}_4]$ and $[\text{AlO}_4]$ monomers. These active monomers are further condensed to form amorphous geopolymer gels such as sodium aluminosilicate hydrate (N-A-S-H) and calcium aluminosilicate hydrate (C-A-S-H) that further solidify particles such as muck, thus improving the compressive strength of burn-free building blocks (Zhao et al, 2020) (Zhao et al, 2021) (Tong et al, 2022) (Chen et al, 2022).

Comparing F3 and F2, the addition of water glass increased the 28-day compressive strength of the burn-free building blocks from 32.5MPa to 36.3MPa. Analysts believe that water glass can not only serve as a binding component, but also provide soluble silicates. Since the dissolution rate of aluminum in fly ash is much faster than that of silicon, the soluble silicates provided in advance can react with the previously released $[\text{AlO}_4]$ monomers to form a higher concentration of prepolymers in a shorter period of time (Chen et al, 2017) (Jafari et al, 2016) (Li and Fan, 2012), which is beneficial to improving the degree of polymerization of the geopolymer gel, thereby improving the strength of the burn-free building blocks.

Comparing F4 and F3, the addition of calcium sulfate hemihydrate increased the 28-day compressive strength of the burn-free building blocks from 36.3MPa to 38.7MPa. On the one hand, calcium sulfate hemihydrate can be further hydrated to form calcium sulfate dihydrate, which can consume part of the free water in the process and reduce the adverse effects of evaporation on the strength of burn-free building blocks in the later period. The formation process of calcium sulfate dihydrate crystals can further solidify the particles of the muck and reduce the voids in the burn-free building blocks. On the other hand, calcium sulfate hemihydrate introduces sulfate ions, which

can further react with cement hydration products to form hydration products such as ettringite, which improves the strength of the burn-free building blocks.

Comparing F5 and F4, the addition of superplasticizer increased the 28-day compressive strength of the burn-free building blocks from 38.7MPa to 40.1MPa. Analysis believe that the anionic groups (such as carboxyl groups, sulfonic acid groups, etc.) of the superplasticizer with a comb-shaped structure can be directionally adsorbed on the surface of the cement particles, forming an ion distribution of a diffusion double electric layer, causing the surface of the cement particles to carry charges with the same electrical properties, generating electrostatic repulsion, preventing cement particles from agglomerating, and promoting the dispersion of cement particles. Moreover, long-chain groups such as polyoxyethylene groups on the side chains can cause steric hindrance in the adsorption layer of cement particles, which is also beneficial to the dispersion of the cement particles (Li et al, 2012). The more uniformly the cement particles are dispersed, the higher the cement hydration reaction area and degree of reaction, and the higher the compressive strength of the burn-free building blocks.

Table 11. The proportion and the 28-day compressive strength of burn-free building blocks when cement is compounded with geopolymer cementitious materials.

Number	F1	F2	F3	F4	F5
Shield muck/kg	50	50	50	50	50
Sand/kg	25	25	25	25	25
Cement/kg	20	20	20	20	20
Fly ash/kg	5	5	5	5	5
Sodium hydroxide/kg	-	0.05	0.05	0.05	0.05
Water glass/kg	-	-	0.05	0.05	0.05
Calcium sulfate hemihydrate/kg	-	-	-	0.25	0.25
Superplasticizer/kg	-	-	-	-	0.5
Water/kg	10	10	10	10	10
28-day compressive strength/MPa	27.6	32.5	36.3	38.7	40.1

3.3 Microstructure of burn-free building blocks

Figures 2 and 3 show the micromorphology of A3 and F5.

The density and the amount of gel of F5 are significantly higher than those of A3, therefore the compressive strength of F5 is significantly higher than that of A3.

Not only fibrous and needle-like hydration products can be seen in the microstructure of F5, but also a large amount of amorphous gels. These amorphous gels are most likely geopolymer gels formed after fly ash is activated. These geopolymer gels with

a unique three-dimensional network structure are filled between particles such as muck and sand, bonding them into a dense whole and greatly improving the compressive strength of the burn-free building blocks.

Figure 2. SEM of the burn-free building blocks of A3 after curing for 28 days.

Figure 3. SEM of the burn-free building blocks of F5 after curing for 28 days.

4 CONCLUSIONS

Using cement and geopolymer cementitious materials, through the process of ingredient design, raw materials screening, homogeneous mixing, uniform distribution, static pressure forming, and maintenance, the shield muck can be transformed into high-strength burn-free building blocks. Its compressive strength can be adjusted within the range of 20-40MPa after 28 days of curing, suitable for different market demands, and providing an engineering reference for the resource utilization of different shield muck.

The formation of amorphous geopolymer gel is the key to product high-strength burn-free building blocks using shield muck. The addition of additives such as calcium sulfate hemihydrate and superplasticizer can improve the compressive strength of the burn-free building blocks made from shield muck.

The key technology of large section pipe jacking for main structure of station in complex water-rich sand bed

Bin Cheng*, Weiran Huang, Xiaobing Shuai & Yangyu Tan

Guangzhou Rail Transit Construction Engineering Consulting Co., Ltd, Guangzhou, China

ABSTRACT: East extension of Guangzhou Rail Transit Line 3 and main structure of West End of Waterfront Station, due to the impact of the relocation of three large pipelines (from west to east are the National Pipeline Network finished oil pipeline, Dapeng natural gas pipeline, Guangzhou Gas Pipeline), it is not possible to adopt the open-cut construction method according to the original design plan, in order to promote the construction of the waterfront station, after safety assessment, the construction of the main structure of the west end adopts the pipe jacking method, which passes under three large pipes, the construction safety risk is bigger. This paper analyzes the technical difficulties and key techniques of pipe jacking in the main structure of metro station in the complex water-rich sand layer, taking the project of Haibang Station large section pipe jacking in the east extension of Guangzhou Metro Line 3 as an example.

Keywords: Complex stratum, type selection, large section, construction risk

1 INTRODUCTION

In the construction of the main structure of the subway station in our country, open excavation, cover excavation and mining method are mainly adopted, with the rapid development of urban rail transit construction in our country, some subway stations do not have the condition of large-scale open excavation because of the influence of underground pipelines, buildings and so on, therefore, it is urgent to find a suitable construction scheme to solve this kind of difficult problem. At present, in our country's Beijing, Shanghai, Shenzhen and other cities, construction schemes such as large section pipe jacking machine, multi-round shield machine and combined tunneling machine are being studied and gradually become the development direction of the industry.

2 PROJECT PROFILE

2.1 Project profile

The Waterfront Station is located at the southwest corner of the Asian Games City in Panyu District, on the east side of the Guangzhou-macao Expressway. The total length of the station is 559m, the width of the standard section is 23.9 m, the width of the enlarged end is 27.8 m, and the total height of the station is 14.53 m. The depth of the cover soil is

about 3.0 m, the standard depth of the station is 17.73 m, and the depth of the extended end is 18.66 m. Under the influence of the surrounding environment, the construction of the waterfront station is divided into five stages, in which the fourth stage structure is the launching well of pipe jacking, the third stage structure is the receiving well of pipe jacking, and the fifth stage is the pipe jacking section. The section of pipe jacking is 11.1 * 8.1 m, and a rectangular pipe jacking machine with super large section is used to carry out the construction of left and right line successively. The length of pipe jacking passage is 48.5 m in left line, 52.5 m in right line, and the distance between pipe jacking passages is 1.5 m, it is designed as a plane straight-line, vertical two thousandth of the longitudinal slope, covering soil thickness of about 9.7 m.

Figure 1. Floor plan of Haibang Station construction site.

*Corresponding author: chb178@163.com

2.2 Geological conditions

From top to bottom, the geological range of pipe jacking is filled layer, mucky layer, mucky soil layer, silty clay layer, residual soil layer, fully weathered layer, strongly weathered layer, etc. . The depth of stable water level is 0.50-4.0 m, and the mud and muddy soil are thick. The excavation area of pipe jacking tunnel is located on silty clay. The geological condition of pipe jacking section is shown in Figure 2.

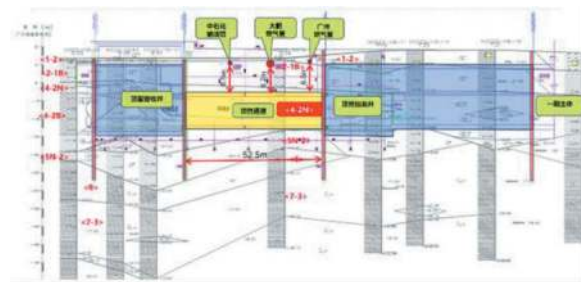

Figure 2. Geological map of pipe jacking section.

2.3 Condition of underground pipelines

The left and right channels of the jacking section pass through the D711 Guangzhou high-pressure gas pipeline, the D762 Shenzhen Dapeng ultra-high-pressure gas pipeline, and the D300 National Oil Pipeline Network (hereinafter referred to as the three large pipelines), pipeline operations in Guangdong, Guangxi, Guizhou, Yunnan, Sichuan, Shaanxi and other provinces. The shortest distance between the launching well and the receiving well is 6.3m and 7.1m, which meets the requirement of safety construction distance more than 5 m stipulated by the law of petroleum pipeline protection. The location relationship of the three main pipelines is shown in Figure 3. The basic situation of the pipelines is as follows:

The finished oil pipeline of National Pipeline Network: diameter is D323.9 mm, pipe material is X52 seamless steel pipe, wall thickness is 6.4 mm, buried depth is 3.68 m, distance from upstream valve chamber is 10 km, distance from downstream valve chamber is 5 km, design pressure is 9.5 mpa, Operation Pressure is 4.0 mpa, transportation medium: Diesel and gasoline alternate transportation.

Dapeng natural gas pipeline: pipe diameter D762MM, pipe material used X65M longitudinal submerged arc welding steel pipe, wall thickness 20.6 mm, buried depth 2.4 m, crossing point about 1.1 km from upstream valve chamber, 6 km from downstream valve chamber, Design Pressure 9.2 MPA, the operating pressure is 6.8 ~ 8.9 mpa, and the conveying medium is natural gas.

Guangzhou Gas Pipeline: pipe diameter is D711MM, pipe material is straight seam double-side submerged arc welding steel pipe, wall thickness is 17.5 mm, buried depth is 3.6 m, distance upstream pressure regulating station 2.4 km, distance downstream valve chamber 6.2 km, design pressure is 5.0 mpa, operating pressure is 3 mpa.

Figure 3. The plane relation diagram of oil and gas pipeline and pipe jacking construction.

3 CONSTRUCTION SAFETY RISK

There are the following construction safety risks in the construction of large section pipe jacking in the seaside station:

- (1) It is difficult to control the formation subsidence, and the high-pressure pipeline protection is required. From top to bottom, the stratum is & LT; 1-2 & GT;; & LT; 2-1a & GT;; & LT; 2-1b & GT;; & LT; 4n-1 & GT;; & LT; 4-2b & GT;; & LT; 4n-2 & GT;; from top to bottom. Pipe jacking is mainly located in the layer of & LT; 4n-2 & GT;;, but there is a large range of deep silt and mucky soil in the upper part of pipe jacking, the maximum thickness is 5m, and the formation is easy to deform during pipe jacking. The distance between the top of the jacking pipe and the upper pipe is about 6.5 m when the jacking pipe runs through three large pipes. The grouting under the pipeline may cause the local uplift of the pipeline, and then cause the deformation of the pipeline, pipeline deformation may cause oil and gas leakage accidents, so high-pressure pipelines need to be protected during construction.
- (2) the safety risk of starting and arriving is high, the pipe jacking is super-large section pipe jacking, the size of section is 11.1 x8.1 m, the location is not accurate and the direction is not well controlled during the starting and arriving of construction, or the quality problem of the end reinforcement, which results in the collapse, mud bursting and water gushing at the beginning and arrival of the pile, serious impact on construction safety.
- (3) the construction risk of main pipe jacking is high, the main pipe jacking engineering consists of two parallel pipe jacking channels, the net distance between the channels is 1.5 m, the following problems are easy to occur during the construction: 1 the lateral pressure during jacking will affect the adjacent pipe-jacking passage, causing deformation and displacement of the adjacent pipe joints, and even causing damage; 2 the soil around the formed channel is disturbed again by the adjacent pipe jacking construction, which is easy to cause the ground and pipe settlement superposition,

causing the destruction of the surrounding environment; 3 at the same time, the attitude control of the pipe jacking machine is difficult during the pipe jacking construction.

4 KEY CONSTRUCTION TECHNOLOGY

4.1 Selection of pipe jacking machine

According to the particularity and difficulties of pipe jacking construction of rectangular tunnel in this project, in order to minimize the jacking construction risk, increase the controllability of the risk and ensure the safe and smooth construction, the project adopts 11.1 m × 8.1 m rectangular mud-water balanced pipe jacking machine construction. The cutter head of the pipe jacking machine is “The center big cutter head + the two sides rectangular cutter head type”, the excavation rate reaches 95%. The cutter head and driving structure of pipe jacking machine are shown in Figure 4.

Figure 4. Drawing of cutter head and driving structure of pipe jacking machine.

The central cutter head structure and the cutter configuration are: The Banner Cutter Head, the opening rate is 35%, and the disk surface is evenly distributed, uses the 6 torsion leg 6 main beam 6 auxiliary beam structure, the main beam and the torsion leg uses the square structure, the auxiliary beam is a box-shaped structure, and the maximum equivalent stress of the cutter head structure is 160MPa, which can meet the force requirements of the cutter head in this standard section. When the cutter head rotates, the soil mass in the silo is forced to be stirred together with the two passive agitators on the front shield partition, the cut-off soil is fully stirred to improve the uniformity of the water-soil mixture in the mud silo.

The cutter head is driven by motor, equipped with 18 groups of 30kw motors, the total driving power is 540kw, the rated torque is 9600KNm, and the bailing torque is 11520KNm, which can meet the requirements of tunneling torque in this formation.

There are 3 kinds of center cutter: scraper, shell copying knife and center knife. The scraper is symmetrically arranged on both sides of the main beam of the cutter head. The shell profiling cutter is arranged on the surface of the auxiliary cutter box and the central part of the main beam, and the central cutter is placed on the central position of the Big

Cutter Head. The principle of knife layout: the diameter of the cutter head is divided into three equal parts, the outer diameter part of each track line is arranged 3 knives, the inner diameter part of each track line is arranged 2 knives. Both scraper and shell profiling knife are 80mm apart; shell profiling knife is located between adjacent scraper. Scraper: 224; shell knife: 112; Outer Ring Knife: 12; Center Tip Knife 1, Pipe Machine Cutter as shown in Figure 5.

Figure 5. Actual picture of the cutter head of pipe jacking machine.

Corner cutter head structure and tool configuration: a total of 4 corner cutter head, using the panel-type cutter head, each corner cutter head configuration of 96 conical tooth cutter. The crankshaft bearing seat is connected with the flange and rotates eccentrically. The corner cutter head is shown in Figure 6.

Figure 6. Eccentric drive diagram of corner cutter head.

4.2 Pipe section lifting

The pipe jacking section is divided into standard pipe section and 3 special pipe sections at head and tail. The biggest weight is the standard segment, the length of each segment is 1.5 m, the weight of each segment is about 106 tons, the hoisting safety risk is bigger, according to the site construction arrangement, the segment hoisting adopts 150 t gantry crane, the gantry crane is shown in Figure 13.

After many years of development, at present, the pipe section hoisting usually uses the special-purpose clamp type pole beam, the utility model has the advantages of firm structure, simple operation,

Figure 7. Schematic diagram of Gantry crane style.

good safety, minimum number of turning holes of the pipe joint (minimum influence on the structural strength), and no damage to the appearance quality of the pipe joint in the lifting process.

Figure 8. A picture of a clamped pole.

Figure 9. Pipe section lifting down well.

In this project, because the width of the wellhead is only 11.6 m and the width of the pipe joint is 11.1 m, the pipe joint can not go down the well because of using the original hoop-type pole, therefore, the vertical lifting hole of the pipe section is increased from the original 3 to 5. On the basis of the original special pole, the two sides of the hoop suspension devices were removed and replaced with wire ropes, so that the width of the suspension device was reduced to the maximum, only slightly wider than the latch, therefore, the lifting requirement in the narrow width working well can be met.

When the pipe section is erected, the eccentric roll-over hole is removed and the two upper lifting holes are used to lift the pipe down the well instead of the clamp structure. When the horizontal space of the working well is restricted by the factors such as the supporting beam and the side wall, pipe joints can also be lifted into the well.

Figure 10. Side hoisting hole of pipe section.

Figure 11. The pitch is erected by the eccentric vertical roll hole before it is lowered into the well.

Figure 12. Down-hole after changing lifting point.

4.3 End reinforcement

Head reinforcement close to important pipelines, high safety risk, small site. The ground reinforcement at the end of the pipe jacking well is carried out strictly outside the protected area of 5 m each of the pipeline center, and is carried out between the pipeline protection edge and the end wall. The ground reinforcement of the launching shaft is carried out by the single-axis mixing pile with a diameter of 1 m, and a row of SMW piles (inserted profiled steel) near the end wall of the launching shaft are used. The first row of Q235h profiled steel with a length of 21 m is fully inserted, and the size is 700 x 300, the second row is inserted one at a time. The width of initial well reinforcement is 1.3-5.4 m. The reinforcement range extends 3m

along the side of pipe jacking channel, during the construction of the mixing pile, the pile position, the verticality, the amount of cement, the down rod of the drill pipe and the speed of raising the rod should be mainly controlled. The design requires that the strength of the reinforcement should not be less than 0.8 mpa, the cement slurry water-cement ratio is 0.8 ~ 0.85, the speed of lower pole is $\leq 50\text{cm/min}$, the speed of raising pole is $\leq 30\text{cm/min}$, the amount of cement used per meter is about 305kg. The actual strength is 3.8 ~ 4.8 mpa by core-pulling test, and the effect of end reinforcement is shown in Figure 13.

Figure 13. Plan of reinforcement of starting well end.

Figure 14. Effect diagram of end reinforcement.

The receiving well end is reinforced by ground reinforcement combined with horizontal grouting in the tunnel, the ground end is reinforced by two rows of something $1000\text{mm}@750\text{mm} \times 750\text{mm}$ large diameter mixing piles, and the horizontal grouting in the tunnel is reinforced by something 42 sleeve valve pipe grouting, the grouting range extends the direction of pipe jacking to 8m, and the position of transverse passage is 10m. The grouting hole is arranged in plum-shaped shape, the spacing is 1.5 MX 1.5 m, the grouting pressure is 0.4 ~ 0.6 mpa, the water cement ratio is 0.6 ~ 1:1. The grouting hole is made of cement. The plan of reinforcing the end of the receiving well is shown in Figure 15

4.4 Breach

4.4.1 Initial breach

Large section, big safety risk, before the hole is broken, first of all, the diaphragm wall to check the

Figure 15. Receiving well head reinforcement plan.

end of the reinforcement, according to the hole depth of 2m control, the number of holes taken from a single hole 9.

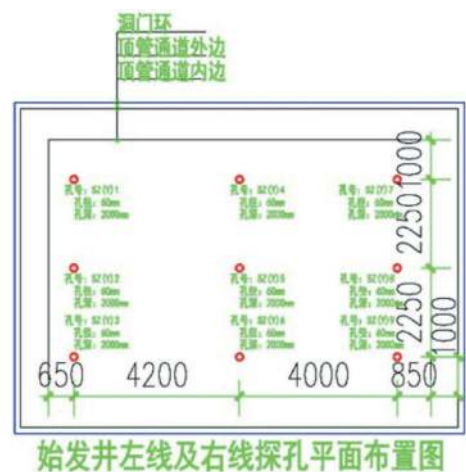

Figure 16. Layout of horizontal probe hole.

In order to reduce the amount of work and speed up the efficiency of the door breaking, the reinforcement cage is partially adjusted during the construction of the connecting wall at the part of the door, and part of the reinforcement is replaced by the box-shaped steel box, which is welded with 1 cm thick steel plate, the length is 8.5 m, the width is 1.05 m, the middle is provided with 4 baffles, and the tube silo is provided for the convenience of concrete pouring at the lower part of the steel box, the width is not less than 0.45 m, in order to prevent the steel box from floating during the concrete pouring process, two water injection pipes are embedded on the top of the steel box, and when the reinforcing cage is lowered, water is injected into the steel box through the water injection pipe embedded on the top.

When the hole door is broken, the time and sequence of the hole door should be mainly controlled. First, the steel plate on the surface of the steel box should be cut off and the connecting wall of 600mm thickness should be broken. Then, the

Figure 17. Connecting wall steel box processing.

Figure 18. Actual picture of the steel box with wall at the end.

pipe jacking machine should be assembled, after the pipe-pushing machine is assembled, the steel plate on the earth-facing surface of the steel box is cut off and the connecting wall with 200mm thickness of the earth-facing surface is broken.

In the course of hole breaking, we should pay close attention to the changes of the hole and set up monitoring points to monitor the structure of pipe jacking well.

4.4.2 Receive hole door broken

The hole of the receiving well is destroyed by the gun and the manual air-axe. The first stage:

1. When the tip of the pipe ejector reaches the diaphragm wall, continue to push, let the tip of the knife into the diaphragm wall as much as possible, reduce the gap between the big disc and the diaphragm wall;
2. Stop digging, the grout is made of cement, bentonite and alumina, which can stop the water and keep the lubrication effect at the same time, easy to continue jacking machine.
3. empty the silo, observe whether there is groundwater infiltration and infiltration of water in the silo, when the infiltration is large, take other measures to deal with or receive the program;

4. then chisel the whole hole door diaphragm wall skin 10-20cm, chisel out the first layer of steel bar and cut.

Figure 19. Schematic diagram of the first stage.

The second stage: to determine the large cutter head, from the bottom to the upper chisel out of concrete and cut off the second layer of reinforcement, the whole break the whole center of the large cutter head;

Figure 20. Schematic diagram of the second stage.

The third stage: push the pipe machine forward to the upper and lower edge of the knife to reach the wall, pushing the process of injecting high-pressure water cooling;

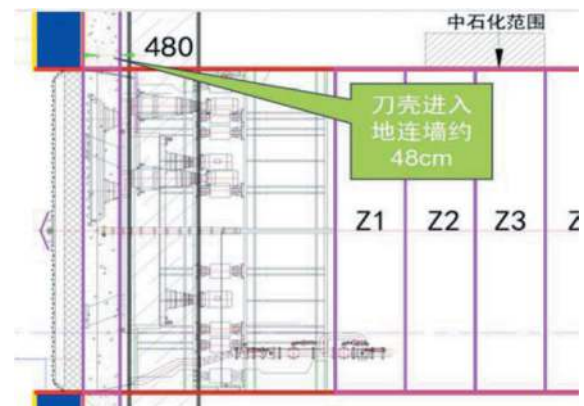

Figure 21. Schematic diagram of the third stage.

Figure 22. The third stage.

The fourth stage: First Chisel off the upper two edge knife disc parts of the connecting wall and reinforcement, after chisel off the lower part;

Figure 23. Schematic diagram of the fourth stage.

Figure 24. Fourth stage.

The fifth stage: pushing the pipe machine into and out of the hole.

In the same way as in the initial stage of tunnel excavation, the instability of the soil on the face of the tunnel may lead to the risk of collapse, mud bursting, water and sand gushing during the process of tunnel excavation and pipe jacking, due to the large size of the tunnel door, it will lead to a long time for manual chiseling. In order to ensure the safety of the pipe jacking machine, a number of measures have been taken:

Figure 25. The fifth stage.

- (1) before the hole is broken, the pipe ejector is pushed into the connecting wall at the receiving end, and then the hole is broken, to ensure that the earth remaining behind the hole is the minimum. Once the hole is broken, the pipe ejector is pushed out of the face of the hole with the fastest speed, minimize water seepage channels;
- (2) before breaking, divide into zones and layers according to the plan strictly, clean up the discarded materials in time, ensure the stress of the face is released evenly, and avoid the water gushing and sand gushing caused by single point breakdown;
- (3) when conditions permit, excavator, Crusher and other large-scale equipment should be used to speed up the breaking speed and complete the breaking of the tunnel door during the period when the deformation of the soil on the face can be controlled;
- (4) the above-mentioned reinforcement measures can also further ensure the stability of the soil on the face of the face and enhance the safety of the tunnel door.

4.5 Double-line close-fitting pipe jacking deviation control

When the large-section pipe-jacking method is used in this project, two tunnels on the left and right lines shall be constructed respectively. As the distance between the two tunnels is only 1.5 m, the latter tunnel on the right line will be more affected by the first tunnel on the left line. During the construction of tunnel by pipe-jacking method, it is necessary to inject drag-reducing mud to lubricate the pipe joints behind the tunnel wall, so the slurry shall be replaced after the construction of pipe-jacking method, the fluid resistance-reducing mud is replaced by a permanently solidified cement slurry to stabilize the tunnel. In the process of thixotropic slurry replacement in the left-hand tunnel, the slurry will diffuse to the surrounding stratum, and play a certain role in stratum reinforcement, due to the influence of unilateral hard formation, the horizontal attitude is difficult

to control. At this time, the ground rotary jet grouting pile (driving empty pile) method is used to soften the ground agitation and increase the horizontal deviation correction space of pipe jacking machine.

By using the external force to change the stratum state of the face of pipe jacking machine, the geological hardness of both sides of the face of pipe jacking machine tends to be uniform, later construction of the right-hand tunnel will suffer less reaction from the shaping of the left-hand tunnel. The pipe-pushing machine's edge cutter can also cut the soft soil layer better, and with the help of the pipe-pushing machine's own hinged oil cylinder, it is easier to achieve posture control, it is favorable for adjusting the attitude of pipe jacking machine. Finally, the attitude of pipe jacking machine is effectively controlled, and the schematic diagram of jet grouting pile is shown in Figure 26.

Figure 26. Schematic diagram of jet grouting pile.

13/2000

5 CONCLUSION

Through the application of key technologies such as pipe jacking machine selection, end reinforcement, pipe segment hoisting and tunnel door breaking, the left line pipe jacking of the large section pipe jacking project of the seaside station began to 2023 on January 28. On March 15, the 2023 pipe jacking was completed. It took 47

days for the pipe jacking to be completed, and the excavation time was 48.5 m, with an average of 1.03 m per day. The right line pipe was 2023 on May 18 and 2023 on June 30. It took 44 days and 52.5 m, with an average of 1.19 m per day. During the pipe jacking construction, the monitoring of the ground and underground pipelines was normal and no early warning occurred.

The successful implementation of large section pipe jacking in Waterfront Station has become the first project of Guangzhou Metro to use pipe jacking method in the main structure of metro station, it solves the problem that the open-cut method and mine method can not be used in the construction of high-pressure pipeline in the main body of the station.

Box jacking construction technology for large cross-section box culverts passing under existing high-speed railways

Chen Cheng, Jiahui Wang & Yuandong Li*

China State Construction Engineering (Hong Kong) Limited, Hong Kong, China

ABSTRACT: The APM & BHS tunnel construction underneath the MTR Airport Express Lane (AEL) railway is one of the critical projects for the Hong Kong International Airport's Third Runway System (3RS) as the railway is constructed on a reclaimed land and spans across the APM & BHS tunnels. This article demonstrates the example of APM & BHS TUNNELS ON EXISTING AIRPORT ISLAND project to describe the detail applications of i) TAM pipe full-section fan-shaped grouting technology, ii) MTBM tunneling machine advanced pipe shed support technology, and iii) combined push-pull technology for the precast box jacking. Firstly, the grouting curtain walls are well established in AEL areas to reinforce the soil in the early beginning of the construction, which seals up a closed box. Then, the grout materials are filled into the sealed area to enhance the integrity and quality of the reinforcements. Secondly, before excavating the tunnel, a row of large horizontal pipe shed supports are installed to strengthen the soil, which guarantees the ground settlement for the subsequent construction works to be within the allowable Alert-Alarm-Action (AAA) levels. Finally, by applying the Anti-jacking system on the tunnel roof level, along with the computerized control of the hydraulic jack system on the tunnel base level, the Pull and Push actions are generated on the precast box structure. With the above techniques, the stability of the box jacking operation is ensured.

Keywords: box jacking tunnel, Micro TBM, Alert-Alarm-Action, Grouting

1 INTRODUCTION

With the development of modern cities, it usually occurs that the to-be-constructed underground facilities pass under the existing important constructions, such as the high-speed railways. Thus, it is important to develop and deploy reliable techniques to efficiently carry out the new project while ensuring the structural safety and daily operation of the existing constructions.¹

During the past decades, several construction techniques emerges [1-5], which provide many available choices for the engineers to build the new constructions under the existing facilities. The current techniques play a role in different stages of the construction. Specifically, in the early beginning of the construction, the soils around the to-be-constructed area need to be reinforced to ensure the construction safety of the sequential operations. Available techniques in this step include the TAM fan-shaped grouting technology. In advance of the tunnel excavation, the soil should be further

reinforced in order to restrict the ground settlement. The technique used in this step includes the MTBM tunneling machine's advanced pipe shed support technology. Finally, during the box jacking operation, the stability of the structure must be secured to ensure the safety of both the existing construction and the current project. The available techniques include the Anti-jacking system on the tunnel roof level and the computerized control of the hydraulic jack system on the tunnel base level, which generates the Pull and Push action on the precast box.

The above techniques developed in the recent decades provide a reliable framework for the construction under an existing structure. Thus, we apply such techniques in the current project of the APM & BHS tunnel construction underneath the MTR Airport Express Lane (AEL) railway, which is one of the critical projects for the Hong Kong International Airport's Third Runway System (3RS). The railway is constructed on a reclaimed land and span across the APM & BHS tunnels, which is a typical example that

*Corresponding author: liyandong@cohl.com

applies the advanced techniques mentioned in the last paragraph.

In the following parts of the article, we will firstly introduce the background of the APM & BHS TUNNELS ON EXISTING AIRPORT ISLAND project in section 2. Then, the critical techniques, including the TAM pipe full-section fan-shaped grouting technology, the MTBM tunneling machine advanced pipe shed support technology, and the combined push-pull technology for the precast box jacking will be introduced in section 3. The strategies to combine the techniques in this project is introduced in section 4. Concluding remarks are provided in section 5.

2 BACKGROUND

The Hong Kong Airport Authority's unmanned vehicle and baggage conveying tunnel project on the airport island is an ultra-large cross-section and ultra-shallow tunnel. It is located in the area which is both the old reclamation area of the Hong Kong Airport and the MTR Protection area. The conditions of the construction site are shown in Figure 1. The main structure of the 30m-long tunnel passes under the existing Airport Express railway. The geological conditions are poor, which increase complexity of the construction environment is complex, where the geological section of the box jacking location is shown in Figure 2. Thus, in order to reduce the ground settlement during the tunnel pushing process, the project team adopted the side-by-side jacking construction method of two box culvert tunnels based on the actual

conditions of the construction site. The tunnel crossing was realized by pushing the precast box culvert. The construction starts from January 2022. By June 2022, the ground settlement during the entire construction process will not exceed 11mm, ensuring the smooth operation of the Airport Express Railway. Owing to the advanced construction techniques adopted in the project, the construction speed is ideal and the construction quality is extremely high, ensuring the smooth completion of the project.

During the construction process, there are several restrictions. Firstly, the nearby Hong Kong International Airport should be strictly ensured to be unaffected by the construction. Secondly, the construction machinery must comply with the height restrictions of the airport, operating time restrictions, construction under the AEL, to be carried out in the limited time (1:00 to 4:30 am). Thirdly, during the construction period, the operation of the three main traffic arteries around the airport shall not be affected. Moreover, the existing underground public facilities and pipelines of the airport are complicated, so they must be protected during construction and excavation, which increases the difficulty of construction.

3 CRITICAL TECHNIQUES

In this section, three critical techniques used in the project, including the TAM pipe full-section fan-shaped grouting technology, the MTBM tunneling machine advanced pipe shed support technology, and the combined push-pull technology for the precast box jacking, will be introduced. The applications of these three techniques in the real project will also be illustrated in detail.

3.1 The TAM pipe full-section fan-shaped grouting technology

The Tube-à-Manchettes (TAM) technique uses the sleeved perforated pipes to inject the grout into the soils, with partial or complete displacement of infilling ground water [6], as can be seen in Figure 3. According to the features of the grout injected into the soil, the TAM can be categorized into two stages, which is named as the cement bentonite grouting phase and the chemical grouting phase.

In the cement bentonite grouting phase, the grout fills up the relict joints of the soil mass and the large voids between the soil particles. In the chemical grouting phase, the chemical grout, which is a chemical solution penetrates and fills up the voids between the soils particles. All the infilling ground water is expelled. When the grout has set, the soil mass becomes a matrix of soil and grout and possess properties quite different from its original soil mass.

The cement bentonite grout with the same mix proportion as that used for the Rock Fissure grouting mentioned in the previous section is injected at 1m stages for each grout pipe from bottom upwards first.

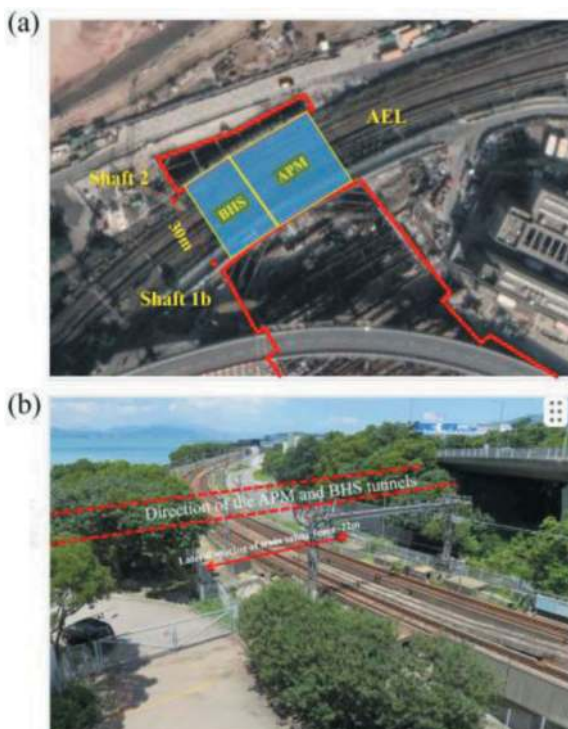

Figure 1. Sketch of the construction site.

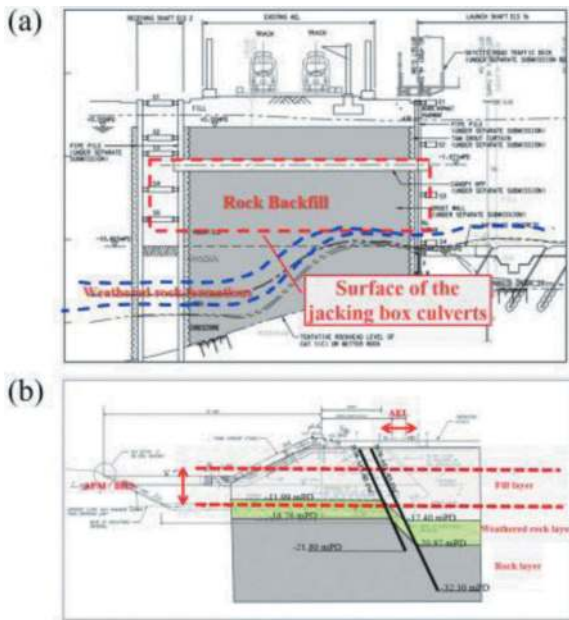

Figure 2. Geological section of the construction project.

Figure 3. Schematic sketch of the TAM technique.

After setting of the cement bentonite grout, chemical grout is injected at 0.33m stages from bottom upward as well for each grout pipe. Grouting records are kept as that for the rock fissure grouting.

A typical application of the TAM technique is to seal soil mass above and underneath a tunnel excavated in soil under compressed air condition, as used in our current APM & BHS TUNNELS ON EXISTING AIRPORT ISLAND project. From Figure 4, it is noticed that the cements is well injected into the rock layer, which seals up a reinforced closed box for the following construction procedures.

3.2 The MTBM tunneling machine advanced pipe shed support technology

After the reinforcement of the soils around the to-be constructed location, the soils are needed to be further strengthened in order to ensure that the ground settlement of the sequential constructions to be allowable within the AAA levels. Such targets can

Figure 4. Excavation surface of the grouting area.

be achieved by applying the Micro-Tunneling Boring Machine (MTBM) techniques [7-9].

The technology of MTBM is used for the advanced support of the pipe shed in the upper part of the box culvert tunnel. The pipe shed is used to bear the load of the covering soil above and provide space for excavation and box culvert pushing below. Especially, for a 30m long pipe shed, the construction error is only within 10mm, which is currently the most accurate pipe shed construction technology in the world. Since the MTBM uses full hydraulic power, the construction disturbance of MTBM is very small. This feature is very helpful for controlling the settlement of the airport railway line above and retaining the clearance height below the tunnel.

Next, we will illustrate the mechanism and procedure of the MTBM in detail.

3.2.1 Preliminary preparation

Since the construction site of the pipe shed is located under the existing Airport Express Railway (AEL), the elevation is -2.47mPD, which is lower than the groundwater level elevation (+3.50mPD). Therefore, relevant preparations should be properly handled before starting the pipe shed construction. The required preparations include (1) full-section grouting at construction location; (2) shaft excavation; and (3) the construction of the base slab and reaction walls. Note that the back-fill should be conducted seven days after the pouring of the reaction walls.

3.2.2 Drilling and installation of the equipment

The MTBM system consists of three parts, i.e., (1) the drilling system; (2) the slurry circulation system; and (3) the central control system, as shown in

Figure 5. Firstly, the drilling system consists of a slurry-water balance shield machine and a hydraulic jack, where each push can drill up to 3m. Then, the slurry system is used to supply clean water and process the slurry carried from the drilling system. The MTBM system is operated via the central control system, which controls the direction and speed of the drilling.

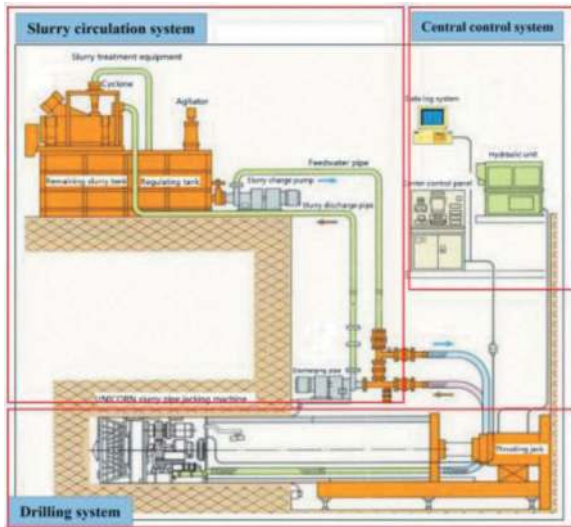

Figure 5. Schematic sketch of the MTBM system.

Besides the installation of the auxiliary equipment, that of the jacking equipment is also important. The pushing equipment mainly consists of four parts. The first part is the installation of the hydraulic jack, whose maximum push is 3000kN, with 1.5m/section. The second part is the installation of the steel backrest, which transmits the push applied to the reaction wall. The third part is the jacking iron, which is placed between the rear end of the steel

pipe and the jacks, where the push is applied to the steel pipe sheds. The fourth part is the guide rails, which support the steel pipes and play a guiding role of the MTBM system.

After the installation of the auxiliary and jacking equipment, the drilling can be started. There are two steps for the drilling operation. Firstly, before starting drilling, an entrance ring needs to be installed, which has two functions: (1) serving as a guide for the drilling; (2) sealing the entrance of the pipe shed to prevent groundwater from flowing into the shaft during the drilling. Then, after the entrance ring is installed, the micro shield machine needs to be installed and checked.

During the drilling, the slurry-water balance should be guaranteed. This construction method uses a slurry-water balance shield machine to transport pressurized slurry into a sealed slurry-water tank to form a mud wall to maintain the stability of the excavation surface. The main component of the slurry is bentonite solution. In order to maintain the stability of the excavation surface, grouting will continue until the construction of the branch shed is completed regardless of whether the MTBM is operating or not. Finally, the laser system is utilized to monitor the drilling procedure and provide real-time corrections.

3.2.3 Grouting

The grouting operations are needed in the drilling process. According to the difference in targets, the grouting operations are categorized into four kinds, i.e., the gap grouting, the steel-pipe-filling grouting, water-stop grouting, and compensation grouting. The first kind is the gap grouting. It is known that the diameter of the micro-shield machine is slightly larger than the diameter of the steel pipe of the pipe shed. Therefore, there is a tiny gap left between the steel pipe and the drilled hole wall after the installation of the pipe shed. In order to minimize the risk of

Figure 6. The procedure of the MTBM tunneling machine advanced pipe shed support technology.

ground settlement, the gap needs to be filled immediately with grouting to reduce. The grouting material is bentonite cement slurry with a design strength of 10MPa.

Then, the steel-pipe-filling grouting is conducted to enhance the rigidity of the pipe shed, which is operated after the gap grouting. The grouting material should be anti-shrink cement to ensure the validity of the grouting.

Besides the gap and steel-pipe-filling grouting, the water-stop grouting and compensation grouting are also needed to further improve the construction quality. In order to ensure that the water head remains below the design water level before drilling, or if an unexpected situation occurs when the groundwater level rises during drilling, water-stop grouting should be performed. The grouting fluid is obtained by mixing sodium silicate solution and cement slurry in equal volumes. On the other hand, during the drilling process of the micro-shield machine, it will cause ground settlement. In order to avoid irreparable losses, corresponding compensation grouting pipes must be installed before the construction of each pipe shed. The slurry is bentonite cement slurry.

3.2.4 Applications in the construction projects

In our current APM & BHS TUNNELS ON EXISTING AIRPORT ISLAND project, the MTBM technique is successfully deployed, where the construction procedure is shown in figure 6. Firstly, the entrance ring is installed to enable sequential operations. Then, both the guiding collar and the jacking equipment are installed with a high standard.

After completing the preparations, the initial drilling is conducted. During the jacking process, the error is strictly controlled by the laser. At the outlet of the tunnel, the foundation ditch support is utilized. In the end, the TBM is connected at the exit of the tunnel.

The entire process was carried out during the night shutdown of the Airport Railway Line (1:00 to 4:30 am). During the construction process, no complaints were received from the MTR Corporation. Related parameters are listed in the following. Outer diameters of the pipe sheds are set as 1430mm, with the number of the pipe sheds equal to 26. The lengths of the pipe sheds are set as 30m for both APM and BHS. The drilling depths (from sea level height) are set as -0.6m for the BHS and -1.0m for the APM. The drilling area is the grouting backfill stone layer. Note that a pretty high standard is required for the drilling process.

3.3 Combined push-pull technology for the precast box jacking

3.3.1 Patterns of the combined push-pull technology

Commonly used tunnel crossing technologies include open excavation, underground excavation, shield tunneling, immersed tube method, etc., which have distinctive applicable scenarios. However, in ultra-shallow burial and ultra-large cross-section scenarios, traditional methods may not be applicable, or may cause significant interference to the surrounding soil and ground, making it difficult to meet engineering requirements.

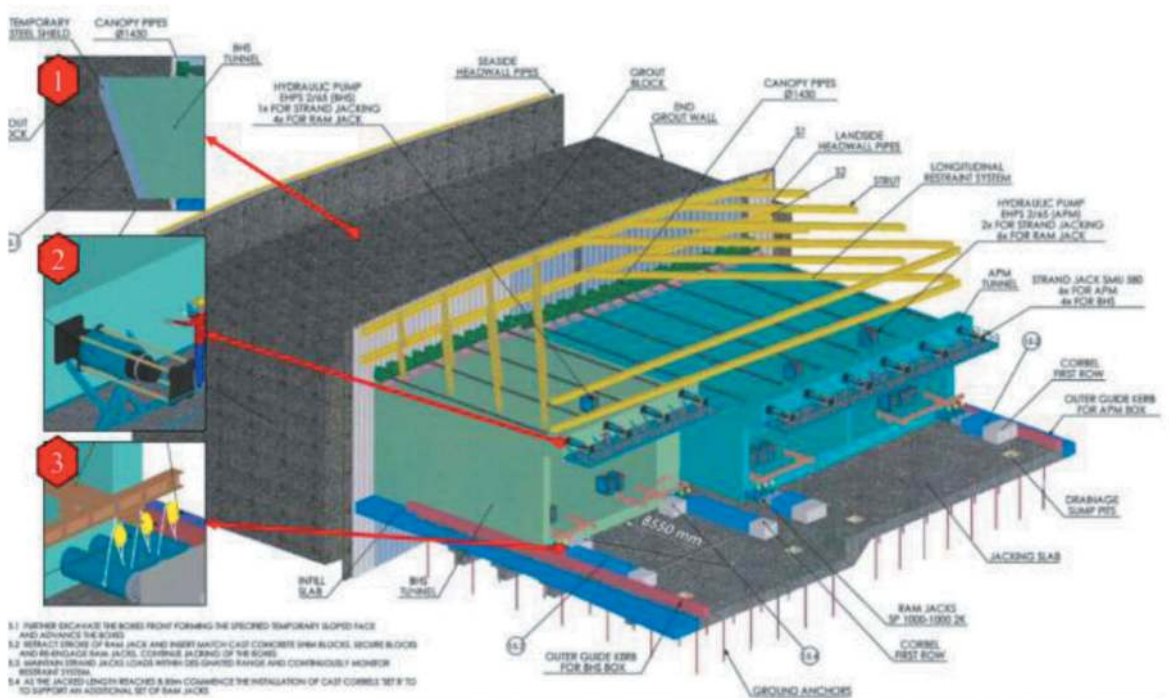

Figure 7. Schematic diagram of main tunnel box culvert jacking construction.

In comparison with the traditional approaches, the push-pull technology [10-12] introduced in this construction method has the admired characteristics of (1) combination of bottom push and top pull, which reduces the subsidence of the ground; (2) small jacking resistance, which relaxes the requirements of the force of the jacking system; (3) high smoothness in the construction process, which efficiently reduces the time consumption; (4) more auxiliary facilities; (5) small ground settlement; and (6) high degree of mechanization and low labour intensity for workers. Schematic sketch of the combine box jacking technique is depicted in figure 7.

3.3.2 *Applicable range*

This construction method is suitable for tunnel construction in complex urban environments and under existing railways, highways, buildings and other areas that have strict requirements for ground settlement. It is especially suitable for situations where the thickness of the covering soil is very shallow. It does not have high requirements on geological conditions and can still be applied even under loose surrounding rock conditions.

3.3.3 *Mechanism of the technique*

Schematic diagram of main tunnel box culvert jacking construction in figure 7. First, a push floor is constructed in the launch shaft and the floor is anchored to the formation. Construct two independent side-by-side box culvert structures (BHS, APM) on the push floor. The tunnel axis is not parallel to the direction of advancement. The outer contours on both sides of the two tunnel box culverts are appropriately thickened and designed to be parallel to the direction of advancement to ensure that the box culverts will travel straight along the horizontal plane in the direction of advancement during advancement.

The power of push-pull combined jacking is provided by a push system acting on the base plate at the bottom of the box culvert and a pulling force system acting on the upright plate at the top of the box culvert. The push force accounts for about 80% of the total power and the pulling force accounts for about 20%. In the push system, one end of the hydraulic jack contacts the base plate at the bottom of the box culvert, and the other end contacts the reaction block anchored on the push base plate to provide push. The pull system uses steel strand jacks to provide power. During the advancement process, friction will occur between the box culvert roof and the horizontal pipe shed support above. The main function of the pull system is to prevent the horizontal pipe shed support and the upper covering soil from moving forward under the action of friction.

The two box culverts are advanced alternately to minimize the resistance to advancement, and the tunnel surface is excavated while advancing. BHS will push forward first, and APM will follow closely, pushing about 1.5m each time until a pushing distance of about 30m is completed. The entire tunnel

box culvert structure enters the receiving well position in the lower area of the Airport Express Railway to ensure that the tunnel crossing can be completed while not affecting the normal operation of existing facilities.

3.3.4 *Construction process and key points for operation*

To prepare for the construction, several steps are needed, which are listed in the following.

Firstly, the jacking floor is designed and constructed, as sketched in Figure 8. The jacking floor locates in the starter well. It serves as a platform for building the main structure of the culvert, which is used to fully support the reaction force generated by the culvert propulsion. The above approaches ensure that no force is transmitted to the surrounding lateral support system.

Secondly, the retaining wall is designed and constructed. A retaining wall is constructed around the jacking floor to bear the lateral load from the soil for the removal of the overhead and the subsequent construction of the box culvert structure. The construction of the retaining wall shall be carried out after the completion of the pouring of the nearby jacking floor, so that the installation of the ground anchor above the jacking floor can be carried out at the same time as the construction of the filling plate and retaining wall.

Thirdly, the tunnel main structure is designed and constructed. The main structure of the tunnel is the part of the BHS and APM tunnels located under the airport express line. The tunnel box culvert structure needs to be precast in the ejector shaft and pushed to the airport express line. Among them, BHS is 19.888m wide×10.995m high×32m long, and APM is 30.85m wide×9.019m high×32m long, with a cross-section area of more than 400m². The front section of the box culvert is not vertical. However, the top protrudes from the ground at an angle of 70° and is parallel to the front excavation face. A vertical plate is designed at the top of the rear end for the installation of the pulling system and temporary working table.

Figure 8. Construction of the jacking floor.

Figure 9. The procedure of the box jacking construction.

Finally, the ADMS system is utilized to monitor the ground settlement. The ground settlement requirements of the tunnel pushing are very strict, so we use the ADMS system to monitor the whole area 24 hours a day during the construction period. The system uses a total station, located in a fixed location, in accordance with the set procedure, every hour will be within the scope of all monitoring mirrors monitoring, and the relevant data transmission back to the office base station. When the settlement value of a certain location exceeds the preset warning requirements, the system will automatically contact the worker to deal with it according to the relevant regulations. The above processes are summarized in figure 9.

Basic information of the tunnel is listed as follows. The weight of the BHS tunnel is 7,700 ton, while that of the APM is 9,500 ton. The maximum design jack force for the BHS tunnel is 141,000kN, while that for the APM tunnel is 210,000kN. The footage per construction cycle is set as 1.5m. The angle of the excavation surface is set as 70°.

3.3.5 Automated jacking system

The automated jacking system includes three parts, i.e., the push system, pull system, and electronic monitoring system. We will introduce these two systems in the following.

The push system uses hydraulic jacks and is supported by a steel bracket fixed to the rear of the base plate of the box culvert, as shown in Figure 10. One end of the jack contacts a steel gasket welded to the rear of the foundation plate of the box culvert, and the other end contacts a row of concrete spacers. The end of the spacer block is supported by a reaction block anchored to the ejector bottom plate, which is restrained by shear keys and four horizontal bars. When the push has been carried out for a certain distance, the reaction block used earlier should be abandoned to avoid the arrangement of the spacer block is too long, resulting in a large eccentric force. There are two kinds of jacks used in the push system, namely SP460 and SEPS2200, respectively. The BHS

propulsion will primarily use long-stroke SP460 jacks. However, the force of the SP460 jack needs to be supplemented by additional SEPS2200 jacks after the propulsion in halfway. APM uses a combination of two jacks from the start of propulsion. Both jacks are powered by an electric hydraulic pump with an additional fuel tank.

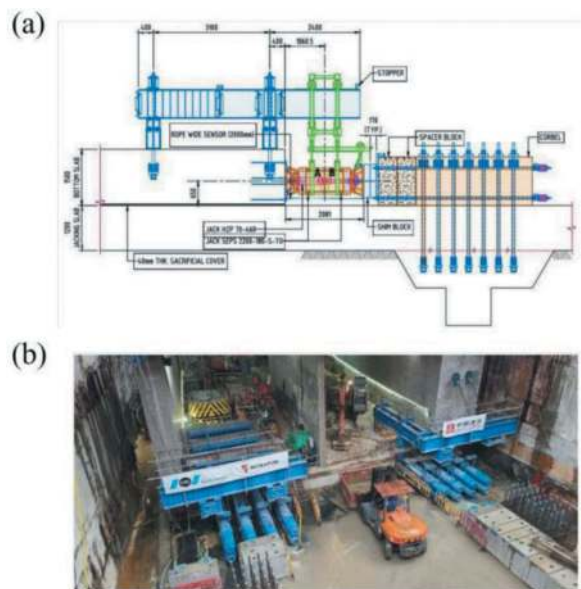

Figure 10. Layout (a) and construction (b) of the push system.

The pull system, also known as the anti-drag system (ADS), acts on the concrete vertical slab at the top of the box culvert. The harness of the steel strand jack used is placed in the respective conduit, located in the center of the horizontal pipe shed support and extends to the end of the horizontal pipe shed support in the receiving well. The main function of the pull system is to avoid the displacement of the horizontal pipe shed support under the action of friction with the top of the box and culvert tunnel, and to

reduce the settlement of the overlying soil. During propulsion, there are four stranding jacks for BHS and six for APM, the jack model is SLU580, which is also powered by an electric hydraulic pump with additional fuel tanks.

The hydraulic jacks and strand jacks mentioned above are connected to a central control station and are operated by staff in the central control room to push the box culvert. The electronic monitoring system is set up so that the staff can simultaneously control one or more sets of jacks, which need to be calibrated before they can be activated. The entire system is operated through an interface called the Bravo system, as shown in figure 11. The pushing load, jack stroke, and pushing distance during propulsion are closely monitored.

Figure 11. The central control station.

3.3.6 Combined push-pull box jacking into the tunnel

Before the jacking, the preparation work must first be completed: (1) the first row of reaction block is cast on the push bottom plate and pulled with the push bottom plate; (2) The temporary suspension system is installed at the end of the box culvert to support the push jack, and the temporary workbench of the wire jack is installed on the vertical wall at the end of the box culvert; (3) Complete the installation of the push jack, one end against the base plate at the end of the box culvert, one end against the reaction block on the bottom plate; (4) Jack hydraulic system and central monitoring system to complete the installation and testing, and complete the functional testing of the entire system.

After the preparations, the box jacking can be operated with two steps, i.e., (1) jacking towards the wall at the launch shaft, (2) jacking crossing underneath the railway line towards the reception shaft, which are illustrated in figure 12. The BHS tunnel weighs 7,700 tons and the APM tunnel weighs 9,500 tons. The footage of each construction cycle is 1.5m, and the tunnel excavation face is at a 70° angle to the ground.

Besides the above steps, a complete circle of the box jacking operation includes preparations of materials and facilities, controlling of the qualities, safety measures, environmental protections and benefit analysis.

3.3.7 Applications

The project of the Airport Island unmanned vehicle and baggage transport tunnel is an ultra-large

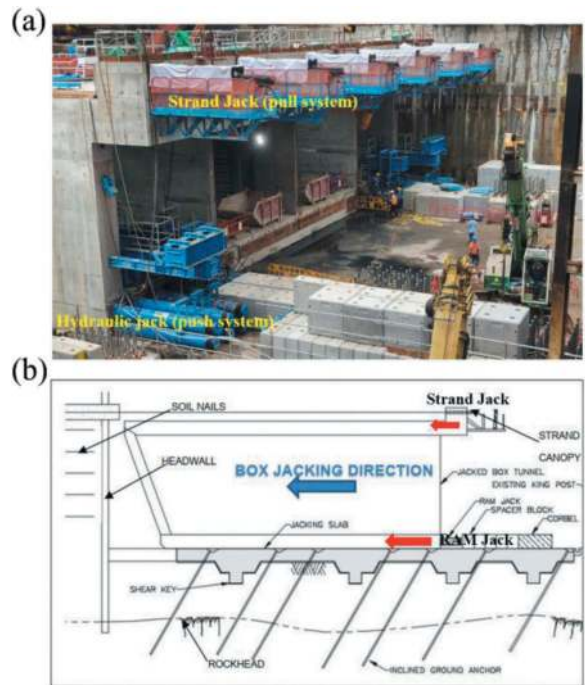

Figure 12. Layout of the box jacking.

section and ultra-shallow buried tunnel, located in the old reclamation area of the Hong Kong Airport and the MTR Protection area, with poor geological conditions and complex construction environment, in which the main structure of the tunnel about 30m long passes under the existing Airport Express railway. In order to reduce the ground settlement during the tunnel pushing process, the project team adopts the construction method of two box culvert tunnels side by side according to the actual situation on the site. The tunnel crossing is achieved by the precast box culvert jacking. The construction period is from January 2022 to June 2022, and the ground settlement during the whole construction process does not exceed 11mm. The combined pull-push box jacking technique ensures the smooth operation of the airport express railway and ideal construction progress. The resultant construction quality is very high, which ensures the smooth completion of the project.

4 CONCLUSIONS

In this article, we introduced the advanced technologies of the (1) TAM pipe full-section fan-shaped grouting technology, (2) MTBM tunneling machine advanced pipe shed support technology, and (3) combined push-pull technology for the precast box jacking and their applications in the APM & BHS TUNNELS ON EXISTING AIRPORT ISLAND project. These techniques show satisfying performances in the real applications. Such construction frameworks show large potential in further applications in future construction projects.

ACKNOWLEDGMENTS

We would like to express our sincerely gratitude to the supportive leadership colleagues on the construction site who made significant contributions to the completion of this article. We would also like to thank China State Construction Engineering (Hong Kong) Limited for providing financial support towards the submission of this paper.

City Rail Link – bored tunnel challenges in Auckland city centre, New Zealand

Thomas Cheung*, Shu Fan Chau & Tom Ireland
Aurecon NZ Ltd., Auckland, New Zealand

Sumi Eratne
City Rail Link Ltd., Auckland, New Zealand

ABSTRACT: The City Rail Link (CRL) Project is a major railway construction project underway in Auckland, New Zealand. It involves the construction of a 3.45 km underground rail link, which will connect the existing Waitemata (Britomart) and Maungawhau (Mount Eden) Stations. For Contract 3, the project includes the construction of two new underground stations, Te Waihorotiu (Aotea) Station near Aotea Square and Karangahape (KHP) Station near Karangahape Road along with the redevelopment of Maungawhau (Mount Eden) Station. The underground works include Twin Tunnel Boring Machine (TBM) tunnels, mined station platform tunnels, mined tunnels, caverns and cross passages, cut and cover tunnels and a cut and cover station. The City Rail Link is expected to significantly improve Auckland's public transport network, providing faster and more reliable train services across the city. The project is scheduled for completion in 2025. This paper describes the overall performance and challenges of Earth Pressure Balance (EPB) TBM tunnelling underneath Auckland's city center. The TBM started from the Mount Eden launching cavern, excavated under Eden Terrace, Central Motorway Junction (CMJ) and broke into KHP Station. The TBM was dragged through the station and re-launched in the mined stub tunnel. It continued her journey, passing through temporary anchors at the Aotea Centre and broke through at AOT station. The first TBM was launched on 17 May 2021, during the Covid-19 period and the last TBM tunnel was completed on 14 September 2022.

Keywords: Tunnelling, TBM, Performance, Bored Tunnel, EPB

1 INTRODUCTION

The construction of City Rail Link (CRL) includes a new 3.45 km double-track rail tunnel underneath Auckland's city center, extending the city's passenger rail system through the Waitemata (Britomart) Station in the Central Business District (CBD) and connecting to the existing regional rail network at Maungawhau (Mount Eden) in the city's inner South (Figure 1 and Figure 2). It is the largest transport infrastructure project ever in New Zealand (NZ) and will help Auckland cater for the demands of population growth over the next 30 years.

Contract 3 (C3) has included the main tunnel, stations, Western Line connection and rail systems and has been delivered by Link Alliance

(LKA), comprising City Rail Link Ltd (CRL), Vinci Construction Grands Projets S.A.S., Downer NZ Ltd, Soletanche Bachy International NZ Limited, WSP (NZ) Limited, AECOM NZ Limited and Tonkin + Taylor Limited. The reference design was undertaken by a Principal Technical Advisor (PTA) consortium led by Aurecon and including Jasmax, Grimshaw, Mott MacDonald, and Arup.

The Earth Pressure Balance (EPB) Tunnel Boring Machine (TBM), named Dame Whina Cooper, has excavated the two 1.6 km long tunnels from Mount Eden to central Auckland.

TBM, segmental lining production, TBM performance and overall tunnel construction quality control are of great importance for the success of a TBM tunnel project. The post construction review

*Corresponding author: thomas.cheung@aurecongroup.com

data from CRL C3 are valuable references for planning, design, and construction of future tunnelling projects in NZ. This paper aims to provide a summary of the post construction review of the CRL C3 TBM Tunnels.

Figure 1. Plan of CRL's alignment.

Figure 2. Section of CRL's alignment.

2 TBM TUNNEL WORKS

Tunnels comprise a cut-and-cover section connecting the completed C2 works in Albert Street to the Aotea Station with twin 7m diameter TBM bored section extending from Aotea Station to Newton Junction. There are two mined caverns at the southern end of the Newton Junction providing turnouts that are connected to cut and cover tunnels. The tunnels include emergency cross passages no greater than 325m centers.

The two bored tunnels are parallel and run underneath some of the city's most iconic areas, such as Grafton, the central motorway junction, KHP Road and the city centre.

The maximum longitudinal tunnel gradient is 3.25 per cent and the minimum horizontal tunnel radius is 141 m. Minimum cover at the Central Motorway Junction (CMJ) is about 7 m (a TBM tunnel diameter) and maximum cover is about 36 m above tunnel crown at Symonds Street.

The TBM worked 24/7, operated by a crew of 12 underground and a team of 12 above ground.

The machine's diameter is 7.15 m, weighs 910 tonnes, and the total length is 130 metres. The TBM was custom built for central Auckland soil conditions by the German tunnel machine company,

Herrenknecht, for the Link Alliance. The driven lengths for Drive 1 MC30 and Drive 2 MC20 are 1631 m and 1619 m respectively and transition at KHP station.

The anticipated excavated material along the proposed alignment is East Coast Bays Formation (ECBF) which has both rock and soil (clay like) characteristics. Under the influence of severe mechanical working, the clay aggregations may be disaggregated and release clay mineral particles. Therefore, a closed mode EPB type TBM is suitable to the ground characteristics at City Centre.

Figure 3. CRL's EPB TBM, Dame Whina Cooper.

3 GEOLOGICAL AND HYDROGEOLOGICAL CONDITIONS

The tunnelling route traverses a wide range of geology and ground conditions. Most of the tunnelling are within the weak rocks of the Waitemata Group rocks (ECBF, a turbidite sequence of alternating Sandstones and Siltstones) that underlie much of the wider Auckland region, while shallower structures at the North and South of the project also encounter younger sediments (Tauranga Group); volcanic materials (Auckland Volcanic Field, AVF); made ground (including reclamation).

The TBM bored tunnel alignment is mainly within the slightly to unweathered very weak ECBF (EU2), the UCS is about 1 to 5 MPa, except near or within the KHP Station. Tunnel excavation at that section is predominately within massive EUs3 and EUG3 (slightly to unweathered weak to moderately strong ECBF, the unit is also referred as "channelized sandstone") materials. The Unconfined Compressive Strength (UCS) is about 10 to 25 MPa. The mined tunnel construction sequence requires at KHP Station that TBM is able to transit through the platform tunnels (MC30 and later MC20) from the South to North.

The section of bored tunnel approaching Aotea Station is expected to encounter weathered rock (EW), with residual weathered material (ER) at the crown level.

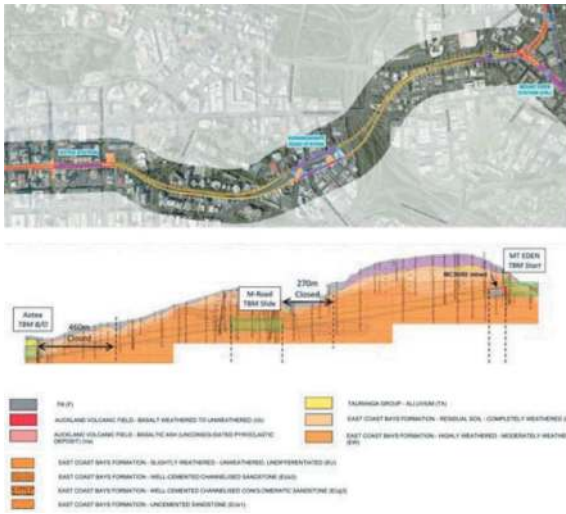

Figure 4. Geological longitudinal section of TBM.

The groundwater hydrogeology along the CRL alignment can be broadly summarised with typical two groundwater systems:

- Perched groundwater system: localized and non-continuous within the upper soils, fluctuates in response to rainfall events and flowing to local topographic sinks or shallow drainage infrastructure. This system is expected to be interrupted by structures including basements, service, roads etc.
- Regional groundwater system: a fully saturated groundwater generally observed below the surface of unweathered ECBF rock. The regional ECBF groundwater table is identified at a level slightly above or generally below the tunnel alignment within the ECBF rock.

Close shield TBM was running along the alignment with pressure so as to limit the ground movement and water ingress.

4 TBM SEGMENTAL LINING

The ring type designed for CRL bored tunnel is the universal type. This type of ring can be applied in both straight and curved sections of the tunnel alignment, without the need to include any special type elements to correct alignment deviation by the TBM during advancement.

The tunnel internal diameter is 6240 mm with six plus one key segment parallelogram ring configuration with trapezoidal key and counter. The concrete lining is 300 mm thick and designed to provide a 100-year design life. It is equipped with a continuous two barrier EPDM-hydrophilic gasket system installed around the radial and circumferential faces of the segments.

The minimum horizontal tunnel alignment radius is 141 m. To accommodate this tight curve two different ring lengths are selected, and their respective tapers were designed to negotiate the full tunnel alignment curvature range. Rings of 1600 mm in length have

been designed with a 60 mm taper to accommodate a minimum radius of 182 m, whilst 1100 mm long rings are designed with an 80 mm taper. The shorter rings will be used along sections with tighter curves and can accommodate down to curves with a - 94 m horizontal radius.

The temporary spear bolts at circumferential joint (i.e. Ring to Ring) are distributed equally around the face of the ring. The pitch of lining rotation is 27.962 degrees. Only a spear bolt is provided on each radial joint (i.e. Segment to Segment) for the key segment. Shear cones are also provided next to the bolt for around circumferential joints at cross passage locations and at break-in or break-out locations. The shear cones are included to increase the shear capacity between rings. They also assist with reducing stepping between rings.

One guiding rod is provided at each radial joint to facilitate the segment installation and reduce the stepping between rings.

Two cone recesses have been detailed on the intrados face of each segment to facilitate the use of a TBM vacuum pad segment erector. Primary grouting of the annulus is undertaken from within the TBM tail skin and secondary grouting is carried out through grout sockets cast-in segments.

Figure 5. Segmental lining configuration.

The concrete compressive strength of the lining is 50 MPa (cylinder strength). Three types of segment reinforcement (see Table) were provided to take account of varying ground conditions and alignment depth. All segment types also included polypropylene fibres to reduce spalling in the event of a fire within the main line TBM tunnels.

5 TBM PERFORMANCE

The project used a 7.15 m bored diameter EPB shield TBM, which was capable excavating in mixed faced conditions and operating in either semi-EPB, chamber full mode and EPB modes. The working

Table 1. Segment type and details.

Type	Details
A1	Steel Fibre Reinforced Concrete (SFRC) with 1.6 m ring, “standard rings”
A3	SFRC and reinforcement bars with 1.6 m ring (Steel ratio around 150 kg/m ³)
B	SFRC and reinforcement bars with 1.1 m ring (Steel ratio around 110 kg/m ³)

EPB pressure at tunnel axis was specified as 4 bars. The TBM was designed for a theoretical advance rate of 80 mm/min.

5.1 Cutterhead design

The cutterhead was designed to consider the TBM operation under the city centre and its ground geology. A cutting wheel equipped with “rippers” and cutters for hard layers and with an opening percentage of 44% to overcome possible clogging due to the weak and plastic nature of ECBF. It did result in some clogging of the cutter discs and the foam ports. The cutter discs located within the centre and long the arms were removed and replaced with rippers to help mitigate clogging and subsequent flattening of the discs. Cutting knives were equipped to cut the cable strands in the temporary anchors at Aotea Centre.

5.2 Penetration, thrust force and torque

The TBM had 13 thrust cylinder pairs and capable of a maximum thrust force of 41,167 kN at 350 bar with maximum torque 7,187 kNm. Operation parameters on thrust force and contact force are summarised in Table 2 and the parameters along the tunnel alignment are presented in Figure 6 and Figure 7. The machine was operating well within its maximum capacity. The operation of thrust cylinders was divided into 5 Groups from A to F. It was noted that the difference in total thrust from each group especially the top and bottom was limited in order to control over-excavation and to manage TBM drive tilting or sliding. This value is not a constant and depends on the geology, alignment and operation diameters.

The designed nominal thrust force of the TBM was 3.16 MN per pad, no ladder reinforcement was required for SFRC segments where normal lower thrust forces were applied. The operational thrust load on the segments was below the design limit. No

Table 2. TBM operational parameters.

Performance Items	MC30 Tunnel		MC20 Tunnel	
	Average	Max.	Average	Max.
Thrust Force (kN)	13,233	23,106	11,392	24,449
Contact Force (kN)	11,918	21,911	9,940	23,679

Figure 6. MC30 Drive thrust force data.

Figure 7. MC20 Drive thrust force data.

segment damage could be observed related to over-stress of the concrete capacity on site.

5.3 Face pressure

Daily Review Meetings (DRM) including the construction team, Construction Phase Services (CPS) team, instrumentation and monitoring team, geotechnical team and the owner verifier were held, and special meetings held during breakthroughs, traversing the temporary ground anchors at Aotea Centre, and during the Central Motorway Junction (CMJ) crossing. Face pressures, grouting with other TBM operational parameters and segment type were reviewed and discussed. A Permit to Tunnel (PTT) and associated parameter sheet were confirmed and issued to the construction team. The target and measured TBM face pressure at tunnel crown for both MC30 and MC20 tunnels are shown in Figure 8 and Figure 9. In general, the actual application face pressure was controlled well within the upper and lower bounds face pressures as confirmed from the DRM. It was noted that the face pressure was outside the bound at some locations, because the TBM operation parameters were adjusted according to the actual ground conditions and based on the monitoring results.

Figure 8. MC30 Drive TBM Face pressure data.

Figure 9. MC20 Drive TBM Face pressure data.

5.4 Ground conditioning and clogging

A foam agent was used for spoil conditioning of the EPB TBM spoil. During TBM operation, the foam agent was mixed with water and compressed air. The mixed material passed through the foam guns and injected into the front of the cutterhead via injection ports. Additional free water was injected into the chamber through independent lines to support and keep the foam in the chamber. Foam injection was controlled by 3 parameters: Foam Expansion Rate (FER); Foam Injection Ratio (FIR); and Foam concentration (C). These parameters were changed from time to time by the TBM operator, depended on the TBM advance. The average setpoint FIR mode of MC30 and MC20 Drives are 57% and 58% respectively. The average foam injection volume is 0.125 m³/ring vary from 0.01 to 0.5 m³/ring.

5.5 Reliability and breakdowns

During the TBM operation on both drives, the time for TBM operation and stoppage were recorded and grouped in 6 major categories: Excavation, Ring Building, Planned Stoppages/ Breaks and travel, Delay-Survey/ error -damage, Delay-System/ Cooling water/ Electrical and Delay-Conveyor/ Electrical. In general, the breakdowns include erector breakdown, TBM jacking rams breakdown, segment feeder damage, belt

conveyor breakdown and cutterhead intervention with maintenance (Figure 10). For MC30 drive, the major stoppages were corona virus disease (COVID-19) lockdown, conveyor belt installation, and TBM thrust ram replacement; for MC20 drive, the major stoppages were MC20/50 mined cavern headwall construction, tower crane breakdown/ windy days and conveyor belt breakdown. Free air interventions were carried out in the project and the locations of stoppages were chosen prior to the critical zones such as cross passage locations, Central Motorway Junction (CMJ) and existing temporary ground anchors zone at Aotea Centre. Also, the major maintenance was scheduled at the station/ cavern transition. The disturbance to the tunnel programme was minimised. Low wear was observed on the TBM cutterhead and cutting tools – mix of discs and rippers during interventions.

Figure 10. Tunnel face inspection during maintenance.

6 TUNNEL CONSTRUCTION

6.1 TBM launch, transition and retrieval

The CRL TBM was shipped from Herrenknecht's factory in China to New Zealand. The machine arrived in kitset pieces in late 2020 and installed at Mount Eden Portal.

After the TBM assembly, the TBM was launched at Maungawhau (Mount Eden) portal in MC30 mined tunnel and advanced north towards the CBD. Temporary steel launching frame (Figure 11) was set up in the MC30 mined tunnel for transferring the launching thrust to the shotcrete lining and ground. For the launching operation, the TBM was operated at a limited thrust output until the completion of a length of tunnelling where the entire TBM and backup gentries were within the excavated tunnel.

Both MC30 and MC20 drives, were excavated under the Symonds Street, CMJ and broke through into KHP mined Station. For MC3 platform tunnel in KHP Station, the TBM transit occurred with only primary lining installed whereas for MC20 the transit occurred after installation of secondary (permanent) lining. Within 21 m at each end of the platform tunnels, the cavern profiles were widened. The widening was required to allow sufficient length for the TBM transit alignment to shift towards the middle of the station and clear the walls of the typical section as shown in

Figure 11. Temporary launching frame in MC30 drive.

Figure 12. Then the TBM was re-launched in the stub tunnel at the end of platform tunnel by using temporary thrust frame set up at the widening platform tunnel.

Figure 12. TBM Transition in KHP MC20 mined tunnel.

After the re-launching, the TBM excavated along the Pitt Street, turned to Vincent Street and finally broke into the Te Waihorotiu (Aotea) Station at Mayoral Drive after passing the temporary ground anchors outside the Aotea Centre.

Figure 13. TBM MC20 drive breakthrough at Aotea station.

The TBM was dismantled after the MC30 drive excavation and re-assemble at MC20 drive for the second drive. After the second tunnel was built, the

TBM was dismantled and moved in pieces to the Ports of Auckland and transported back to the TBM manufacturer. The company deconstructed the machine and re-used suitable parts on multiple TBMs in the future.

6.2 Production statistics and progress

The tunnel production statistics and the time-chainage progress curves are summarised in Table 3 and presented in Figure 14 and Figure 15 accordingly. The production rate at MC30 for the first two months learning period was low, thereafter it was increased. The production was nearly stopped due to COVID-19

Table 3. Tunnel production statistics.

Items	MC30 Tunnel	MC20 Tunnel
Launch Date at Mount Eden Portal	17 May 2021	26 April 2022
Breakthrough Date at Aotea Station	22 Dec 2021	14 Sep 2022
Total Duration	7.3 Months	4.7 Months
Average Day (m)	7.4 m	9.4 m
Best Day (m)	33.6 m	34.0 m
Average Week (m)	51.9 m	69.5 m
Best Week (m)	162.1 m	187.2 m

Figure 14. TBM MC30 drive progress chat.

Figure 15. TBM MC20 drive progress chat.

Level 4 lockdown (i.e. approved to maintain minimum TBM operation with limited number of workers without segment production in the precast yard) for more than a month. Based on experiences gained from the first drive, the production rate in the second drive MC20 tunnel was higher.

6.3 On-site segment damage

The segment or ring damages during erection, excavation, advancing, and post construction activities were inspected and recorded. The damages were classified into three main groups: cracking, concrete spalling, and leakage. The damaged segments were inspected and repaired in accordance with the agreed repair. There were total 398 defects recorded for MC30 drive and 208 for MC20 drive. It indicated the damage rate occurred at every 2.6 rings in MC30 drive and improved to a frequency of 5.1 rings in MC20 drive. The majority of damage were cracks and it was improved by the experience in first drive and modification of the length of concrete pad on the segment.

6.4 Grouting

After the TBM excavation in the excavation cycle, the TBM left a gap between the excavation profile and the segmental lining. The theoretical cut diameter was 7.15 m, and the external diameter of the segmental lining was 6.84 m, leaving a theoretical void of 155 mm and 3.4 m³/m. This void was filled with cementitious grout, which was pumped through the tail shield pipes during the excavation cycle. Grouting was performed to the theoretical volume within $\pm 10\%$. The injection pressure was monitored to ensure the surrounding ground and water pressures were balanced. Monitoring of the injection pressure indicated if any voids were present, or if there was a blockage in the grouting line. The lining was designed to withstand maximum grout pressure of 1 bar above prevailing groundwater pressure. Figure 16 and Figure 17 presented the grout volume against the ring number. The injection volume was generally within the tolerance. It was noted that the gap was filled up with primary grouting at the cross passage location (Figure 18).

Figure 16. TBM MC30 drive grout volume.

Figure 17. TBM MC20 drive grout volume.

Figure 18. Primary grouting materials filled up TBM TAIL VOID.

Secondary grouting was also undertaken if there was evidence that primary grouting through the tail skin did not fully fill up the annulus between the lining and the ground.

6.5 Tunnel spoil

Up to 1,500 tonnes of spoil was excavated each day. Spoil from Mt Eden was a mix of clean fill, managed and contaminated. The spoil was either wet spoil extracted by the TBM from conveyor belt, or a clean, dry type of spoil removed during initial tunnelling operations. Clean fill was disposed of at the Three Kings Quarry in Mt Eden. All other spoil – managed or contaminated – was trucked to various disposal sites at Mercer in Waikato. The measured weight and excavated materials were important parameters to determine the ground geology and actual excavation volume. Depending on different ground conditions, the quantities of soil conditioner and additional free water were adjusted to obtain an optimum moisture content (MC) in spoil to ensure the effectiveness of TBM excavation, face support and mucking out.

6.6 Central Motorway Junction (CMJ)

The CMJ forms the intersection between three major motorways: Northern Motorway (SH1), Southern Motorway (SH1) and Northwestern

Motorway (SH16), which is one of the busiest roads in New Zealand. The MC30 and MC20 alignment lie in close proximity to three existing structures which are considered to be potentially adversely affected by the tunnelling works (Figure 19 and Figure 20). The structures are:

- 1) Upper Queen Street Retaining Wall Proposed MC30 alignment is approximately 1.5 m west of the nearest belled pile.
- 2) Newton Bridge No. 1 The respective horizontal clearances to Abutment O and Pier N from MC20 are approximately 2.0 m and 6.5 m respectively.
- 3) Soil nail retaining wall adjacent to the SH16 off ramp Clearance between the CRL tunnel crown and the CMJ retaining wall is approximately 7.52 m for MC20 and 9.5 m for MC30.

The ground cover to the tunnel crown for MC30 ranges between 9.0 m and 25.4 m and for MC20 ranges between 7.2 m and 23.1 m. Considering the change in ground cover, 3D Finite Element Model for tunnelling under the CMJ (Figure 21) were set up by LKA to assess the induced effects and determine the required face pressure.

TBM intervention was carried out for maintenance before entering CMJ to minimise the risk of stopping at CMJ so as to avoid unacceptable ground movement. The last tunnelling crossing the CMJ was completed in July 2022 with negligible monitoring readings.

Figure 19. CRL Tunnels at CMJ (facing South).

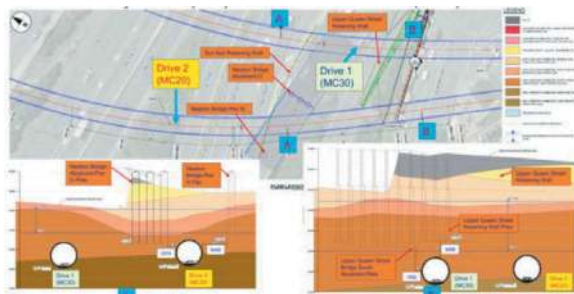

Figure 20. Geological Section at CMJ.

Figure 21. 3D finite element model for tunnelling under the CMJ.

6.7 Existing temporary ground anchors at Aotea Centre

Based on the desk study, there were ground anchors connected to Aotea Centre structures which were in the way of the CRL TBM drives (Figure 22). The retaining walls that were built during the construction are located along Mayoral Drive. Ground anchors investigations including investigation boreholes and CCTV were carried out at construction stage. It was found that the anchors are for temporary use and the head plates been cut which indicated that the anchors were inactive.

Knife tools were included on the Free air intervention was carried out within the anchor zone to remove the anchors from the tunnel face (Figure 23) which could reduce the risk of damaging the TBM. The last tunnelling crossing the ground anchors was completed successfully in September 2022.

Figure 22. Ground anchors at Aotea Centre.

6.8 Ground volume loss due to TBM tunnelling

The tunnels passed beneath residential and commercial areas, extensive and comprehensive instrumentations and monitoring were designed and implemented during construction. The instrumentations included individual and arrays of surface settlement markers and extensometers, piezometers, inclinometers, and convergence monitoring points inside the tunnels. The ground settlements recorded from the settlement marker arrays in different locations along the tunnel alignment have been back analysed by using the Gaussian ground movement model to determine the tunnelling volume loss. The

trough width parameter of 0.7 was fitting the Gaussian curves. The range of volume loss was determined to be between 0.1% and 0.4%.

7 CONCLUSION

The CRL Tunnels was the first TBM tunnel passing through the CBD area. The last TBM breakthrough was completed on 14 September 2022. The use of the EPB machine made a significant contribution to the success of the Project. The post construction review on TBM operation and performance, segmental lining manufacturing and building, tunnel construction, and quality control, has been reviewed and a summary has

been provided in this paper. It provides valuable reference for planning, design, and construction of future tunnelling projects in New Zealand.

ACKNOWLEDGMENTS

The paper is published with the permission of the City Rail Link Limited for which the authors would like to gratefully acknowledge. The design and construction of the project is currently undertaken by the Link Alliance.

Research and application of multi-curve small turn continuous belt conveyor*

Liwei Cui, Huigan Xu, Jianyong Shen, Jinming Cheng, Pengyang Song, Qinghua Qin
& Wang Yang

China Railway Engineering Equipment Group Co., Ltd., Zhengzhou, China

ABSTRACT: Through the analysis of the turning conditions, the definition of small turning belt machine is proposed, and the concepts of natural turning and forced turning are proposed for different turning radii. Through the force analysis of natural turning and forced turning, the corresponding turning adjustment measures are proposed. Through the analysis of turning radius and bandwidth under forced turning conditions, the concept of linear meter arc length difference is proposed, and it is used as an index to judge the difficulty of turning. Through the pumped storage power station project, the feasibility of forced turning measures under small turning radius is verified, and the theoretical and practical experience is provided for the slag discharge of the belt machine under the subsequent small turning condition.

Keywords: Small turn, Belt conveyor, Natural turns, Forced turns

1 PREFACE

Continuous belt conveyor as TBM supporting slag system, foreign countries as early as 1991 belt machine continuous slag system applied to tunnel construction, so far continuous belt machine slag technology has been very mature. Domestic tunnel continuous belt conveyor started late, as early as 2005 Liaoning Dahuofang water diversion tunnel project for the first time introduced continuous belt machine and TBM supporting slag system, which also marked the tunnel continuous belt machine officially applied in domestic tunnel construction. After the first stage of 21st century technology introduction, the second stage of 2010-2014 digestion and absorption, the third stage of 2015-so far independent research and development, continuous belt slag technology has been very mature, as a tunnel boring machine supporting slag extraction system is widely used in railway, highway, water diversion, urban subway, municipal water supply and other fields. The continuous belt conveyor has incomparable advantages over the slagging of mine carts. With the increasingly complex working conditions, new requirements are put forward for the belt conveyor to continuously transport slag under a small turning radius.

2 THEORETICAL ANALYSIS OF SMALL TURNING BELT CONVEYOR

According to its tape characteristics, the belt machine determines that the ideal movement route of the belt machine should be a straight line, that is, the belt machine head and tail connection and the trajectory of the tape material should be projected as a straight line

in the horizontal plane; However, with the diversification of application scenarios, the belt machine curve should be the normal demand. When the belt conveyor is running in a curved (turning) section, the shape of the tape (mainly the upper branch tape) becomes the key point for reliable transportation. Therefore, the basic requirements for the turning section tape are not disengaged, not damaged, and not deviated.

2.1 Definition of small turning belt conveyor

According to the “Technical Code for Shield Construction of Metro Tunnel Engineering”, “the radius of the curve of the subway tunnel plane is less than 300m as a small curve tunnel”; In rail transit design, less than 40D (D is the tunnel diameter) is defined as a small curve tunnel. The turning radius of traditional highways, railways and water conservancy tunnels is generally more than 1000m, and in recent years, TBM method has been gradually adopted for the excavation of roadways in the fields of pumped storage and metal mines, which has posed new challenges to the slagging of belt conveyors; According to the analysis of engineering characteristics, the slagging system needs to have a small turning radius slag discharge capacity, according to the different turning radius, the turning conditions of the belt conveyor can be divided into the following four categories.

2.1.1 Super large curve turning (turning radius $R > 1000m$)

Such working conditions have basically no effect on the long-distance belt conveyor system and do not require special consideration.

*Corresponding author: 1247992810@qq.com

2.1.2 Large curve turning (turning radius $500 < R < 1000m$)

The running trajectory of the tape can be regarded as a curve, the turning radius has a significant impact on the running quality of the tape, and it is necessary to carry out special design for certain parameters of the parts (idlers) that support the tape in the turning section, which has made the tape naturally pass through the turning section.

2.1.3 Small curve turning (turning radius $100 < R < 500m$)

Natural turning measures can no longer meet the turning needs of the tape, and mandatory measures need to be taken to force the tape to operate within a certain range.

2.1.4 Ultra-small curve turning (turning radius $R < 100m$)

Super large curve turns and large curve turns belong to the natural turning range, and through reasonable design of relevant parameters, the tape can pass the turning section smoothly. Small curve turns and ultra-small curve turns belong to the forced turning range, and special structural design needs to be added to force the tape to operate within the specified range. The turning radius of the small radius turning belt conveyor is less than $500B$ (B is the belt width).

2.2 Force analysis of natural turns

In order to ensure that the plane turning belt conveyor can achieve autonomous guidance when bending operation, the conveyor belt needs to meet three conditions at the turn: first: the force balance condition of the turning section; Second: stress and strain constraints; Third: the conveyor belt on the outer roller cannot leave the roller and float up.

The resultant force balance condition of the turning section, when the tape is running steadily at the turn, its resultant force FTC direction is pointing to its inside along the radius of the turning line, and the resultant force acts on the tape to make it deviate inward. The gravity of the material and tape at the turning point is due to the existence of the curve elevation angle in the idler group, and its component produces the thrust force FG pointing to the outside of the curve; The centrifugal inertial force FQ when turning is directed to the outside of the curve; The inner curve elevation angle of the idler, the centrifugal friction between the conveyor belt and the idler FR points to the outside of the curve, and the combined force of the above forces is used to offset it. to ensure that the tape runs automatically in the corner. The tape is also affected by the reaction force of the roller and the action of the resistance during operation, where the direction of resistance points to the opposite direction of operation. Therefore, the stable operation of the tape at the plane bend should meet the following conditions (the positive direction of

the specified force is to point to the outside of the bending line), as shown in the figure.

Figure 1. Mechanical model of plane turn.

When the material passes through the material in the plane bend of the force analysis trough idler group in operation, the cross-section of the material can be approximated as a combination of trapezoidal interface and chord arc section, and the idler corresponding to the cross-section is divided into three parts, and its force relationship is shown in the figure.

Figure 2. Friction between the material and the conveyor belt gravity and idler.

The tape turns naturally only through the following three measures:

- (1) Increase the tilt angle of the idler frame γ ;
- (2) Increase the angle γ_1 of the idler groove on the inner side of the turn;
- (3) Reduce the angle γ_3 of the idler groove on the outside of the turn;

When the tape turns, the resultant force of the tape tension is balanced with the gravity component of the material and the tape, the centrifugal force of the material and the tape, and the friction between the tape and the idler, the tape can achieve a natural turn.

2.3 Force analysis of forced turns

Within the forced turning range, the difficulty of the specific project can be evaluated according to the size of the linear meter arc length difference; Combined with similar TBM small turning engineering cases in the past, we derive the difference between the inner

and outer arc lengths within the unit length according to the arc length formula, that is, the arc length difference in linear meters as the difficulty factor for judging the turning difficulty of the belt machine.

$$N = B/R \quad (1)$$

In the formula:

N: Under the condition of a specific turning radius, the difference between the outer and inner motion trajectories of the inner tape per unit arc length, in mm/m;

B: Tape width, unit mm;

R: turning radius, unit m;

Figure 3. Turning diagram.

Note: $N \leq 5$ Less difficult; $5 < N \leq 10$ difficulty is moderate; $10 < N \leq 15$ Difficult; $15 < N \leq 20$ Extremely difficult.

When the tape is transported under small radius conditions, the inner tape of the turn is relaxed, and the tension of the tape on the outside of the turn is too large, so the stroke difference and tension difference between the inner and outer sides are too large, resulting in the combined force of the tape, that is, the misalignment force is relatively large, and the adjustment measures of natural turning are simply taken: increase the tilt angle of the idler frame γ ; Increase the angle γ_1 of the inner idler of the turn; Reduce the angle γ_3 of the idler groove on the outside of the turn; The force equilibrium condition has not been reached; At this time, it is necessary to increase the pressure roller on the inside of the turn, the lower edge of the pressure roller is lower than the upper edge of the roller, so the inner side of the tape runs along the wavy line, the tension between the inner and outer sides of the tape is reduced, and the tension component of the inner tape is converted into the positive pressure of the roller and the upper roller, thereby increasing the friction between the tape and the roller, so as to achieve the balance of force.

Figure 4. Running trajectory of the inner and outer ends of the tape in the turning section.

3 PROJECT OVERVIEW AND KEY DIFFICULTIES

3.1 Project overview

The power station consists of upper reservoir, lower reservoir, water transmission system and underground plant system, with a total installed capacity of 1.2 million kilowatts, the power station undertakes peak shaving, frequency regulation, project regulation, energy storage and other projects.

The ventilation tunnel passes through the roof arch of the factory building and is connected to the traffic hole, with a diameter of 9.53m and a total of 7 turning sections. The turning radius of the traffic hole plane is all $R=100\text{m}$, the longitudinal slope of the turning section is 3%, the maximum longitudinal slope of the local section is 4%, and the maximum longitudinal slope of the remaining cave sections is 5.9%; The plane turning radius before the ventilation tunnel enters the plant adopts $R=90\text{m}$, the turning radius of the remaining holes adopts $R=100\text{m}$, and the longitudinal slope is all 2.5%.

Figure 5. TBM tunneling route.

3.2 Engineering difficulties

(1) Small curves, many curves, annular slag out

The tunnel route is circular with a total turning angle of 430° , including 7 turns, 1 small turning radius of 90m + turning angle of 180° , and 6 turning radius of 100m . The overall route is complex, there are many turning sections, the turning angle is large, the turning radius is small, and the turning direction is inconsistent; At present, there is no similar tunnel line using belt machine system slag engineering case for reference.

(2) 180° continuous small turn to remove slag

The whole tunnel includes a continuous small turning route with a turning radius of 90m, a turning angle of 180°, and a turning section length of 300m; Small turning radius and large turning angle lead to large tension of the tape, the running resistance of the whole machine increases, the tension difference between the inside and outside of the tape increases, resulting in deviation, wear, inner folds and outer flipping tape phenomenon, due to the inner elevation of the turn, it is easy to scatter when turning.

(3) Large section, multiple crushing belt

The tunnel section excavation diameter is 9.53m, and there are many crushing zones in the construction route, the maximum particle size is 800mm, and the particle size of 400-500mm is more common. Due to the large diameter of the excavation hole and the large capacity of the belt machine system, there is a large amount of large particle size slag material at the crushing belt to put forward higher requirements for the belt machine slag discharge system, and at the same time bring the risk of material blocking, scratching the tape, damaging the roller, breaking down the funnel and so on.

4 BELT MACHINE SLAGGING SCHEME

4.1 Technical solution of the whole machine

This technical scheme adopts 3 sets of fixed small turning belt conveyor and 1 set of small turning continuous belt machine front and rear lap with slag discharge method, of which: the length of No. 1 belt machine is 330m, covering from the ventilation hole to the second turning section; The No. 2 belt conveyor has a length of 550m and covers the third turning section; The No. 3 belt conveyor has a length of 340m, covering the fourth turning section with a turning radius of 90m + a turning angle of 180°; Machine 4 is a continuous belt conveyor with a total length of 970 m, which dynamically passes through the 5th, 6th and 7th turns as TBM continues to advance. The technical scheme of the belt machine slagging system is shown in Figure 6, and the main technical parameters are shown in Table 1.

Figure 6. Layout diagram of the technical scheme of the belt machine slagging system of one project.

Table 1. Main technical parameters of belt machine slagging system.

Iems	With (mm)	Turning radius (m)	Turning angle (°)	Turn length (m)	Conveying length (m)
1#	1000	100	114°	200	330
2#	1000	100	33°	55	540
3#	1000	90	180°	330	340
4#	1000	100	100°	170	970

4.2 Targeted design

The cross-sectional layout of the turning section of the small turning belt conveyor is shown in Figure 5. Therefore, in order to ensure the smooth operation of the slagging machine in the turning section, the following targeted technical measures are taken:

- (1) Multi-stage lap connection of the belt conveyor reduces the belt tension of the turning section and reduces the driving power;
- (2) Adopt high-quality tape and lock edge design to prolong the life of the tape;
- (3) The 180° turning section adopts a special structure, the upper idler group adopts a deep U-shaped design, and the lower idler group adopts a deep V-shaped or oblique arrangement, which reduces the tension difference on both sides of the tape, reduces the risk of mistracking, and prolongs the life of the tape;
- (4) Adjustable idler sets, special stop rollers and pressure roller structures are arranged along the belt machine;
- (5) Design protective functions such as tape anti-rollover, tape tear monitoring, etc;
- (6) The reinforced belt conveyor bracket is adopted, which has a solid structure and can resist the large tensile load of the turning section;
- (7) By converting the contact friction form between the tape and the roller line into surface contact friction, the pressure between the tape and the roller is reduced, thereby reducing the edge wear of the tape and improving the service life of the tape.

5 ENGINEERING APPLICATIONS

TBM equipment of pumped storage power station project began boring in October 2021, the early use of dump truck slag, with the extension of the boring distance, the material transportation efficiency decreased, so TBM monthly advance is generally about 200m, when the boring mileage exceeds 1km, using car slag, TBM advance is generally about 150m.

From July to August 2022, the installation and commissioning of the belt conveyor will be carried

Figure 7. Structural layout of turning section.

out. After using the continuous belt conveyor in September, the monthly advance of more than 300 meters was created, the maximum daily advance was 21.6 meters, and the slag discharge of 180° turning radius + 90° turning radius and 6 100m small turns was completed.

Table 2. TBM advance statistics.

6 CONCLUSIONS

Through multi-machine integrated control, multi-point drive, deep grooved section and flexible tape and other technical measures, the slag discharge system of small turning belt has completed the research and development and application of the first long-distance, high-speed, sharp-turn belt slagging

system in China, greatly improving the excavation efficiency, solving the problem of slagging of a complete set of mechanized equipment for large-diameter and sharp-turn TBM, ensuring the synchronous progress of excavation and support, and the excavation efficiency is about 3 times that of manual drilling and excavation, while improving the image of safe and civilized construction of the tunnel.

With the continuous development of pumped storage power station and similar projects, the application of small turning belt machine technology in this field will continue to progress, it is recommended to combine the successful application experience of this project, fully consider the feasibility of belt machine system application, optimize the tunnel construction line, further promote and apply small turning belt machine technology, and promote the improvement of the construction level of TBM complete set of machinery.

Slurry treatment technology based on calcium oxide and seawater of extra-large diameter slurry balance shield machine in Zhuhai area muddy silty clay stratum

Ruiwen Dong*, Zhou Zhou & Wenjiang Liao

Guangzhou Rail Transit Construction Supervision Co., Ltd, Guangzhou, China

ABSTRACT: Aiming at the problem of insufficient slurry treatment efficiency caused by geological conditions during the excavation process of the extra-large diameter slurry balance shield machine in the Zhuhai tunnel project, this paper introduces the geological conditions of the shield machine excavation in detail, analyzes various factors and shortcomings that affect slurry treatment efficiency, and proposes methods to improve slurry treatment efficiency. A better additive ratio was obtained through slurry treatment experiments. The results show that additive combination of 6% calcium oxide and 50% seawater is beneficial to improve the slurry treatment efficiency under the good maintenance premise of slurry treatment equipment parts.

Keywords: Slurry separation equipment, Mix additions, Field experiments

1 INTRODUCTION

In recent years, with the continuous development and construction of China's infrastructure, medium and large urban subways, large-diameter tunnels and underwater tunnel projects, and based on the increasing requirements of settlement control, the demand and quantity of extra-large diameter slurry balance shield machine have increased. The slurry treatment function is becoming the key factor in choosing the construction method of super large diameter slurry balance shield machine.

In order to improve the efficiency of extra-large diameter slurry treatment brought by the extra-large diameter slurry balance shield method, many technicians have carried out research. Chen et al. introduced the method of adding lime to improve silty soil, Zhang Lihua et al. introduced the method of adding lime and fly ash to improve dredging sludge with high water content. Zhao S et al. used sodium bentonite and dispersant to prepare slurry. Wan Z et al. studied the properties and interactions of soil improvement additives. Zumsteg R et al. found that some polymer solutions help mud to have high shear resistance and low clogging properties at the same time. Min et al. Zumsteg et al. found that the ratio of chemical additives in the slurry mixture was very important to the efficiency of the mixture. Yang W et al. studied the properties of the curing agent modified soil through experiments.

It can be seen that slurry treatment will affect the formation of mud film, slag carrying capacity, slurry making ability, etc., which will further affect the tunneling efficiency, and play a vital role in the extra-large diameter slurry balance shield.

2 BACKGROUND

The Zhuhai tunnel project passes through a 2276m full-section weak stratum, the length sea bedrock intrusion of the left and right lines is 387m and 464m. The composite strata of the shield tunneling bedrock protrusion are muddy silty clay, silty clay, medium coarse sand, sandy cohesive soil, fine medium sand, moderately weathered granite, and locally existing tough stone and quartz veins from top to bottom, as shown in Figure 1. In the interval of LK0+872~LK2+918 tunneling mileage, the tunnel vault is silt and muddy silty clay, the side wall is muddy silty clay, sand and silty clay, and the tunnel bottom is muddy silty clay, sand and silty clay, of which (2)-2-1 muddy silty clay accounts for about 65% of the main muck components after the tunnel face excavation, light and dark gray, containing organic matter and a small amount of shell debris, locally containing medium sand, with rancid smell, saturated, flow plastic-soft plastic state, soft soil, with high water content, micro permeability, high compressibility, large porosity ratio, low shear strength, high sensitivity, particle size of 0.005mm-0.05mm. (2)-2-1 physical properties of muddy silty clay are shown in Table 1. Due to the existence and high proportion of muddy silty clay, the slurry shield machine is prone to a large amount of slurry in the formation during the excavating formation process and the slurry is difficult to be treated in time, which leads to the adverse consequences of mud performance decline.

Liquid limit $W_L/\%$	43.6
Plastic limit $W_p/\%$	26.8
Plasticity index $I_p/\%$	16.8
Liquidity index I_L	1.28

3 PROCESS

In order to realize slurry treatment function, the slurry treatment system is mainly composed of slurry inlet and outlet pipelines, slurry making and adjusting system, slurry separation equipment system, pressure filtration equipment system etc. The slurry outlet pipeline in the inlet and outlet slurry pipeline is the connecting pipeline between the shield machine slurry tank and the slurry separation equipment system, and the slurry inlet pipeline is the connecting pipeline between the adjusting pool and the shield machine slurry tank. The slurry making and adjusting system comprises 8 stage sedimentation pools, a making pool, a storage pool, an adjusting tank, and a water tank, which main function is to

ensure that the slurry performance is in a good state by sedimentation, making and adjusting. To achieve the purpose of recycling, the slurry flows into the 8 stage sedimentation pool through the chute and then flows into the slurry inlet through the adjusting tank. Figure 2 is slurry treatment process and the dotted line part in the figure is for emergency use.

The main functions of slurry treatment include the following three points: (1) providing mud film for the tunnel face during shield tunneling to ensure the stability of the tunnel face; (2) The slurry is fed into the slurry bin to ensure pressure on the face, side, vault and bottom surface of the tunnel, so that the pressure on the outside of the slurry balance shield machine reaches a relatively stable equilibrium state; (3) After the slurry is discharged to the adjusting tank through multi-stage sieving treatment by slurry separation equipment, sedimentation pools and pressure filtration equipment. The slurry is re-fed to the adjusting pool to ensure the muck removal while improving the utilization rate of the slurry.

3.1 Slurry separation

The slurry separation equipment system comprises three sets of separation equipment and two centrifuge equipment system, as shown in Figure 3. Each set of separation equipment comprises a slurry distributor, a clay block-slurry separator, a coarse sieving equipment, A slot, B slot, a No.1 slurry pump,

Figure 1. Vertical section.

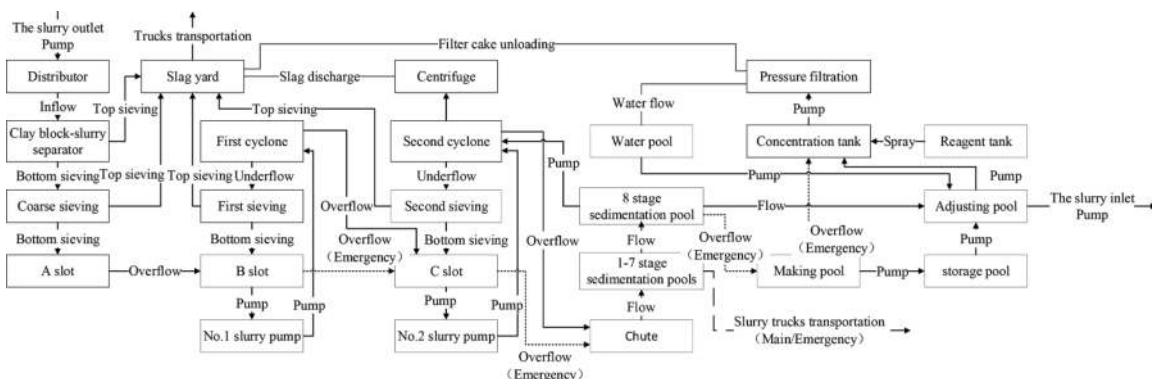

Figure 2. Slurry treatment process.

a first cyclone equipment, a first sieving equipment, a C slot, a No.2 slurry pump, a second cyclone equipment, a second sieving equipment. The first stage of the coarse sieve equipment filters with particles size greater than 0.2mm, the second stage of the first cyclone equipment filters with particles size of 0.074-0.2mm, and the third cyclone filters with particles size of 0.02-0.074mm.

Figure 3. The slurry separation equipment.

3.2 Pressure filtration

The plate pressure filtration equipment system includes a concentration tank, a reagent tank and five plate pressure filtration equipment (as shown in Figure 4.). The operation specific process of the plate pressure filtration equipment system needs to pump the slurry of the adjusting tank to the concentration tank and add the slurry flocculation and precipitation agent to the reagent tank. The reagent is sprayed into the chute through the pipeline and fully reacts with the slurry and then overflows into the concentrator tank. The slurry flocculation sediment at the bottom of the concentration tank is pumped to the plate pressure filtration equipment through the slurry pump. The plate pressure filtration equipment adopts the method of pressing the filter plate, filtering, one blowing, extrusion, diaphragm pressing, and two blowing to squeeze the water out of the slurry to the water tanks on both sides and recycle it. At the same time the slurry flocculation sediment form the filter cake with low water content and then the residual slurry overflows back into the concentration tank. The pressed filter plate is opened to start unloading and transporting to the slag yard.

4 PRESENT

The slurry treatment system mainly carries out the work of slurry preparation, filtration and slag removal, and adapts to the slurry preparation formula with the change of formation properties in the shield tunneling process and filters the slurry through the muck truck and transports the waste residue of the filter press out of slurry treatment plant. Due to the formation properties, sedimentation tank capacity,

Figure 4. The plate pressure filtration equipment.

separation equipment efficiency and filter press equipment efficiency of various factors, including the time spent repairing the filter press trolley, the time spent by the construction personnel cleaning the filter cloth, the time spent repairing the slurry pump, and the time taken to reduce the liquid level of the sedimentation tank, resulting in mud viscosity cause high specific gravity and sedimentation pools level, which affect slurry treatment efficiency and limit the efficiency of shield tunneling. The stratum geology is a natural attribute that cannot be changed. The capacity of the sedimentation pools need to expand the construction land to build a sedimentation pool with a larger capacity. The efficiency of the separation equipment need to be improved by increasing the separation equipment, but the separation equipment occupies a larger area. The construction land needs to be expanded to build a larger separation equipment foundation, and the expansion of the capacity of the sedimentation pools and the improvement of the efficiency of the separation equipment are difficult to achieve.

The capacity of the sedimentation pools on the left line of slurry treatment plant is 1,500 cubic meters, and the capacity of the adjusting pool is 2,000 cubic meters. The shield machine adds 550-750 cubic meters slurry and 350-360 cubic meters muck per ring, with a total of 900-1110 cubic meters per ring. There are 3 sets of the separation equipment, each set sieves 50-150 cubic meters slurry per ring. There are 8 filter press equipment, each of which processes about 16 cubic meters slurry per hour, totaling about 3,000 cubic meters. According to the analysis and calculation of the slurry and muck treatment in the excavation, it can be obtained that 3.3 rings can be excavated normally per day and 6 rings can be excavated on site. The slurry treatment efficiency at the construction site is low, which is far from meeting the excavation needs. Considering the lack of pressure filtration efficiency on the left line, three new plate pressure filtration equipment were added to the right line, each of which processed 40 cubic meters muck per hour, with a total of 2,880 square meters muck. At the same time, two new centrifuge equipment were added, each of which processed 40-50 cubic meters per hour,

totaling 1920-2400 cubic meters, and processed an average of 2160 cubic meters of muck per day. According to the analysis and calculation of the treatment of mud and muck and waste slurry in the excavation, it can be obtained that 5.6 rings can be excavated normally per day, and 6 rings can be excavated on site, which can basically meet the needs of excavation. In summary, based on the analysis of the left and right lines, it can be concluded that a total of about 9 rings of normal excavation can be carried out daily. If the number exceeds 9 rings, the muck can only be disposed of by slurry trucks. According to the on-site construction situation, it is difficult to improve the efficiency of slurry treatment on the left line by increasing personnel, equipment and physical methods. At the same time, the efficiency of slurry treatment on the right line still needs to be improved. Chemical methods can be used to improve the efficiency of pressure filtration equipment and slurry treatment.

In response to this situation, the construction site mainly improves the efficiency of slurry treatment by improving the efficiency of pressure filtration equipment and adopts the following methods. (1) adding a slurry pump in the 3 stage sedimentation pool to extract muck to the slurry trucks for slurry treatment, but it does not solve the root cause and has low economic benefits. (2) Adding 2‰ solid calcium oxide (as shown in Figure 5) to the making pool react with the slurry pumped from the 8 stage sedimentation pool to the making pool through an emergency slurry pump to improve the efficiency of the pressure filtration equipment. The calcium oxide undergoes a chemical reaction to release heat, generate calcium hydroxide, and consume the water in the slurry, achieving the goal of reducing viscosity and improving fluidity. At the same time, the calcium oxide increase the concentration of calcium ions and improve the slurry performance at the micro level. However, in order to ensure solid calcium oxide can undergo sufficient chemical reactions to achieve good results, this method can only add a smaller amount of calcium oxide, which will cause a little of slurry treated. (3) An external liquid preparation tank is set up next to the sedimentation pools to prepare about 2‰ calcium hydroxide solution, as shown in Figure 6. It is pumped to the making pool to fully blend with the solid calcium oxide and slurry mixture in the making pool. It should be noted that due to the presence of a large amount of carbon dioxide in the air, the calcium carbonate precipitation often occurs in the external liquid preparation tank. After adopting the methods mentioned in (2) and (3) above, the efficiency of the pressure filtration equipment will be improved to a certain extent. The construction site mainly adopts the method of (1) for slurry treatment, which can basically ensure the slurry circulation during conventional diameter shield tunneling, but it is obviously insufficient for extra-large diameter slurry shield tunneling.

Figure 5. 2‰ solid calcium oxide.

Figure 6. 2‰ calcium hydroxide solution.

5 EXPERIMENT

5.1 Preparation

According to slurry treatment construction site and the research status of scholars at home and abroad, a simple slurry treatment experiment was carried out for slurry treatment with high slurry gravity in Zhuhai tunnel project and the effect of different additives on slurry treatment was preliminarily analyzed. Yixin Chen et al. found that the version of plain soil was mud-like, which changed when pinched by hand and could not be compacted. After the silty soil was mixed with calcium oxide, the soil changed from lumpy to scattered. With the increase of calcium oxide content, the soil was more and more easy to crush, which also indicated that the improved soil was more and more easy to be compacted under the external force. From the macroscopic viscosity change, it can be seen that the mixed calcium oxide is conducive to the agglomeration and discretization of natural soil and the viscosity is greatly reduced. Min et al. found that through the study of slurry analysis of ζ potential, pore characteristics of filter cake and microstructure of filter cake indicates that the slurry prepared from water has a high ζ potential, less cations attracted to slurry particles, more water molecules, and thicker bound water film. At the same time, the electric repulsion between particles in the slurry is greater, making the particle dispersion more uniform. The thicker the bound water film and

the more dispersed the particles increase the distance between particles and aggregates in the filter cake. Based on comprehensive data analysis, it can be concluded that the total pore volume of water filter cake is relatively large, mainly composed of pores inside the filter cake. Low pore connectivity leads to less effective pores in the filter cake formed by seawater slurry than pores. The pores in the aggregated body, including bound water and free water, are blocked by a thick water film, which reduces the effective porosity and leads to high water content, high porosity and low permeability of the filter cake. For slurry prepared with different proportions of seawater, adding a large amount of cations to the slurry will reduce ζ potential. The repulsive force between particles weakens, and particles aggregate into a large number of aggregates. Due to a large number of cations adsorbed on the slurry particles surface, the number of adsorbed free water molecules decreased, which results in a relatively thin bound water membrane. Under the influence of pressure, particles in the aggregate become tightly packed. The pore size of the filter cake is small, mainly composed of pores between aggregates, with good connectivity. The thinner the water film, the fewer times the waterway is blocked. The effective porosity of the filter cake produced by seawater containing slurry is greater than that formed by the slurry prepared from water. As the seawater content increases, the permeability coefficient of the obtained filter cake also increases. The research results indicate that when the seawater content in the mud is less than 50%, filter cakes with permeable zones are formed. When the seawater content in the mud exceeds 50%, only filter cake is formed. As the seawater content in the mud increases, the thickness and permeability of the filter cake increase, while the water content and porosity decrease.

The strata in the LK0+872~LK2+918 section of the Zhuhai tunnel project are mainly composed of silty clay, which has strong slurry making ability and high mud slurry density and viscosity. Due to the poor economic efficiency of using slurry trucks to dispose, this experimental study mainly improves the efficiency of slurry treatment from two aspects including directing treatment through sedimentation and improving the efficiency of pressure filtration equipment. This experiment is based on on-site additive materials, using additives including seawater and calcium oxide. Seawater is mainly used for direct treatment through sedimentation, while calcium oxide is mainly used to improve the efficiency of pressure filtration equipment, with a focus on the study of calcium oxide additives.

5.2 Working conditions

According to the research of Yixin Chen et al. and Min et al., considering the slurry treatment situation of the pressure filtration equipment in the Zhuhai

tunnel project, the optimal concentration of 6% calcium oxide is proposed. During the experiment, it is necessary to ensure that the temperature of each working condition is consistent. Based on the actual situation of the construction site, the slurry treatment work should be completed in a short period of time, mainly studying the mud situation of each working condition at 2 and 24 hours. Working conditions 1-8 are the slurry treated by the separation equipment at the outlet, as shown in Figure 7(a)-(h), with the slurry density of 1.41g/cm^3 during the experiment. The experimental conditions can be divided into four groups. The first group consists of conditions 1 and 2 to study the slurry treatment capacity of solid calcium oxide. The second group consists of conditions 3 and 4 to study the slurry treatment capacity of calcium hydroxide solution with different solvents. The third group consists of conditions 5 and 6 to study the sludge water treatment capacity under the sole action of excess solvents. The fourth group consists of conditions 7 and 8 to study the slurry treatment capacity under the action of excess calcium hydroxide solution. Working conditions 9-16 are the inlet mud of the adjustment pool, with the slurry density of 1.34g/cm^3 . The experiment was operated in the same way and with the same purpose to study the effect of slurry density on slurry treatment. A total of 16 different working conditions were set up for the slurry treatment experiment, as shown in Table 2.

Table 2. Different working conditions experiment.

Working conditions	Slurry	Additions
1	Slurry at the outlet (100g, slurry density 1.41g/cm^3)	None
2		6%calcium oxide(6g)
3		6%calcium oxide(6g) and 6%water(6g)
4		6%calcium oxide(6g) and 6%seawater(6g)
5		50%water(50g)
6		50%seawater(50g)
7		6%calcium oxide(6g) and 50%water(50g)
8		6%calcium oxide(6g) and 50%seawater(50g)
9	Slurry at the inlet (100g, slurry density 1.34g/cm^3)	None
10		6%calcium oxide(6g)
11		6%calcium oxide(6g) and 6%water(6g)
12		6%calcium oxide(6g) and 6%seawater(6g)
13		50%water(50g)

15		6%calcium oxide(6g) and 50%water(50g)
16		6%calcium oxide(6g) and 50%seawater(50g)

Figure 7. Field experiment diagram of working conditions 1-8.

5.3 Results

Under the same indoor temperature, different observations and mixing results were obtained for operating conditions 1-8 and 9-16 for 2 hours and 24 hours. Compared to working condition 1, working condition 2 has lower mud density and viscosity. Working condition 1 is the basic operating condition of operating condition 1-8 and operating condition 9-16 is the basic operating condition of operating condition 2, as shown in Table 3 and Table 4. From the comparison of the 2 hours and 24 hours stirring conditions recorded in Tables 3 and 4 above, it was found that there was little change by stirring observed in working conditions 1-8. The main difference was that the grainy increased in working conditions 7 and 8. The reason for this situation may be due to the reaction between calcium hydroxide solution and carbon dioxide in the air, which generated calcium carbonate precipitation. There is not much change in the mixing situation observed during the 2 hours and 24 hours of working conditions 9-16. The main difference is that there is a slight layering of the slurry in working condition 1, indicating that layering may occur under the static condition of low mud density slurry in the Zhuhai tunnel project and this situation is likely related to the geological properties of muddy silty clay. The grainy increased in working conditions 15 and 16, which may be due to the reaction between calcium hydroxide solution and carbon dioxide in the air, resulting in the precipitation of calcium carbonate. Observing the stirring situation at 2 hours and 24 hours under operating conditions 1-16 indicates that the reaction between additives and slurry is basically completed within 2 hours and the sedimentation and layering state is relatively stable. The states of low slurry density and high slurry density under the same additive conditions are basically similar, mainly analyzing working conditions 1-8. In the first set of working conditions, condition 2 has the strongest resistance and the

highest viscosity at this time, which can cause pump jamming and pipe blockage. At the same time, the construction personnel cleaning the filter cloth for a longer time is not conducive to improving the efficiency of the pressure filtration equipment. In the second set of working conditions, condition 3 is similar to condition 4, with stronger resistance and higher viscosity at this time. This may be due to the proximity of the muddy silty clay in this project to the sea, resulting in its pore water already containing seawater components for experimenting. In the third set of experimental conditions, condition 5 is similar to condition 6. The effect of excessive solvent will greatly reduce the specific gravity and viscosity of the mud. Due to the fact that the pressure filtration equipment mainly relies on the slurry pump to pressurize the mud, excessive solvent will cause the slurry pump to have to be transported multiple times, resulting in a heavier load and reduced service life of the parts. This can easily form a “sandwich” situation of the filter cake, which is not conducive to improving the efficiency of the pressure filtration equipment. In the fourth set of experimental conditions, condition 7 is similar to condition 8. At this time, due to the presence of more solvents and solutes, more additional slurry needs to be treated after reacting with the slurry, increasing the load of the slurry pump. However, the slurry at this time meets the requirements for storage in the concentration tank, with good fluidity, high bottom density and viscosity and certain grainy, indicating a decrease in the density and viscosity of the bottom slurry during the mixing process. Based on the actual situation on construction site, it is ideal to add 6% calcium oxide and 50% seawater to the slurry outlet in the concentration tank under condition 8.

Based on the above experimental results, working condition 8 with 6% calcium oxide and 50% seawater added to the slurry outlet and working condition 16 with 6% calcium oxide and 50% seawater added to the slurry inlet are more ideal. This improves the

flowability while slightly increasing the specific gravity and viscosity of the bottom mud, in order to improve the efficiency of pressure filtration.

5.4 Polymer mud treatment experiment

Many scholars have found that polymers have a good effect on slurry treatment. In response to the current situation of this project, it has been decided to use 2‰ white powder agent PAM to flocculate the slurry in the concentration tank. After using PAM for slurry treatment, it was found that the effect was not ideal and the efficiency of the pressure filtration equipment was not significantly improved. Therefore, it was decided to add a mixed agent of 2‰ white powder agent PAM and 2‰ yellow powder agent PAC for flocculation. The efficiency of the pressure filtration equipment has been improved to a certain extent, but PAM and PAC flocculation are prone to pump jamming and pipe blockage, resulting in reduced service life of the slurry pump parts and connection pipeline between the slurry pump and the pressure filtration equipment taking a long time to clear. In order to find suitable reagents to improve the efficiency of the pressure filtration equipment, solidification agent experiments and coating agent (polymer formed by copolymerization of propylene derivatives with different functional groups) treatment experiments were carried out. The experiments found that the solidification agent did not have an ideal effect on mud water treatment, and the coating agent solution has an ideal effect on mud water treatment, as shown in Figure 8. However, the dosage of the coating agent solution needed to reach concentration of 20%. Considering the actual situation, the concentration tank capacity is not enough to use 20%

concentration of coating agent, And the high price of the coating agent leads to lower economic benefits.

Figure 8. Coating agent treatment.

6 CONCLUSIONS

In this project, the slurry making slurry ability is strong and the slurry at the slurry outlet has high density and viscosity. However, the slurry treatment ability is weak. If the main reliance is on slurry trucks to dispose, it will lead to extremely low economic benefits. In response to this situation, construction site experiments were conducted to study ways to improve the efficiency of slurry treatment by using different additives to improve the efficiency of pressure filtration equipment. The main conclusions of the experimental research are as follows: (1) Firstly, the strata of the extra-large diameter slurry

balance shield machine in this site is mainly composed of muddy silty clay, which contains high levels of powdery particles, causing significant losses to the slurry treatment equipment. Therefore, attention should be paid to the maintenance of equipment parts during slurry treatment, reducing their failure rate and extending their service life, which helps to improve the efficiency of slurry treatment. (2) Based on the actual needs and on-site treating conditions, a large amount of slurry is formed by extra-large diameter slurry shield tunnelling. Experimental research was conducted on the different concentrations combination of water, seawater and calcium oxide additives for muddy silty clay stratum. The results showed that the use of seawater has a good promoting effect on mud water treatment. On the other hand, in response to the current situation where the addition of low amounts of calcium oxide is insufficient to digest the slurry treatment requirements by increasing the amount of calcium oxide added and conducting group experiments. In order to improve the efficiency of the pressure filtration equipment and achieve the goal of treating a large amount of slurry, 6% calcium oxide and 50% seawater were determined to improve the slurry fluidity while slightly increasing the density and viscosity of the bottom slurry. (3)The theory of how the polymer formed by the additives combination in this project can promote the slurry treatment still needs further research. The this project experimental results can provide reference for the slurry treatment of extra-large diameter slurry balance shield tunneling method in muddy silty clay stratum and soft soil strata.

ABSTRACT: The main challenge of implementing and constructing a new tunnel in urban areas is to control and mitigate excessive ground surface disturbances. In general, ground surface settlements due to tunnel construction in soft ground conditions can be expected. According to detailed geotechnical monitoring results of the MRT Orange Line Project in Bangkok, significant ground heaves were observed during and after the passing of shield machines at shallow depth. This paper aims to reports unusual ground movements which developed when earth pressure balance shield machines were employed to excavate twin tunnels in the soft clay layers. A numerical simulation using a three-dimensional finite element method was also established to simulate the tunnelling process based on the operating parameters and in order to investigate the ground responses in this regard. Based on this finding, it can be seen that the computed results are presented in the same trend compared to the field measured data

Keywords: Tunnelling, Shield machines, Soft clay, Ground heaves

1 INTRODUCTION

Shield tunnelling method has been widely utilised in the construction of subway tunnels in urban areas. Excessive ground movements that may encounter during the construction should be strictly controlled to minimise the impacts on adjacent structures e.g. buildings, structures and utilities (Duangsano et al, 2023). These generally depend on several factors e.g. geological and geotechnical conditions, tunnel geometry, tunnel depth, and quality of workmanship and management (ITA/AITES, 2007).

Tunnelling in soft ground conditions with a shallow overburden may face the risk of instability due to ground heave and blowout (Bezuijen and Brassinga, 2015; Vu and Broere, 2023). In practice, the face pressure is a support pressure to balance the soil and water pressures. If it is not sufficient to resist against the surrounding pressures, active failure (collapse) is likely to occur. On the other hand, blow-out, also referred to as

passive failure, and appears if the applied pressure is high enough to push the soil towards the ground surface (Vu et al., 2015). In addition, tail void grouting pressure is commonly high enough to guarantee the flow of grout material and to resist the ground moving into the gap between a shield and tunnel lining.

According to the construction of MRT Orange Line (East Section) Project in Bangkok, Thailand, twin bored tunnels were excavated and constructed in soft clay layers with shallow overburden. The soil cover from ground surface level to the tunnel crown is 6.6 m approximately which is equivalent to one time tunnel diameter (1D). During the excavation, foam and pressurized air travelled to the surface. In addition, significant ground heaves and blow-out were observed as presented in Figure 1.

This paper aims to present the responses of ground heaves and blow-out for due to tunnel excavation in soft clay layers in associated with operating pressures

of shield machines. In addition, a numerical computation is performed in order to investigate and compare the results with the field data.

2 PROJECT DESCRIPTION

Mass Rapid Transit Authority of Thailand (MRTA) has officially implemented the MRT Orange Line (East Section) Project to complete the mass railway system network. The project consists of both an underground and elevated structures within an approximate distance of 22.57 km. The underground section is divided into three contracts. The contents reported in this article focus for the design and construction of contract E1.

Twin tunnels of Westbound (WB) tunnel and Eastbound (EB) tunnel were utilized along the tunnel alignment. Since tunnels had to be initially commenced from the MRTA station (launching station), the observation test section was established to preliminary investigate the performance of Tunnel Boring Machine (TBM) and ground responses during the tunnelling process as shown in Figure 2. In this part of the initial drive, it was also used for trial and error in applying an optimum balance mode that resulted the acceptable ground settlement.

2.1 Geological conditions

Bangkok subsoil is relatively uniform throughout the entire area. The uppermost 2.0 m thick layer is the fill material, which is underlain by 6.0-15.0 m thick of soft clay layer. A medium clay layer is found at the depth of approximately 8.0 m from the surface. Below the medium clay is stiff clay; the thickness is about 4.0-15.0 m. The first sand layer is generally found at a depth of 25 to 30 m. The piezometric pressure head construction was observed at about 13 m below the ground surface during the construction.

The WB tunnel was excavated at the depth below the ground surface between 6.55 m and 8.12 m, while the elevation of the EB tunnel was 6.55 m throughout the soft soil conditions of the soft clay and medium

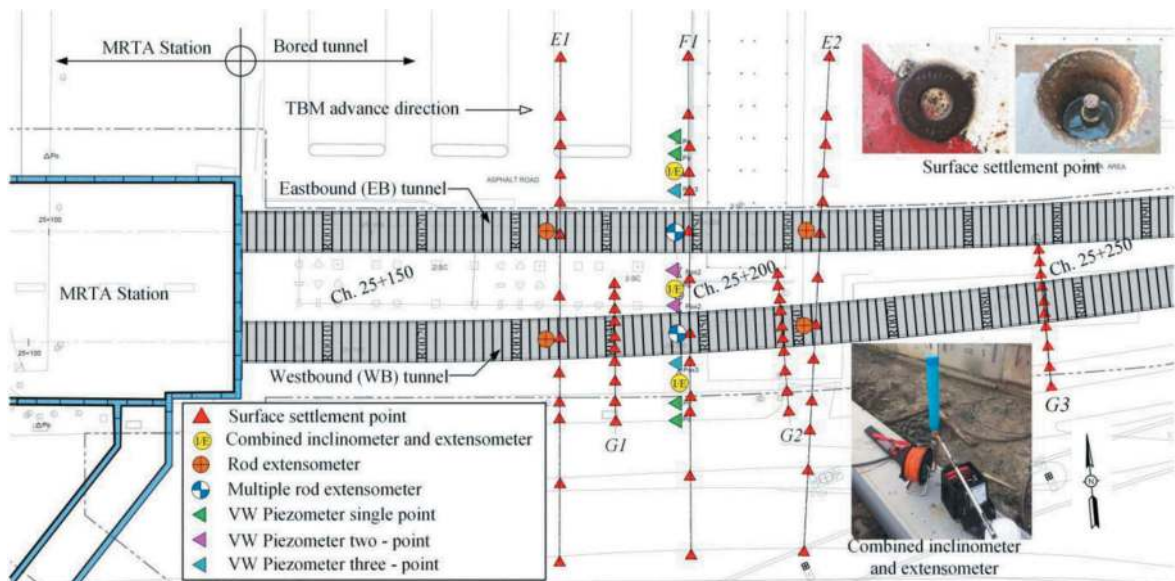

Figure 2. Plan view on the construction site at the observation test section.

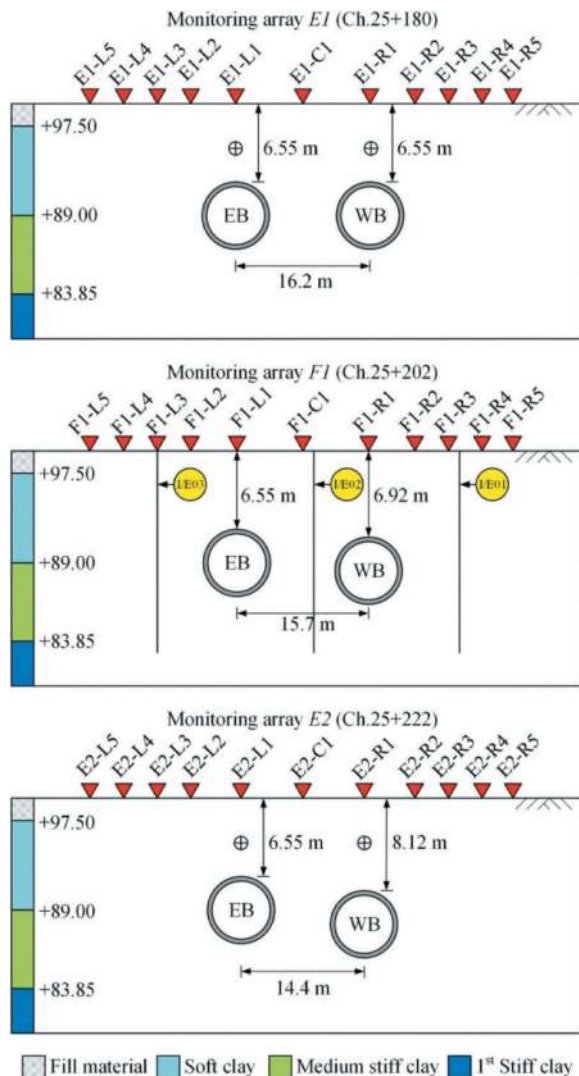

Figure 3. Layout of geotechnical instruments.

stiff clay layers. A center-to-center distance between twin tunnels varied from 16.2 m to 14.4 m at this area.

2.2 Instrumentation and monitoring

Instrumentation and monitoring system plays an important role in underground construction activities (Kong, 2003). Several geotechnical instruments were intensively installed to observe the potential ground responses along this area. Instrumentation layouts associated with tunnel positions and geological condition are illustrated in Figure 3.

Three main arrays of typical monitoring sections (E1, F1 and E2) were set to entirely cover the side-by-side twin tunnels. Each array consisted of 11 settlement markers located on the ground surface level to directly measure ground movements in the vertical direction. To capture the development of ground movements in the horizontal direction to the shield advances, there were three sets of combined inclinometer and extensometer were installed at section array F1. Three additional arrays of G1, G2 and G3

positioned in a part of WB tunnel alignment, were also proposed to observe ground surface settlement.

It is noted that particular attention in this article is paid to the surface settlements and lateral ground deformations induced by the tunnelling during the construction.

3 CONSTRUCTION OVERVIEW

3.1 Tunnel construction

Three Earth Pressure Balance (EPB) shield machines were employed to excavate and construct tunnel lining in this project. The main principle of the EPB shield machines is to control the stability of tunnel face by monitoring and adjusting the pressure inside the chamber to achieve a balance pressure (Suwansawat, 2002). Tail void grouting is injected simultaneously to fill the void between the TBM and tunnel lining. The shield machine has 6.58 m diameter and 9.615 m length. The main component of the EPB shield machine is illustrated in Figure 4.

A precast reinforced concrete of segmental tunnel lining was employed for twin bored tunnels. The internal diameter of the tunnel is 5.7 m. The thickness is designed to be 0.3 m and the segment length of 1.4 m is adopted. Each ring of tunnel lining consisted of five segments plus one key segment (5+1 configuration).

According to the construction plan, TBM no.1 was firstly used to excavate the WB tunnel from the MRTA station. Subsequently, TBM no.2 was operated for the construction of EB tunnel from the same station to the next station. The lagging distance between two shield machines along the tunnel alignment was more than 500 m.

Prior to the commencement of construction, target face pressures, tail void grouting pressures and other relevant parameters were entirely estimated along the tunnel route. During the early stage of tunnelling or also known as the initial drive, a number of data were recorded to observe the performance and control the quality for further excavation process (referred to the learning curve). The face pressure can be monitored using six pressure cells installed inside the earth chamber, whereas the injection of primary grouting pressure was measured by a pressure cell installed inside the shield machine.

3.2 Shield operating parameters

Face pressures and tail void grouting pressures monitored from the excavation of TBM no.1 are illustrated in Figure 5. The face pressure at tunnel axis of which 180 kPa was maintained throughout the monitoring area. Meanwhile, a fluctuation of the primary grouting pressure was recorded, ranging between 175 kPa and 220 kPa with an average pressure of around 195 kPa.

Furthermore, the actual face pressures at tunnel axis for excavation of the EB tunnel by TBM no.2

Figure 4. Shield machine component.

was typically operated with an average value of 160 kPa, being lower than that of TBM no.1. The tail void grouting pressure was measured at approximately 180 kPa. The shield parameters obtained from TBM no.2 are revealed in Figure 6.

Apparently, along the observational section, the face pressures and tail void grouting pressures applied for the construction of twin tunnels were significantly higher than the overburden soil pressure.

Figure 5. Recorded parameters of TBM no.1.

4 GROUND HEAVES

Due to large support pressures, an instability caused by a blow-out occurred during tunnel excavation at this location. To investigate the relationships between the ground responses and the advancement of the shield machines, maximum ground movements along each tunnel alignment are plotted

Figure 6. Recorded parameters of TBM no.2.

against the various positions of shield face. It should be noted that ground behaviour is considered affected by the process of tunnel excavation by shield machines only (i.e. before, during and immediately after shield passing) not by consolidation settlements (i.e. long term settlement).

4.1 WB tunnel – 1st tunnel excavation

Figure 7 presents longitudinal ground surface movements for six recording points measured in different distances from tunnel face induced by TBM no.1. It can be noticed that when the shield approached array E1 and G1, the ground surface experienced a small heave. However, it largely increased to almost 25 mm after the shield passing and reaching array F1. Obviously, ground heave continued to gradually rise, particularly monitoring point F1-R1 when the face of the shield was positioned at array G2. Array G3 was the last array at this section, ground deformation was still observed to move upward before and after shield passing. Based on the recorded data, the occurrence of ground heave appeared when the face of the TBM approaching, and it could be inferred that a higher ground heave was indicated during the primary grouting process.

4.2 EB tunnel – 2nd tunnel excavation

Surface heave was also recorded along the excavation route of the TBM no. 2 as shown in Figure 8. The development of upward ground displacement was observed, although the shield was operated and controlled at lower support pressures compared to the TBM no.1. Similarly, ground heave occurred more than 5 mm when the face of shield machine was approaching the monitoring point F1-L1. Moreover, there was a noticeable increase by almost 10 mm after the shield passing. In comparison, the recorded ground heave induced by the advancement of TBM no.2 was relatively smaller than that of the first tunnel excavation.

5 NUMERICAL SIMULATIONS

5.1 Numerical models

A three-dimensional finite element analysis is employed to investigate the effects of TBMs excavation in a shallow section associated with face pressures and grouting pressures on ground surface settlements and ground lateral movements. To simulate the staged construction process and ground responses, finite element (FE) code PLAXIS3D is utilized. The 3D FE-model is set up with dimensions of 120 m long in x-direction, 100 m wide in y-direction and 50 m deep in z-direction. The discretization with a total number of 174,786 elements and the geometrical configuration of numerical simulation are illustrated in Figure 7.

It should be pointed that this study is principally focused on the influence of soil movements due to tunnelling by EPB techniques, therefore, an advancement of the twin tunnels is simulated according to the step-by-step approach (Do et al., 2014; Do and Dias, 2017), with an advance rate of 1.4 m in each step (equal to the tunnel lining width). The simulation of TBM advancement is illustrated in Figure 8.

In the numerical simulation, the face pressures acting on the face from the shield machine at axes of the first tunnel and the second tunnel are applied as 180 kPa and 160 kPa, respectively. These pressures are modelled by considering a pressure distribution with a linear increase along with the depth by assuming as a trapezoidal profile to account for the increment of the pressure in the chamber based on the recorded data.

The tail void grouting pressure is simulated by applying a radial pressure perpendicular to the soil around the tunnel following the measured data. In the FE simulation, the values of grouting pressure are chosen as 194 kPa and 184 kPa applied for the first and second tunnels, respectively. These values are defined according to the average grouting pressures during the excavation in the observation test section. The tunnel lining is subsequently applied after TBM excavation. Both structures of TBM and tunnel lining are simulated by plate element. Material properties considered in the modelling are given in Table 1.

The excavation sequences for the twin tunnels are modelled as follows: the WB tunnel is excavated first, and then the EB tunnel is advanced following with a certain lagging distance behind the face of the WB tunnel. Thus, in the analysis model the first tunnel is driven and constructed through the boundary before the initial driving of the second tunnel is simulated.

Table 1. Material properties of TBM and tunnel lining.

Properties	TBM	Tunnel Lining

Unit weight, γ (kN/m ³)	75	24.5

Figure 7. Longitudinal heave induced by TBM no. 1.

Figure 8. Longitudinal heave induced by TBM no. 2.

Figure 9. Geometry and finite element mesh of 3D model.

The soil is modelled using solid elements. A linear elastic, perfectly plastic Mohr-Coulomb constitutive model with non-associated flow rule is employed. Geotechnical design parameters are taken based on Geotechnical Interpretative Report (GIR) of the project as summarised in Table 2.

5.2 Numerical results and comparisons

This section presents the behaviours of ground movements in vertical and lateral directions during the excavation of the twin tunnels. In addition, a comprehensive comparison is made between

ground movement induced by the EPB shield machines from the measured field data and the simulation results from the FE analysis. One typical monitoring array F1 is selected as a representative to present and analyse the developments of ground deformations induced by tunnel construction.

5.2.1 Ground surface movements

Figure 11 illustrates the development of the ground surface displacements in the transvers direction of the monitoring array F1, caused by the excavation of the WB tunnel and EB tunnel.

According to the measured field data as presented in Figure 11 (a), the response of ground surface

Table 2. Geotechnical parameters.

Soil type	SPT N-Value	γ_t (kN/m ³)	S_u (kN/m ²)	ϕ' (°)	E'_{ref} (kN/m ²)	E'_{inc} (kN/m ²)	ν (-)	k_0 (-)

Figure 10. Simulation of TBM advancement.

tended to immediately move upward during the face approaching the observed section, an approximated value of 12.5 mm was recorded. Then, the ground deformation dramatically increased to around 30 mm above the tunnel centerline when the tail of the shield was positioned at the monitoring section. After the shield passing, the maximum value experienced a gradual rise to almost 35 mm.

Similarly, the measured ground heave resulting from the second tunnel (EB) was experienced as demonstrated in Figure 11 (b). As clearly shown in the plot, an initial small displacement as the shield approached was measured at the EB tunnel centerline, while a large heave up to 15 mm was observed after the shield passing. This also caused the peak value that gradually increased to 40 mm.

The surface vertical displacements computed by numerical analyses were compared to the field measured data at the monitoring section F1. As can be seen, the development of ground deformation obtained from numerical calculation showed a similar pattern and provided good agreement, although smaller displacements were demonstrated. The largest portion of ground movements occurred after shield passing and was mainly caused by tail void grouting process. A maximum predicted heave induced by twin tunnels based on numerical calculation was approximately 30 mm.

Moreover, the results showed that the maximum heave did not occur at the tunnel face immediately, it occurred well behind from the shield after the grouting pressure was performed.

The contour plots of the surface vertical movement obtained from the FE calculation of WB and EB tunnel excavation is presented in Figure 12. According to the simulation of WB tunnelling depicted in Figure 12 (a), ground surface movement occurred while the TBM face was approaching, and it significantly increased at the tail section of the shield machine. The ground heave was characterized by a single peak curve behind the section F1 during the WB shield face was at the observed section.

After the WB tunnel passed through the model boundary, excavation of the EB tunnel was then simulated. In accordance with the EB tunnel excavation as

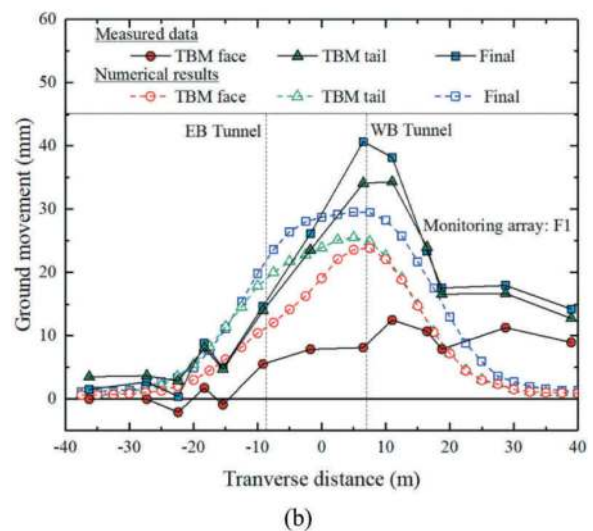

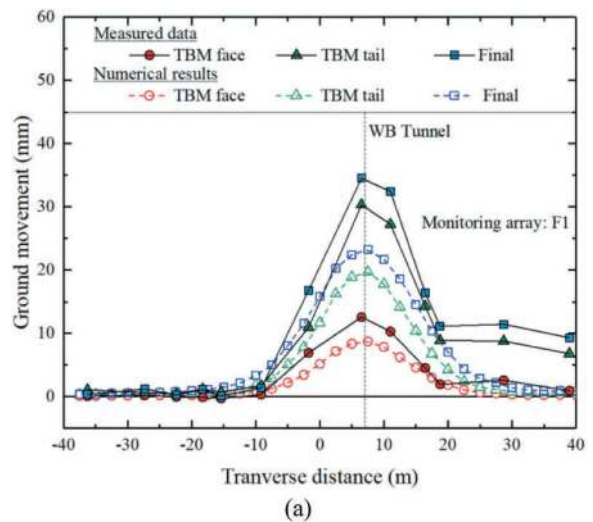

Figure 11. Ground surface displacement in transverse direction tunnelling; (a) WB tunnel, (b) WB & EB tunnels.

illustrated in Figure 12 (b), the ground heave began to exhibit the twin peak curves in front of the TBM face due to face pressure of EB tunnel. Then, the twin peaks moved toward each other gradually due to the grouting progressed and merged into one large single peak. The contour shades were densely distributed near the previous peak induced by WB tunnel, indicating the significant increments of vertical movement in those positions.

5.2.2 Soil lateral movements

In this project, a series of combined inclinometers and extensometers were mostly installed along the side of the tunnel alignment to measure ground deformations in horizontal direction. Figures 12 shows lateral deflections of three inclinometers (IEX1, IEX2 and IEX3) in the perpendicular direction to the tunnel axis during the excavation of the WB tunnel and the EB tunnel.

Based on the observation of the ground deformations after the excavation of the WB tunnel,

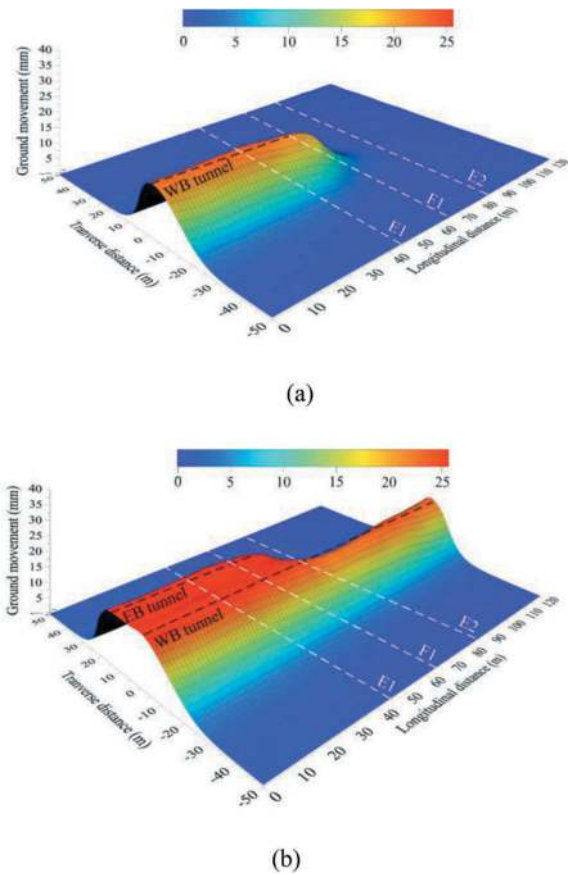

Figure 12. Contour of ground movement due to tunnelling; (a) after WB tunnel, (b) after WB & EB tunnels.

outward movement at the level of the tunnel spring-line as the shield passing was demonstrated. It was found that the maximum lateral magnitude measured by the IEX1 and IEX2 were 22.2 mm and 15.0 mm, respectively. On the contrary, the effect on the IEX3 due to excavation by TBM no.1 was minimal. This is because a distance between the position of the first tunnel and the instrument was very large.

Likewise, the outward movement measured by IEX2 and IEX3 were observed. The largest movement recorded in IEX3 was 12.6 mm which was nearly located at the level of tunnel axis. It is interesting to note that the measured data of lateral movement by IEX2 substantially decreased to around 8.0 mm because of TBM no.2 advancement.

In addition, the general trend of the lateral movements resulting from the numerical simulations was similar to those measured data, with outward movements from the position of tunnels.

Overall, all inclinometers indicated a similar pattern of lateral ground movements. Large outward movements commonly appeared at the tunnel spring-line associated with high face pressures and grouting pressures. This outward deflection recorded by inclinometers reduced rapidly below the level of tunnel position.

6 CONCLUSIONS

The observation and comprehensive instrumentation data performed during the construction of twin

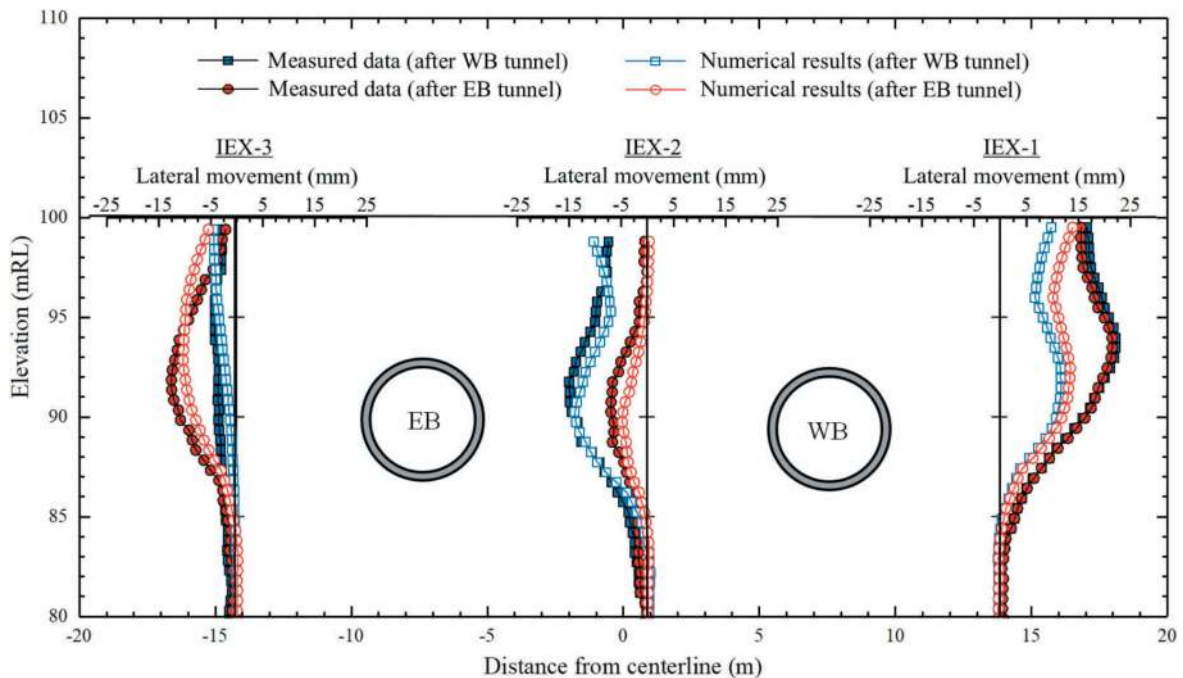

Figure 13. Lateral ground movements after excavation of twin tunnels in shallow overburden.

tunnels in the MRT Orange Line (East Section) project gave a better understanding of the interaction between the soil and the TBM during the tunnel process in a shallow overburden section. The numerical calculation was also carried out to compare the results obtained from the measured field data. Therefore, the main conclusions derived from this study can be summarised as follows:

- Based upon the observational test section, TBM driving parameters including face pressure and grouting pressure have significant effects on ground movements in both vertical and horizontal directions, particularly in shallow overburden.
- Two main parameters of the TBM driving parameters utilised along the monitoring section were recorded, and it can be clearly seen that ground heave and blow-out were obviously induced by applying relatively high face support pressures and tail void grouting pressures compared to the in-situ soil stress.
- The maximum ground heave of 35 mm was measured after the excavation of first tunnel (WB), while the highest upward movement at the tunnel centerline induced by the construction of the second tunnel (EB) was approximately 15 mm. This difference can be attributed to that the second tunnel mostly excavated by using lower support pressures.
- Ground heaves immediately occurred as the shield approaching the monitoring section, and it was found that a noticeable increase in upward ground movements were observed during the process of primary grouting injection.
- The numerical simulation of the EPB shield machine advancement by 3D FE analysis was conducted based on the operational parameters obtained from the recorded data. The simulation results provided the identification and confirmation of the behaviours of observed ground movements in both vertical and horizontal directions.

ACKNOWLEDGMENTS

The authors would like to appreciate Mass Rapid Transit Authority of Thailand (MRTA) and CKST joint Venture for their valuable project data.

Research and application of key technologies for the TBM tunnel construction under extremely complex geological conditions

Huan huan Feng* & Kai rong Hong

China Railway Tunnel Group Co., Ltd., GuangZhou China

State Key Laboratory of Shield Machine and Boring Technology, ZhengZhou China

ABSTRACT: With the Gaoligong Mountain Tunnel of Dali-Ruili Railway, Qinling Tunnel of Hanjiang to Weihe River Project, Xianglu Mountain Tunnel commenced successively in China, the TBM entrapment in water-rich fragmentation in extreme soft stratum and rockburst in extremely hard rock under high ground stress have been increasingly prominent problems in TBM construction. On the basis of the summary analysis on the cases of partial tunnel collapse and TBM entrapment and their contributory factors in the projects, we conduct systematic investigation of the key technologies for TBM tunneling: (1) For now there is no way to make accurate quantitative forecast of the geological conditions in medium or long distances ahead; for the soft and broken stratums with joint development, carbonaceous slate and fault fracture zone, special measures against machine entrapment must be taken and proper rescue solutions can be devised based on the length of the segment with unfavorable geological conditions; (2) The anomalies in the tunneling parameters are important indicators that reveal the geological conditions ahead of heading face. Before TBM tunneling, proper tunneling parameters should be chosen based on the preliminarily anticipated surrounding rock conditions such as full-section hard rock and weak and broken rock. In the boring process of TBM, it is necessary to correct the pre-estimation of geological conditions and take corresponding regulatory measures based on the abnormal changes of boring parameters; (3) Aiming at the situation that the existing TBMs are difficult to adapt to the existing geological conditions, the transformation technology of TBMs is analyzed and discussed with the engineering cases of Tao River Water Diversion Tunnel, Hongyan River to Shitou River Water Diversion Tunnel, and Hanjiang to Weihe River Water Diversion Tunnel. Finally, the new problems of TBM tunnel construction under extremely complex geological conditions and their countermeasures are prospected and discussed.

Keywords: TBM construction, fault, weak and broken, rock burst, jamming, TBM transformation, Standard registration

1 INTRODUCTION

Since the full-face hard rock tunnel boring machine (TBM for short) was applied to the water diversion tunnel of the Xi'erhe Cascade I Hydropower Station in Yunnan^[1], the water diversion tunnel of the Tianshengqiao-II Hydropower Station^[2], the water diversion tunnel of the Datong River-to-Qinwangchuan Basin Water Diversion Project, etc.^[3] in the last century, the TBM equipment and construction technologies of China have been significantly improved^[4], such as Shanxi Wanjiazhai Yellow River Diversion Project^[5], Liaoning Dahuofang Water Tunnel^[6] and Qinling Tunnel of the Xi'an-Ankang Railway^[7] which were successfully completed later. However, as the Strategy for Large-Scale Development of Western China and the traffic network planning are making progress step by step, the geological conditions encountered during the construction of a TBM tunnel are more complex^[8],

and engineering problems or accidents, including rock burst^[9], large deformation^[10], sudden water inflow^[11], tunnel collapse^[12], etc., occur occasionally, having an extremely negative impact on the safety and high-efficiency construction of tunnels. Compared with China, the geological conditions of tunnels in other countries are less diversified, but many TBM tunnel projects have been also hampered by extremely geological conditions, for example, TBMs were struck in the construction of the Gotthard Base Tunnel in Switzerland^[13]. To solve the rock burst problems of TBM tunnels, Huang Feng^[14], Feng Xiating^[15], Su Guoshao^[16], Øyvind^[17] et al. analyzed and researched the process of rock burst development, the sound signal characteristics of rock burst process, etc., and Qiao Zhibin^[18], Zhao Xiangwei^[19], Zhang Tianyu^[20], Guo Yanhua^[21] et al. put forward the identification method of rock burst levels of TBM tunnels; Du Lijie^[22], Wu Haiyuan^[23], Ma Tianhui^[24] et al.

*Corresponding author: skl_fhh@163.com

conducted research into the rock burst prediction technology based on micro-seismic monitoring in TBM tunnels and its applicability; Xu Xiangdong^[25] employed the discrete element method to carry out numerical simulation verification for common rock burst control methods, Zhang Peng^[26], Wang Zuorong^[27], Li Yuanlai^[28] et al. used the rock burst problems in water diversion tunnel projects of the Jinping-II Hydropower Station and the HWWD Project as the research objects to summarize and analyze the countermeasures actually taken during their construction, and Du Li jie^[29], Yang Chunbao^[30] et al. summarized and refined the prevention and control technology for rock bursts in deep-buried tunnels and proposed preventive measures for different levels of rock bursts, involving slight, moderate and strong rock bursts. To solve the problems of TBM tunnel deformation, Kim^[31], Huang Xing^[32], Chen Weizhong^[3] et al. separately conducted research into the surrounding rock deformation and reinforcement mechanism of TBM tunneling and impact of large deformation on the TBM tunneling process; Cai Dawei^[34], Huang Xing^[35], Shang Yanjun^[36] et al. analyzed the deformation characteristics of surrounding rocks, TBM jamming process and countermeasures by taking the diversion tunnel of the Hongyan River-to-Shitou River Water Diversion Project, the diversion tunnel of the Water Diversion Project from Datong River to Huangshui River, the Shanggongshan Tunnel in Kunming, etc. as an example; Wang Yujie et al.^[37] researched and put forward the classification standard for TBM construction adaptability under the large deformation conditions of surrounding rocks. Li Shucai^[38], Kang, Daehun^[39], Liu Bin^[40] et al. conducted research into the application of advanced geological prediction technology to the prediction of mud gushing and water inflow of tunnels; Gao Kun^[41], Li Zhaopeng^[42] et al. carried out research and analysis of measures taken to solve mud gushing and water inflow in TBM tunnels by taking the water delivery tunnel of the Tao River Water Diversion and Supply Project and the Qinling Tunnel of the HWWD Project as an example. To solve the problems of rock bursts and large deformation of TBM tunnels, the predecessors have carried out long-term research into the formation mechanism, generation process, early prevention and control, treatment measures taken at a late stage, etc. and have obtained relevant results.

From the perspective of construction technology, this paper focuses on systematically summarizing and analyzing engineering difficulties and innovative technical measures based on the TBM tunnel project in typical complex geological conditions in China, with the aim to better solve technical difficulties of TBM construction under extremely complex geological conditions, and also proposed relevant recommendations in terms of equipment reconstruction, tunneling parameter regulation and control, and so on.

2 COMMON UNFAVORABLE GEOLOGICAL CONDITIONS IN TBM TUNNELS AND INFLUENCE

2.1 *Weak and broken surrounding rocks*

Within the range of influence of faults, the self-stability of surrounding rocks is poor, and stone falling and collapse easily occur, having a serious impact on the TBM tunneling speed. For example, for Lot 4 of the main line construction of the Water Supply Project of Transferring Water from the Songhua River, the TBM section includes 7km-long limestone and 39 fault fracture zones, with the width of zone of influence ranging from 50m to 250m. In the weak and broken strata where joints were developed, the excavation surface is irregular and peeling and stone falling occur very easily, causing TBM jamming (see Figure 1).

Figure 1. TBM Jamming.

2.2 *Extremely hard rock strata with high abrasiveness*

According to the current TBM equipment and construction technology level, the intensity of rocks which are relatively easy to tunnel ranges from 30MPa to 120MPa, and if the intensity varies between 180MPa and 250MPa, the construction schedule and cost risks incurred will be unaffordable; if it is higher than 250MPa, it will be difficult to tunnel, and in addition to the compressive strength of rocks, the quartz content, rock integrity, abrasiveness and other indexes will also have a direct impact on the TBM tunneling efficiency (e.g. the Qinling Tunnel of the HWWD Project passed through the complete granite section (see Figure 2), where the quartz content was up to 40%, the rock abrasiveness value was up to 5.24, and the single-cycle tunneling time reached 4~5h).

Figure 2. High-strength full-face granite.

The main engineering difficulties encountered by TBM in tunneling through extremely hard rocks with high abrasiveness include TBM tunneling failure, low rock-breaking efficiency of the cutter head, difficulty in ensuring the service life of the main shaft, serious damage to tools, etc., and will greatly reduce the TBM tunneling speed and the utilization rate of tunneling and significantly increase the construction schedule and costs.

2.3 Rock burst in the hard rocks with high ground stress

Under the conditions of high ground stress, rock bursts frequently occur in the process of TBM construction, having a serious impact on the construction of tunnel project, such as 43 rock bursts, with an accumulative length of about 1,894m^[43], happened in the Qinling Tunnel of the Xi'an-Ankang Railway. As the burial depth of tunnels increases, the frequency of occurrence of rock bursts in mountain tunnel projects in China is increasing; for example, the in-progress Qinling Tunnel of the HWWD Project, the Xianglushan Tunnel of the Central Yunnan Water Diversion Project, etc. will face serious rock burst problems. Failure to treat rock bursts timely will endanger personal safety, safety of machinery and equipment and structural stability of tunnels (see Figure 3).

Figure 3. Damage of bracing system caused by rock burst.

2.4 Comparison of construction efficiency under different conditions

TBM utilization rate, tunneling speed, tool wear, etc. are the direct manifestations of the TBM construction

efficiency and are also directly influenced by geological conditions. The preliminary geological survey is often hard to faithfully reflect the geological conditions encountered in the construction of tunnels at a later stage due to the large high burial depth of tunnels, etc. Even for the same class of surrounding rocks, the actual TBM tunneling progress is also not exactly the same as the expected progress. Taking the TBM tunneling of the Middle Tianshan Tunnel as an example, geological conditions are relatively poor, and the utilization rate of TBM equipment primarily ranges from 20% to 35%. The TBM tunneling efficiency varies under different surrounding rock conditions (see Table 1):

3 TBM CONSTRUCTION TECHNOLOGY IN UNFAVORABLE GEOLOGICAL SECTION

3.1 Advanced geological prediction technology

3.1.1 Advanced geological prediction HSP technology

This technique is mainly used to analyze and determine the scale, nature and extension of unfavorable geological bodies which may exist ahead of a tunnel, such as lithologic boundary, fault, and fracture zone of rock mass, and each monitoring cycle is 50m, and the number of times of prediction can be increased according to the actual surrounding rock conditions on site, and its main disadvantage is the low ability to predict groundwater.

3.1.2 Induced polarization (IP)-based advanced water exploration technology

For water-rich strata, the IP-based advanced water exploration technology shall be adopted, which provides a feasible approach to the advanced detection and positioning of water-bearing structures and the water quantity estimation of water-bearing bodies^[44]. In a water inflow section, it is recommended to bore some deeper advanced water exploration holes to the greatest extent possible for the purpose of understanding as much as possible the development of groundwater over a longer distance ahead of the tunnel face.

Table 1. Comparison of boring efficiency of middle tianshan tunnel in different surrounding rocks.

Class of surrounding rock	Design progress m/month	Actual average progress/ m/month				
		Metamorphosed sandstone	Keratophyre	Metamorphosed sandstone (fault)	Granite	Metamorphosed sandstone developed in the quartz vein
Class II	450	/	/	/	216	/
Class III	400	401	346	426	184	190
Class IV	260	180	147	150	141	154
Class V	150	/	/	/	52	/

3.1.3 Integrated geological prediction technology

In high-risk tunnel intervals, an advanced geological prediction technique combining multiple prediction methods is typically adopted to improve the accuracy and precision of geological prediction. For example, in the construction of the Middle Tianshan Tunnel, the integrated assurance technology of TBM construction safety in unfavorable geological sections is established, mainly including an integrated advanced geological prediction technology combining short-distance forecast and long-distance forecast, geophysical prospecting and drilling, and geological sketch and tunneling parameters.

Most of the existing techniques for geological prediction ahead of the tunnel are used for qualitative prediction of geological conditions and cannot accurately and quantitatively predict the geological conditions over a medium and long distance ahead of the tunnel, and it is also difficult to accurately identify the conditions of surrounding rocks ahead.

3.2 Treatment measures for the rock burst section

3.2.1 Countermeasures against minor rock bursts

- 1) Water spraying to soften surrounding rocks: Use the TBM water spraying system to directly spray high-pressure water onto the surface of rocks excavated to soften the surface and further promote the release of original stress of rock strata;
- 2) Densification of anchor bolts and short holes for stress relief: Set high-density anchor bolts within the range of 90° on the tunnel arch, and bore the short holes for partial stress relief within the range of 120° on the arch;
- 3) Emergency concrete spraying: After the surrounding rocks stand above the shield, the emergency concrete spraying system shall be used for the sealing treatment of rock surfaces as early as possible;
- 4) Reinforcement of the McNally support system: A combination of “arched truss + rows of rebars + connecting rebars” is one of the common measures against rock bursts.

3.2.2 Countermeasures against moderate rock bursts

To dispose of moderate rock bursts, the support methods are optimized and a combination of temporary support + permanent support is adopted: (1) The ordinary gasket-type anchor bolts are changed to the expansion shell-type prestressed hollow grouting anchor bolts with a large base plate to apply the prestressing force in advance; (2) ordinary concrete is changed to nanomaterials or steel fiber and imitation fiber concrete to quickly close and reinforce surrounding rocks; (3) it is recommended to use steel arches made of H150 profile steel, and meanwhile, the diameter of rebars in the rebar row is properly increased.

3.2.3 Countermeasures against strong rock bursts

In the section where strong rock bursts may occur, conventional support measures will be unable to cope with such rock bursts, and generally, advanced stress relief should be conducted. The following measures are taken to effectively reduce the intensity of rock bursts: bore holes with an advanced water hammer drilling rig, inject water within a certain range, change the physical and mechanical properties of rocks, and lower the brittleness of rocks and the ability of energy storage. After the rock mass stands above the shield, steel segments can be installed for initial support reinforcement for support reinforcement.

3.3 Treatment measures in weak and broken strata

3.3.1 Grouting reinforcement for the strata where joints were developed

- 1) Advanced grouting reinforcement inside the cutter head. The technology for advanced grouting reinforcement inside the cutter head is widely used, i.e. chemical grouting is used in shallow holes in the cutter head to form the wall for grouting, while high-strength and fast-setting curing agents and cement-water glass slurry are injected in medium-length holes for reinforcement.
- 2) Advanced grouting reinforcement of TBM tailskin. The technology for advanced grouting with a drilling rig is employed in the position of TBM tailskin, and no construction experience is available for reference in China now. CRTG performed tests in the construction process of the Gaoli Gongshan Tunnel of the Dali-Ruili Railway, replaced multiple types of drill pipes and bits, tested fast drill pipes, self-feeding pipe roofs and geological drill pipes, and realized the integration of drilling and grouting.

3.3.2 Support processing for carbonaceous slate stratum

In the limestone section of the tunnel of the Water Supply Project of Transferring Water from the Songhua River, TBMs passed through a total of 2 carbonaceous slates surrounding rocks, leaving the cutter head and the cutter holes prone to be covered and plugged, and collapse and serious falling occurred on the top. The following countermeasures shall be taken:

- 1) Initial support reinforcement. After the surrounding rocks stand above the shield, supports shall be installed in time, and measures of reinforcement of fully-laid rebar rows, longitudinal connection of profile steel, densification of arches and concrete spraying for whole sealing, are formed to eradicate the hidden dangers of supports behind the shield. Different support methods shall be separately used for the crown, gripper shoe and tunnel bottom.

- 2) Cutter head cleaning. When the torque is close to the rated value, the cutter head shall be stopped immediately and cleaned manually according to the on-site tunneling situation to prevent the cutter head from being overloaded and protect the cutter head and tools from being damaged, and meanwhile, the aperture ratio of the cutter head is increased and the water spraying system for the cutter head is stopped to make the output of slate rock mass easy.

3.3.3 Measures for passing through fault fracture zone

- 1) Crown: A combination of supports, including steel arch, rebar row, connecting rebar, and shotcrete, can effectively deal with ordinary fracture zones; however, in addition to the above measures, the emergency shotcreting and supporting system can also be used to timely seal the serious fracture section if necessary;
- 2) If falling or collapse occurs in the position of gripper shoe, the measures are generally taken: square timber forms are put under the gripper shoe, concrete is poured, and emergency shotcreting is conducted in advance.

Different measures are taken for different types of weak and broken strata, such as joint development zone, carbonaceous slate zone and fault fracture zone. The classified support technology system shall be built for TRMs passing through the weak and broken strata, with the aim of better solving the problems in a targeted way, such as tunnel deformation and collapse and TBM jamming.

4 TBM TUNNELING PARAMETER REGULATION OF DIFFERENT STRATA

4.1 Full-face hard rock

The key to realizing the high-efficiency tunneling of TBMs is to properly master the matching relationship between the parameters and the compressive

strength of surrounding rocks, without considering rock bursts. Taking the TBM tunneling data of the tunnel in the HWWD Project as an example, the main TBM tunneling parameters under different surrounding rocks are proposed (see Table 2):

4.2 Soft surrounding rock

The parameters of tunneling through weak surrounding rocks shall be controlled in a targeted way. Taking the TBM tunneling parameter control of the Water Supply Project of Transferring Water from the Songhua River as an example (see Table 3):

- 1) Speed of cutter head: From the cutter head thrust and the rock-breaking effect in the previous cycle, it is judged that the rock debris will be uniform with few large blocks and the speed of cutter head can be improved if the cutter head thrust is relatively large; the rock debris will not be uniform, with more large blocks, and the speed of cutter head should be lowered if the cutter head thrust is relatively small.
- 2) Torque of cutter head: Under the weak surrounding rock conditions, the torque of cutter head is typically controlled at about 75% of the rated torque;
- 3) Gripper shoe pressure: If the TBM tunneling conditions are met, the minimum gripper shoe pressure shall be selected.

If a tunnel collapses, corresponding control measures shall be taken for different positions of collapse:

1. If collapse occurs in the cutter head and the tunnel face, TBM tunneling shall be stopped immediately and the cutter and the belt conveyor shall continue to operate, and determine whether the cutter head needs to be retracted according to the quantity of rock debris;
2. If collapse occurs behind the shield, the TBM shall be stopped without delay and supports shall be set in case of serious collapse, and after the completion of support setting, tunneling can be resumed.

Table 2. Optimal range of tbm boring parameters in different surrounding rock conditions.

Compressive strength of surrounding rocks/ MPa	Average thrust cylinder pressure/ bar	Speed of cutter head/r/min	Torque/ kN·m	Penetration/ mm/r
≥260	300~310	6	850~950	0.9
240~260	300~310	6	850~950	1.0~1.2
220~240	300~310	6	850~1050	1.0~1.5
200~220	300~310	6	1050~1200	1.2~2.2
180~200	300~310	6	1200~1350	2.5~3.2
160~180	300~310	5~6	1350~1600	2.8~3.5
100~160	180~300	4~5	1500~2200	4~8
80~100	100~180	2~3	1800~2200	9~12

Table 3. TBM boring parameter comparison table under the full cross-section carbonaceous slate.

Different stratum conditions	Tunneling speed/ mm/min	Torque of cutter head/ kN·m	Speed of cutter head/r/min	Penetration/ mm/r	Thrust pressure/ bar	Gripper shoe pressure/ bar
Carbonaceous slate	10~26	400~3800	1.8~4.5	3~10	60~120	194~254
Fault fracture zone	52~70	1630~3360	4.8~5.9	9~13	255~294	255~294
Normal tunneling section	62~80	2200~3310	6~6.7	9~13	273~323	273~323

4.3 Impact of different water contents

In a dry and soft rock tunnel dominated by sandy mudstone and argillaceous sandstone, TBMs have strong adaptability, the fluctuation of various tunneling parameters is small, and the tunneling efficiency is relatively high; in a water-bearing loose sand layer, TBMs have a certain adaptability, and auxiliary measures are taken to ensure normal TBM tunneling. Taking the TBM construction of the tunnel in the Tao River Water Diversion Project as an example (see Figure 4), in the loose sand layer section with the water content of 6%~11.8%, the TBM tunneling thrust increased with the water content. The maximum fluctuations of thrust and torque are 298% and 148%, respectively.

Figure 4. Changing curve of TBM boring parameters of aquiclude of tao river water diversion tunnel.

The changed rock conditions are reflected in the changes in various parameters related to TBM equipment and tunneling progress. Before TBM tunneling, appropriate tunneling parameters shall be selected according to the expected surrounding rock conditions; During the TBM tunneling process, the prediction of geological conditions shall be corrected and corresponding regulation measures shall be taken according to the abnormal changes in tunneling parameters, so as to ensure TBMs in the optimal tunneling state.

5 TARGETED TBM DESIGN AND RECONSTRUCTION TECHNOLOGY

To adapt to the demand for tunnel construction under various geological conditions, a variety of TBMs emerge, including open-type, single-shield and double-shield TBMs, and various types of TBMs have different abilities to adapt to the same geological condition, so the local system of a TBM shall be subject to targeted reconstruction for better meeting the construction demands when complex geological conditions are encountered or the existing TBM is difficult to adapt to the tunnel to be built.

5.1 TBM tunnel reconstruction of the Hongyan River-to-Shitou River Water Diversion Project

The TBM equipment used in the Hongyan River-to-Shitou River Water Diversion Project was second-hand, with poor adaptability. It was stuck a total of nearly 50 times. For this reason, targeted reconstruction of the equipment was conducted many times.

- 1) Main drive improvement: Add a set of variable frequency speed control devices, which can regulate the speed of cutter head to control the amount of muck according to the conditions of surrounding rocks of the tunnel face, so as to cope with poor geological conditions or pass through the fault fracture zone; improve the existing ABB two-speed motor into the 200 kW motor, which is a variable frequency motor having an IP67 rating for ingress protection; install 2 new variable-frequency drives to realize the “1+1” mode, use the bus control mode to realize synchronous running of 5 motors, and realize the vector control to make the cutter head drive have the function of low-speed rotation and large-torque output ;
- 2) An increase in excavation diameter: Move the side disc cutter housing outwards to increase the excavation diameter of the cutter head, so that the excavation diameter of a TBM increases from 3.655m to 3.755m and the amount of deformation is reserved for the TBM passing through the area of surrounding rock deformation quickly, and the TBM’s ability to adapt to convergence and deformation of surrounding rocks can be improved;

- 3) An increase in the conveying capacity of belt conveyor: Replace a 10mm-dia. directional control valve with a 16mm-dia. one, so that all flows provided by a drive hydraulic pump can be used to drive 1# belt conveyor, the running speed can reach 2.3m/s, and the running ability can be increased by 15%; replace the hydraulic pump with a displacement of 100cc of 1# belt conveyor with one with a displacement of 140cc;
- 4) Optimization of the shield structure: lengthen the front shield: extend the front shield forward and lengthen it to protect the cutter head and reduce the amount of muck, so that the tunnel face has certain self-stability or a small amount of collapse will not make the cutter head stuck; bottom sealing of the internal telescopic shield: seal the telescopic shield to prevent muck from entering the shield, omit the muck removal process in the telescopic shield during the TBM tunneling period, and facilitate the rapid passage of a TBM; shortening and semi-sealing of the tail-skin: the aperture opening ratio of the tailskin is 70° after reconstruction so that the inflow of slag caused by side arch collapse can be reduced.

After reconstruction, the geological adaptability of TBMs can be significantly improved, and especially after the completion of main drive reconstruction, the average daily footage is 11m, the maximum footage per shift is 26.7m and the daily maximum footage is 35.2m, and the TBM tunneling efficiency is increased by over 50% compared with that before reconstruction.

5.2 *TBM reconstruction of the tunnel of the HWWD project*

5.2.1 *Cutter head reconstruction*

- 1) Cutter head panel: Use the steel sheet of appropriate specifications for welding and repair according to the wear of the cutter head panel, so as to make it flush with the datum plane. a new wear-resistant composite plate with a welding thickness of 20mm is formed on the cutter head panel after repair, so as to improve the abrasive resistance;
- 2) Wear ring and slag-retaining block on the side: Increase the thickness of the first and second wear rings as well as the slag-retaining block on the side from 50mm to 70mm, and meanwhile, replace its material with Q690;
- 3) V-shaped guard block: On the premise that the same forming size can be ensured, use a 63.5mm-thick ASTM A572 steel plate as the bottom plate, set a 9~13mm wearing layer on the surface, and bevel the bottom welding position to ensure the welding quality;
- 4) Cutter housing: For a cutter housing which has been repaired multiple times and undergone large wear and deformation, the wear-prone contact

surface can be designed as a replaceable block to avoid the whole cutter housing from being replaced after wear, provided that the original cutter housing size is not changed.

5.2.2 *Support system optimization*

To better deal with the complex geological conditions, such as weak and broken surrounding rocks, an emergency concrete-spraying manipulator shall be installed behind the TBM shield. The TBM equipped with a transfer pump behind a concrete conveying shield for shotcrete areas is used, the emergency concrete-spraying manipulator behind the shield is utilized for initial concrete spraying so that initial shotcrete can seal surrounding rocks, and after this section enters the mechanical shotcrete area, the mechanical injection method is employed to respray concrete until the design thickness is reached.

5.2.3 *Reconstruction of the bottom slag removal system*

Rock bursts frequently occurred in the process of TBM tunneling, so that more rock slag falls off from the main beam bottom of a TBM, seriously restricting the construction efficiency. The bottom slag removal system provided with the original TBM equipment fails to meet the requirements for quick slag removal from the main beam bottom on site due to the limited range of slag removal, complicated slag removal procedures and large quantities of transport. The adoption of an innovative belt conveyor will directly transport rock slag from the main beam bottom to the outside of a tunnel so as to accelerate slag removal and omit the processes of loading to dumper trucks, transport and reshaping.

5.2.4 *Reconstruction of the advanced drilling rig system*

To ensure the integrity of rocks after tunneling, there is an intact ring area of rock mass within 1m in the radial direction of the wall surface of an excavation hole; meanwhile, the regional stress within the vertical distance of 1m~5m in the radial direction of the wall surface of an excavation hole on the tunnel wall is released. A water hammer drilling rig is used to bore holes within the range of circumferential 100° on the upper part of a tunnel at an angle of elevation of 5°-9°. The borehole diameter should be the diameter of the supporting drill bit, the spacing between boreholes should be 60-100cm, and the appropriate and reasonable spacing should be kept to maintain the self-stability of surrounding rocks; tunneling shall be conducted at intervals of about 15-25m, and drilling shall be carried out once. Taking the water diversion tunnel of the HWWD Project as an example, it is especially necessary to introduce an advanced water hammer drilling rig and use it as a technical reserve for the construction of extremely strong rock burst sections.

6 CONCLUSIONS AND PROSPECTS

The characteristics of extremely complex geological conditions, such as weak and broken strata, full-face granite and high ground stress rock bursts, and their impact on the TBM construction are systematically compared and analyzed. The adoption of advanced geological prediction technology, targeted construction technology, tunneling parameter regulation technology, targeted TBM reconstruction technology, etc. can better guarantee the high efficiency and safety of TBM construction under complex geological conditions. However, more systematic and in-depth research shall be conducted to solve the engineering difficulties, such as rock bursts and large deformation, and relevant research recommendations are proposed according to the construction experience and research results of similar projects in the early stage:

- 1) Quantification of the advanced geological prediction technology. The advanced geological prediction technology is a powerful tool for helping TBMs deal with unfavorable geological conditions, but now, it is still in the qualitative or semi-quantitative stage in most cases, so it plays a limited role in guiding the safe and high-efficiency tunnel construction using TBMs, and the accuracy and degree of intelligence of geological prediction need to be improved;
- 2) Strengthening of the R&D of a new tunneling equipment technology. There is a lot of room for improvement of the existing open-type or shield-type TBMs in terms of dealing with extremely unfavorable geological conditions, including rock bursts or large deformation, and the R&D and application of new equipment, such as dual-structure and double-support^[45] equipment, are urgently needed now; at the same time, a multi-purpose hybrid tunnel boring machine combining the advantages of shields and TBMs is developed, which is also one of the approaches to dealing with extremely unfavorable geological conditions.
- 3) In-depth analysis of the impact of tunneling parameters. The disturbance of surrounding rocks varies with different TBM tunneling parameters, including tunneling speed, penetration, speed, etc., so that its impact on the process of releasing the energy stored in surrounding rocks differs, and tunneling parameters are reasonably regulated to remove the necessary conditions for the occurrence of rock burst and large deformation, which may be an effective means to prevent rock bursts and large deformation.

ABSTRACT: The new Railway line between Rishikesh and Karanprayag is under construction in the State of Uttarakhand, India with a total length of 125 km. Package 4 of the project includes 10.490 km (Twin bore TBM Tunnel, Upline & Downline) being constructed using two 9.11 m diameter Single Shield Hard Rock TBMs. Rock masses such as shale, slate, phyllite and schist, and the rock mass of weakness/fault zones are incapable of sustaining high stresses in such high overburdened tunnels leads to squeezing ground condition during tunnel construction in the tectonically active Himalayan region. Package 4 route is not an exception and mostly consists of high schistose Phyllite and Quartzite Phyllite rock mass being considered in TBM specifications which enables to investigate the ground ahead of TBM and monitor the constructed tunnel, aimed towards reducing the risk, using state of the art technologies in TBMs. Squeezing potential of rock strata along the Mechanized tunnel part being assessed with empirical, semi-empirical, analytical, and numerical methods based on the geotechnical and geomechanical parameters of the rocks, identified/interpreted in the tunnel route and presented through GBR, GDR and GIR Reports before tunnel construction and expected squeezing behaviour under average to high overburden conditions, which is also being evaluated during tunnel construction with the actual tunnel convergence measured around the shield. Void measurements around the shield is being done by adapting three special instruments along the shield near the tunnel crown capable to measure the void above after each advance and during stoppages of the TBMs. Comparison of the analytical and numerical analysis with the actual data collected in the first 2.7 km of upline tunnel path shows good correlations mostly with the previous studies done in the Himalayan region.

Keywords: TBM, Shield, Tunnel, Squeezing, Hard rock, Convergence

1 INTRODUCTION

The 125 km length Railway line between Rishikesh and Karanprayag in the State of Uttarakhand, India comprises of 17 tunnels 12 stations and 35 bridges. Tunnel 8 (Package 4) of the project from chainage 47+360 to 63+117, includes 15.1 km double line tunnel located between Devprayag and Janasu (Figure 1), out of which 10.490 km (Twin-bore TBM Tunnel) being constructed using two 9.11 m diameter Single Shield Hard Rock TBMs (Figure 2). Tunnel and TBM general specifications are mentioned in Table 1.

2 TBM INVESTIGATION AND MONITORING DEVICES

The utilization of Shielded TBMs for the Rishikesh to Karanprayag railway project Package 4 is a viable option, given the favourable conditions of the rock strata specified in the GBR, the expected topographical advantages along the tunnels, and the positive social, environmental, and financial considerations. To enhance the operation of these TBMs, state-of-the-art technologies have been incorporated, which offer the capability to precisely control the machines' advance rate and simultaneously assess the rock strata ahead of

TBM Boring Diameter	9,110 mm
TBM Front Shield Outer Diameter	9,050 mm
TBM Middle Shield Outer Diameter	9,030 mm
TBM Tail Shield Outer Diameter	9,010 mm
Total Shield length	10,675 mm
Nominal Radial Gap (Void) Behind TBM Front Shield	30 mm
Nominal Radial Gap (Void) Behind TBM Middle Shield	40 mm
Nominal Radial Gap (Void) Behind TBM Tail Shield	50 mm
Segment Outer Dia.	8,700 mm
Segment Inner Dia.	7,800 mm
Average Ring Length	1,700 mm
Number of Segments in Universal Ring	7 + 1 key
Total Installed Power	4,200 kW
Number of Thrust Cylinders	42
Nominal Thrust @ 420 bar	108,619 kN
Standby Thrust @ 500 bar	129,308 kN

Figure 2. TBM SHAKTI (S-1309A) factory acceptance test.

the TBM face and the excavated tunnel. These technologies include:

- Exploratory probe drilling equipment: Used to investigate the ground ahead of the TBM cutterhead through 20 inclined drill holes within the TBM shield perimeter and 6 horizontal drill channels through the cutterhead.
- Seismic investigation equipment: Enables extended investigation of the rock mass body in front of the TBM and verifies direct investigations conducted through boreholes and probe holes.
- Disc cutter load monitoring system (DCLM): Monitors the load on four disc-cutters positioned at different locations (radii) on the cutting wheel while the cutterhead rotates, providing insights into the rock strength in various positions on the face.
- Ring convergence monitoring system (RCMS): Monitors deformation and convergence of the segmental ring through effective measurements using a wireless system starting immediately after the ring installation.
- Muck weighing equipment: Measures the weight of the excavated material via the TBM conveyor belt.
- Variably sized TBM shields: Employed to create additional space in the tail shield to accommodate ground convergence during shield advance.
- Facilities to overcut up to 9310 mm diameter by shifting the 19” gauge cutters and changing with 20” disc cutters.
- Void measurement system (VMS): Measures the void between the shield and the rock using three cylinders in the front and middle shield’s roof section. This system operates during TBM stoppages, such as ring building time. Continuous measurements during each advance, considering the distance between these cylinders (1700 mm as illustrated in Figure 3), allow for the recording of ground convergence in the same position during subsequent measurements.

3 GEOLOGICAL AND GEOTECHNICAL PROPERTIES OF THE ROCK ALONG THE TUNNEL ROUTE

The single shield TBMs shall excavate the twin tunnels of approx. length of 10.5 km each through the Chandpur formations of Jaunsar group comprising mainly of Phyllite and quartzitic phyllite with varying content of quartzite in them. Several drill hole investigations along with laboratory and geophysical investigations were performed to evaluate the rock mass conditions along the tunnel. The drill holes up to depth of 600 m were conducted to verify the expected site conditions based on site topography and geological traversing and mapping.

The in-situ state of stress was inferred from the hydrofracture field tests performed at the site. Vertical stress is one of the principal stresses and is due to gravity loading. The best estimates for the in-situ stress ratio for different overburdens and zones are calculated using Sheorey’s equation validating from the site test results. The state of stress in the

horizontal plane is considered isotropic. Figure 4 Shows geological longitudinal section of package 4 and Table 2 represents the best and cautious estimates of various geomechanical properties along the various critical sections along the TBM tunnel lengths zone.

Figure 3. Void measurement cylinders position on the shield.

4 SQUEEZING ANALYSIS APPROACH AND METHODOLOGY

Squeezing of the host ground is the large time-dependent deformations that occur around the tunnel geometry. The time-dependent deformations are produced by the disturbance of the

primitive stress field due to the excavation of the tunnel. The rock mass around the tunnel boundaries is strained under the influence of induced stresses. The deformations may terminate during construction or continue over a long period of time (Barla, 1995). In the landmark paper on tunnelling by Karl Terzaghi (1946), the prerequisite of the squeezing ground conditions is defined as the high percentage of microscopic or sub-microscopic particles of micaceous minerals or of clay minerals with low swelling capacity. Following the definitions of Terzaghi, several approaches are identified by various authors to assess the potential of squeezing problems in tunnelling.

4.1 Singh et al. (1992) an empirical approach

Using 39 individual case histories primarily from Himalayan formations, Singh et al. (1992) conducted a study in which they collected data on rock mass quality (Q) and overburden, led to the establishment of a discernible boundary line, clearly distinguishing between squeezing and those of non-squeezing rock, as presented in Equation 1, in which data points positioned above this demarcation line signify instances of squeezing conditions.

$$H = 350Q^{1/3} \quad (1)$$

Where, H is overburden (m); Q is rock mass quality (Barton et al. 1974).

4.2 Goel et al. (1995) an empirical approach

Goel et al. (1995) proposed a straightforward empirical method that utilizes the rock mass number N . This number is defined as the stress-free Q , aiming to mitigate the uncertainties associated with determining the accurate rating of the SRF parameter in Barton et al.'s (1974) Q . The definition is as follows:

$$N = (Q)_{SRF=1} \quad (2)$$

Goel et al. (1995) conducted a comprehensive analysis of tunnel sections, taking into account overburden depth (H), tunnel span or diameter (B), and the rock mass number (N) and generated a log-log diagram (Figure 5) in which the plotted data points revealed a clear distinction between squeezing and non-squeezing cases, represented by Equation 3.

$$H = (275N^{0.33})B^{-1} \quad (3)$$

4.3 Verman (1993) an empirical approach

In a field study involving nine Himalayan tunnels, Verman (1993) employed the ground reaction curves (GRC). Through the use of empirical correlations and the GRC, Verman developed a design chart for classifying ground conditions into three categories: self-supporting, non-squeezing, and squeezing. In this approach the maximum tunnel span (B_s) that the ground can sustain without experiencing squeezing is defined as Equation 4.

$$B_s = 3.2Q^{0.4} \quad (4)$$

Based on the actual span and the span defined in Equation 4, the ground is categorized as follows:

- 1) Self-supporting if $B - B_s < 0$,
- 2) Non-squeezing if $H (B - B_s)^{0.1} < 483Q^{1/3}$,
- 3) Squeezing or rock burst if $H (B - B_s)^{0.1} > 483Q^{1/3}$.

Where, H is overburden (m); B_s is tunnel span; Q is rock mass quality (Barton et al. in 1974).

4.4 Jethwa et al. (1984) a semi-empirical approach

Jethwa et al. (1984) delineate the degree of squeezing using the coefficient N_c which represents the ratio of the rock mass uniaxial compressive strength (UCS) to the in-situ stress and establish their approach for classification of degree of squeezing based on the Equation 5 and the criteria outlined in Table 3.

Figure 5. Goel et al. (1995), approach for predicting squeezing conditions.

$$N_c = \frac{\sigma_{cm}}{P_0} = \frac{\sigma_{cm}}{\gamma H} \quad (5)$$

Where, σ_{cm} is rock mass uniaxial compressive strength; P_0 is in situ stress; γ is unit weight of rock mass; and H is tunnel overburden.

Table 3. Classification of squeezing behaviour Jethwa et al. (1984).

N_c	Type of behaviour
< 0.4	Highly squeezing
0.4 – 0.8	Moderately squeezing
0.8 – 2.0	Mildly squeezing
> 0.2	Non squeezing

4.5 Aydan et al. (1993) a semi-empirical approach

Drawing from their experience with Japanese tunnels, Aydan et al. (1993) introduced a relationship between the strength of intact rock (σ_{ci}) and the overburden rock pressure (γH), using the same equation as (5). This relationship assumes that the uniaxial compressive strength of the intact rock (σ_{ci}) and that of the rock mass (σ_{cm}) are equivalent. Based on the data from surveyed tunnels in squeezing rock conditions in Japan, Aydan et al. (1993) reveals that squeezing conditions are likely to arise when the ratio $\sigma_{ci}/\gamma H$ is less than 2.0.

4.6 Hoek and Marinos (2000) semi-empirical approach

Hoek (1998) employed the ratio of the rock mass uniaxial compressive strength (σ_{cm}) to the in-situ stress (p_0) to gauge the likelihood of tunnel squeezing

issues. Hoek and Marinos (2000) further demonstrated that plotting tunnel strain ε_t against the ratio σ_{cm}/p_0 offers an effective method for assessing tunnelling problems in the presence of squeezing conditions.

Hoek (2000), through axi-symmetric finite element analyses involving derived an approximate relationship for tunnel strain ε_t using Equation 6 and Equation 7 considering $p_i = 0$.

$$\sigma_{cm} = (0.0034m_i^{0.8})\sigma_{ci}\left\{1.029 + 0.025e^{(-0.1m_i)}\right\}^{GSI} \quad (6)$$

$$\varepsilon = 100 \times \left(0.002 - 0.0025\frac{p_i}{p_0}\right)\left(\frac{\sigma_{cm}}{p_0}\right)^{\left(2.4\frac{p_i}{p_0}-2\right)} \quad (7)$$

Where, σ_{cm} is rock mass uniaxial compressive strength; σ_{ci} is uniaxial compressive strength of the intact rock; m_i is Hoek–Brown parameter for intact rock; GSI is Geological Strength Index; ε is tunnel strain (defined as the percentage ratio of radial tunnel wall displacement to tunnel radius); P_0 is in situ stress; P_i is internal support pressures.

Drawing from the above analysis and examining case histories, Hoek (2000) presented the curve depicted in Figure 6 as an initial estimate for evaluating tunnel squeezing problems.

The result of the empirical and semi-empirical approaches considering geomechanical properties of tunnel route is illustrated in Table 4. As it is clear from the following results, the approaches developed mostly from the Himalayan region shows almost same predictions for squeezing condition in this project. The Hoek and Marinos (2000) approach implemented to evaluate maximum deformation based on Equation 7 which the results are given in Table 4.

Figure 6. Classification of squeezing behaviour (Hoek and Marinos, 2000).

4.7 Deformation analysis of tunnel at tail shield

4.7.1 Analytical analysis of deformations at tail shield

Carranza-Torres and Fairhurst (2000) determined that the Convergence Confinement Method (CCM) consists of three fundamental components: the Longitudinal Displacement Profile (LDP), the Ground Reaction Curve (GRC), and the Support Characteristics Curve (SCC).

As an initial approximation, ground reaction curves were generated based on the estimated geomechanical properties using Rocsupport software, employing Carranza-Torres' approach (2004). These curves were used to assess the maximum ground deformations that may occur up to the point of first support contact, which corresponds to the end of the tail shield at 9.85 meters.

Tunnel boring machine (TBM) jamming in squeezing conditions arises when the available thrust is insufficient to maintain TBM progress or to facilitate a TBM restart, as indicated by Ramoni and

Anagnostou (2011) and Zhao et al. (2012). To address this issue, one possible approach involves determining the closure of the TBM shield gap.

In the preliminary analysis utilizing Rocsupport, the maximum feasible deformation compared with the gaps between the TBM shield and the excavation diameter across various combinations of overcuts to assess the potential for TBM jamming in squeezing conditions. However, if these deformations surpass the prescribed limits, the point at which this gap closes concerning the tunnel face is determined using a Longitudinal Displacement Profile (LDP) plotting radial displacement against the distance from the tunnel face. Should the computed distance be less than or equal to the length of the TBM shield (9.85 meters), it signifies the development of a load buildup on the machine, which may lead to TBM jamming. In such cases, a more detailed analysis employing the Finite Element Method (FEM) undertook to assess and address the situation.

The LDP computed using the semi-analytical approach outlined by Vlachopoulos and Diederichs (2009), which offers a preliminary estimation of expected deformations, guiding the identification of sections where FEM approaches may be required. The analysis will yield results in the form of a plastic radius (R_{pi}) and the maximum displacement at the tunnel perimeter ($u_{r,max}$).

The comprehensive analysis results for all critical sections, as determined through the analytical method employing Rocsupport, are provided in Table 5. These results are presented as the maximum expected displacement at the end of the tail shield, the anticipated maximum tunnel convergence, and the plastic radius of the excavated tunnel at each critical section.

Based on the analysis above, there is no anticipation of the ground making contact with the shield in any of the sections. Consequently, no pressure buildup is expected, provided that suitable overcuts are implemented at the appropriate locations. It's

Table 5. Tunnel deformation at critical sections as per analytical approach (Rocsupport).

Chainage	Max displacement at tail shield (mm)	Tunnel Convergence at tail shield (%)	Plastic Radius (m)
49+310	1.59 mm	0.03%	4.93 m
49+440	123.37 mm	2.71%	10.94 m
51+020	36.63 mm	0.80 %	7.73 m
51+100	1.9 mm	0.04 %	4.8 m
53+250	8.39 mm	0.18 %	6.95 m
53+650	5.42 mm	0.12 %	6.29 m
54+725	32.94 mm	0.72 %	8.9 m
55+340	13.21 mm	0.29 %	6.94 m
56+105	12.75 mm	0.28 %	7.37 m
56+300	14.78 mm	0.32 %	7.68 m
56+680	6.24 mm	0.14 %	6.49 m
57+740	36.79 mm	0.81 %	9.13 m

worth noting that second section (chainage 49+440) represents the scenario with the most significant deformation and convergence.

4.7.2 Numerical analysis of deformations at tail shield

As stated above, based on the analytical analysis, most critical section will be at the chainage 49+440 which is further analysed using FEM (Plaxis) to further evaluate any squeezing risks.

The Axisymmetric finite element model provides more detailed results by incorporating the elastoplastic behavior of the ground and accounting for the presence of the TBM shield and segmental lining. In FEM analysis, the initial stress is defined as the mean stress. Notably, the stepping of the shields has not been considered in this analysis, adopting a conservative approach. For all other sections not exhibiting squeezing issues according to analytical methods, control can be achieved through various overcuts, obviating the need for further refined analysis. It is also expected that in these sections, the ground will not come into contact with the TBM shields. Consequently, to drive the TBMs or initiate a restart, a nominal thrust force sufficient to overcome friction due to the machine's self-weight should suffice. The results of the FEM modelling are presented in Figure 7 to Figure 9.

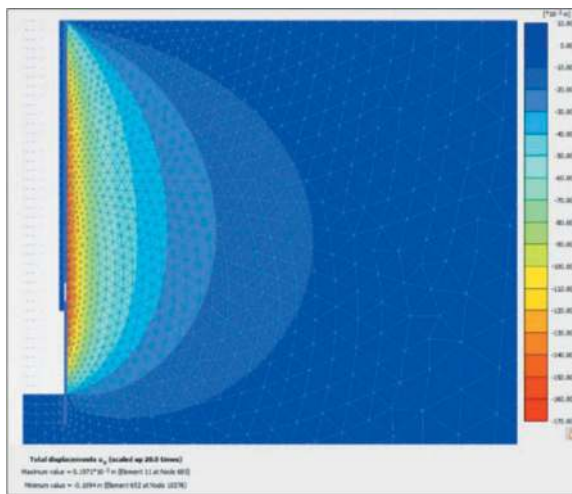

Figure 7. FEM analysis on chainage 49+440, Maximum ground displacement behind the TBM (170 mm).

The thrust required to overcome the friction force between the shield and the rock mass can be determined using Equation 8.

$$F_r = p_s S \mu \quad (8)$$

Where p_s is the pressure acting on the shield, μ is the friction coefficient, and S is the contact surface area between the shield and the rock mass.

The contact surface area of the shield and rock can be calculated as per Equation 9.

Figure 8. FEM analysis on chainage 49+440, maximum ground displacement at TBM tail shield (160 mm).

Figure 9. FEM analysis on chainage 49+440, maximum displacement on the segmental lining (0.33 mm).

$$S = 2\pi r_s L_c \quad (9)$$

Where r_s signifies the shield radius, and L_c is the length at which contact takes place.

The friction coefficient is variable, typically falling within the range of 0.15 to 0.35 for sliding friction during TBM advancement and 0.25 to 0.45 for static friction during TBM restart.

Likewise, the analysis to ascertain the maximum thrust necessary for both sliding and restarting the TBMs, utilizing the equations described in Equation 8, was carried out, yielding the following results:

- Maximum thrust required for sliding: 47,500 kN
- Maximum thrust required for TBM restart: 61,071 kN

Since the calculated thrust forces are lower than the maximum nominal thrust force of the TBM, they are deemed acceptable.

5 CONVERGENCE MEASUREMENT IN TBM TUNNELLING

As mentioned in Part 2, the machines are equipped with three void measurement cylinders along the shield, spaced at a distance equal to the advance length (1700 mm). These void measurements are conducted during TBM stoppages, both short stoppages (e.g., during ring building) and long stoppages (e.g., routine maintenance, probe drilling, tunnel conveyor extensions, etc.). The TBM operator measures the void behind the shield, recording this information along with the precise time and the shield's chainage in the data logger. These recorded data are used to assess the actual convergence around the TBM. Figure 10 displays the data obtained through the void measurement system at various chainages in the first 2.7 km of the upline tunnel.

To account for tolerances in the advance length and to exclude incorrect records (resulting from not measuring the same location with the void measurement cylinders), records in which two readings have a tolerance greater than ± 50 mm in chainage are not considered in the Ground Convergence calculations. Ground Convergence is derived from the readings of the void measurement system during TBM advancement and is presented in Figure 11, where GC1-2 represents the convergence measured by the first and second void measurement cylinders, and the same format applies to GC2-3 and GC1-3.

Furthermore, the Ground Convergence Rate is calculated considering the time between two measurements. Figure 12 illustrates the Ground Convergence Rates, in which GCR1-2 representing the rates obtained from the first and second void measurement cylinder data, and the same nomenclature applies to GCR2-3 and GCR1-3.

Additionally, as previously mentioned, planned stoppages occur during tunnel execution, with durations ranging from several hours to one or more days. During these stoppages, void measurements are conducted, and the data analysis is carried out, utilizing precise convergence measurements taken at a single point while eliminating abnormal data. This process ensures a pure and accurate assessment of the Ground Convergence Rate, as depicted in Figure 13.

The most critical section within the 2.7 km length of the tunnel was situated between chainage 49+000 to 49+500, where the highest Ground Convergence Rate (GCR) was recorded. The ground closure around the shield in this specific section closely matched with the measurements derived from both the analytical and FEM analyses. Considering some convergences was attributed to wedge falls occurring

Figure 10. Gap/Void measured behind the shield along the shield using data obtained from three void measurement cylinders.

on the tunnel crown, resulting in the recording of 250 mm void behind the shield.

6 CONCLUSIONS

In this paper, a comprehensive exploration of various approaches for assessing squeezing ground conditions, spanning empirical, semi-empirical, analytical, and numerical methods, has been discussed and their applications have been demonstrated within the context of the Rishikesh to Karanprayag railway project, Package 4 (Tunnel 8). Notably, among the empirical and semi-empirical approaches, the Aydan et al. (1993) approach, based on a diverse dataset from different rock types and not confined to the same Himalayan region database, yielded distinctive results in the evaluation of squeezing conditions for this case study. Throughout these evaluations, it became evident that certain critical squeezing zones shared consistent outcomes across different methods, corroborated by FEM analysis. The most critical zone was identified around chainage 49+440, where site data were collected and meticulously assessed, employing state-of-the-art TBM technologies for monitoring tunnel convergence. In the initial 2.7 km of the upline tunnel (spanning from chainage 48+180 to 50+880), the highest Ground Convergence Rate was observed in close proximity to the same chainage, as evaluated through empirical, semi-empirical, and analytical approaches. Furthermore, continuous data collection and evaluation within the project are essential for adapting actual Ground Convergence (GC) and Ground Convergence Rates (GCR) to the evolving rock conditions and TBM excavation parameters.

ACKNOWLEDGMENTS

The authors express their heartfelt gratitude to Rail Vikas Nigam Limited as the project client, Larsen & Toubro as the project contractor, Herrenknecht as TBM supplier, and TUMAS-ALTINOK Joint venture as detailed design and project management consultant of the project for their invaluable support and collaborative efforts in providing a wealth of worthwhile and useful database. This data has been instrumental in commencing the journey of developing an approach to address squeezing conditions in TBM tunnelling in Himalaya.

ABSTRACT: The vertical jacking method has been widely used in water intake and drainage segmental tunnels. The construction method of standpipes by lifting could mainly be divided into upward shield method, vertical jacking method and vertical pipe jacking method. Comparing with the other two methods, the vertical jacking method has the advantage that its equipment is simpler. However, the vertical jacking force intensity is uncertain because it depends on many factors. The higher the pipe diameter, the higher the normal stresses, being the critical moment the starting of the jacking process. Based on numerical simulations, this paper intends to research on the structural behaviour of this method on large section standpipes and analyze the factors that controls the jacking process. The research results show: 1. The deformation of the main tunnel is a combination of two effects: the longitudinal sinking and the vertical ovalization. 2. The circumferential compressive stresses in the bottom segments of the main tunnel are greatly reduced due to the vertical force of the jack. 3. The shear of the transverse joint between two rings mainly appear in the joint between the opening ring and the contiguous one. 4. The thickness of the segment has little effect on the mechanical response of the structure for typical segment depth. 5. With the decrease of the opening area, the internal force of the open ring structure decreases, while the internal force of the contiguous rings decreases or remains basically unchanged.

Keywords: segmental tunnel, large section standpipe, vertical jacking method, mechanism, control factors

1 INTRODUCTION

When constructing large drainage outlets for extending into rivers, lakes, or seas in soft soil areas, water-based construction methods such as island construction pits or floating sinking pits are often used. Sometimes the method costs a lot, and it is also susceptible to the influence of wind and waves, resulting in longer construction periods. In recent years, mechanical methods for building vertical pipelines or tunnels have become increasingly common. Currently, three common mechanical methods have been adopted: upward shield method, vertical jacking method and vertical pipe jacking method.

The upward shield method is primarily carried out in Japan [Kondo et al., 2004, Ito K et al., 2004] (Midosuji Comprehensive Conduit Project in Osaka, Japan). The construction method is similar to shield machine boring and segment installation, with the only difference being that the boring is done in an upward direction.

The vertical pipe jacking method was applied in Argentina's "Riachuelo Lot 3" outfall project. The lifting equipment pushed the pipe sections upward into the soil layer. The destruction mechanism and morphology of the overlying soil layer are analyzed in some tests [Wei et al., 2021, Wei et al., 2022, Wei et al., 2023].

*Corresponding author: yimin.gao@upc.edu

The vertical jacking method is mainly applied in China, which is similar to the vertical pipe jacking method construction process, but the difference lies in soil removal equipment. The vertical jacking method only need the lifting equipment to raise the pipe sections to the water surface.

Comparing with the other two methods, the vertical jacking method has the advantage that its equipment is simpler. However, the vertical jacking force is uncertain between different projects because it depends on many factors. The higher the pipe diameter, the higher the normal stresses, being the critical moment the starting of the jacking process. Different lifting forces will significantly affect the internal force response and mechanical properties of the tunnel structure, which are the points of the structure design.

In order to investigate the mechanical behavior of tunnel with vertical jacking method, many on-site experimental researches have been carried out. However, the most common monitoring is the structural convergence. [Dong et al., 2012, You et al., 2012, Wang et al., 2021].

Considering the limitations and cost-effectiveness of on-site experiments, numerical simulations were widely used to verify other structural responses. The results demonstrate: as the jacking force increases, the maximum misalignment deformation between the open ring and adjacent rings also increases. [Wang et al., 2011]. The crown of open ring and the adjacent three standard rings' deformation response is greater than that of bottom [Xu et al., 2021]. The applicability of numerical models in the vertical jacking method has been confirmed. Considering the research results mainly also concentrating on the deformation structural response and not considering more detailed load cases. This paper intends to research on more structural response throughout the entire vertical jacking construction process with shell-contact numerical model [Liu et al., 2021] Through parameter analysis, this study aims to provide support for the design of this construction method.

2 STUDY CASE

A certain power plant project is constructed near the coast in Shanghai. Its intake tunnel is constructed by the shield method, built at a depth of 8.45 meters below the seabed. The intake tunnel consists of 30 segments with an outer diameter of 3700mm and a segment thickness of 350mm. The segment ring width is 985mm, as shown in Figure 1.

The intake tunnel consists of 30 segment rings, with the 3rd, 4th, 9th, 10th, 15th, 16th, 21st, 22nd, 27th, and 28th rings being open rings (every six rings), while the rest are standard rings. The crown of the open rings is made of steel structure segments, used for vertical jacking. The opening range is two rings (1970mm×1970mm). Comparing other projects, the ratio of the open area to the inner diameter is relatively high, belonging to the large section [Wang et al., 2021].

Figure 1. Illustration of study case.

As shown in Figure 2, the segmental lining ring consists of 3 steel-concrete segments and 4 reinforcement concrete segments, of a circular arc of 30.5°, 82.24°, 30.5°, 58°, 58°, 58° and 42.76°, respectively. Adjacent segments (including the radial and circumferential direction) are connected by 8.8-grade bolts (yielding strength 640 MPa). Concrete grade C50 is adopted for each component of the specimen, the main reinforcement bars are HRB400 steel bars (yielding strength 400 MPa) with a diameter of 28mm@150mm (inside face) and 22mm@150mm (outside face). The steel-concrete segments' steel parts are Q235 (yielding strength 235 MPa) and the concrete strength of grade was C50.

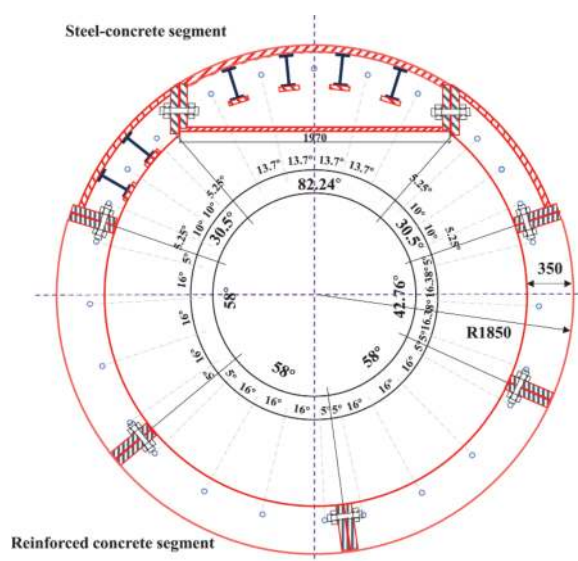

Figure 2. Layout of s tunnel linings (dimensions in mm).

According to the actual construction process, the process can be simplified the following steps (shown in Figure 3):

- (1) Initial Stage
The intake shield tunnel has been constructed, loaded by external soil and water pressure, tunnel self-weight, etc. (including top vertical soil pressure of 61.57kPa, top water pressure of 235.1kPa, and a ground overload of 30kPa.)
- (2) Vertical jack stage
The first pipe section is securely connected to the top cover of the tunnel. The circumferential bolts

Figure 3. Schematic diagram of working condition.

connecting the special riser pipe section with the surrounding tunnel segments at the lifting port are removed. Vertical jack force is loaded at the bottom of open rings to lift the pipe upward. The force intensity is always variational according to the non-linear variation of the frictional force of the structural lifting and the gravity of external soil, etc.

(3) Open stage

The first pipe section is vertical pushed out during construction, forming the open. After completing the lifting operation, two weighing beams are installed with tightening the tie rod bolts to secure the first pipe segment onto the beams. Once safety is confirmed, the hydraulic jack is used for the next pipe lift. Subsequently, the second section of the pipe is connected, the weighing beams are removed. The open is present throughout the entire process.

(4) Completion stage

The third stage is repeated multiple times until the vertical pipe is constructed, including the final vertical pipe structure, final joints, and longitudinal connecting beams. The vertical pushing force on the pipe is reduced to zero.

(5) Water diversion stage

Water is diverted into the tunnel. The self-

weight of water, internal water pressure and water flow effects are included. The water pressure load consists of two parts. The first part is the self-weight of water, and the second part is the internal water pressure value, calculated at 254.10kPa based on the highest water level.

3 NUMERICAL MODEL

3.1 Simulation assumptions

The calculation principles are as follows:

- (1) The calculation model is based on a load-structure pattern.
- (2) Coulomb friction is used to simulate the “pressure-shear coupling” at the joints.
- (3) Ideal elastic-plastic models are applied for the circumferential and longitudinal bolts.

3.2 Model dimensions and materials

Shell element is intended for simulation of segmental linings. A total of 30 ring segments are simulated, and the arrangement of the segments is the same as the chapter 2. (As shown in Figure 4).

Figure 4. Model of segments and standpipe sections.

The concrete structural portion is simulated by layered shell element. Both the concrete layer and the reinforcement layer are simulated. The steel structural portion is simulated by equivalent stiffness method. The flexural and compressive stiffness of the simulation structure is equivalent to that of the actual lining segments. The calculation formula is as follows.

$$E_{1x}A_{1x} = E_{2x}A_{2x} \quad (1)$$

$$E_{1y}A_{1y} = E_{2y}A_{2y} \quad (2)$$

$$A_{2x} = b_{2x}h_{2x} \quad (3)$$

$$A_{2y} = b_{2y}h_{2y} \quad (4)$$

Where, $E_{1x}A_{1x}$, $E_{1y}A_{1y}$ are the axial stiffness of the actual segments in x direction and y direction; $E_{2x}A_{2x}$, $E_{2y}A_{2y}$ are the axial stiffness of the segments in the equivalent model in x direction and y direction; b_{2x}, b_{2y} , h_{2x}, h_{2y} are the width and height of the segments in the equivalent model in x direction and y direction. The material parameters used in the numerical model are listed in Table 1.

Table 1. Material models and parameters.

Type	Material	Young's modulus (N/m ²)	Poisson's ratio
Segment (Concrete part)	Concrete	3.45×10^7	0.167
Segment (rebar)	Steel	2.1×10^{11}	0.3
Segment (Steel part)	Equivalent model (0.58m width)	2.08×10^7	0.3
Standpipe	Concrete	3.45×10^7	0.167

3.3 Joints and bolts simulation

Considering the actual joint of the project (the edge of the concrete is surrounded by the steel), a series of rigid beams are used to simulate the thickness of the segments and the steel joints. The contact parts are modeled with contact elements to simulate the joints' compressive behaviours. The circumferential and longitudinal bolt positions are set according to their actual locations. (As shown in Figure 5)

Figure 5. Model of segments and joints.

The parameters of the joints are shown in Table 2 below:

Table 2. Parameters of joints.

Type	Stiffness (N/m ²)
Longitudinal joint compression	1.2×10^{10}
Longitudinal bolt tensile	1.7×10^{10}
Circumferential joint compression	2.5×10^{11}
Circumferential bolt tensile	2.9×10^{11}

3.4 Boundary conditions

The ground reactions corresponding to the tunnel deformation are simulated by ground springs located along the entire periphery of the tunnel. The geological parameters are shown in Table 3.

Table 3. Parameters of stratum.

Type	Stiffness (N/m ²)
Horizontal direction	1.8×10^7
Vertical direction	1.3×10^7
Longitudinal direction	3×10^6

3.5 Simulation loading process

Based on the construction process in chapter 2, the simulation process is also divided into five loading cases.

(1) Initial stage

Following the previously mentioned method, the model and boundary conditions are established. Then the external soil and water loads are loaded.

- (2) Vertical jack stage
The water-stop device is activated. In order to simulate the most extreme condition, the bottom of all open rings are loaded vertical downward (the vertical jack force is the maximum of the whole process).
- (3) Open stage
All crown segments are pushed out in most dangerous condition. Since the pushed-out segments cannot transfer bending moments, the longitudinal axial force is primarily transmitted through the water-stop frame and the remaining segments. All crown segments are moved out.
- (4) Completion stage
The final standpipe structure, the final joints are activated. Then the standpipe is loaded with soil and water loads.
- (5) Water diversion stage
The self-weight of water and internal water pressure are loaded inside the main tunnel. The impact of water flow on the riser is also considered.

4 STRUCTURAL RESPONSE OF PROCESS

4.1 Deformation characteristics

Among all the loading cases, the two most significant deformation characteristics are as the longitudinal sinking and the vertical ovalization.

In the vertical jack stage, the tunnel is influenced by the invert force by the jack at the opening position, causing the entire tunnel to move downward. The maximum downward deformation is at the central position, reaching 28mm.

In the open stage, the open rings deform vertically, resulting in an 8mm convergence between the crown and invert. Influenced by the deformation of the open ring, under the internal force transmission from the open ring, also deform vertically. The closer to the open ring, the deformation phenomenon is more obviously. These two phenomena both occur under the open stage, as shown in the Figure 6.

Figure 6. Deformation in y direction under open stage (dimensions in mm).

4.2 Internal force characteristics

In the initial stage, the bending moments and axial forces in each ring are the same. The maximum positive bending moment occurs at the crown of the lining ring (56 kN·m), and the maximum negative bending moment appears near the spring position (-60 kN·m). The axial force in the entire ring is maintained between -400 and -600 kN.

As shown in Figure 7, the greatest internal force changes happen in two stages. In the vertical jack stage, the positive bending moment at the crown and invert of the open ring decreases by 45 kN·m and the negative bending moment at the spring decreases by 40 kN·m. The axial force at the spring decreases by 50 kN, the axial force at the bottom decreases by 400 kN, which means it is virtually no axial force.

In the open stage, the negative bending moment at the spring changes from negative to positive (variation is around 25 kN·m), and the positive bending moment at the invert changes to negative. The axial force at the spring decreases by 100 kN, and the axial force at the bottom changes from compression to tension.

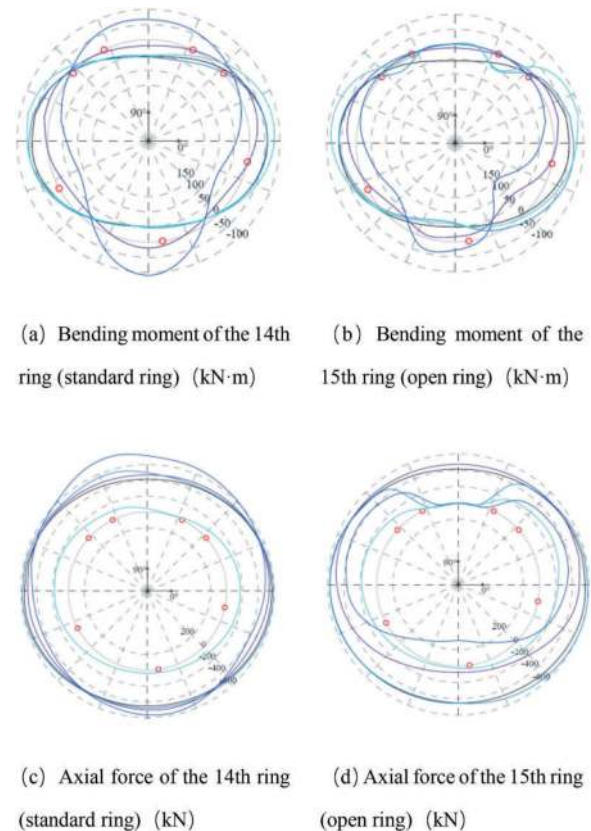

Figure 7. Internal force under different stages.

As shown in the Figure 8, the shear force between rings is primarily radial shear in the open stage, and the maximum radial shear occurs between the open ring and the contiguous one. The invert radial shear force between rings reaches 60 kN/m. The reason for this is that the open ring's vertical deformation trend

is stronger than that of the standard ring, resulting in inconsistent deformation, where the occurrence of inter-ring force transmission happens.

Figure 8. Shear force between 16th/17th ring in the open stage.

5 IMPACT ASSESSMENT OF DIFFERENT FACTORS FOR DESIGN

5.1 Thickness influence

In the case study project, calculations are carried out with thickness of 300mm and 350mm. In the initial stage, both schemes exhibited similar deformations under external loads, resulting in an 1mm convergence between the crown and invert. The deformation differences during the transition from the initial stage to the water diversion stage are within 1mm.

Figure 9. Maximum bending moment and axial force of different thickness in open stage.

The greatest differences in internal forces occur in the open stage. As shown in Figure 9, the bending moment of the 350mm thick scheme is larger than that of the 300mm thick scheme (less than 10 kN·m, with a difference of 5%), and the axial force is also larger (maximum less than 50 kN, with a difference of 5%). Therefore, the thickness of the lining segments has a relatively small impact on the structural internal forces.

5.2 Open size influence

In the case study project, calculations are also carried out with different open size (Original scheme: 1970mm×1970mm open, covering two rings in its entirety. Scheme 2: 1300mm×1300mm open. Scheme 3: 1000mm×1000mm open).

The different deformation trends of the two new schemes compared to the original scheme occur in the remaining structural portion at the crown of the open ring. The reason for this is that in the original scheme, two complete ring segments are moved out, whereas the two new schemes retain a portion of the segments.

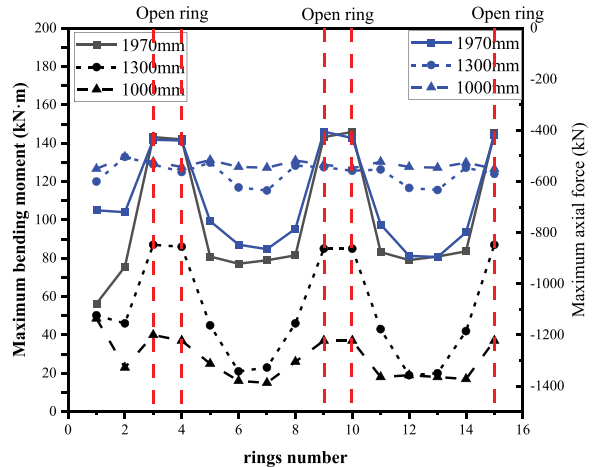

Figure 10. Maximum bending moment and axial force of different open size in open stage.

As shown in Figure 10, in open stage, as the open size decreases, the maximum bending moment of the open ring decreases, meanwhile the maximum axial force increases. With the open size decreases, the maximum bending moment and maximum axial force of the regular ring decrease. The smaller open area, the smaller jack force in use, enabling its internal force change.

In the completion stage, with the reduction in the open area, there is a partial stress concentration phenomenon at the crown of the remaining segments of the open ring. Although not illustrated in this paper, it should also be given attention.

6 CONCLUSIONS

In the summarized study case, shell-contact models have been used to simulate the structural behaviour of tunnels constructed by vertical jacking method on large section. The focus of the presented work was to explain the mechanism of this method and introduce the impact assessment of different factors for design.

The numerical results show that there are two most significant deformation characteristics during construction. The longitudinal sinking and the vertical ovalization deformation are caused by vertical jack force and the open area forming. At the same

time, the structural response of reduction in the axial force at the bottom of the open ring is obvious. The maximum radial shear occurs at the bottom between the open ring and the contiguous one.

Furthermore, the study also indicates that the thickness of the lining segments has a minimal impact on the structural mechanical response. The bending moment and axial force for 300mm thickness lining segments are smaller than those for 350mm thickness lining segments, but the variation is less than 5%. Different thicknesses of lining segments have almost no effect on the structural response. The design of lining segment thickness should primarily consider whether the cross-sectional reinforcement is reasonable. And as the open area decreases, the overall bending moment of the open ring structure decreases due to the reduced uplift load applied. At the same time, because of the reduced area, there are residual lining segments at the crown of the open ring, leading to an increase in structural axial force. The design of the lining segment open size should fully consider the different internal forces resulting from various open sizes, as well as the potential influence of residual lining segments on the structure and the possibility of stress concentration phenomena.

Future work related to this study includes the situ experiment check, in which promote the applicability of this numerical method.

ABSTRACT: The Shanghai Airport Connection Line is the first project to utilize fully prefabricated internal structures in a large-diameter shield tunnel in China. This paper elaborates on the automatic and synchronous construction of the fully precast internal structures in this project, including the design of internal structures, the automatic construction equipment, the process of synchronous assembly, and the control index of construction quality. To begin with, design information, involving precast arc parts and formed partition walls is introduced. Secondly, the composition and working principle of the adjustment device for prefabricated arc parts and assembling equipment for precast partition walls are carried out. In addition, automatic construction schemes and the process of synchronous shield excavation using those above devices are described respectively. Eventually, the construction quality control index of precast arc parts and prefabricated partition walls is elaborated. By utilizing the above-mentioned equipment and a series of construction techniques, automatic and synchronous construction of fully prefabricated internal structures in a large-diameter shield tunnel, which is in the form of a single hole with double tracks, has been realized. Moreover, the above approaches have significantly and effectively improved construction accuracy, quality, and efficiency.

Keywords: Fully Prefabricated Internal Structure, Automatic Construction, Synchronous Assembly, Prefabricated Arc Parts, Prefabricated Partition Walls

1 INTRODUCTION

With the continuous development of urban transit technology, the construction of large-diameter shield tunnels has increased gradually, and the method has also been improved continuously. Large-diameter shield tunnels are more suitable for single-hole with two tracks than single-hole with one track or double-hole with two tracks tunnels because they are capable of effectively shortening the construction duration and reducing risks and costs (Pan *et al.*, 2020).

Foreign projects, such as Line 9 in Barcelona, Spain (Ormazabal, Viñolas and Aguado, 2008); Apennine Tunnel in Italy (Finzi-Contini, Gori and Semproli, 1995); Seikan Tunnel in Japan (Matsuo, 1986), and so on, are explorations on the single-hole with double tracks tunnels form. Meanwhile, in recent years, domestic projects also carry out explorations on such forms of tunnels, such as Line 11 (Zhou, 2015) and Line 16 (Cao *et al.*, 2015) of the Shanghai Metro; the Weisan Road river-crossing tunnel in Nanjing (Wang *et al.*,

*Corresponding author: xian.liu@tongji.edu.cn

2016); Laoshan Tunnel interval in Line 11 of Qingdao Metro (Wang *et al.*, 2017) and so on.

Internal structure in the tunnels from above projects adopts the form of cast-in-place or partially cast-in-place and partially prefabricated, which is characterized by high construction danger, construction difficulty, and low efficiency. However, utilizing fully prefabricated internal structures can effectively solve the above problems.

Additionally, for single-hole with two tracks tunnels, researchers have mainly focused on the aerodynamic effects on the internal structure caused by trains (Chen *et al.*, 2023; Peng *et al.*, 2023), or changes in mechanical properties of the structure under seismic effects lead by the constructional formation (Zhang *et al.*, 2013; Dai *et al.*, 2021; Yao *et al.*, 2022). Even fewer studies on fully prefabricated internal structures are presented, and construction technology and fabricated processes of tunnels are seldom described systematically.

Based on the JCXSG-2 section of the Shanghai Airport Line, this paper researches the automatic and synchronous construction technology of fully prefabricated internal structures inside large-diameter shield tunnels. This paper will elaborate on the automatic and synchronous construction of the internal structures in this project from the design information, automatic equipment, process of synchronous assembly, and control index of construction quality. By the above approaches, automatic and synchronous construction of fully prefabricated internal structures inside large-diameter shield tunnels has been realized, which may serve as experience and reference for similar projects in the future.

2 DESIGN INFORMATION

The Shanghai Airport Line (Chen *et al.*, 2022), which adopts the form of single-hole with double tracks, first utilized fully prefabricated internal structures in large-diameter shield tunnels in China. The total length of the JCXSG-2 Section is 4.97km, and the internal precast structures are divided into prefabricated arc parts, precast partition walls, top connecting parts, and evacuation platforms. The plan of the JCXSG-2 Section and the internal structures are shown below.

This section will introduce detailed design information on the internal structures including arc parts and partition walls.

Figure 1. Plan of the JCXSG-2 Section.

Figure 2. The internal structures.

2.1 Design of arc parts

The size of a single arc part, which uses the C40 concrete, is $9.5\text{m} \times 2.834\text{m} \times 2\text{m}$, with a weight of 33.5 tons. The universal wedge block, which has a double-sided wedge, has the amount of 50mm. Four M36 leveling bolts are set under the arc parts for temporary support. In addition, C40 self-compacting fine gravel concrete is used to fill the gap between the arc parts and the tunnel segments after assembly to eliminate the influence of segment misalignment deformation. Six M36 bolts are used to connect adjacent arc parts. Detail of the prefabricate arc parts is illustrated in the following figure.

Figure 3. Detail of the prefabricate arc parts.

2.2 Design of partition walls

The size of prefabricated partition walls, which use C40 concrete, is 9.136m in height, 0.4m in thickness, and 1.99m in width, with each weighing 21.65t. Standard blocks, which can be divided into four types (I, II, III, and IV), are made for each single precast partition wall. Five M30 bolts are utilized to connect adjacent partition walls, and the bolt holes are sealed by polymer cement mortar after construction. Furthermore, the sealant is used to block the gaps between partition walls to prevent air leakage. The 30mm gap between bottom of the partition wall and top of the arc parts is firstly connected by double rows of M36 bolts (total 10 M36 bolts), then filled with self-compacting high-strength cement-based grout after assembling is completed. Details of the partition standard block and its bottom are revealed below.

Figure 4. Detail of the partition standard block and its bottom.

The top connectors of the partition walls, consisting of top arc steel plate, steel ribbed plate, and steel baffle plate, are made of Q235B. Each upper part of a single set of top connectors is connected to the shield segments with eight M20 bolts, which are bonded with rigid epoxy adhesive. The gap in the top connectors is filled with C30 fine aggregate concrete. The top connectors of the partition walls are shown below.

Figure 5. Top connectors of the partition walls.

3 AUTOMATIC CONSTRUCTION EQUIPMENT

This section will propose the fine-tuning equipment of arc parts and assembly equipment of partition walls.

3.1 Fine-tuning equipment of arc parts

The fine-tuning equipment consists of outrigger support shoes, walking slide shoes, fine-tuning mechanism assembly, stepping cylinders, stepping support

shoes, and so on. The machine is set inside the arc parts to realize the functions of stepping, jacking, traversing, and yawing in three degrees of freedom. The fine-tuning equipment is shown in Figure 6.

Figure 6. Fine-tuning equipment of arc parts.

3.2 Assembly equipment of partition walls

Assembly equipment of partition walls mainly contains tracks, a traveling mechanism, a partition wall assembly mechanism, a frame, auxiliary mechanical arms, a top mounting platform, cranes, electrical cabinets, hydraulic pump stations, and so on. This instrument enables the adjustment of partition walls at six degrees of freedom and facilitates their high-precision assembly. The equipment is shown in Figure 7.

Figure 7. Fine-tuning equipment of arc parts.

4 PROCESS OF SYNCHRONOUS ASSEMBLY

This section will illustrate the synchronous assembly of arc parts and partition walls by utilizing the above devices.

4.1 Synchronous assembly of arc parts

Figure 8 illustrates the flowchart for the construction process of arc parts, which encompasses the following steps:

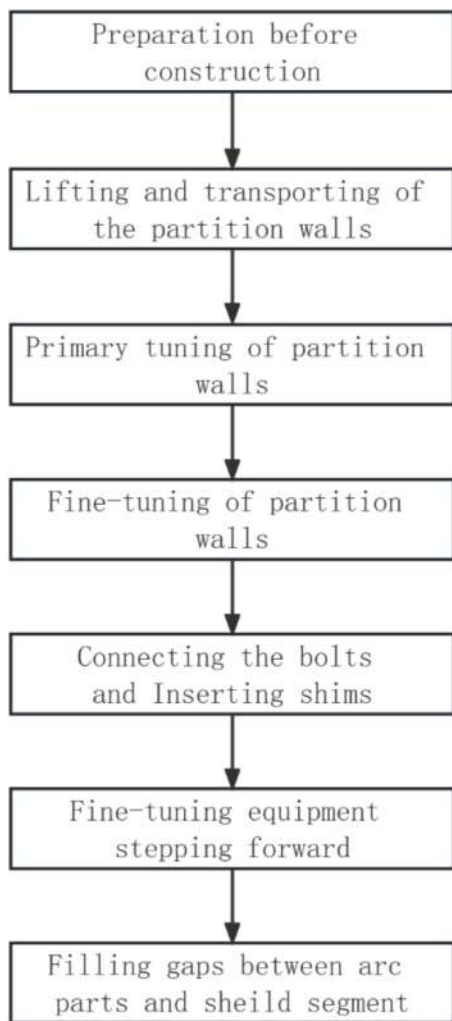

Figure 8. Flow chart for synchronized construction of arc parts.

- 1) Lifting and transportation of prefabricated arc parts. The fine-tuning equipment is set inside the assembled arc parts, which are shown in Figure 9.
- 2) Preliminary seating of prefabricated arc parts, including utilizing an arc part crane to assemble the arc parts and visually align the centrelines of the arc parts.

Figure 9. Location of the fine-tuning equipment.

- 3) Fine-tuning of prefabricated arc parts, involving the use of fine-tuning equipment to adjust the arc parts into their final positions. This step includes the utilization of internal support in arc parts and fine-tuning equipment to support the leg boots for the positioning of arc parts and attitude fine-tuning. Measurement systems are used on the arc parts to determine the degrees of freedom of the fine-tuning. After completing the above operation, the fine-tuning equipment steps forward and repeats the assembly cycle proceeds. Further details of this step are provided in Figure 10 and Figure 11.

Figure 10. Adjustment and location of the arc parts.

Figure 11. Fine-tuning of the arc parts.

- 4) Installation and pre-tightening of top connecting bolts and ground bolts, as well as the placement of shims in the bottom gap.
- 5) The fine-tuning machine steps forward into the preparation position for the installation of the subsequent arc parts, which is shown in the picture below.
- 6) Filling the gap between arc parts and shield segment through the reserved grouting holes.

4.2 Synchronous assembly of partition walls

Figure 13 depicts the flowchart for the construction process of partition walls, which involves the following steps:

- 1) Transportation of the prefabricated partition wall by a transport vehicle into the frame of

Figure 12. Fine-tuning equipment Stepping forward.

Figure 14. Fine-tuning equipment Stepping forward.

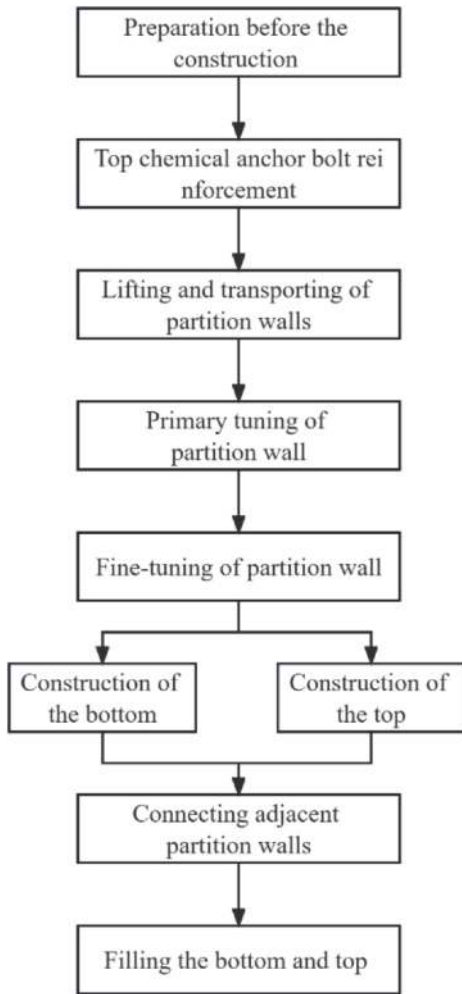

Figure 13. Flow chart for synchronized construction of partition walls.

the assembly cart, as shown in Figure 14. During this process, it is essential to ensure the marked points on the partition wall have entered the measurement range of the camera.

- 2) Utilizing the camera to detect the position information of the marked points on the partition

wall. Position information is then used to calculate the stroke of the 6-degree-of-freedom control cylinder on the main mechanical arm, and guide the main mechanical arm to quickly align with the pin holes reserved on the partition wall.

- 3) Using the pin cylinder to push the pin into the interior of the partition wall. Once the pin is in place, the side of the partition wall is locked.
- 4) Extending 2 end face pressing cylinders and rotary pressing cylinders for partition walls in the thickness and width directions, respectively, which will complete the limitation of partition walls in the thickness and width direction.

Figure 15. Compression of the end face and rotary face.

- 5) Retracting the main mechanical arm lifting cylinder, and elevating partition walls from the transport vehicle. After all, the partition wall transporter exits the dolly frame area.
- 6) The laser distance measuring sensor is utilized to detect whether the turning gap of the partition wall meets the turning requirements. If the gap reaches the requirements, the lifting cylinder system will lift the partition wall to a certain height and turn it over. However, if the gap does

not meet the requirements, the system will issue an alarm signal, which indicates it is impossible to carry out the turning operation. When the partition wall is turned over, the overturning cylinder on the bow beam is utilized to pull the entire bow beam and partition wall to turn over together by 90 degrees.

Figure 16. Rotation and forward of partition walls.

- 7) The equipment of partition walls backs up and stops when it reaches the assembled partition walls. Simultaneously, adjusting the attitude of partition walls, which is based on the measured deviation between the 3 measuring points in the partition walls by total station and theoretical axis of the tunnel.
- 8) Fine-tuning of partition walls in three translational directions and three rotational directions is performed to align the partition walls with the middlebox culvert of the upper arc parts.
- 9) Inserting shims into the bottom of partition walls, tightening the bottom and side connected bolts. Furthermore, utilizing the installation platform to instruct the bolts between partition walls.

Figure 17. Tightening bolts in the bottom of partition walls.

Figure 18 Demonstrates the flowchart for the construction process of the top connector, which involves the following steps:

- 1) Drilling holes in the shield segment and placing anchors based on the central axis of the segment at the top arch of the tunnel.
- 2) Jacking up the top connector along with the prefabricated partition walls to the underside of the vault.
- 3) Coating epoxy adhesive on the outside of the curved plate of the top connector. Subsequently, installing the top connector promptly and fixing them with bolts.
- 4) Fill the top and bottom of the connector with sponge pads.
- 5) Installing the longitudinal prefabricated reinforcement cage. It is important to ensure that the joints of the cage and top connectors are in the form of staggered joints.
- 6) Fulfilling concrete after the deformation of the shield tunnel is stabilized.

Figure 18. Detail of the partition standard block and its bottom.

5 CONTROL INDEX OF CONSTRUCTION QUALITY

This section innovates the control index of construction quality for prefabricated arc parts and partition walls.

5.1 Control index of arc parts' construction quality

The name and direction of each degree of freedom for precast arc parts and equipment are demonstrated in Figure 19. Based on the indicated directionality, the table below presents the construction standard of the precast arc parts.

The indexes proposed above define the translational directions X, Y, and Z and the rotational directions α (pitch), β (roll), γ (yaw), respectively. In addition, the maximum gap between each arc part is also a significant parameter to ensure the constructional quality. By adhering to these indexes, the quality of construction including assembled accuracy and safety can be effectively controlled.

Figure 19. Directionality of the arc parts.

Table 1. Construction standard of the precast arc parts.

No.	Controlling parts	Tolerance	Note
1	Faulting in the vertical direction	8mm	dx
2	Faulting in the horizontal direction	8mm	dy
3	Maximum gap between each arc part	≤10mm	dz
4	Pitch angle α	±0.15°	
5	Roll angle β	±0.05°	
6	Yaw angle γ	±0.05°	
7	Gaps in the filler layer	50-100mm	

Figure 20. Directionality of the partition walls.

5.2 Control index of partition walls' construction quality

The name and direction of each degree of freedom for precast partition walls and equipment are demonstrated in Figure 20. Based on the indicated directionality, the table below presents the precision control indexes of the partition walls.

The indexes proposed above mainly define the rotational directions α (pitch), β (roll), γ (yaw), respectively, as well as deviation from the

Table 2. Construction indexes of the prefabricated partition walls.

No.	Controlling parts	Tolerance
1	Pitch angle α	±0.15°
2	Roll angle β	±0.06°
3	Yaw angle γ	±0.05°
4	Deviation from the centrelines of partition walls and arc parts	±5mm
5	The gap between each wall	≤7mm
6	Gaps in the filler layer	20~30mm

centrelines of partition walls and arc parts, the gap between each wall, and gaps in the filler layer. By adhering to these indexes, the quality of construction, including assembled accuracy and safety can be effectively controlled. Since the translational directions of the arc parts, which are the same as the partition walls, have been defined and controlled, only the deviation from the centrelines of partition walls and arc parts is required to command.

6 CONCLUSIONS

Based on the Shanghai Airport Line, this paper carries out elaboration and study on the automatic and synchronous construction technology of internal structures inside large-diameter shield tunnels, conclusions are obtained as follows:

1. Utilizing fully prefabricated internal structures can effectively shorten the construction period, and improve the construction precision and quality simultaneously.

2. By using automated construction equipment, difficulties caused by large volumes and heavy quality of prefabricated parts can be effectively solved. Moreover, construction automation has been realized, and construction safety is effectively guaranteed.

3. Through a variety of reasonable construction techniques, automatic and synchronous construction of internal structures and shield tunnels are accomplished, which may serve as experience and reference for similar projects in the future.

The Sicilian job, 21 TBMs simultaneously at work to modernize the railway infrastructure of the largest island in the Mediterranean Sea

Remo Grandori*

Director Plant & Equipment at Webuild, Milan, Italy
Senior TBM Expert at Webuild, Milan, Italy

Roberto Bono*

Senior TBM Expert at Webuild, Milan, Italy

ABSTRACT: The railway infrastructures in Sicily have recently undergone an important upgrade that involves new lines connecting the cities of Palermo, Catania and Messina. These railway lines develop largely underground and 21 TBMs will be simultaneously at work to excavate 184 km of tunnels. This extraordinary amount of tunnelling work is concentrated in a limited geographical area and shall be completed in very short time, 3 to 5 years depending on the lots. An enormous effort has been deployed to mobilize and set up the technical and logistic organization to satisfy the need for human resources, for TBMs and other machineries, for primary services such as water and power, for construction materials and transport services. The complex geological formations to be excavated, which mostly involve squeezing ground of sedimentary formations in presence of methane gas, required the development of important innovations for the TBMs, both in terms of structural design, safety devices and data management. In addition, all the TBMs have been designed and manufactured according to the Green TBM concept, a whole new design development by Webuild. Finally, to satisfy the massive requirements of precast segments, several automated, robotic and green precast segment factories have been developed and set up at different locations in Sicily. These factories allow to double the production capability for each working line and at same time to reduce the manpower and increase the quality of the product. These factories auto produce part of the power needed for their functioning and are almost completely autonomous in terms of water consumption thanks to recycling and the use of rainwater.

The article describes in detail the above summarized.

Keywords: Tunnelling, Green TBM, Gas, Squeezing, Precast, Robotic, Continuous Mining, Eko Cruise

1 INTRODUCTION

In Sicily, the railway infrastructures and network will undergo a dramatic implementation in the next 5 years. The works to be carried out, which is worth over 6 billions of euros, includes 184 km of new tunnels to be excavated by 21 TBMs contemporary in operation. The effort required to design the tunnels, procure the TBM, the plants, the equipment, the materials, the human resources and set up the logistics organization has been enormous.

The magnitude of the Project, the difficult logistic and the complex geologies required the implementation of several innovations and special measures.

2 THE PROJECT

The Project is quite complex given its geographical extension and the variability of the geological formations. For this reason, has been divided in two different lines, and each line in several construction lots (Figure 1):

- Messina-Catania Line:
Lot 1 (Fiumefreddo – Taormina)
Lot 2 (Taormina – Giampilieri)
- Catania-Palermo Line:
Lots 1+ 2 (Fiumetorto–Montemaggiore-Lecarcara),

*Corresponding author: r.grandori@webuildgroup.com; r.bono@webuildgroup.com

Lot 3 (Lecarcara – Caltanissetta Xirbi),
 Lot 4a (Caltanissetta Xirbi – Enna),
 Lotto 4b (Enna – Dittaino)

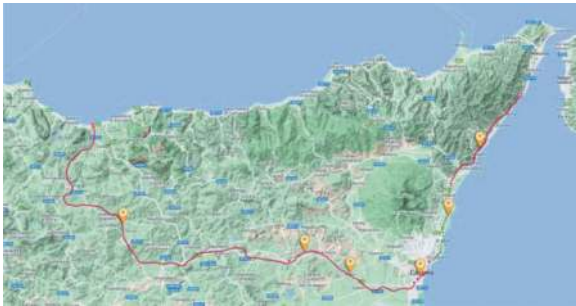

Figure 1. Sicily new rail lines Messina-Catania-Palermo.

2.1 21 TBMs contemporary at works

The 21 TBMs that will be used in Sicily are of different types based on the hydro-geological conditions to be faced:

- Messina Catania Line
 - Lot 1: n°1 Dual Mode + n°1 EPB
 - Lot 2: m°2 Dual Mode + n°1 EPB
- Catania-Palermo Line
 - Lots1+2: n° 4 EPB
 - Lotto3: n°5 EPB
 - Lotto 4a: n° 6 EPB
 - Lotto 4b: n°2 EPB

The excavation diameters vary between 9.16m and 9.48m, depending on segments thicknesses and shields conicities.

2.1.1 Alignment and TBM site locations

The project alignment from Messina to Catania runs almost parallel to the coast while from Catania to Palermo it crosses the Island from South-East to North-West

The chorography of the island, rich in mountains and hills, forces the railway to a continuous alternation of viaducts and tunnels, with only rare sections in embankment.

2.1.2 Investments

Over 1,2 billions € have been invested in the order for the 21 TBMs and related auxiliary plant, segment factories and Drill & Blast equipment used for the excavation of the shorter tunnels and connecting tunnels.

2.1.3 Materials

The amount of concrete and steel reinforcement to build the Project is huge and concentrated in a relative short lapse of time.

Beside the aggregates, that can be found in the island, all other construction materials shall come from Italy mainland by vessels, and this poses severe problems to the logistic organization for the construction of the project.

2.1.4 Schedule

All the TBMs have been ordered and the first Dual Mode TBM that will excavate the 9* 2=18 km long Sciglio Tunnel arrived on site in October 2023.

The other TBMs will be delivered to site progressively in the last quarter of 2023 and in the first half of 2024.

The Messina Catania Line shall be completed in 2028, while most of the Palermo Catania Lots are foreseen to be completed in 2026 and this places a strong pressure on the progress that the TBMs to be used on this line must achieve.

2.2 Geology and main criticalities

The geology of Sicily is complex and the tunnels alignments cross different formation, from hard rock (dolomite) to weak rock (fillades, marl, chalks, sandstone) to loose ground (mostly clays and locally sandy- gravel alluviums).

While crossing these different geologies it is expected to encounter several critical issues, the major of which are described below.

2.2.1 Presence of gases

126 km of tunnels out of the total 184 to be excavated in the Project will have to be bored in presence of methan and H₂S gases.

Due to this, 17 out of the 21 TBMs have been designed and manufactured according to ATEX provisions as per the applicable norms in Italy (NIR 44).

The Multi Service Vehicles that transport the segments and the other tunnelling equipment will also be designed and manufactured to operate in presence of Gas.

2.2.2 Squeezing

The presence of week clay formations under cover will cause severe convergence of tunnel walls against the TBM shields and the segmental lining.

2.2.3 Freatic water tables

Ground water level is locally quite high above the tunnels routes and this required the TBMs and the lining to be able, where needed, to drain the water and reduce the pressure in the excavation chamber and on the precast lining.

3 TBM'S & INNOVATIONS

3.1 TBM types

As indicated in paragraph 2.1, out of the 21 TBMs, 3 will be Dual Mode TBMs (Open/EPB) and 18 EPB TBMs.

All these TBMs have been specifically designed for the application, with several innovations developed by Webuild in cooperation with the two suppliers (CREG and CRCHI).

Figure 2. The first green TBM dual mode by CREG.

Figure 3. The first CRCHI EPB TBM for the project.

3.2 Operation in gassy formations

All 17 TBMs for the Palermo-Catania line have been designed and manufactured to be able to advance in presence of methane gas. This according to the design guidelines and technologies developed in Italy and named NIR 44.

The basic concept of this design is (Figure 4) the physical separation volumes in the TBM system and along the tunnel as well the ventilation flows management.

Basically, the methane contaminated air is confined in the TBM excavation chamber (kept full of conditioned muck) and any eventual seepage of gassy air through the screw conveyor gate is kept separate and conveyed into a sealed back-up conveyor belt from where the contaminated air is sucked and conveyed through a pipeline behind the back-up where the gas is diluted by the main tunnel ventilation.

Naturally, in all volumes in which the TBM system and the tunnel are kept separated, gas sensors are installed which automatically intervene in the

Figure 4. ATEX TBM system volumes schematic.

event of gas percentages exceeding established limit values.

3.3 Dual mode TBMs

N° 3 out the 5 TBMs that excavate the Messina-Catania railway line are Dual Mode TBMs, capable to operate in full EPB mode with screw conveyor as well in open mode with a belt conveyor.

Figure 5. Dual mode TBM layout.

CREG developed a special design to allow to change the configuration from EPB to Open and viceversa in less than 5 working days.

This required a new special design of the cutterhead with mobile buckets that can be retracted and extended out of the cutterhead structure.

At the same time both the screw and belt conveyor have been permanently lodged inside the TBM shields despite their “full capacity” dimensioning.

Figure 6. Dual mode TBM probe drill system.

3.4 Continuous Mining two modes

The Continuous Mining system (CMS) allows the installation of the segmental lining contemporary with the boring stroke (the last meter of the stroke).

In the TBMs for the Sicilian Projects this system has been improved and extended allowing two different operational modes automatically selected by the PLC of the TBM

- **Mode 1** is the standard mode in use when the boring thrust and its distribution in the different cylinders follow within the normal operating range. In this mode all segments could be assembled contemporary with the excavation provided that the TBM penetration allows sufficient time for the operation.
- **Mode 2** is automatically selected by the PLC when the distribution and level of thrust in the different cylinders follow outside certain parameters.

When in Mode 2 the first 2 segments in the ring are installed with the TBM in stand by and only the remaining 5 segments in the ring are installed while the TBM is completing the boring stroke.

When in Continuous Mining Mode:

- the PLC avoids the pressures in the different thrust cylinders to raise above of fall below the set triggers levels.
- The center of the boring thrust is maintained stable unless a steering action modifies its position.

The continuous mining system is expected to increase the average TBM production by 15-20% depending on the ground conditions.

Figure 7. Thrust cylinders arrangement.

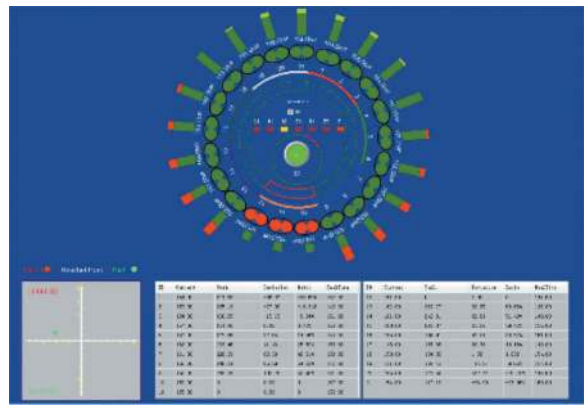

Figure 8. CMS control by center of thrust.

3.5 EKO Cruise system

The EKO Cruise is an automatic cruise system that has the target to optimize the TBM and auxiliary operating parameters reducing the power consumption of the TBM at equal Advance Rate.

Similarly to the cars cruise systems, the operator set the desired advance rate and then the PLC of the TBM adjust the operation parameters precisely for the purpose of optimizing energy consumption, reducing wear and maintaining (in EPB mode) the design pressure in the excavation chamber.

To achieve the goal, the system automatically:

- keep the muck pressure in the excavation chamber within the design range when in EPB mode
- optimizes the thrust and the revolution speed of the cutting head to maximize excavation efficiency
- optimizes the speed of the back-up conveyor belt adapting it to the actual penetration of the TBM

3.6 Green TBM

TBMs have been historically developed and selected considering mostly geology and productivity.

The Green TBM concept was introduced with the aim to reduce power consumption of TBMs without compromising on productivity, but on the contrary, focusing on an increase in productivity as one of the measures to reduce consumption.

The intended aim is to reduce power consumption by 20 -25% at same diameter and type of TBM.

This target is achieved with a package of interventions in the design, operation and management of the TBM, including:

3.6.1 Cutterhead design improved efficiency

Cutting head structures design reduces friction during rotation and favors the flow of material in the excavation chamber.

At same time the ground conditioning system is potentiated and high-pressure water jets have been introduced to help penetration & prevent clogging phenomena.

Figure 9. Ovoidal thrust rams to reduce friction.

3.6.2 Use of high efficiency components

High efficiency electric motors (IE4), Permanent Magnetic motors have been adopted as well VFD for the control of motors and Eko type Transformers.

Figure 10. Increase of power efficiency by IE 4 motors.

3.6.3 EKO Cruise

See chapter 3.5 above.

3.6.4 Continuous Mining – See chapter 3.4 above.

3.6.5 Automatic Utilities management system

The TBM is equipped with an automatic control system targeted to save power consumption which acts in the following areas:

- it starts and stops the motors that drive the pumps of the hydraulic system according to the operational needs of use and power.
- turns on and off the other TBM and back-up service utilities according to the needs during the different phases of the advance.

Figure 11. PLC switch on/off the system utilities.

3.6.6 Optimal hydraulic system design

The main thrust system pumps are activated automatically in sequence according to real needs.

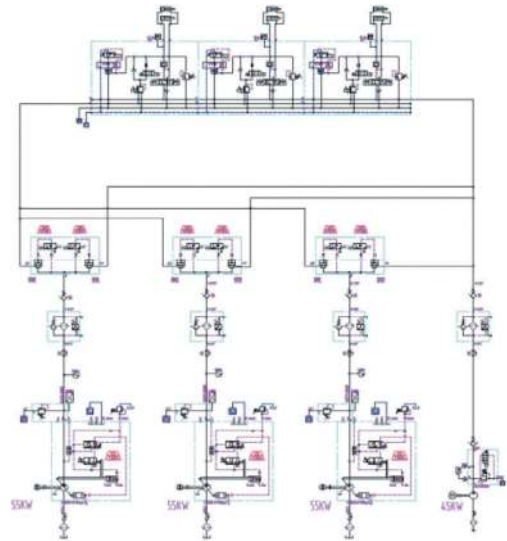

Figure 12. Hydraulic pumps activated in sequence.

3.6.7 Optimize energy efficiency of the board systems

Normal TBMs have a power factor correction system that allows them to maintain average values between 0.88-0.92. Through the installation of a more extensive power factor correction system the load factor is optimized to values of 0.95-0.97, thus reducing the absorbed power by about 5% and reducing the heating produced by the system.

The Power Quality required by the TBM system is then further improved by special devices that reduces the harmonics.

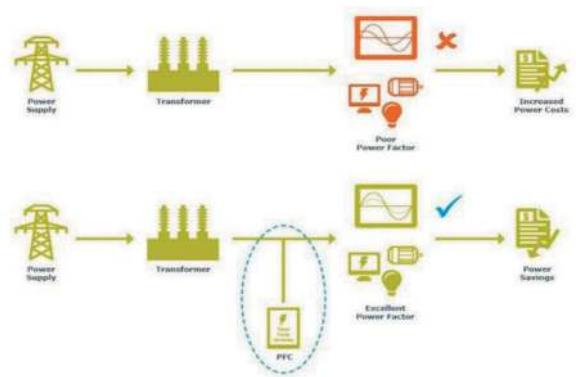

Figure 13. Improved power quality by reducing harmonics.

3.7 Continuous in situ invert lining

Tunnel design foresees a secondary invert lined in situ that form the base of the rails track.

A continuous casting system (Figures 7) was developed along the back-up of the TBM for the construction of this slab with the aim of:

- speed up the casting and avoid limiting the advancement of the TBM
- avoid secondary construction sites along the tunnel
- form a base for the transit and exchange of MSVs
- improve the safety of work

The railway

Figure 14. Continuous invert lining system.

3.8 Predictive AI maintenance software system

The TBMs are equipped with additional sensors and with a predictive maintenance software capable of scheduling maintenance interventions and prevent the occurrence of catastrophic failures to major components.

4 PRECAST SEGMENTS

4.1 Segments design

Starting from the segmental lining design initially developed by different design companies for each lot of the project, a standardization of the geometric design of the segments and of the related steel reinforcements was carried out, this to facilitate the centralized production of the segments in highly automated factories as well as the logistics of storage and transport to the different TBM portals.

This standardization was extended to segment accessories and seals.

Figure 15. Typical tunnel section with service lines.

4.2 Production strategy

The amount of segments to be produced is extraordinary: 102.000 rings, 714.000 segments and 2,2 millions cubic meters of concrete.

The production of such a large amount of segments has been mostly concentrated in 2 main factories from where the segments were transported to the secondary storages located at the TBM portals.

Figure 16. The first robotic & green precast factory.

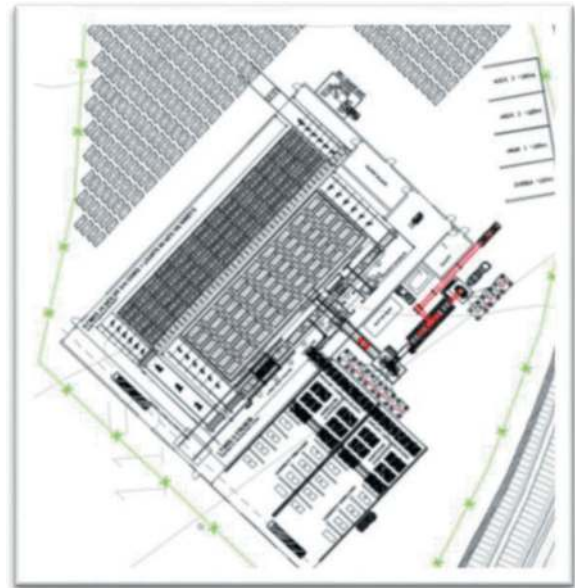

Figure 17. Precast factory layout.

4.3 Robotic & Green factories

The huge demand of segment to be produced required to develop new fully automated segment factory designs, able to produce from 170 to 270 segments per day per each production line with minimal manpower requirement.

These factories are equipped with solar panels to produce up to 40% of the total consumed power as well with water recycling systems integrated by the collection of the rain water which makes these factories substantially autonomous as regards the plant's water consumption.

Figure 18. N° 4 robots ensure the short cycle and efficiency.

Further to the above recycled plastic spacers are used to store the segments in the store yard.

Figure 19. Demould and rotating clamp.

Figure 20. Robot detail and green spacer.

4.4 Productivities

The extensive use of robots and of innovative design arrangement of the production, curing and post curing lines allows to produce 1 segment every 4 or 6 minutes per production line depending on the specific factory design.

These productivities are obtained with reduced manpower been the entire process automated.

4.5 Quality & Safety

The extensive use of automation and robotic reduces the manual operations down to a minimum, thus reducing the probability of injuries to the personnel involved. Furthermore, a laser sensors system verifies the presence of personnel in dangerous areas and automatically stop production.

The curing process is monitored by sensors placed in each mould and recorded by the segment tracking system.

5 LOGISTIC CHALLENGES

Sicily is an island and all TBMs, plants and construction materials must be transported by ship from mainland Italy, except concrete aggregates available mainly in the Etna volcano area.

The huge amount of infrastructures works concentrated in a relatively short period of time risked putting the port and road infrastructures into crisis, especially during the summer season when the island is invaded by a flow of tourists from all over the world.

To overcome this criticality, alternative road solutions were studied, which involved the construction of new dedicated accesses to the island's motorway system.

At the same time, storage areas have been identified to accumulate materials during the wintertime and limit transport peaks in the summer months.

5.1 TBM transport

The transport of the TBMs from the port of arrival on the island to the different portals required careful verification of the road system, including viaducts, tunnels and urban crossings. The dimensions and weights of the major components of the TBMs have been limited so as not to exceed the limits permitted by the road system.

5.2 Power supply & Generation

Sicily, especially in its central area, does not have an electrical grid sufficiently widespread and capable to supply the power to all the TBM portals.

This problem has been overcome by providing for the use of liquid gas generating stations where the electrical grid was not available.

5.3 Water supply

An even bigger problem is the unavailability of sufficient water flows to support the contemporary mechanized excavation of all the tunnels. To overcome this problem, various aqueducts are being studied and will be constructed before the start of boring.

5.4 Muck treatment & Disposal

The TBMs used in the project are either EPB or Dual mode EPB/Open TBM.

Consequently, important settling and biodegradation pools systems have been provided in each TBM portal.

Part of this muck will be then added with lime for subsequent use in the project.

5.5 Logistic camps

To accommodate the several thousand of technicians and workers employed in the works, low environmental impact camps were created with extensive use of photovoltaic panels for the self-production of energy.

6 OTHER INNOVATIONS

6.1 Segment tracking system

Despite having maximized the standardization of the segment design, the variable geological conditions

required to adopt two different segments thicknesses and different types of steel reinforcement.

The planning of the production, storage and transportation of the different segments to each portals required to integrate the segment tracking software to allow the management of the logistics and produce the different types of segments according to the actual needs, so as to never stop the TBMs.

6.2 WeView IT platform

Figure 21. Operation data control.

A team of engineers from Webuild in cooperation with the specialized software house Tunnelsoft developed an IT platform, WeView, to monitor in real time from a central control room (Figure 21) the operation of the 21 TBMs and of all the related plants & systems utilized on the construction sites.

WeView monitors also the main environmental parameters, helping the management in keeping under control the environmental aspects and in the monitoring of the environmental targets (e.g. GHG reduction) and their achieving.

The platform allows also allows:

- the monitoring of the electric power consumption of each user.
- the control of the water consumption according to efficiency targets

The data are organized and elaborated automatically and notified by email and through app. Generate production reports, rock/support classification reports, geological mapping, QC/QA reports, water and energy consumptions and related efficiency.

Reports and alarms are automatically generated informing in real time the responsible staff through SMS and Email. The elaborated data are made available in real time to PC, smartphones and tablets and, as stated before, to the project control room.

Figure 22. Sicily new rail lines Messina-Catania-Palermo.

7 CONCLUSIONS

The complex of railway tunnels to be excavated in Sicily it is unprecedented due to the combination of the simultaneous excavation of so many TBMs, the geological complexity, the presence of gas, the many innovations introduced and the difficult logistic and lack of basic infrastructures on the island.

The technical details of the individual innovations implemented and their behavior during the execution of the works will be the subject of separate presentations as the works will progress.

The same will be for the productions and the geological difficulties that the 184 km of tunnel will reserve and the special measures that will be eventually necessary to overcome them.

The project, once completed, will allow Sicily the infrastructural development that was missing since ever and, once connected to the Messina bridge which construction is expected to start soon, will finally connect Sicily to Italy and to the rest of Europe.

ACKNOWLEDGMENTS

The authors would like to thank Webuild partners in the project construction, Ghella and Pizzarotti, the designers Rocksoil, Proger, SWS, PINI, the Client RFI and the TBM suppliers CREG and CRCHI.

Evaluating TBM design and performance, 30 years apart: The Lesotho Highlands Water Tunnel, phase 1 and phase 2

Brad Grothen*

Robbins, Solon, Ohio, USA

ABSTRACT: Two massive tunnel projects 30 years apart: The Lesotho Highlands Water Project (LHWP) is a multi-phased project that has taken place over decades to provide water to the Gauteng region of South Africa and to generate hydroelectricity for Lesotho. Phase I tunneling began in 1992 and utilized multiple Main Beam TBMs to bore long tunnels in basalt and dolerite ground conditions.

Phase II, now under construction, consists of 38 km of transfer tunnel to be excavated by both TBM and drill & blast. Water from the Polihali reservoir will flow by gravity through the Polihali Transfer Tunnel on its way to Katse Dam. Two 5.4 m diameter Double Shield TBMs will bore 17 km long sections of the Polihali Transfer Tunnel, one designated Polihali-West and the other Katse Outlet-East. The tunnels will travel through basalt and dolerite with some sections of breccia, pillow lava, tuff and agglomerate at depths ranging from 91 to 994 m below the surface.

In order to bore in the challenging conditions, the machines are fitted with 19-inch disc cutters and two-speed gearboxes that efficiently use power to generate high torque at low RPM when in sections of squeezing geology or fracture zones.

This paper will detail the design for the TBMs to be used on the Phase II tunnel, while comparing the modern-day machines to the history-making Main Beams used in the 1990s. It will derive some conclusions and lessons learned about boring in volcanic rock at depth utilizing Main Beam vs. Double Shield TBMs.

Keywords: Tunnelling, Hard rock, Main Beam, Africa

1 INTRODUCTION – PROJECT BACKGROUND

The Lesotho Highlands Water Project (LHWP) is decades in the making. A cooperative effort between Lesotho and South Africa, Phase 1 of the project sought to rejuvenate South Africa's heavily populated and arid Gaucheng Province. Its first phase began in 1992 and involved construction of the 180 m high Katse Dam, part of the Orange (Sequ) River system in Lesotho. The dam, finished in 1998, supplies water to South Africa's Vaal river system via a water transfer tunnel and two delivery tunnels. A total of 82 km of tunnels were constructed between 1992 and 1996. The project went online in 2003.

Today, the contribution of Phase 1 of the LHWP to the economic activity of Lesotho has been remarkable. Royalties, the sale of electricity, construction activities and other project-related revenue have provided an important economic boost to Lesotho. In 2002, it was calculated that the project's contribution to the economic activity of Lesotho was 5.4% of the GDP (lhda.org.ls, 2023).

The water from the LHWP is used in six provinces of South Africa. It cools the Eskom power stations in Mpumalanga, keeps Sasol and Free State gold mines operational, supplies the vast industries and sprawling urban areas of Gauteng, provides water to some of the southern towns of Limpopo and the platinum mines of the northwest, as well as the diamond mines and people of Kimberley and surrounding areas. Under drought conditions, emergency water can, and has, been transferred to the Caledon River and to the Eastern Cape and southern Free State through the BloemWater network.

Phase 2 of the Lesotho Highlands Water Project, now underway by the Lesotho Highlands Development Authority (LHDA), builds on the successful completion of Phase 1 in 2003. It delivers water to the Gauteng region of South Africa and utilises the water delivery system to generate electricity for Lesotho. Phase II will increase the current supply rate of 780 million cubic metres per annum incrementally to more than 1.27 billion cubic metres per annum. At the same time, it will increase the quantity of electricity generated at the Muela hydropower

*Corresponding author: grothenb@robbinstbm.com

station and is a further step in the process of securing an independent electricity source to meet Lesotho's domestic requirements (LHDA, 2020).

The water transfer component of Phase 2 comprises a Concrete-Faced Rockfill Dam (CFRD) and saddle dam at Polihali, downstream of the confluence of the Khubelu and Senqu (Orange) Rivers, and a gravity tunnel that will connect the reservoir at Polihali to the Katse reservoir. In addition, two 1 km long, drill and blasted river diversion tunnels were built prior to the construction of the Polihali Dam.

The 38 km long Polihali Transfer tunnel will be constructed by both TBM and drill and blast, and allows water from the Polihali Reservoir to flow by gravity to the reservoir at Katse.

2 PHASE 1

The first phase of the massive project included approximately 80 km of tunneling and construction of two dams and an underground power station. The project's co-owners, the Kingdom of Lesotho and the Republic of South Africa, awarded the contract for the 13 km-long south delivery tunnel and the 45.6 km-long transfer tunnel, both located in Lesotho, to the Lesotho Highlands Project Contractors (LHPC). LHPC was a joint venture of Spie Batignolles (France), LTA Ltd. (South Africa), Ed Zublin AG (Germany), Balfour Beatty Ltd. (U.K.) and Campenon Bernard (France).

LHPC leased a refurbished Main Beam TBM to excavate the shorter delivery tunnel. The contractor also ordered three new open-type TBMs, manufactured by Robbins, to bore the longer transfer tunnel. Yet another Main Beam TBM, manufactured by Wirth, was ordered for the North Delivery Tunnel.

The 5.18 m diameter south delivery tunnel connects the Muela adit with ventilation shaft #5 to the north. At this point the excavation junctures with the 5.1 m diameter north delivery tunnel, which continues 22 km to the Axle River outfall in South Africa.

The transfer tunnel, proceeding from the Katse Dam to the Muela Power Station, is one of the world's longest water supply pressure tunnels. It is made up of three 4.99 m diameter drives with lengths of 10.9 km, 17.3 km and 17.4 km. The transfer tunnel diverts water from the dam to the power station (see Figure 1).

Figure 1. Schematic Overview of the Lesotho Highlands Tunnels (Finnsson, 1994).

2.1 Geology

The transfer tunnel route passes through basaltic flows of the Lesotho/Drakensberg formation, volcanic rock with variable amygdaloidal content. The area includes blocky conditions in faulted areas and within some of the doleritic dykes also found along the route. The unconfined compressive strength (UCS) of these rock formations ranges from 80 MPa to 176 MPa.

The south delivery tunnel site lies in sedimentary rock of the Stormberg Group, upper formation of the Karoo sequence, a deposit formation in the extensive Karoo Basin. Most of the tunnel route passes through the Clarens formation, located beneath the Lesotho/Drakensberg formation. The Clarens section consists mainly of horizontally layered sedimentary rocks composed of fine- to medium-grained siltstone and sandstone with occasional doleritic dykes and layers of claystone. The UCS of the softer rocks in this area varies from 10 MPa to 40 MPa.

3 TBM DESIGN AND EXCAVATION

3.1 The south delivery tunnel

The 5.18 m dia machine, the first TBM to begin work at Lesotho, featured 37 cutters, each 432 mm in diameter. Six 185 kW motors provided 1,110 kW to the cutterhead, which operated at 7.28 rpm. The 270 metric ton machine had a 1.5 m boring stroke and a thrust of 7,400 kN. Manufactured in 1979, the refurbished Main Beam was already a tunneling veteran before its journey to Lesotho, having bored more than 24 km on projects in the U.S. and Canada.

The refurbished Robbins Model 186-206 began boring the 13 km-long south delivery tunnel in February 1992 and achieved breakthrough in August 1993, an astounding 20 months ahead of schedule. The tunnel excavation consisted of three drives: 2.1 km from Hololo south to Muela, 5.2 km from Ngoajone south to Hololo and 5.7 km from Ngoajone north to ventilation shaft #5.

The refurbished Main Beam achieved outstanding results on the south delivery tunnel despite two breakthroughs and start-ups of the TBM and back-up system along the way. The machine's average rate of penetration (ROP) was 3.86 m per hour (8.8 mm per revolution). The TBM advanced at an average 39.9 m per day in three eight-hour shifts and 878 m per 22-day month. The best day advance of the drive was 82.9 m, with a best week of 384.0 m and a best month of 1,324.4 m. Rock support measures in the south delivery tunnel included spot bolting as well as some systematic rock bolting with mesh and shotcrete (see Figure 2).

3.2 The transfer tunnel

3.2.1 Design of the TBMs

The new Robbins MK 15, an open hard rock machine, offered a bore diameter of 5.018 m. The

Figure 2. Advance rates in the South delivery tunnel.

TBM's cutterhead was dressed with four center cutters, 22 face cutters and eight gauge cutters, all 432 mm in diameter. Three 560 kW motors supplied 1,680 kW to the cutterhead, producing a torque of 1,588 kNm. The 320 metric ton machine had a 1.525 m boring stroke and a thrust of 8,300 kN. Cutterhead speed was 10.1 rpm (see Figure 3).

Figure 3. The MK15 open-type TBM at the tunnel portal.

The two Robbins Main Beam TBMs were supplied with boring diameters of 5.03 m. At Lesotho these machines were equipped with 35 disc cutters, each 432 mm in diameter and load rated to 222 kN, producing a total cutterhead thrust of 9,723 kN. The machines were both equipped with backloading cutterheads. The flexible design of these high-performance TBMs also allowed later installation of 483 mm dia cutters to achieve a cutter load of up to 312 kN for situations in which increased power was needed for superior performance on the job. The machines also featured five 315 kW water-cooled motors supplying a total of 1,575 kW to the cutterhead. The TBMs have a boring stroke of 1.866 m and a cutterhead speed of 10.0 rpm.

Each of the four Robbins TBMs on the Lesotho Project had its own trailing back-up system, including a rock drill. The drill was part of an assembly mounted on a 7 m-long sliding deck about 20 m behind the cutterhead on the top level of each TBM's backup. This arrangement allowed probe drilling concurrently with TBM advance (see Figures 4 and 5).

Figure 4. One of the 5.03 m diameter main beam TBMs supplied for the transfer tunnel.

Figure 5. Schematic of the main beam TBMs provided for Phase 1 transfer tunnel.

Locomotives and rotadump cars operated behind each of the TBMs to remove muck produced during tunneling operations. Each service train was made up of seven 12 m³-capacity muck skips. Depending on the difficulty of the excavation gradient, either 25 metric ton, 180 hp or 35 metric ton, 200 hp diesel locomotives were used to haul the filled muck trains.

LHPC installed a precast concrete invert segment in each tunnel to support tracks for the muck-handling trains. These segments remained in the operating water delivery system to facilitate tunnel maintenance and repair.

3.2.2 TBM excavation

The Robbins MK 15 began boring the Katse tunnel section from the Katse Dam site to ventilation shaft #3, a distance of 10.9 km, in May 1992, and reached breakthrough in September 1994. With an average ROP of 3.89 m per hour (6.4 mm per revolution), the TBM achieved an average monthly advance of 364 m, with a best day, week and month of 62.9 m, 289.0 m and 987.0 m, respectively.

Difficult rock conditions prevailed in the non-amygdalesoidal basalt areas of this section of the transfer tunnel. Blocky ground at the tunnel face and rock

falls from the crown area resulted in substantial downtime to clean the invert and cutterhead and install appropriate rock support. In addition, some challenging conditions forced reductions in TBM thrust and ROP, decreasing the machine's advance rate in these areas to about 30 percent of the progress achieved in stable rock. Although the tunnel route also included two doleritic dykes, one 95 m long and the other 82 m long, the TBM advanced surprisingly well through these difficult sections. About 15 percent of total job time was devoted to rock support, which included bolting, rock straps, mesh and shotcrete. Overall, TBM utilization reached 31 percent (see Figure 6).

Figure 6. Katse tunnel utilization.

The first Main Beam TBM (Muela tunnel section) began boring the 17.4 km-long transfer tunnel section from Muela south to the Hlotse adit in June 1992. Maintaining an average ROP of 4.59 m per hour (7.7 mm per revolution), the machine broke through in September 1994. The TBM's average advance rate was 33.4 m per day and 656 m per month. The Main Beam set world tunneling records for its diameter class with a best day advance of 86.3 m, a best week of 399.8 m and a best month of 1,344.3 m.

The TBM set these records despite some challenging geology along the tunnel route. Rock jointing necessitated rock support measures, especially at the beginning of the drive. Overall, rock support required 24 percent of total job time, with machine utilization reaching 29 percent (see Figure 7).

In July 1992, shortly after boring began on the transfer tunnel's Muela-Hlotse section, the Robbins Model 167-267 TBM started its 17.3 km long drive from Hlotse to ventilation shaft #3. The machine achieved an average ROP of 4.10 m per hour (6.8 mm per revolution), while maintaining average advance rates of 27 .6 m per day- and 620 m per month. The TBM turned in a superior performance with a best day advance of 66.8 m, a best week of 325.0 m and a best month of 1221.0 m.

Figure 7. Muela tunnel utilization.

Challenging rock conditions in this section of the transfer tunnel required rock support measures accounting for 11 percent of total job time, with another substantial delay (29 percent) due to job site problems. Nevertheless, machine utilization reached 38 percent (see Figure 8). Final breakthrough occurred on October 14, 1994.

Figure 8. Hlotse tunnel utilization.

4 PHASE 2 TUNNELING

In 2022, the 38 km long Polihali Tunnel was announced as part of the LHWP Phase 2. The approximately M9.2 billion Polihali Transfer Tunnel contract was awarded to the Kopana Ke Matla joint venture, which includes Yellow River Company (China); Sinohydro Bureau 3 (China); Unik Civil Engineering (South Africa) as the main joint venture partners. Subcontractors include Nthane Brothers of Lesotho, Esor Construction and Mecsca Construction of South Africa.

The Polihali Transfer Tunnel will transfer water by gravity from the Polihali reservoir to the Katse reservoir. From Katse, water is transferred via the

delivery tunnel to the ‘Muela Hydropower Station constructed in Phase I, and then on to the Ash River outfall outside Clarence in the Free State on its way to Gauteng (see Figure 9).

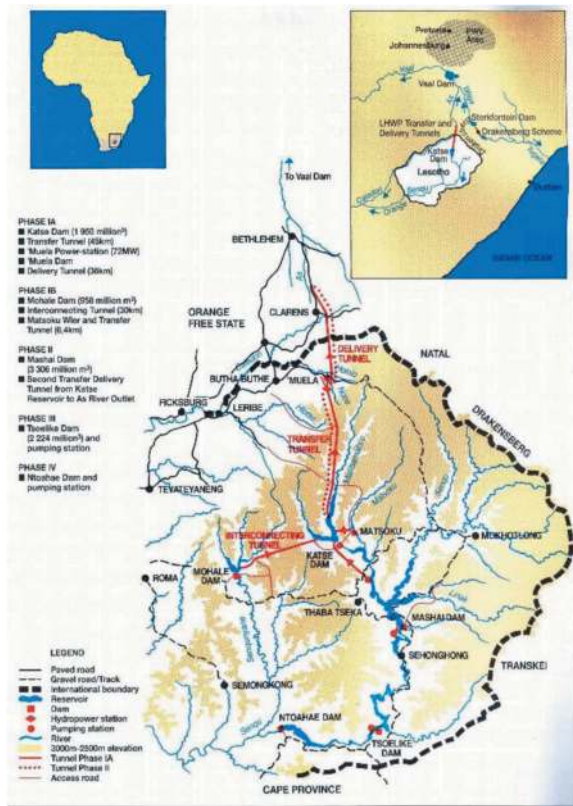

Figure 9. Map of LHWP works, Phases I and II (Lhda.org).

4.1 Tunnel specifications & geology

The Polihali tunnel includes two approximately 17 km long TBM-driven tunnels, designated as TBM Drive from Polihali-West and TBM Drive from Katse Outlet-East, and two approximately 1.5 km long D&B-driven connecting tunnels (one at each end), designated as Polihali Connecting Tunnel and Katse Outlet Connecting Tunnel. The Polihali Tunnel will have a finished diameter (ID) of 4.5 m and a relatively flat slope of 0.032%. The tunnel will be constructed in hard rock at depths to invert ranging from 91 to 994 m below ground surface. The TBM-driven portion of the tunnel will be lined with a drained, initially-bolted, gasketed, precast concrete segmental tunnel lining (PCTL) installed concurrently with TBM tunnel excavation (see Figure 10).

Geology along the tunnel alignment consists of highly amygdaloidal basalt (28%), moderately amygdaloidal basalt (28%), non-amygdaloidal basalt (28%), doleritic basalt (10%), and dolerite (5%). About 1% of the geology is estimated to consist of other rock types including breccia, tuffites, pillow lavas, olivine basalts, and agglomerate. These rock types are often associated with problems in terms of tunnel stability and excavation.

Figure 10. Schematic of Polihali tunnel path.

4.2 TBM design for challenging conditions

In order to excavate in the challenging conditions, the two 5.4 m diameter Double Shield TBMs have been designed with advanced features.

4.2.1 Multi-speed gearboxes

Customized cutterhead drives can be instrumental in getting through difficult ground. Designing a machine with high-torque, continuous boring capabilities allows that machine’s cutterhead to restart with break-out torque in difficult ground. The net effect is that the machine can keep boring in the event of a face collapse and can effectively bore through fault zones and running ground where the potential for cutterhead jamming exists. Multi-speed gearboxes give the machine the ideal EPB torque if larger sections of soft ground are anticipated (Figure 11).

Figure 11. Torque-speed curve for the LHWP Phase II TBMs.

When compared to the Phase I TBMs, the Phase II machines also have much higher thrust – in some cases nearly four times higher (see Table 1). The combination of higher thrust capabilities and multi-speed gearboxes is ideal for variable rock conditions.

Table 1. Comparison of 5 m diameter TBMs, Then and Now.

	Cutterhead Power (kW)	Thrust (kN)
LHWP Phase I MB TBMs	1,110 to 1,680	7,400 to 9,473
Modern MB TBM	2,310	10,898
LHWP Phase II DS TBMs	1,920	29,500

4.2.2 Stepped shields and shield lubrication

When blocky rock or squeezing ground is expected, using a shielded TBM can be tricky. The risk of a machine's shield becoming stuck is real and can be the source of major delays. Designing for these conditions involves creating the shortest possible shield length, with stepped shields if necessary (particularly if a Double Shield TBM is used). Stepped or tapered shields involve each successive shield having a slightly smaller diameter than the last to accommodate for any squeezing or ground convergence as the TBM excavates. Radial ports in the shields can be used for application of Bentonite to provide lubrication between the shield and tunnel walls, again to avoid a stuck machine. Should the machine become stuck, there are additional solutions: hydraulic shield breakout can be used in trapped conditions. The radial ports can be made to inject pressurized hydraulic lubricants to free a shield that has already become stuck (see Figure 12). Lastly, additional thrust jacks between the normal thrust cylinders can supply added thrust in a short stroke to break loose a stuck shield.

Figure 12. Shield lubrication system.

4.2.3 Enhanced probe drilling and grouting

One of the key lessons learned from projects in difficult ground is that more drill ports, and more types of drills, are necessary components of shielded tunneling in difficult ground. Multiple probe drills can be installed on the TBM, with ports to provide probing patterns in a 360-degree radius. High-pressure grout

injection can be done through these same ports to stabilize ground up to 40 m ahead of the face (or more if using specialized drills). The type of grout injected can also be specialized—for example chemical or polymer grout can be used to seal off groundwater.

In order to minimize water inflows and increase water tightness of the segments, grouting can be done through the TBM tail shield as well.

4.3 TBM supply

The two Double Shield TBMs are currently being built at Robbins partner facilities, CCC Tianhe Mechanical Equipment Manufacturing Co., Ltd. (CCCCTH) in Jiangsu Province, China. A representative example of a Double Shield TBM is shown in Figure 13 below.

Figure 13. Example high-performance double shield tbm design.

5 CONCLUSIONS

While the original Main Beam TBMs provided for Phase I were able to excavate in the challenging conditions, there were many delays and stoppages. Modern TBM design, from 360-degree probe drilling to multi-speed gearboxes, offers advantages in these types of challenging ground. They have been proven to get through fractured, and variable ground by detecting such conditions ahead of the TBM grouting to seal off water inflows and utilizing multi-speed gearboxes. While the Double Shield TBMs have not yet been launched at the Polihali Tunnel, these two epic projects, 30 years apart, clearly elucidate the advances of the TBM industry. Advance rates and utilization will be monitored throughout these tunnels in order to compare and contrast to the Phase 1 TBMs.

ABSTRACT: Based on the principles of influence and the path of factors on the ultimate bearing capacity of a segmental lining, this study investigates the relationships between the load-bearing capacity of the lining members, the structure function of tunnel failure, the ultimate bearing capacity of the segmental lining, and load conditions. This research provides fundamental knowledge for assessing the safety of segmental lining and designing the loading procedure. The ultimate bearing capacity of a tunnel structure depends to a large extent on its failure behavior. The load or action leading to tunnel failure is diverse, including but not limited to sudden local loading or unloading, accidents, crashes, vehicle fires, and terrorist bombings. A functional model for the ultimate bearing capacity of a segmental lining has been developed. Then, the principles of influence and action path of loading on lining capacity, as well as the effects of loading path, loading mode on the structure function of failure, are analyzed. Finally, the principle of equivalent loading for the model test is discussed. The results indicate the ultimate bearing capacity of a segmental lining is influenced by the forms and paths of loads acting on the tunnel lining, in addition to the strength of materials, structural dimensions and interaction between components. The capacity of the tunnel lining is a variable that is significantly affected by load conditions. Therefore, when considering the results from specific full-scale tests or model tests, it is important to take into account their application scope and limitations. The failure mode of a segmental lining is an important factor that affects the tunnel capacity. The approximation of load conditions in model tests cannot alter the value of structure function of system failure. Additionally, the similarity criterion for the structure function of system failure must be met.

Keywords: segmental lining, load conditions, ultimate bearing capacity, analytical solution, functional model

1 INTRODUCTION

Compared to the traditional sequential tunneling method, the shield tunneling method offers advantages of safety and fast construction, especially for tunnels located in soft and water-rich ground, such as those under-crossing rivers or requiring strict ground settlement control. However, due to the application of shield tunnels in different strata and the presence of numerous joints in the lining system, they are susceptible to various disasters. These include man-made disasters such as water gushing (Feng et al., 2023), local loading (Zhang Y. M., et al., 2023), or unloading (Zhang J. Z., et al., 2023),

as well as natural disasters, like earthquakes (Zhang S. H., et al., 2020). The consequences of these disasters can be catastrophic. Moreover, the design and construction of shield tunnels are facing a trend of larger cross-sections and complex structural forms (Zhu, et al., 2022; Liu et al., 2018). All of the phenomena prompt research concerning the tunnel safety, including the ultimate bearing capacity (Lu et al., 2012; Blom et al., 1999; Afshan et al., 2017), failure mechanisms (Zhang et al., 2019), and long-term performance (Zhu et al., 2022) of segmental linings, among others.

Owing to the complexity of determining the ultimate bearing capacity of a segmental lining

*Corresponding author: dxp3000@163.com

system (referred to as the lining system), the model testing is one of the primary research approaches. According to the simulation methods for the surrounding ground, the model test is classified into two categories: the ground-lining model (Feng et al., 2023; Zhang Y. M., et al., 2023; Zhang J. Z., et al., 2023; Zhang S. H., et al., 2020; Wang et al., 2020) and the load-lining model (Liu et al., 2018; Lu et al., 2012; Blom et al., 1999; Afshan et al., 2017; Zhang L., et al., 2019). The ground-lining model mostly adopts a small-scale, such as 1:10, 1:15, and uses materials like gypsum, micro-concrete or organic plastic to simulate the tunnel lining, as well as the rock mass. On the contrary, in a load-lining model, either a full-scale 1:1 or a small-scale 1:10 is typically used. The tunnel lining is modeled alone, and jacks are positioned along the normal direction of the lining to simulate the surrounding rock. It is well known that the ultimate bearing capacity of a lining system is significantly influenced by the segment joints (Lu et al., 2012; Blom et al., 1999; Afshan et al., 2017; Zhang L., et al., 2019; Ye et al., 2011; Wang et al., 2021). Thus, in addition to satisfying geometric similarity and material similarity, what principles or similarities should be followed in designing the model test to assess the strength of the lining? To address this problem, firstly, a functional model for the ultimate bearing capacity of a lining system is described. Then, a comparative study is conducted to examine the effects of loading conditions on the ultimate bearing capacity of lining components. The structure failure function is also analyzed, along with the principles and pathways of how loading conditions impact the ultimate bearing capacity of a lining system. Finally, a case study is conducted on the failure history of a single-ring lining system. The study investigates the equivalence principle, method and effect of the loading scheme in small-scale model tests.

2 LOADING SCHEMES FOR LOAD-LINING MODEL TESTS

In a load-lining model, the loading is directly applied to the model lining through jacks, making it easier to accurately control the direction and magnitude of the load. The load-lining model is discussed in this paper.

In the load-lining model, the loading scheme is subdivided into three types based on the loading path and the degree of load concentration:

- (1) Constant eccentricity and distributed loading method. According to this method, the jacks are grouped, and the loading ratio between the groups is maintained in loading history (Lu, 2019; Liu, 2017). For example, in the study of the subway section tunnel with an outer diameter of 6.2m, Lu et al. (2012) used 24 jacks to simulate the ground resistance, soil and water pressure, surcharge, etc. Afshan et al. (2017)

used 18 jacks. For this incremental loading mode, a constant ratio, M/N , between bending moment M , and the axial force N at any cross-section of the lining structure is maintained, as shown by curve A in Figure 1.

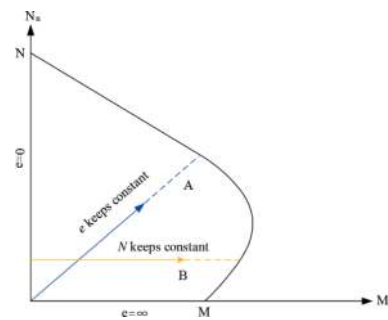

Figure 1. Loading path.

- (2) Constant eccentricity and point loading methods. For example, the water pressure is applied first, and then, the 4 jacks are utilized to simulate the earth pressure. The incremental load is applied until the lining structure fails (Zhang L., et al., 2019). In loading history, the ratio between the vertical and horizontal loads, as well as eccentricity, is kept constant. Nakamura et al. (2003) used a 6-point loading method for double-circular rectangular-shaped shields.
- (3) Constant axial force N and radial distribution loading method. This loading method is employed in all the full-scale tests for the BRT tunnel (Blom et al., 1999; Blom, 2002; Vervuurt et al., 2007), using 28 jacks to simulate the ground pressure.

The loading procedure is as follows: firstly, a radial uniform pressure is applied to generate an axial force N in the lining structure. Then a radial load distributed in the form of cosine function (Figure 2) is applied until the lining structure fails. Throughout this process, the axial force N is maintained at a constant level, as shown by curve B in Figure 1.

Figure 2. Loading subdivided into uniform load and ovalization load.

It should be noted that in the aforementioned loading scenarios, multiple jacks can be arranged for the full-scale test. Nevertheless, in the small-scale

model test, a large number of jacks cannot be used due to insufficient space. To address this dilemma, the impact of loading conditions will be analyzed first, using the functional model for the ultimate bearing capacity of a lining system.

3 FUNCTIONAL MODEL FOR THE ULTIMATE BEARING CAPACITY OF A SEGMENTAL LINING SYSTEM

Ultimate bearing capacity is an important research topic in the field of lining system failure behavior (Blom et al., 1999; Ye et al., 2011; Wang et al., 2011). A functional model for the ultimate bearing capacity of the segmental lining with inclined bolts was proposed by Chen and Dong, et al. (2023).

The system capacity can be expressed in terms of the failure mode function, joint capacity, and segment capacity, as follows:

$$\begin{aligned} F &= \Phi(M_{\text{lim}}^{\text{joint}}, M_{\text{lim}}^{\text{seg}}) \cdot F_{\text{mode}} \\ &= \Phi(M_{\text{lim}}^{\text{joint}}, M_{\text{lim}}^{\text{seg}}) \cdot \chi(\mathbf{I}(t)) \end{aligned} \quad (1)$$

Where, $\Phi(M_{\text{lim}}^{\text{joint}}, M_{\text{lim}}^{\text{seg}})$ is a dimensional quantity that represents the strength contribution of the joint and segment, and F_{mode} is a dimensionless quantity that represents the contribution of the system failure mode function. Function F represents the ultimate bearing capacity of the lining system

Two critical parameters are calculated as follows:

$$M_{\text{lim}}^{\text{seg}'} = -\frac{N^2}{2f_c b} + \frac{h}{2} \cdot N + f_y A_s (h_0 - a'_s) \quad (2)$$

$$M_{\text{lim}}^{\text{joint}} = \frac{-3N^2 + 3Nh_{\text{joint}}f_c b}{6f_c b} \quad (3)$$

Where, $M_{\text{lim}}^{\text{seg}}$, $M_{\text{lim}}^{\text{joint}}$ is segment and joint strength, respectively; f_c is the concrete compressive strength; f_y is the yielding strength of the reinforcement rebar; A_s is the cross-sectional area of the reinforcement; h_0 is the effective height of the segment cross section; h is the segment height; b is the segment width; N is the axial force; and a'_s is the concrete cover; h_{joint} is the joint height.

Note that the ring joint is considered an irrelevant component in terms of its load-bearing functionality within a segmental lining system, as indicated by the “relevant/irrelevant” notation. In tunnel engineering, the ring joint typically cannot be designed in practice to serve as a load-carrying part, even though the ring joint is of significant importance to a lining system.

The failure mode can be expressed in terms of the state variable vector at time t , as follows:

$$\begin{aligned} F_{\text{mode}} &= \chi(Y_i(t)) = \chi(x_i(t)) = \chi(I_i(t)) \\ &= \chi(I_1^{\text{joint}}, I_2^{\text{joint}}, \dots, I_{NJ}^{\text{joint}}, I_{NJ+1}^{\text{seg}}, I_{NJ+2}^{\text{seg}}, \dots, I_{NJ+NS=n}^{\text{seg}}) \\ &= \chi(\mathbf{I}(t)) \end{aligned} \quad (4)$$

Where, F_{mode} is the failure mode function of the lining system in terms of the failure index vector at time t .

$\mathbf{I}(t) = (I_1(t), I_2(t), \dots, I_n(t))$ is the failure index vector at time t .

$$I^{\text{joint}} = \frac{M^{\text{joint}}}{M_{\text{lim}}^{\text{joint}}} \quad (5)$$

$$I^{\text{Seg}} = \frac{M^{\text{Seg}}}{M_{\text{lim}}^{\text{Seg}}} \quad (6)$$

Where, I^{joint} , I^{Seg} is the failure index of the segment joint and segment, respectively; M is the moment induced by the external load and can be computed using a theoretical or numerical model.

The advantage of expressing the failure mode function expressed in terms of the failure index vector instead of the bending moment is discussed below.

The joint failure index and segment failure index are dimensionless quantities that range from 0 to 1. The failure index has a clear physical interpretation. Thus, the load-bearing states of segments or joints can be evaluated and compared using a universally normalized measuring scale.

The functional model for the ultimate bearing capacity of a segmental lining establishes a direct mapping relationship between various causal factors and the ultimate load-bearing capacity of the lining system, which clarifies the constituent elements of the ultimate load-bearing capacity of the segmental lining, as well as the principle of each influencing factor on the ultimate bearing capacity. From Equations. (2)- (6), it can be seen that all three components of lining strength are sensitive to the loading conditions, such as type, direction, distribution, and path of loading.

4 INFLUENCE PRINCIPLE AND PATH OF LOADING EFFECT ON LINING STRENGTH

4.1 Analysis method and verification

Based on a series of full-scale tests, Blom (2002) derived an analytical method for the mechanical response of segmental lining, which can consider the nonlinear rotation characteristics of segment joint, and analyzed a single-ring failure history using this analytical method. For verification purpose, the analytical case is chosen as study case. The study case is based on Botlek Railway Tunnel, with physical and material parameter is shown in Table 1.

Segment joints are illustrated as shown in Figure 3.

Table 1. Physical dimensions and material properties.

Parameter and symbol	Values	Unit
Tunnel radius, r	4.525	m
Ring width, b	1.5	m
Segment thickness, h	0.4	m
Joint height, h_{joint}	0.17	m
Young's elastic module of concrete, E_c	36	GPa
Poisson's ratio of concrete, ν	0.2	
Compressive strength of concrete, f_c	64	MPa
Joint compressive stiffness, k_c	230	GPa/m

Figure 3. Geometry of lining: i is location index of segment joint.

The loading mode is as shown in Figure 2. In Blom's model, non-linear behavior of a single ring is analyzed without considering the interaction between the soil and the lining. The loading procedure is as follows:

- (1) Firstly, the uniform load is applied ($\sigma_0 = 0.5\text{MPa}$).
- (2) Then, the ovalization load (σ_2) is applied step by step.

In this study, the moment-search-method (MSM), developed by Dong (2015), is used to calculate the failure history of the lining system. The MSM adopts the segment joint model proposed by Dong (2013). According to Dong, the rotation curve of the segment joint is shown in Figure 4.

Figure 4. M-φ curve of segment joint.

The M-φ curve in Figure 4, can be described by the following formula (Dong, 2013):

$$\theta_{joint} = \begin{cases} \frac{M}{k_c I_{joint}} & M \leq M_t^{joint} \\ \frac{2N}{9k_c b \left(\frac{h_{joint}}{2} - \frac{M}{N}\right)^2} & M_t^{joint} < M \leq M_c^{joint} \\ \frac{1}{2} \frac{f_c^2 b}{k_c (3Nbf_c h - 6Mbf_c - 3N^2)^{1/2}} & M_c^{joint} < M \leq M_{lim}^{joint} \end{cases} \quad (7)$$

Where, M_t^{joint} is the critical moment for joint opening; M_c^{joint} is the critical moment for joint yielding; M_{lim}^{joint} is the joint capacity; I_{joint} is the joint inertia moment; and k_c is the joint compressive stiffness.

In addition, the critical moment is derived as follows (Dong, 2013).

$$M_t^{joint} = \frac{N \cdot h_{joint}}{6} \quad (8)$$

$$M_c^{joint} = N \left(\frac{h_{joint}}{2} - \frac{2N}{3bf_c} \right) \quad (9)$$

The vertical displacement at ring bottom obtained using MSM is compared with that of Blom in Figure 5.

Figure 5. Comparison of displacement at ring bottom between MSM and Blom's algorithm.

It can be seen that the displacement history at bottom obtained by MSM agrees well with the calculation results of Blom, and the load effect will be analyzed by MSM in this study.

4.2 Effect of loading conditions on lining strength

To simplify the calculation of equivalent resultant loads under different loading conditions, two cases are constructed based on blom's analysis. The cases are used to compare loading mode 1 and 2, which are the distribution loading and centralized loading, respectively, under constant eccentricity:

Case 1: vertical uniformly distributed load p + horizontal uniformly distributed load q ($p > q$);

Case 2: vertical concentrated load P_v + horizontal uniformly distributed load q ;

The load magnitude is as follows: based on Blom's analysis case, $\sigma_0=0.5\text{MPa}$, and the maximum ovalization load σ_2 is $\sigma_0\times 8\%$. Thus, uniform distribution load p, q is $810\text{kN/m}, 690\text{kN/m}$, respectively. In accordance with the loading procedure, firstly apply uniform loading $q=690\text{kN/m}$, and then apply ovalization loading ($p-q$)= 120kN/m . Ovalization loading ($p-q$) is divided into 80 load steps, the incremental load in each loading step is 1.5kN/m in Case 1 and the corresponding point load is 6.7875kN in Case 2.

Since the magnitude of individual load step at the ovalization loading stage (Stage 2) for Cases 1 to 2 is equivalent, the number of load steps is then used as the representation of the loading history.

The comparison of the ultimate bearing capacity of the lining system for Case 1 to 2 is shown in Figure 6.

Figure 6. Comparison of the lining strength.

For Case 1 and 2, loading stage 1 is identical and loading stage 2 is equivalent. However, the lining strength of Case 1 is 1.7 times that of Case 2. From Figure 6, it can be observed that in the ultimate bearing capacity test of a lining system, it is not appropriate to design the loading procedure solely based on the "load equivalent" principle. What causes the formation of this phenomenon? It will be investigated in the following manner.

4.3 Influence principle and path of load effect

Based on the functional model for lining strength, the influence of load effect on the composition elements of lining capacity can be analyzed separately. Firstly, the influence of the load effect on segment and joint strength is investigated. The variation of axial force in Case 1 is shown in Figure 7.

In Figure 7, it can be observed that the axial force increases with the increase in ovalization loading. The axial force reaches its peak at the load step $LS=34$. Among them, the axial force at segment joints increases, while the axial force at the ring bottom decreases. The axial force at the bottom decreases at a rate of 0.4% , and the rates of increase for J1 to J4 are: $0.4\%, 4.9\%, 7.14\%$, and 1.08% , respectively. Thus, the axial force remains approximately constant (less than 10%) throughout the ovalization loading ($p-q$) history. Consequently, the

Figure 7. Axial force history in load case 1.

ultimate bearing capacity of the joints and segments remains essentially constant in the failure history. The variation of the ultimate bearing capacity of the joints is shown in Figure 8.

Figure 8. Variation of the joint strength in case 1.

The variation rates of the strength of the joints J1 to J4 in ovalization loading stages are $0.3\%, 3.7\%, 5.3\%$, and 0.8% , respectively. Thus, the strength of the joints is approximated to remain constant during ovalization loading.

The variation of joint strength for Case 2 is shown in Figure 9. From the Figure 9, it can be seen that the change in the strength of the segment joint is within 10kN.m/Ring . Compared with 215kN/Ring before the ovalisation loading, the change rate of the ultimate bearing capacity of the joints from J1 to J4 is $0.6\%, 2.8\%, 2.9\%$, and 0.8% . The ultimate bearing capacity of the segment joints is approximately constant.

According to the function model for segmental lining strength, it is evident that the influence of Case 1 and Case 2 on the component's strength function Φ is not the primary factor contributing to the significant difference in the ultimate bearing capacity of the lining system.

Another factor that affects the ultimate bearing capacity of the lining system is the failure mode. In fact, the failure modes of Case 1 and Case 2 are significantly different, even though they have equivalent load magnitude. The evolution of the failure indices for Case 1 and Case 2 is shown in Figure 10.

Figure 9. Variation of the joint strength in case 2.

As can be seen in the Figure 10, there is a significant difference between the failure mode functions for Case 1 and Case 2. In Case 1, the structure functions at failure are as follows:

$$\begin{cases} I_1 = 0.99 \\ I_2 = 0.40 \\ I_3 = 0.99 \\ I_4 = 0.96 \\ \vdots \end{cases} \quad (10)$$

(a) Case 1

(b) Case 2

Figure 10. Failure mode of case 1 and case 2.

For Case 2, the structure functions at failure are as follows:

$$\begin{cases} I_1 = 1.00 \\ I_2 = 0.97 \\ I_3 = 0.99 \\ I_4 = 0.95 \\ \vdots \end{cases} \quad (11)$$

The difference in the structure of the failure mode function is the main reason for the significant disparity in the ultimate bearing capacity between Case 1 and Case 2,

As can be seen from the examples of Case 1 to 2, the loading have an influence on influence the ultimate bearing capacity of the lining system by affecting the failure mode function.

5 DESIGN PRINCIPLE OF LOADING PROCEDURE BASED ON THE FUNCTIONAL MODEL FOR LINING STRENGTH

As mentioned previously, the loading conditions have a significant impact on the ultimate bearing capacity of the segmental lining system. Meanwhile, in the small-scale model test, it is not possible to arrange as many jacks as in the full-scale test due to the limitations of model dimensions. So, how can we balance this contradiction in the model test?

The Blom's constant axial force N loading is selected as the study case. As shown in Figure 2, according to Blom, a uniform loading σ_0 (0.5 MPa) is applied initially, followed by a cosine-distribution ovalization loading with a maximum value of 1/80th of 8% of σ_0 per step. In other words, the maximum load p_0 at each loading step is 0.75 kN/m. When this case was implemented in the Netherlands laboratory, 28 radial jacks were used to simulate the uniform and ovalization cosine loading. Obviously, if a small-scale model test with a similarity ratio of $n=10$ is used, the maximum diameter is within 1m. In this case, it is impossible to implement the arrangement of 28 jacks, and the centralized loading method is generally used for small-scale test. So, how should the jacks be arranged to achieve the approximation of the cosine loading?

Two points loading methods are examined, as shown in Figure 11.

For centralized loading in Figure 11a, the vertical and horizontal directions are loaded with the incremental equivalents of the cosine loading, i.e:

$$P_V = \frac{1}{3}p_0r = 2262.5\text{kN/ring} \quad (12)$$

$$P_H = P_V = 2262.5\text{kN/ring} \quad (13)$$

For centralized loading in Figure 11b, the load is applied only in the vertical direction. The value of the load is 2 times the P_V .

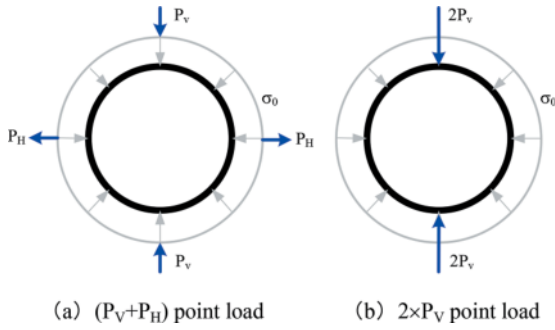

Figure 11. Centralized loading.

The comparison of ultimate bearing capacity is shown in Figure 12. The ultimate bearing capacity of (P_V+P_H) and $2\times P_V$ point loading increases 18.88% and 22.64% compared to the cosine loading method, respectively. The rate of change in ultimate bearing capacity of segment joints is less than 1.5% for cosine mode loading until the failure of the segmental lining system. The rate of change in the ultimate bearing capacity of the joints in the (P_V+P_H) and $2\times P_V$ loading methods is less than 1.5% and 3%, respectively. Therefore, the change in the ultimate bearing capacity of the segmental lining system is not caused by a change in joint strength.

Figure 12. Effect of loading pattern on lining strength.

In fact, the primary reason for the change in lining strength is the alteration of the lining failure mode due to the loading mode. For example, the failure index of J2 under different loading patterns is shown in Figure 13.

Figure 13. Effect of loading mode on failure index of J2.

Therefore, it is not appropriate to replace the ovalization cosine loading with the vertical centralized loading. Meanwhile, from Figure 13, it can be seen that the (P_V+P_H) loading method does not fundamentally alter the failure mode structure. Thus, an attempt is made to add a correction factor $\varpi=1.1$ to the point loading, i.e., applying the load $\varpi\times (P_V+P_H)$. The ultimate bearing capacity and the structure of the failure function are shown in Figures 14 and 15.

Figure 14. Lining strength for (P_V+P_H) multiplied by correction factor ϖ .

Figure 15. Failure mode for (P_V+P_H) multiplied by correction factor ϖ .

It can be seen that multiplying (P_V+P_H) by the correction factor ϖ to replace cosine loading is feasible. As long as the ultimate bearing capacity of components and the failure modes are similar, the ultimate bearing capacity of the lining system must also be similar, according to the functional model for lining system strength. This paper provides a theoretical basis for the design of loading in small-scale model tests.

6 CONCLUSION

- (1) Currently, the ultimate bearing capacity of segmental lining is primary determined through the full-scale and small-scale tests. It should be noted that the ultimate bearing capacity of a segmental lining system is not an inherent property of the tunnel structural system itself, and the lining

capacity is influenced by various factors, including the load conditions imposed on the structural system, the lining materials, lining structure and dimensions of component, and the interaction between these components. The ultimate bearing capacity of a lining system is a variable greatly influenced by the loading conditions. Therefore, the results of a specific capacity test should explicitly indicate its scope and limits.

- (2) In the design and data analysis of model tests, the loading conditions should be carefully and thoroughly considered. It is evident that selecting an appropriate load condition for model testing, whether it is full-scale test or small-test, is not a simple task. This includes considering factors, such as the type and forms of loading, the magnitude of loads and the path (whether to keep the ratio of M/N constant or the axial force N constant).
- (3) The ultimate bearing capacity of a segmental lining is a function in terms of the ultimate bearing capacity of the segment joints and segments, failure mode of the lining system.
- (4) In the segmental lining test for ultimate bearing capacity, it is necessary to ensure similarity in geometric dimensions, material properties (such as the elastic modulus, compressive strength of segment concrete), component strength, and structural failure mode. This means that the strength of the lining system must exhibit similarity. The approximation of loading conditions in the model test should not alter the failure mode structure function of the lining system.
- (5) The function model for the ultimate bearing capacity of segmental lining provides a theoretical basis for loading design in small-scale model tests. For different loading procedure, as long as the component capacity and failure mode similarities are satisfied, the ultimate bearing capacity of the lining system must be similar.

ABSTRACT: Past experiences of EPB TBM projects in soft sedimentary deposits such as Singapore Marine Clay and Fluvial Sand demonstrated the relatively high ground movement during tunnel boring operations. A volume loss of up to 3% is therefore adopted during the preliminary impact assessment and execution of tunnelling in these soils. In end 2022, five tunnels of excavation diameters ranging from 6.7m to 12.2m under-crossed an almost-flat, highly settlement sensitive pavement with ground cover between 11m to 20m. A comprehensive set of control measures were established to limit the surface ground movement. These measures included real-time remote settlement monitoring with readings published hourly in the vicinity of the TBM, application of higher-than-normal face pressure (more than 90% of the full ground overburden), robust muck reconciliation regime counter-checked amongst three independent measurement methods, regular testing of excavated spoil samples for each advance, selection of appropriate ground conditions and timely adjustment of the conditioning quantities injected to suit the changing geology during TBM advancement. With these measures, the surface movement was controlled during the parallel boring of the five tunnels to within the bounds of monitoring accuracy. This paper shares the lessons learnt in particular the success of the observational method and the implementation of relatively higher face pressures during TBM driving.

Keywords: Tunnelling, Settlement, Observational, Volume loss, PVD, Face Pressure

1 INTRODUCTION

Past experiences of TBM tunnelling in Singapore Marine Clay and Fluvial Sand suggest high surface settlement with volume loss of up to 3% [1, 2, 3] and occasionally reaching as high as 5% or beyond [4]. Even with the advancement in TBM technology and increased tunnelling experience in such geology, volume loss of up to 1.89% is still recorded in Thomson-East Coast Line, the most recent Mass Rapid Transit (MRT) tunnelling project in Singapore [5]. The Singapore Land Transport Authority (LTA) Civil Design Criteria recommends volume loss of 3% for impact assessment arising from EPB (Earth Pressure Balance) TBM (Tunnel Boring Machine) tunnelling of up to 6.6m excavated diameter in Kallang Formation [6].

In 2022, 5 nos. of tunnels with almost parallel alignment were launched almost simultaneously at the Eastern Region of Singapore and the ground settlement after the TBMs have passed was almost negligible or within the bounds of monitoring accuracy (less than 5mm). Towards the last 300m of the tunnel drive, the TBMs encountered Marine Clay and Fluvial Sand while undercrossing an operational pavement with stringent settlement criteria. The project site is situated on reclaimed land which generally comprises of Reclamation Fill and Kallang Formation (Marine Clay and Fluvial Sand) overlaying Old Alluvium. Prior to development of the area, Prefabricated Vertical Drains (PVD) with surcharge were installed in 1970s to accelerate the consolidation process. In addition to undercrossing an operational pavement in Marine Clay and Fluvial Sand, the TBMs had to

*Corresponding author: Grace.Hangadi@arup.com

tunnel through a cluster of PVDs which were installed some 40 years ago and left-in-place.

In order to mitigate the risks that could adversely affect the sensitive pavement, several measures were put in place including carrying out trials for each TBM to fine tune operating parameters, developing special tools to cut the PVDs and verifying through trial the ability of the TBM to cut cleanly without dragging, allowing only one TBM to under cross at a time, selecting closely-spaced surface settlement points and carrying out real-time (hourly) monitoring, etc. This paper will elaborate on some of these measures put in place to achieve safe tunnelling in Marine Clay and Fluvial Sand with negligible surface movement.

2 TUNNEL ALIGNMENT AND GEOLOGY

The 5 constructed tunnels are of the following excavated diameter: 1 no. of 12.3m, 2 nos. of 7.5m and 2 nos. of 6.7m.

The 12.3m diameter tunnel axis ranges from 13m to 35m deep below ground level whereas the 7.5m diameter tunnel axis ranges from 16m to 35m deep below ground level. The 6.7m diameter tunnels' depth at axis ranges from 17m to 26m.

The TBMs traversed through Old Alluvium, mainly of Class B and C for 1.3km followed by mixed face of Old Alluvium (OA) and Kallang Formation for 300m under an operational pavement. The simplified geological condition along the tunnel alignment is illustrated in Figure 1.

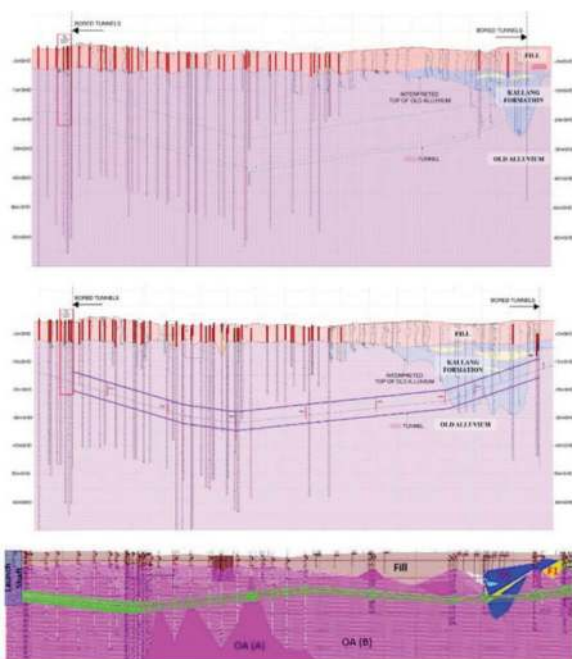

Figure 1. Geological profile along tunnel alignment (12.3m diameter – top, 7.5m diameter – middle, 6.7m diameter – bottom).

Due to limited surface access to carry out extensive and intrusive site investigation in the vicinity of the pavement, the interface between the Reclamation Fill/ Kallang Formation and Old Alluvium were inferred based on non-intrusive geophysical survey data and the available site investigation boreholes and Cone Penetration Tests (CPT) data in the vicinity. Figure 2 illustrates the geophysical survey data gathered along the tunnel alignments in the vicinity of the pavement.

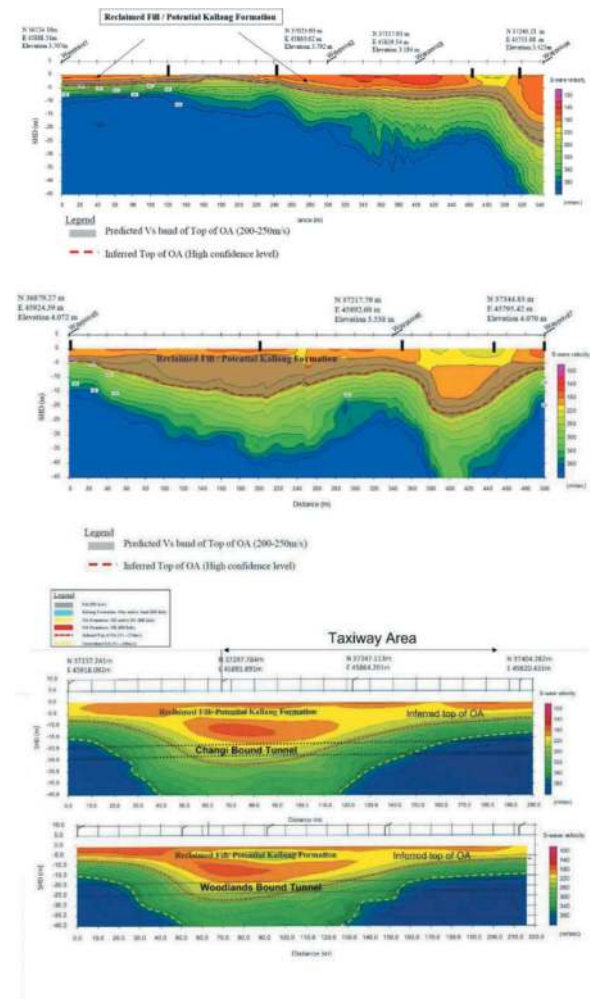

Figure 2. Geophysical survey data along tunnel alignments in the vicinity of the pavement.

The geotechnical design parameters for indication of ground properties can be referred from Table 1.

3 INSTRUMENTATION AND MONITORING

Conventional instruments such as surface settlement markers and borehole instruments which protrude above the ground surface and require access for reading collection could not be installed in the project site environment. Automatic Deformation Monitoring System (ADMS) comprising of optical prism and automated total station was adopted to monitor settlement of turf and non-pavement structures in real-time. Reflectorless ADMS which utilised an

automated total station to measure and track the alteration of a point on the surface with preset coordinates was adopted for monitoring of pavement in real-time.

The accuracy of reflectorless ADMS is influenced by monitoring radius, rain and sunlight glare. With 3m high total station, the monitoring accuracy is within 2mm for up to 100m of monitoring radius. During light rain, the monitoring radius is reduced to 80m for similar accuracy range, however, during heavy rain, reading may not be able to be taken. During early afternoon between 12noon to 4pm, high fluctuation of readings was observed due to sunlight glare.

3.1 Monitoring of pavement

The pavement was monitored in grid of 15m by 7.5m as per required Standards set by the relevant

Authority of Singapore. In order to remain operational, the Standard requires the pavement to maintain longitudinal slope not exceeding 1.5%. However, considering the criticality of the pavement, strict settlement control was imposed and the settlement limit for the cumulative bored tunnelling works is set at 45mm with maximum rotation of 1/400.

4 TRIAL DRIVES

In order to verify the TBM operating parameters in similar ground condition as that under the pavement as well as to demonstrate that the cumulative settlement achieved during tunnelling is less than the settlement limit, trial drives were conducted for each TBM prior to undercrossing of the pavement. During the trial

drive process, the instrumentation readings were reviewed closely and frequently and TBM operating parameters were adjusted and fine-tuned according to the actual tunnelling performance. The trial also considered the materials and mix proportions of the ground conditioning.

4.1 *Muck testing and soil conditioning*

During the trial drives of approximately 35m long, the TBMs transitioned from the stronger Old Alluvium into weak and more permeable Kallang Formation. As the TBM approached the geological transition, muck testing was carried out at every ring (approximately 1.6m to 2m interval) to monitor the change in density, slump as well as water content. The frequent muck testing provided an indication on the actual ground type being tunnelled through and enabled timely adjustment of soil conditioning. In Old Alluvium, combination of 40% foam and 10% dispersant was adopted to minimise cutter wear and at the same time, adequately workable for muck disposal by conveyor belt. In mixed-face Old Alluvium and Marine Clay, combination of 15% foam and 20% encapsulator was adopted and adjusted to 10% foam and 30% encapsulator if Fluvial Sand was also observed. In Kallang Formation, only encapsulator was adopted and the injection ratio ranged from 15% to 30% depending on the percentage of Fluvial Sand observed. To mitigate risk of uncontrolled water inflow in the event of TBM encountering Fluvial Sand, water absorbing and binding polymer was made available on standby and to be injected into screw conveyor with injection ratio of 2% to 5%.

4.2 *Face pressure and muck reconciliation*

In Old Alluvium, the applied face pressure ranged between 40% to 50% of overburden pressure. As geological transition was largely interpreted and there was limited geological information due to access constraints, face pressure was stepped up gradually from 40% to 80% of overburden pressure as the TBM approached the theoretical transition zone.

During the trial drives, muck reconciliation was carried out for every ring and the applied face pressure was adjusted according to the muck reconciliation percentage and surface settlement monitoring. For 7.5m and 6.7m diameter tunnels, the muck reconciliation was carried out by muck skip count and belt weigher in the tunnel or weighing bridge/gantry crane at the shaft. For the 12.3m diameter tunnel, conveyor belt sensors and muck pit volume were utilised for reconciliation. Rather than solely basing the over-excavation ratio on the permissible limit of 10% (for tunnel diameter more than 10m) and 15% as stipulated by the Building Control Authority, the trend of the muck reconciliation percentage was also considered in the face pressure and backfill grout pressure adjustment.

During the undercrossing of the pavement, the TBM was climbing up at a gradient of 3.5% to 5% and

the ground cover to the tunnel crown was approximately 12m for the 12.3m diameter tunnel and 15m for the 7.5m diameter tunnels. Low ground cover and low undrained shear strength of Marine Clay in the area were a concern for adopting a high face pressure and backfill grout pressure in view of potential blow-out or excessive heave. The Recommendations for Face Support Pressure in Soft Ground [7] suggests that the applied pressure at tunnel face should be kept below 90% of the vertical overburden pressure at tunnel crown. Past experiences in Singapore [4] demonstrate that higher face pressures in the range of 90% to 120% of vertical overburden pressure have been used. However, these tend to cause higher settlement sometime after the passage of the TBM. Therefore, it was decided not to exceed 100% overburden pressure, however, when necessary, depending on actual real-time surface settlement monitoring readings and over-excavation trend, the face pressure could be increased to beyond 90%. The maximum face pressure applied during tunnelling under the operational pavement was 92% of vertical overburden pressure for the 7.5m diameter tunnel and 89% for the 12.3m diameter tunnel. The face pressures were reviewed for each ring and adjusted as required. Considering the limited ground cover, the soft Marine Clay with OCR close to 1 and the stringent settlement limit, the close review of muck properties, muck reconciliation trend and real-time instrumentation readings were crucial factors in dynamically adjusting the TBM operating parameters. With this approach, despite the significant challenges the measured settlement was maintained below 5mm at the operational pavement. As of today, one year after completion of bored tunnelling works, there is no significant post-tunnelling settlement observed.

5 TUNNELLING THROUGH PVDs

Tunnelling through PVDs poses risk of excessive settlement arising from downdrag during cutting and entanglement of the PVDs with the cutting tools of the TBM [8]. To mitigate the risk, a trial was conducted during the design stage of the TBM to verify suitability of the cutting method and devices. The setup of the trial is illustrated in Figure 3. During the trial, comparison between tensile strength of the PVD and friction between PVD and ground which holds the PVD from being dragged during cutting, observations on cuts made on PVD, pulling force and surface settlement during cutting were made. The proposed PVD cutting tools with Castolin coating shown in Figure 4 were also tested. These special cutting tools were installed at some of the ripper, scrapper and bucket locations of the cutting wheel immediately prior to entering the zone influencing the operational pavement.

PVDs were encountered as anticipated during the TBM drive in Kallang Formation, however, no significant ground movement or variation in TBM parameters was observed when tunnelling through the PVDs. Some of the PVDs were observed in the

muck being discharged and some were found in the TBM cutterhead chamber during cutterhead intervention (CHI) as shown in Figure 5.

Figure 3. PVD cutting trial setup.

Figure 4. PVD cutting tools – fresh cutters (left), worn cutters (right).

Figure 5. PVD encountered during tunnelling.

6 DISCUSSIONS AND LESSONS LEARNT

The control of ground movement when tunnelling through Kallang Formation and the interface of Old Alluvium mixed with Kallang Formation has been a challenge in Singapore. This is partly as a result of the nature of the soils forming the Kallang Formation namely very weak Marine or Estuarine clay as well as the saturated and permeable fluvial sand that is often present in the form of discrete lenses making

detection through site investigations difficult. Sections of Singapore MRT projects such as North-East Line, Circle Line, Downtown Line and Thomson East Coast Line have been bored through this medium, with greater understanding being gained and tunnelling performance improving progressively.

The key improvements can be attributed to: a) better identification of the Kallang Formation boundaries during site investigations, b) selection, trial and injection of ground conditioning materials and frequent testing of the excavated spoil and changing the type, quantity and mix ratio of the conditioning accordingly to suit, c) application of appropriate face pressure with minimum fluctuations, d) uninterrupted injection of backfill grouting during TBM advance using redundant ports in case of chokage, and e) more accurate methods of muck reconciliation. The frequent, accurate and timely monitoring of surface settlements is another contributory factor which promptly informs in the event any revision is needed to the applied face pressure. It is worthy to note that all cutter tool changes were carried out either in competent Old Alluvium or in a pre-installed grout block prior to entering the zone of the operational pavement. In the case of the five tunnels described in this paper, all the above-mentioned mitigation measures were put in place.

With the development in instrumentation and monitoring technology, real-time settlement readings using automated instruments with minimal physical installation and access could be taken in the vicinity of the TBM to enable timely adjustment of TBM face pressure. Applied face pressure plays a critical role in controlling ground movement directly above and ahead of the tunnel face. Whereas over the length of the shield, the settlement is controlled by the injection of bentonite slurry into the annulus and behind the shield by the backfill cementitious grout. The injection pressures of bentonite slurry along the shield and backfill grout depend on the magnitude of the applied face pressure and therefore, indirectly influenced by the applied face pressure. For all the five TBMs, the face pressure applied in Kallang Formation did not exceed the overburden pressure though it was close. As the pressures applied was closed to overburden pressure, timely adjustment of the pressure, especially at the geological transition, was crucial in controlling the ground settlement.

The experience from North-East Line showed that at certain times face pressure was increased to 120% of overburden pressure and the corresponding volume losses were higher compared to when the face pressure was kept within the range of 80% to 100% of overburden pressure. Similar experiences were noted in a project in South Korea [9] and the optimal face pressure was numerically demonstrated to be below full overburden pressure. That study also reported an increase in long-term consolidation settlement with the adoption of high face pressures.

Singapore LTA Civil Design Criteria recommends a volume loss of 3% for impact assessment arising

from EPB TBM tunnelling in Kallang Formation. In the light of recent experiences, should this be considered as over-conservative? There is no clear answer to this question since the bigger challenge is knowing exactly where the boundary of Kallang Formation and its constituent members especially Fluvial Sand are located. Furthermore, it also depends on the capability of the tunnelling equipment as well as the experience and competency of the tunnelling crew. For this project, a volume loss of 1% (for the 12.3m diameter tunnel) and 1.5% (for the 7.5m and 6.7m diameter tunnels) in Kallang Formation was assumed during the design stage and for the setting the settlement limit or work suspension levels which proved to be satisfactory.

The lessons learnt from this project to control ground settlement in both Kallang Formation and at the mixed interface between Old Alluvium and Kallang Formation to negligible magnitude are summarised as follows:

- Comprehensive site investigation to locate the boundary of Kallang Formation as well as Fluvial Sand.
- Incorporating additional features on the TBM for smooth injection of different types of ground conditioning to suit Old Alluvium, Marine Clay, Fluvial Sand and a mixture thereof.
- Allocating sufficient ports with redundancy for injection of: ground conditioning to tunnel face, excavation chamber and screw conveyor; bentonite slurry around the shield; and backfill grout behind the shield.
- Taking frequent soil samples at screw conveyor discharge and testing (preferably at each ring when approaching geological transition) to identify the changes in ground type.
- Measuring real-time ground movements in the zone of influence of the TBM.
- Changing the face pressure as necessary based on ground settlement and over-excavation trends.
- Accurate muck reconciliation.
- Setting up a clear protocol and following up with good communication among tunnel crew and supervision team.

7 CONCLUSIONS

In conclusion it can be stated that with appropriate control measures, it is possible to achieve negligible surface movement while tunnelling in Singapore Kallang Formation consisting of Marine Clay and Fluvial Sand. The special tools installed on the TBM cutterheads were designed and trialled to cut PVDs cleanly without dragging down and the tools performed as expected. The key lessons learnt from the project are summarised in the paper.

ABSTRACT: To cope with the high population density and intense commercial activities in China's metropolitan cities, multifunctional large-diameter tunnelling projects have sprung up in recent years as examples of safe and efficient underground transportation infrastructure. Since 2006, when two of the world's largest Mix-shield machines ($\Phi 15.43\text{m}$) were used in the Shanghai Yangtze River Tunnel Project, dozens of mega tunnel projects with diameters exceeding 14m have been completed in China up to now. On the basis of accumulated experience in real projects, mega-diameter tunnel boring machines have realized long-term improvements in design and manufacturing, and the technology in this field has also developed significantly in terms of safety and performance. This paper focuses on one of the key technologies in this field – long-term technology development of the accessible cutting wheel, in terms of its upgrading with regard to reliability, pressure resistance and sealability. This paper analyses the technical challenges presented by different geological conditions to the design of the cutting wheel through project examples in Shanghai, Nanjing, Wuhan, Shantou, Jiangyin, Jinan and other places, as well as the solutions and technological innovations.

Keywords: Tunnel project, Ultra-large Diameter Shield, Accessible Cutting Wheel

1 PREFACE

Since the 1990s, because of the rapid development of China's transportation infrastructure construction, the shield method has been used widely for construction on large-scale urban subway projects. Since 2000, railway and highway tunnel construction also began to use the large shield method, therefore the shield tunnel diameter continues to increase, the tunnel one-time excavation distance continues to extend. Many tunnels go through rivers, lakes and oceans, the depths are ever-increasing, which poses a challenge to construction safety. In 1994, Herrenknecht designed a 14.2m accessible cutting wheel for the Elbe Tunnel with complex hydrogeology in Hamburg. And in 2006, Herrenknecht applied the accessible cutting wheel technology to two 14.43m Mix-shield machines in the Shanghai Yangtze River

Tunnel project. Since then, the accessible cutting wheel has been adopted in the Nanjing Yangtze River Tunnel, Wuhan Sanyang Road Tunnel, Shantou Suai Tunnel, Jinan Yellow River Tunnel, Jiangyin Jingjiang Yangtze River Tunnel and so on, with the rapid development of the technology.

Accessible cutting wheel means that the internal atmospheric pressure space in the cutting wheel for the operation personnel to carry out the cutter tools changing operation is created by increasing the thickness of the cutting wheel on the basis of the conventional cutting wheel. All the cutter tools that need to be replaced in this space are installed in the cutter house, and the gate set in the cutter barrel seals the atmospheric pressure space in the cutting wheel from the external environment. Thus, the cutter tools inside the cutting wheel can be replaced under normal pressure.

Table 1. The comparison between accessible cutting wheel and conventional cutting wheel.

	Accessible cutting wheel	Conventional cutting wheel
Structure	The cutting wheel is a closed box structure with complex structure and certain air tightness	The cutting wheel is simple in structure and easy to maintain
Cutter tool	Higher manufacturing precision of the cutter house and barrel, and the cutter tools can be replaced under normal pressure	Cutter tool installation structure is simple, easy to install
Scope of application	Suitable for geological environments with high water pressure or unstable formations	The ground adaptability is good
Cutting tool changing	Cutter tool change can be achieved under normal pressure, short tool change time, high efficiency, low tool change cost	Cutter tool replacement requires pressure operation, low tool change efficiency, high risk, and high tool change cost

Table 2. Cutting wheel layout.

Layer	Tool Type	Height
1st layer	Replaceable ripper and center tool	210mm
2nd layer	Advance ripper	190mm
3rd layer	Replaceable scraper	180mm
4th layer	Standard scrapers and bucket	160mm

2 ACCESSIBLE CUTTING WHEEL IN SOFT GROUND

2.1 The accessible cutting wheel technology of Herrenknecht's large-diameter Mix-shield was introduced to China for the first time on the Shanghai Chongming Yangtze River Tunnel Project (Figure 1). The total length of the tunnel is about 7,470m, and the main strata are primarily silt and sandy silt. The cutting wheel structure adopts the structural form of 6 star-shaped main arms and 6 triangular auxiliary arms, with an excavation diameter of 15.47m and an opening ratio of about 28%.

Since the Shanghai Chongming Yangtze River Tunnel project, other projects represented by this cutting wheel type include the Nanjing Yangtze River Tunnel (Figure 2), Shanghai Changjiang West Road Tunnel, Hangzhou Qianjiang Road Crossing Tunnel, Shanghai A30 Tunnel and Shanghai Beiheng Road Crossing Tunnel (Figure 3), among others.

2.2 The total length of the Nanjing Metro Line 10 Yangtze River-Crossing Tunnel is 3,600m, with

Figure 1. Shanghai Chongming Yangtze River Tunnel project.

Figure 2. Nanjing Yangtze River Tunnel project.

Figure 3. Shanghai Beiheng Road Crossing Tunnel project.

a segment inner diameter of 10.2m and outer diameter of 11.2m, single-hole two-line surface. Minimum curve radius 1,500m, with the maximum longitudinal slope of 28%. Tunnel maximum overburden is 37m, while the minimum overburden is 9.4m (receiving shaft), the overburden is generally between 14-18m in the middle river section. The stratum encountered by the tunnel is mainly clay, silt, fine sand, coarse gravel and conglomerate and gravelly mixed soil.

After experiencing the construction process of the Shanghai Chongming Yangtze River Tunnel and Nanjing Yangtze River Tunnel, the design was further developed in terms of safety and efficiency of tool change method. The Herrenknecht design team successfully designed an accessible cutting wheel for this project, which is suitable for the range of 11m-12m segment outer diameter.

Compared with the Shanghai Chongming Yangtze River Tunnel and Nanjing Yangtze River Tunnel, the design of the cutting wheel is limited by the space

Figure 4. Nanjing metro line 10 crossing the river section.

layout, and its structural type is in the form of 5 main arms and 5 small auxiliary arms, with an excavation diameter of 11.64m and an opening ratio of 35% (Figure 4).

For the kind of cutting wheel type as accessible cutting wheel suitable for the segment outer diameter of the 11m-12m range there are representative projects such as the Beijing-Zhangzhou High-Speed Railway Qinghuayuan Tunnel (Figure 5), Hangzhou Wangjiang Road River Crossing Tunnel and the Sutong GIL Tunnel (Figure 6).

Figure 5. Beijing-Zhangzhou High Speed Railway Qinghuayuan.

Figure 6. Sutong GIL integrated pipe corridor.

2.3 The main geology encountered in the Jinan Yellow River Tunnel is silty clay, fine sand, calcareous nodules and fully weathered diorite.

In view of the geological characteristics of the project, summarizing the experience with accessible cutting wheels in past tunnel construction, combined with the 6 main arms of the accessible cutting wheel in the Shanghai Chongming Yangtze River Tunnel and other similar projects, as well as the large opening ratio of the accessible cutting wheel in Nanjing Metro Line 10 and other similar projects, the cutting wheel structure of this project is designed with 6 main arms and 6 auxiliary arms, with an opening ratio of about 50% (Figure 7).

Figure 7. Yellow River Tunnel in Jinan.

At present, the accessible cutting wheel type is mainly applied in the range of segment outer diameter 13m-17m, the representative projects for this cutting wheel type also include the Nanjing Five Bridges River Tunnel (Figure 8), Hangzhou Gengshan East Road Tunnel (Figure 9), Hangzhou Xiasha Road Tunnel, GuangZhan Railway Zhanjiang Bay Tunnel (Figure 10), and Jiangyin Jingjiang Yangtze River Tunnel (Figure 11).

Figure 8. Five Bridges Clip River Nanjing Tunnel.

Figure 10. Zhanjiang Bay Tunnel of Guangzhou-Zhan High Speed Rail.

Figure 11. Jianguyin Jingjiang Yangtze River Tunnel.

3 ACCESSIBLE CUTTING WHEEL UNDER COMPLEX GEOLOGY

3.1 The total length of the Qingdao Jiaozhou Bay 2nd Sea Crossing Tunnel is about 14.36km, with a shield section of 3.25km. Three tunnels, namely two main tunnels and one service tunnel respectively. The main tunnel segment has an outer diameter of 15m and a width of 2.1m. 88% of the tunnels are in rocky terrain for the whole face, and the remaining part is in complex geology. The rock strata include tuff, andesite, breccia, orthogneiss and long quartzite. Soft soils are clayey soft soils and silty clays. Several fracture zones or transition zones are widely distributed.

For this project profile and its geological conditions, the optimized design structure based on the summary of the past composite cutting wheel, this accessible cutting wheel is 6 main arms and 6 small auxiliary arms, the opening ratio 30% (Figure 12).

Figure 12. Qingdao Jiaozhou Bay 2nd Sea Crossing Tunnel.

Other projects represented by this cutting wheel type are the Wuhan Sanyang Road Tunnel (Figure 13), Foguan Intercity Shiziyang Tunnel (Figure 14), Nanjing Jianning West Road Tunnel (Figure 18), Shantou Bay Tunnel of Shantou Railway (Figure 19) and Wuhu Yangtze River Tunnel (Figure 20).

Figure 13. Wuhan Sanyang Road Tunnel.

Figure 15. Shantou Su'ai Tunnel.

Figure 19. Shantou Bay Tunnel.

Figure 16. Nanjing Heyan Road Tunnel.

Figure 20. Wuhu Yangtze River Crossing Tunnel.

Figure 17. Shenzhen Mawan Sea Crossing Tunnel.

3.2 Wuhan Metro Line 8 Yangtze River Crossing Tunnel is the fourth river crossing subway line in Wuhan. The tunnel length is 3,186m, the distance of crossing the Yangtze River 1,500m, tunnel excavation diameter 12.5m.

The tunnel crosses both sides of the Yangtze River for a total of about 2100m through the upper part of the stratum of soft soil (4-2 to 4-2b), the lower part of the layer of fine sand, less abrasive to the tools; in the middle section of the river crossing for the upper part of the layer of fine sand, the lower part of the composite strata such as weathered rock, including: about 495m of Q4 rounded conglomerate; about 1370m of (15b-1) strong weathering conglomerate; about 705m of (15b-2) weakly cemented conglomerate; about 430m of (15b-3) moderately cemented conglomerate; and three kinds of rock layers overlap the top and the bottom (Figure 21).

As the main stratum of the river central section is soft at the top and hard at the bottom, and the range of weathered rock in the lower part is relatively small, a mixed configuration of disc cutter and rippers is adopted, which means that it can handle the long-distance excavation in the soft ground layer,

Figure 21. Distribution of geological conditions of Wuhan Metro Line 8.

Figure 22. Wuhan Metro Line 8 River-Crossing Section.

and also effectively solve the problem of the weathered rock layer in the smaller range.

4 TARGETED INNOVATION

4.1 Layered design of the cutter tool

Based on the analysis of geological conditions of coarse gravel sand and cobble-gravel mixed soil in the Nanjing Metro Line 10 Yangtze River Crossing Tunnel, and the research on the wear condition of the cutting wheel in similar geological conditions of the past projects, the height of the cutting tools is specially designed, and the layout of four layers of cutting tools is adopted.

4.2 Further development of accessible cutting tool change

An anti-disorder device for detecting the cutting tool is provided on the replaceable cutting tools. Additional signs and devices are installed to prevent the cutting tool from being assembled at the wrong angle.

Figure 23. Improved schematic of the atmospheric tool change.

4.3 Video monitoring system for excavation chamber and air cushion chamber

It was the first time for the Nanjing Metro Line 10 Yangtze River Crossing Tunnel that a camera device was applied to the monitoring of the tunnel surface and cutter tool to facilitate the checking and observation of the condition of the tool and surface. The detection technology can accurately and safely monitor the angle, depth and distance of the target object. Accurate images can be recorded, stored and retrieved (Figure 24).

Figure 24. Camera peering into tool conditions.

The video monitoring system for excavation and air cushion chamber has been widely used on large diameter shield machines in subsequent projects since the Nanjing Metro Line 10 Yangtze River Crossing Tunnel, such as the Wuhu Yangtze River Crossing tunnel, Nanjing Jianning West Road, Jiangyin Jingjiang Yangtze River Tunnel and Qingdao Jiaozhou Bay 2nd Sea Crossing Tunnel.

During the advancing process of the shield tunneling machine, most of the cutting tools on the cutting wheel can be easily inspected using the relevant functions of the accessible cutting wheel, but the wear of bolt mounted scrapers and bucket lips cannot be detected. In addition, sometimes when the shield machine is stopped, it is necessary to check the excavation surface in front of the cutting wheel to observe whether there are foreign objects inside the excavation face and whether the excavation face is stable. When carrying out maintenance work for shield tunnelling machines in the excavation and air cushion chambers, it is also necessary to monitor the operation of personnel in the excavation and air cushion chambers to

ensure safety. Therefore, the shield tunnelling machine for this project is equipped with a set of pressure-resistant, waterproof and self-illuminated telescopic cameras above the excavation chamber, and a set of pressure-resistant, waterproof and self-illuminated fixed cameras are installed above the air cushion chamber. The telescopic camera can extend to the back of the cutting wheel to observe the steel structure of the cutting wheel, the side tools of the main arm of the cutting wheel, the bucket lips, and the tunnel face. The fixed camera observes the air cushion chamber.

Figure 25. Schematic of the working process of the telescopic camera in the excavation bin.

During the construction process of the Nanjing project, the telescopic camera was used to observe the structure of the cutting wheel, the tunnel face and the clogging situation on the cutting wheel. The camera imaging was clear and the effect was good (Figure 26).

Figure 26. Picture taken by telescopic camera.

4.4 High-flow flushing system of cutting wheel center

To reduce the probability of mud cake formation in the cutting wheel center for the accessible cutting wheel, a high flow center flushing system is used (Figure 27).

- 6 center flushing nozzles are set to flush the center of the cutting wheel
- 6 center flushing nozzles between the main arms of the cutting wheel, flushing outward toward the center of the cutting wheel
- The independent center flushing pump has a maximum flow of 920m³/h and a maximum pressure of 16.2bar.

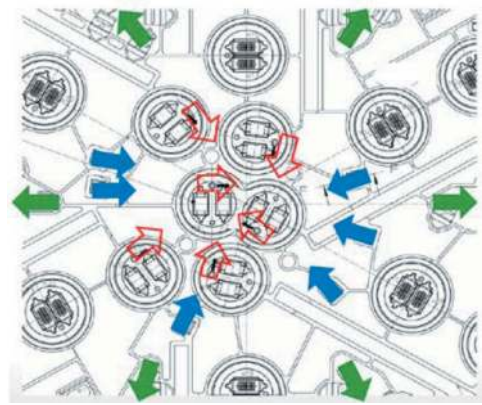

Figure 27. Center flushing nozzles arrangement.

The center flushing system in the accessible cutting wheel with disc has been upgraded on the basis of the center flushing system used for the Nanjing Yangtze River Crossing Tunnel and other projects, as well as of the center flushing system used for the Jinan Yellow River Crossing Tunnel and other projects, which has been optimized based on the anti-clogging measures of the center cutter and to realize the flushing targeted at the center disc.

The center area of the cutting wheel is designed with a high flow mud and water flushing cycle:

- Flushing port to realize sub-area control, to ensure the flushing flow rate
- 6 center flushing ports
- Flushing between 6 main arms
- 6 cutter house flushing ports
- Center flushing pump flow: 1000m³/h

4.5 Disc rotation monitoring system

The disc cutter rotation monitoring system (DCRM) is an independent monitoring system. The disc rotation monitoring device is installed on the fixture of each disc, which can continuously monitor the rotation and temperature status of the disc and display the status of the disc in the main control cabinet.

The goal is to monitor non rotating cutters and improve efficiency in cutter maintenance.

Downtime required for manual inspection of disc cutters can be reduced.

The overall downtime by maintenance could be minimized. This allows for a better tool management plan, facilitates full utilization of the disc cutters service life and makes the entire tunnel boring process more efficient. In addition, damages or secondary wear on adjacent disc cutter housings or cutting wheel steel structure could be reduced.

4.6 Disc cutter spacing

Herrenknecht carefully researched and analyzed the arrangement characteristics of the disc cutters and realized a disc spacing of 80mm, which plays

a certain role to break through hard rock and improve the excavation efficiency. The disc cutter spacing for the same size disc from 100mm to 80mm has gone through three stages:

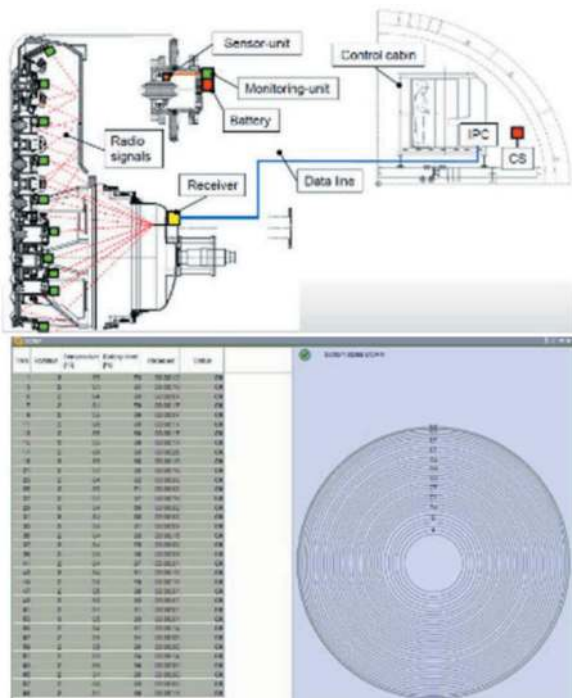

Figure 28. Schematic of cutter rotation monitoring.

Phase I: represented by Shantou Su'ai Tunnel Project and Nanjing Heyan Road Tunnel, the disc is designed with two axes and two blades, and the disc spacing is 100mm.

Phase II: represented by Shantou Bay Tunnel of Shantou-Shantou Railway and Nanjing Jianning West Road Tunnel, the cutter is designed as a double-axis with a disc spacing of 90mm.

Phase III: represented by Qingdao Jiaozhou Bay 2nd Sea Crossing Tunnel, with disc spacing of 80mm.

4 SUMMARY

The innovative features of Herrenknecht's accessible cutting wheel in the course of engineering practice in large-diameter shield tunnel projects are as follows:

- Installation of 19-inch single-edged disc (full-section rock formation)
- Mixed arrangement of accessible disc cutters and accessible ripper on the cutting wheel.
- Accessible disc and accessible ripper can be interchangeably mounted in the same housing.
- Real-time monitoring of disc rotation, temperature
- Wear monitoring of steel structure
- A safer aid for access, replacement and troubleshooting of accessible cutting tools in the cutting wheel
- Procedures for tool management, tool replacement planning and forecasting
- Improvement and enhancement of high flow flushing capacity and efficiency of cutting wheel centers
- Excavation chamber telescopic camera monitoring system

Accessible cutting wheel technology still needs to be further improved. For example, in the formation dominated by clay soil, by increasing the flushing system capacity or other measures to improve the flow of slag to increase the efficiency of excavation. In the hard rock stratum with relatively high rock strength, how to improve the rock breaking ability of the accessible cutting wheel and boring efficiency and how to improve the stability of the installation structure of the cutter house still need further study.

ABSTRACT: The complicated geological conditions and unreasonable tunneling parameters will cause the abnormalities or damage of the TBM tools and increase the tool consumption, which are adverse to the tunneling efficiency of TBM and the construction cost control. Based on the systematic description of the common failure modes of the TBM tool, we have studied and analyzed such tunneling parameters as total thrust, cutterhead speed and tool penetration, such geological parameters of different surrounding rocks as uniaxial compressive strength and quartz content, as well as the influence rule for the wear, abnormalities or damage of the tool. Taking Zhongtianshan Tunnel as an example, we have made statistics for and analyzed the tool consumption and failure modes, and proposed the specific optimization methods in terms of tool selection, inspection and maintenance. Finally, we have proposed that the configuration technology for the tools with adjustable clearance shall be further developed, to ensure the rock-breaking efficiency of tools under different geological conditions. In the meantime, we will intensify the R&D and application of the new tool condition monitoring system strongly adaptive to the work environment of TBM.

Keywords: tunnel, TBM, hob, complicated geology, tunneling parameters, tool failure, tool wear

1 INTRODUCTION

Tools are the core part of a rock tunnel boring machine (TBM), so their performance and type selection are directly related to the construction efficiency of TBM and also influence the economic cost of engineering projects^[1,2]. According to the statistics, the TBM downtime caused by inspection and tool replacement and tool consumption cost under complex geological conditions separately account for about 15% and 30% of the total construction time and cost of TBM^[3]. The failure modes and causes of tools are analyzed, and it is particularly important to conduct research into the optimization measures in terms of type selection of tools, tunneling parameter control, etc.

Jonak, et al^[4] held that the prediction for TBM cutter load and life is crucial for TBM cutter design

and maintenance, and they studied the feasibility of using a multilayer perceptron neural network as tool for predicting. Moosazadeh, S, et al^[5] did the research that the impact to EPB-TBM cutter life, reliability and maintainability from the mixed geological condition and underground water, based on on-site data of Tabriz urban railway projects. Farrokh, E.^[6] summarized different methods for TBM cutter life and wear in soft soil formations, and found the predictability of TBM cutter life by comparing the data of 23 TBM cutter projects in soft soiled formation around the world. It made great values for establishing the TBM cutter wear model that Mousapour, H, et al^[7] designed and constructed a tunnel boring machine laboratory simulator for measuring the TBM cutter wear rate, penetration rate, and torque. Karami, M, et al.^[8] believe that the volume of the plastic zone as well as the actual

*Corresponding author: skl_fhh@163.com

penetration depth in the highly fracturing rocks are also about 40% and 42% higher than in the slightly fractured rocks under applying the same TBM parameters.

Duan Zhiwei^[9] carried out field tests on domestic tools under different surrounding rock conditions based on the Xinjiang EN Tunnel Project and concluded that the wear rate of a disc cutter in the marlite stratum is 1/8 of that in diorite and granite strata; Wu Zhipeng et al.^[10] analyzed the failure modes and damage causes of tools by taking the TBM construction in a hydropower plant in Vietnam as an example and proposed that tool wear was primarily affected by tool quality, surrounding rock conditions, construction environment, etc.; Yan Changbin et al.^[11] established a prediction technique of tool consumption based on different surrounding rock conditions and different disc cutter diameters through the fit analysis of tool consumption data, and verified this technique through field tests in a water delivery tunnel project of Lanzhou water source region; Ebrahim et al.^[12] researched and analyzed the quantitative relation between different abrasion indexes and the amount of tool wear through the laboratory abrasion tests for disc cutters abrasion based on multiple cases of TBM tunnel projects; Yang Yandong et al.^[13] established a tool consumption evaluation method and a prediction model through theoretical formula model inference and regression analysis of field data and concluded that there was an exponential function relationship between the tool wear rate and the product of rock mass integrity coefficient and rock abrasion index. Xia Ming^[14] established a selection method of TBM tools and a method for repairing cutter heads and tools through field tests in the tunnel for the Hanjiang-to-Weihe River Water Diversion (HWWD) Project; Zhang Ling^[15] made a solution to the improvement of tool mounting structure through the cause analysis of TBM tool failure; Li Jinlin^[16] analyzed the consumption of TBM tools in the highly-abrasive hard rock section by taking the Qinling Tunnel Project of the HWWD Project as an example. Li Xiaoling^[17] analyzed the failure modes of tools for shield construction engineering and proposed measures for tool management and maintenance. The above-mentioned research was conducted into the evaluation and prediction of TBM tool wear, selection and repair of tools, etc. and was of guiding significance to the type selection, optimization and consumption evaluation of tools to some degree; however, there is a lack of systematic research on different failure modes of tools and influencing factors, so it is difficult to provide a solid basis for the optimization of tools and the establishment of management measures, and more engineering practice data will be combined for a more in-depth summation and analysis.

This paper analyzed the influencing factors of tool consumption by relying on the Qinling Tunnel Project of the HWWD Project, the Middle Tianshan Tunnel Project, etc. and producing the statistics on the consumption of tools under different geological conditions so as to analyze the deficiencies in the application and management of tools and made

recommendations on optimization to better solve the problems of type selection and management of tools and further to improve the construction efficiency of TBM and save construction costs.

2 COMMON FAILURE MODES OF TOOLS

2.1 Normal wear

When tools are used for rock breaking, the rock breaking efficiency is related to the edge width of cutter ring, and as the amount of cutter ring wear increases, the crushing area also increases and if such an increase reaches a certain range, the tunneling speed will be influenced; the wear that occurs in this case is called normal wear.

2.2 Chord wear

Chord wear is the phenomenon that the disc cutter ring wears into one or more chords, which is the most common mode of abnormal tool wear. The main causes of chord wear of cutter rings are as follows:

- 1) The cutter ring itself has a quality problem;
- 2) The tool bearing is damaged and fails to rotate;
- 3) Starting torque is not set properly during the tool assembly;
- 4) Seal assembly damage results in oil leakage of tools; meanwhile, rock slag enters the seal chamber, causing damage to the tool bearing;
- 5) Stones enter the gap between the disc cutter and the cutter housing, causing tools to be stuck;
- 6) Parameters are not properly controlled during the tunneling of equipment, resulting in overloading of bearings;
- 7) The tool bearing locks due to overheating.

2.3 Cutter ring breaking

During the process of tunneling, the cutter ring breaks from time to time. The main causes are as follows:

- 1) Geological conditions suddenly change or a foreign object is stuck between the cutter edge and the surrounding rock, resulting in local overloading of the cutter ring;
- 2) The interference fit between the cutter ring and the cutter body is too large;
- 3) The cutter ring has a quality problem;
- 4) When the cutter head starts rotating, the thrust force is too large or the advance rate is too fast, resulting in a sudden collision between the tool and rocks;
- 5) When the direction of TBM is adjusted, the magnitude of adjustment is too large.

2.4 Oil leakage of tools

There are plenty of causes for oil leakage of tools, mainly including:

- 1) Failure of tool bearing or seal assembly;
- 2) Inappropriate assembly or inclusion of foreign objects during the repair of tools;

- 3) Insufficient performance of the water spraying system for the cutter head, causing overtemperature of shafts and lubricating oil;
- 4) Overloading of tools caused by a sudden change in geological conditions or improper manual operation, so that bearing rollers peel off, while the peeled-off metal fragments and particles further cause the failure of seal assembly;
- 5) A quality problem of the seal assembly itself.

3 INFLUENCING FACTORS OF ABNORMAL DAMAGE TO TOOLS

3.1 *Analysis of the impact of tunneling parameters on the abnormal damage to tools*

3.1.1 *Total thrust force*

If tunneling is conducted through soft surrounding rocks or low-intensity surrounding rocks, only a small amount of total thrust force will be imposed on the cutter head to break rocks from the tunnel face. The load force on the tool is relatively small, the cutter ring wears slowly, and the service life of disc cutter bearings is relatively long in a low-load state; meanwhile, the temperature at which the tool can operate normally is relatively low, and the sealing elements are not prone to abnormal damage. If tunneling is conducted through high-intensity surrounding rocks, a relatively large amount of total thrust force should be imposed on the cutter head to break rocks from the tunnel face. The load force on the tool is relatively large, the cutter ring wears quickly, and in particular, the side disc cutter area undergoes more wear and tear; the disc cutter bearing rotates in a high-load state, causing its service life to be significantly shortened; the temperature at which the tool operates is relatively high, lubricating oil and grease are failure-prone at a high temperature, and sealing elements fail due to fracture after aging. As the intensity of rocks increases during the tunneling of a TBM, the higher the total thrust force required by the cutter head to break rocks from the tunnel face is, the larger the tool consumption is.

3.1.2 *Tool penetration*

If a TBM is used for tunneling under similar geological conditions and at the same speed of rotation, the thrust force applied to the cutter head must be increased to get larger tool penetration and enhance the tunneling speed. As the tool penetration increases with the thrust force, i.e. the force applied to the tool increases to cause the cutter ring to undergo plastic deformation to different degrees and leave its edges twisted or broken, the wear of cutting ring increases; the bearing load is too large and even overloading occurs, resulting in abnormal damage, such as large-spot pitting, peeling and spalling.

3.1.3 *Speed of cutter head*

During the tunneling of a TBM, the tool penetration and the speed of cutter head are typically increased to improve the tunneling speed. The penetration of cutter

head curvilinearly varies with the thrust force of cutter head, and when this thrust force reaches the rated thrust force, the tunneling speed can further increase only by improving the speed of cutter head. After the speed of cutter head increases, the linear distance of the tool rotation per unit time increases accordingly. Firstly, the rotation of tools speeds up, the edge is prone to breaking after overloading of the cutter ring, and the abnormal consumption of tools increases; secondly, the tool temperature significantly rises, leaving seal assembly, lubricating oil and grease prone to failure.

Taking the Qinling Tunnel Project of the HWW D Project as an example, (1) the hydraulic cylinder thrust of a TBM is controlled at 280~320bar: when the tool penetration is 2mm/r, the rate of abnormal damage to tools is 8.83%; when the tool penetration is 4mm/r, the rate of abnormal damage to tools is 12.22%; (2) the TBM penetration is controlled at 3~4mm/r: when the hydraulic cylinder thrust of a TBM ranges from 260bar to 280bar, the rate of abnormal damage to tools is 11.54%, and when the hydraulic cylinder thrust of a TBM varies between 280bar and 320bar, the rate of abnormal damage to tools is 12.22%. It can be seen that the rate of abnormal damage to tools is directly proportional to the tool penetration and the TBM thrust force, but it is very difficult to accurately analyze the degree of influence of a factor because there are many factors that cause abnormal damage to tools. In the construction of a TBM, full consideration shall be given to the impact of different tunneling parameters, geological conditions and type selection of tools on the abnormal damage to tools as well as the impact on the TBM tunneling efficiency.

3.2 *Analysis of the impact of geological conditions on the tool wear*

Based on the statistics on the actual replacement of tools in a TBM interval of the Qinling Tunnel Project of the HWW D Project, the impact of the uniaxial compressive strength (UCS) of different surrounding rocks and the quartz content on the tool wear is analyzed through the comparison of tool consumption under different conditions.

3.2.1 *UCS of surrounding rocks*

When the quartz content is fixed, an interval in which the quartz content is 70% is taken as an example (Figure 1), and it can be seen from Figure 1 that the higher the uniaxial compressive strength is, the larger the tool consumption is, the higher the degree of influence on the tool wear is.

3.2.2 *Quartz content of surrounding rocks*

When the uniaxial compressive strength is fixed, an interval in which the uniaxial compressive strength is 150MPa is taken as an example (Figure 2), and it can be seen from Figure 2 that the tool consumption is positively correlated to the quartz content and the rate of change gradually increases.

Figure 1. Curve of uniaxial compressive strength - tool consumption relation.

Figure 2. Curve of quartz content - tool consumption (the vertical axis - tool consumption (pcs./m), the horizontal axis - quartz content (%)).

Combined with the engineering statistics of Qinling Tunnel Project and the above-mentioned analysis results, the relation curve of uniaxial compressive strength, quartz content and tool consumption is drawn (Figure 3).

From the above Figure 3, it can be judged, on the whole, that there is an approximately linear relationship among the uniaxial compressive strength, the quartz content and the tool consumption to deduce the tool consumption under different conditions (as shown in Table 1), which can be used for tool replacement and management in the process of similar TBM project in the future. In addition, however, tool consumption is also affected by multiple factors, and in special cases, such as collapse of tunnel face and rock burst, tool consumption will also be greatly influenced. For example, the first peak between K28-29: this is a transition section between quartzite and

granite, where the rocks on the tunnel face are broken, joints are developed, and a lot of abnormal damage to tools occurs, resulting in a deviation from the uniaxial compressive strength and the quartz content and trend; peak after K34: after K33+860, the burial depth of the tunnel exceeds 1,300m, the frequency of rock bursts is relatively high, and the rock bursts are dominated by moderate rock bursts or above, and strong rock bursts occasionally happen, leading to an irregular law of tool consumption.

4 ENGINEERING CASE ANALYSIS

4.1 Middle tianshan tunnel

Middle Tianshan Tunnel is located in the east segment ridge area of the mid-range of the Tianshan Mountains between Toksun County and Hoxud County and is the controlled project of the new Turpan-Korla section of the Southern Xinjiang Railway. The tunnel, with a total length of 22,467m, passes through different strata, mainly including metamorphosed sandstone, granite, and schist with marble. The inlet section was constructed with 8.8m-dia. open-type TBMs, and the surrounding rocks of Classes II and III approximately accounted for 78.8% of the total tunnel length (Table 2).

4.1.1 Tool consumption

1) Analysis of total tool consumption

The TBM cutter head is configured with a total of 6 single disc center cutters, 62 frontal disc cutters, 3 side disc cutters and 2 double-edged reaming cutters, all of which are made of 17" disc cutters; in addition, 8 edge buckets and 4 front buckets are provided (see Figure 9). In the process of TBM construction, a total of 4,407 frontal disc cutters, 445 side disc cutters, 154 center cutters and 32 reaming cutters were replaced. For the statistics on the replacement reasons of tools, see Table 3.

Through study and comparison, the TBM tunneling parameter control of the Middle Tianshan Tunnel is basically reasonable, and two major

Figure 3. Construction chainage - uniaxial compressive strength, quartz content and tool consumption (the left vertical axis - USC (mpa), the right vertical axis - quartz content (%)/tool consumption (pcs./m), the horizontal axis - construction chainage).

Table 1. Tool consumption for different intensities of surrounding rocks and different quartz contents (pcs./m).

Uniaxial compressive strength (MPa)						
Quartz content (%)	75~100	100~125	125~150	150~175	175~200	200~230

Figure 4. Schematic diagram of tool configuration.

reasons for the large abnormal consumption of tools are as follows: 1) TBMs passed through 4 dense zones of granite joints (with a total length of over 600m) and 1 fracture zone of dense sandstone joints with schist developed in the quartz vein in total. The hardness of surrounding rocks was uneven, joints were well developed, the

direction of principal stress was basically consistent with that of tunnel axis, and large rocks frequently collapsed, causing tools to be smashed and edges to be broken; meanwhile, tools were stuck between large stones and failed to rotate, causing chord wear as well as the failure of tool bolts, oil leakage of tools, and other forms of damage; 2. The TBM passed through the 2,755m-long complex tunnel section of the Variscan granites. In this section, geological conditions were extremely complex, the tunnel face and the tunnel walls on both sides underwent rock bursts and collapse from time to time, and steps and boulders were formed on the tunnel face, causing the cutter head to impact on boulders in the process of rotation and further causing the abnormal damage to tools, and the tool consumption increased by geometric progression.

- 2) Consumption of frontal and side disc cutters
A total of 2,367 frontal and side disc cutters were normally replaced, accounting for 48.8% of the total consumption and a total of 2,485 frontal and side disc cutters were replaced due to abnormal causes, such as chord wear, oil leakage, and cutter ring fracture, accounting for 51.2%, and the abnormal replacement of tools greatly affected the tunneling progress of TBMs.
- 3) Center cutter consumption
A total of 119 center cutters were normally replaced, accounting for 77.4% of the total consumption, and 35 center cutters were replaced due to abnormal causes, accounting for 22.6%.

Table 3. Statistics for replacement reasons of tools.

Replacement reason	Frontal and side disc cutters		Center cutter		Reaming cutter	
	Qty. (pcs.)	Percentage (%)	Qty. (pcs.)	Percentage (%)	Qty. (pcs.)	Percentage (%)

4.1.2 Analysis of tool failure modes

1) Tool wear

Tool wear accounted for nearly 3/4 of the tool failure, among which normal wear of tools accounted for 48.8%, and this type of tool replacement should be arranged as a whole and tools should be replaced in bulk, with the aim to minimize the impact on tunneling; chord wear of tools accounted for about 25.1% of the tool failure, and it would be very difficult if chord wear occurred in a tool but was not timely found, and in this case, its failure cause could be accurately identified only after the tool subjected to chord wear was dismantled and was fully tested.

2) Oil leakage of tools

The oil leakage of tools was also common, accounting for 10% of the tool failure.

3) Fracture or peeling of a retainer ring

A retainer ring peeled off from time to time during construction, accounting for 1.9% of the total tool failure. The main cause of this situation was improper installation, poor welding, being broken by stones, or peeling of the retainer ring.

4) Loosening, falling, breaking, and stripping of tool bolts

Tool bolts were also subjected to loosening, falling, breaking and stripping frequently, accounting for 8.1% of the tool failure. The causes of these tool bolt problems mainly included degradation of tool bolt performance, improper installation of tools, quality problems of bolts, failure of the pretension torque of tool bolts to reach the given value, etc.

4.2 Tunnels in the HWWD project

The length of the Qinling Tunnel in the HWWD Project is 81.779km, and by taking a lot located in the high and middle-altitude mountainous zone of the ridge area of the Qinling Mountains and the low and middle-altitude mountainous area south of the Qinling Mountains as an example, the total length of this lot was 18.717km and its elevation ranged from 1,050m to 2,420m, the maximum burial depth of the tunnel was about 2,000m, and the quartzite, granite and diorite through which the tunnel passed accounted for more than 75% of the total surrounding rocks, among which the quartz contents in the quartzite, granite and diorite could be up to 97%, 30% and 18%, respectively; in the lot, the maximum rock intensity was up to 320MPa, so 8.02m-dia. open-type TBMs were used for construction. 17" center disc cutters, 20" frontal disc cutters and side disc cutters were mainly used for rock breaking; the tool layout is shown in Figure 5:

4.2.1 Analysis of tool consumption

In the HWWD Project, tools were badly worn during the tunneling due to high uniaxial compressive strength, high wear value and high quartz content,

Figure 5. Schematic diagram of tool layout.

resulting in high tool consumption and frequent replacement of tools. Tool consumption is primarily caused by normal wear; in addition, abnormal wear will occur occasionally, mainly including edge breaking or fracture of cutter ring, eccentric wear of tools, etc.

1) Consumption of single disc cutters

In a TBM construction section, a total of 5,961 single disc cutters were replaced, including 5,094 cutters replaced due to normal wear, accounting for 85.46%, and 867 cutters replaced due to abnormal wear (see Figure 6), accounting for 14.54%. The specific proportion is shown in Figure 7 below.

Figure 6. Abnormal wear of tool.

Figure 7. Failure statistics of single disc cutter.

2) Center cutter consumption

In the first TBM tunneling section, a total of 161 double center cutters were replaced (see Figure 8), including 90 cutters subjected to normal damage and 71 cutters subjected to abnormal damage (see Figure 9).

3) Cutter gear consumption

In the first TBM tunnel section, a total of 2,687 cutter gears were replaced, reaching 0.32 pieces

Figure 8. Failure statistics of center cutter.

Figure 9. Statistics for center cutter failure.

per linear meter; the replacement of cutter gears was mainly caused by normal wear, accounting for 91%, while the abnormal replacement was primarily due to bolt fracture and peeling of cutter gears caused by the impact of high-intensity rock mass, accounting for 9%; the consumption of cutter gears mainly occurred in the transition area of the cutter head where tools were worn quickly, resulting in the replacement of cutter gears in this area accounted for over 80%.

4.2.2 Analysis of tool failure modes

In the first tunneling section of the HWWD Project, a total of 938 disc cutters were subjected to abnormal wear, of which the edge breaking of cutter ring was 44%, eccentric wear was 32% and other causes accounted for 24%, and the specific analysis was as follows:

- 1) With the frequent rock bursts in the HWWD Project, rock collapse was caused by rock bursts and hit disc cutters violently, resulting in edge breaking and fracture of cutter rings, which was the main factor causing the edge breaking and damage of cutter rings.
- 2) There were many reasons for the eccentric wear of disc cutters; for example, ① tool bearings, cutter body and cutter rings were damaged by the impact of overloading and failed to be timely replaced; ② stones squeezed into the gap between the cutter housing and the disc cutter, causing tools to be stuck; ③ seal assembly damage resulted in oil leakage of tools; meanwhile, rock slag entered the seal chamber, causing damage to the bearing; ④ during the assembly of tools, an improper adjustment to the starting torque caused tools to fail to rotate normally.

- 3) In addition to the two major failure modes (viz. edge breaking and eccentric wear) hereinbefore, the proportion of other causes, such as bolt loosening or fracture, end cover displacement, and broken threads of end cover, also reached 24%, and the “loosening, peeling and breaking” of bolts fixing tools were among the technical difficulties encountered in the use and management of TBM tools in extremely hard strata.

5 COUNTERMEASURE ANALYSIS

5.1 Type selection of tools

In the strata where disc cutters are prone to wear, wear is the main form of tool consumption. According to different geological conditions, the corresponding cutter head and tool configuration shall be selected, the clearance between tools shall be properly adjusted to protect tools from the secondary wear caused by excessive crushing of rock surface, the frequency of cutter head inspections shall be increased during construction so as to find any problem in advanced and solve it timely, and the normal operation of all tools shall be protected from being affected by a problem of any individual tool, such as quick wear and edge breaking. After the external reasons for the quick wear of a disc cutter, such as equipment, are eliminated, the configuration of the disc cutter itself is particularly critical:

- 1) Select a reasonable torque configuration, adjust the tool torque accordingly in case of a change in geological conditions, and improve the service life of tools to prevent eccentric wear and chord wear of tools due to insufficient force of friction;
- 2) Select high-quality floating seals and bearings to ensure that disc cutters will not be subjected to abnormal wear due to the failure of floating seals and bearing when tools operate;
- 3) Select cutter rings suitable for the current geological conditions; for example, where surrounding rocks seriously collapse and peel from the tunnel face, the thickened cutting edges and cutter rings shall be used, the medium and high gradient hardness treatment shall be adopted to improve toughness, and other measures shall be taken; where the intensity of rock is relatively high, a cutter ring with a wider cutting edge should not be used; otherwise, the rock-breaking efficiency will be reduced and the rate of wear of cutter rings accelerated.

In the strata where disc cutters are prone to wear, the new process treatment of cutter rings can also produce good results; for example, if a cutter ring is inlaid with a superhard alloy, the service life of the cutter ring can be extended in case of low intensity of rock strata ($\leq 40\text{MPa}$), and the high wear resistance of the alloy can be utilized to improve the tool wear resistance.

5.2 Tool inspection method

5.2.1 Requirements for tool inspection frequency

- 1) Routine inspection standard for tools: The routine inspection frequency of tools is determined according to the TBM tunneling velocity (v), and in case of $v < 2.6\text{m/h}$, tools shall be inspected once every 3 tunneling cycles; in case of $2.6\text{m/h} < v < 3\text{m/h}$, tools shall be inspected once every 4 tunneling cycles; in case of $v > 3\text{m/h}$, tools shall be inspected once every 5 tunneling cycles;
- 2) If the main engine violates greatly, abnormal noise is produced from the cutter head, and an abnormal increase in the cutter head torque or the tunneling thrust force occurs, the TBM shall be stopped immediately and the cutter head shall be inspected;
- 3) If a tool inspector finds that long strips of slag are produced continuously for over 5min when observing the mucking conveyor belt, the TBM shall be stopped and tools shall be inspected;
- 4) If any objects, such as tool bolts and scrapers, appeared on the conveyor belt, the TBM shall be stopped and the cutter head shall be inspected.

5.2.2 Main contents of tool inspection

- 1) Remove slag from the cutter head and clean it;
- 2) Measure the tool wear at intervals of 20m~30m. The limit value of wear of a center cutter is 38mm, the limit value of wear of a frontal disc cutter is 38mm, the limit value of wear of a side disc cutter is 18mm, and a daily inspection will be considered, as appropriate, in special cases;
- 3) Inspect whether tools are subjected to chord wear, oil leakage, breaking and displacement of cutter rings, and peeling of retainer rings and whether tool bolts are loosened, broken, and peel off, and use a tool to hit bolts to judge the fastening of bolts;
- 4) Inspect the conditions of the scraper and its bolts;
- 5) Inspect whether the water spraying system for the cutter head is intact.

5.3 Judgment criteria for tool replacement

Different types of tools shall be replaced according to different criteria:

- 1) Normal replacement of tools: The wear of a cutter ring reaches its limiting value, the wear of a frontal disc cutter and a center cutter reaches 38mm, and the wear of a side disc cutter reaches 18mm;
- 2) Abnormal replacement of tools: Tools are subjected to chord wear, oil leakage, cutter ring breaking and a displacement cutter ring (more than 5mm);
- 3) Tool replacement due to an adjustment to height difference: the height difference between two adjacent frontal disc cutters is less than 15mm and the height difference between side disc cutters is less than 5mm;
- 4) Replacement of a group of tools: the 1# frontal disc cutter must be replaced when a group of center cutters is replaced; No. 55~No. 62 frontal disc cutters shall be replaced at the same time when side disc cutters are replaced.

5.4 Relevant requirements for tool replacement

- 1) In case of tool replacement, all contact surfaces of a tool must be polished with an angle grinder to ensure the contact surfaces are smooth and free of foreign objects; the contact surface between the bracket and the tool must be washed thoroughly with clean water and dried with clean cotton cloth before assembly, and finally, a torque wrench shall be used to tighten it to the required torque;
- 2) The brackets disassembled from an old tool must be matched in an exact way (i.e. the brackets on the cutter body side with a retainer ring and the brackets on the cutter body side with a retainer ring shall be separately arranged), and a cutter that is removed from a cutter housing shall be replaced by a new cutter and this new cutter shall be installed on the corresponding cutter housing. If brackets and cutter housings need to be replaced, they must be replaced in sets, i.e. 4 cutter housings and 2 brackets need to be replaced;
- 3) Before a cutter is installed in a cutter opening, inspect whether the cutter housing is secured, and then install the cutter after no problem is found. If a sign of wear is found or a cutter housing bolt is broken, reinstallation shall be conducted, and glue shall be applied to a bolt before the bolt is connected with the cutter housing; before bolts are installed, bolt holes shall be thoroughly washed to ensure that no impurities exist in bolt holes and then bolts can be installed. A bolt must be manually screwed into 4-5 threads and then tightened with an impact wrench, and it is strictly forbidden to use an impact wrench to install bolts; finally, a torque multiplier shall be used to tighten bolts in place as required, and the bolt tightening sequence is diagonal fastening;
- 4) The personnel responsible for tool replacement shall record in the tool replacement record form the cutter housing No., mileage of tool replacement, operating time of cutter head, new cutter body No., old cutter body No., new tool condition, and person responsible for tool installation, and notify the records to the chief operator for recording.

6 CONCLUSIONS AND RECOMMENDATIONS

Different types of surrounding rocks, such as full-face hard rocks and fault fracture zones, produce different failure modes of TBM tools; a variety of geological parameters, such as UCS and quartz content of surrounding rocks, have varying degrees of impact on tools; inappropriate TBM tunneling parameters will also cause abnormal damage to tools, such as total thrust force, speed of cutter head, and tool penetration. For the consumption of different types of tools, the causes shall be accurately analyzed and targeted measures shall be taken to effectively control the consumption of tools and finally realize a reduction in construction costs and an increase in the construction efficiency. On the basis that the causes of damage to tools are accurately analyzed and countermeasures are

properly taken, research into tool configuration technology, tool status monitoring technology, etc. shall also be strengthened to reduce the abnormal damage to tools. The specific conclusions and recommendations are as follows:

- 1) There is an approximately linear relationship among the uniaxial compressive strength, the quartz content and the tool consumption on the premise that the impact of special circumstances (e.g. tunnel face collapse and rock burst) on the abnormal damage to tools is not considered.
- 2) The tool configuration technology with an adjustable cutter clearance is further researched and developed. At present, the design of TBM tool configuration is mostly based on the configuration experience and construction effect of similar projects in the early stage for analogical design, and once the tool configuration mode is determined, it will not be changed in the later construction; thus, it is difficult to meet the rock breaking requirements under different geological conditions of the same tunnel. Given that the optimal rock-breaking clearance of disc cutters varies with different surrounding rock conditions, the adjustable cutter clearance is only realized on the laboratory test platform now but has not been applied to projects, so the cutter head design and manufacturing technology with an adjustable cutter clearance shall be further researched to ensure the TBM tunneling efficiency under different geological conditions.
- 3) The R&D and application of a new tool status monitoring system shall be strengthened. The tool status monitoring system has now been widely applied to super-pressure disc cutters on a large-diameter shield, but as there is violent vibration, external interference and other adverse impact during the tunneling of TBM equipment, causing the existing disc cutter status monitoring system shows poor adaptability and low data acquisition accuracy in the TBM tunneling process; on the other hand, there are relatively convenient conditions for checking the TBM tool status on site, so the tool status monitoring system is rarely used in TBM devices. Meanwhile, driven by the trends of unmanned, information-based and intelligent development of equipment, manual inspection of the tool status from time to time is difficult to meet the demands, so it is necessary to master the tool status in real time and predict its running status, and it is most urgent that a new monitoring system that can highly adapt to various TBM working environments should be further researched and developed on the basis of the existing tool status monitoring systems, such as ultrasonic detection method and electrical method.

ABSTRACT: Aiming at the construction method of “tunnel first and station later” in subway project, this paper proposes an innovative construction method of rapid station construction of tunnel with large shield tunneling and small shield construction. In this construction method, the small shield tunnel passes through the station section first, and then the large shield tunnel is used to dig and expand the small shield tunnel to form the side platform station. This construction method was first applied to Zhangbei station of Shenzhen Metro Line 14. Compared with the traditional construction method, the construction method has good economic and social benefits as well as technical innovation and advanced nature, which enrich the construction technology of subway engineering and provides a reference for subsequent similar projects.

Keywords: Metro stations, Stations posterior to tunnels, Shield tunneling method, Construction method, Engineering application

1 INTRODUCTION

The development of urban rail transit has brought more and more convenience to people. At the same time, with the continuous expansion of urban rail lines, various situations that may occur in the process of line selection, planning and construction need to be considered. For example, due to the influence of external reasons such as land expropriation and demolition, the construction period of subway stations lags behind, or the decision to add stations in the construction process of subway lines leads to major changes in the overall construction period planning, which restricts the key goals of subway line tunnel “tunnel” and station “roof”. As a result, the trial operation node of the whole subway line is delayed, resulting in the delayed opening of the subway. The construction method of “tunnel before station” is a better way to solve the above problems. For this reason, the domestic and foreign engineering circles have actively explored the construction technology of “tunnel before station” [1,2], and formed a variety of construction methods. The main

difference lies in the differences in the excavation methods of the station after the shield tunnel passes through the station section, such as mine method, pipe shed method, joist method, half-shield method, open excavation method, cover excavation and reverse work [3].

The pipe shed method means that a curved pipe shed is built above two intersectional tunnels at the same time as the two tunnels, and soil is excavated below the pipe shed and part of the pipe segments are removed to form an island platform. This method has been widely used in the construction of subway stations in Iran [4].

In China, the construction method in which the shield tunnel is formed first and then the station is excavated by mining method was used earlier, that is, after the shield tunneling machine passes through the station section, the mining method is used to expand the excavation, dismantle the shield tunnel segments in the station section, and build the underground station [5]. This technology is applied to the East [6] Shankou station of Guangzhou Metro Line 6 and the intersection section of the tunnel of the left

*Corresponding author: 11021234@qq.com

line of Zhengzhou Metro Line 2 and the tunnel of the liaison line of Line 1 and Line 2 [7].

The construction method of shield tunneling first and open excavation means that after shield tunneling passes through the station section, the station is excavated according to the traditional open excavation construction method of underground station. During the construction process, the tunnel structure of the station section was protected to avoid collapse, and finally the tube segments in the station were removed to form an underground station [8]. The application cases of this construction method in China include Wuyangcun Station of Guangzhou Metro Line 5 [9], Beihe East Station of Beijing Metro Line 6 Phase 2 [10], Jingshun Road Station of Beijing Metro Line 14 [11], and Gaolin Station of Xiamen Railway Line 2 [12]. Typical examples abroad include Line 5 in Riyadh, Saudi Arabia [13], and the western section of the Tel Aviv Metro Red Line in Israel [14]. In addition, the shield tunneling method was applied in the construction of Shenzhen Metro Renmin South Station [15].

This paper puts forward a fully mechanized “tunnel first and station later” construction method, that is, small shield tunneling first enlarging and digging forming station construction method. This paper elaborates the technical key points of this construction method and introduces the first application project case of this construction method in the country, so as to provide reference for subsequent similar projects.

2 CONSTRUCTION METHOD FOR METRO STATIONS BY USE OF LARGE-DIAMETER SHIELD TUNNELING MACHINES EXPANDING SMALL-DIAMETER SHIELD TUNNELS

2.1 Construction technology flow

The principle of this construction method is that the small shield adopts glass fiber reinforcement segments, the small shield passes through the station section first, and then the large shield is used to expand and dig, and the large shield tunnel is used as the platform of the station, and the station is quickly constructed. The construction process is shown in Figure 1, and the specific construction steps include:

- (1) Make four end walls of the two shafts at both ends of the station (Figure 2 (a)).
- (2) The shield machine has passed through the end wall and the section of the station (Figure 2 (b)). After arriving at the next station to complete acceptance, the shield machine falls out of the shaft.
- (3) The shafts at both ends of the station are dug from the ground, and some internal structures such as the bottom plate and side wall are applied (Figure 2 (c)).
- (4) Remove the connection bolts of the shield lining segments, and backfill the shield holes in sections and layers (Figure 2 (d)).

- (5) The large shield machine is hoisted into one of the shafts and started (Figure 2 (e)).
- (6) The large shield traverses the section where the station is located, receives and lifts out of another shaft, and finally completes the expansion of the station (Figure 2 (f)).

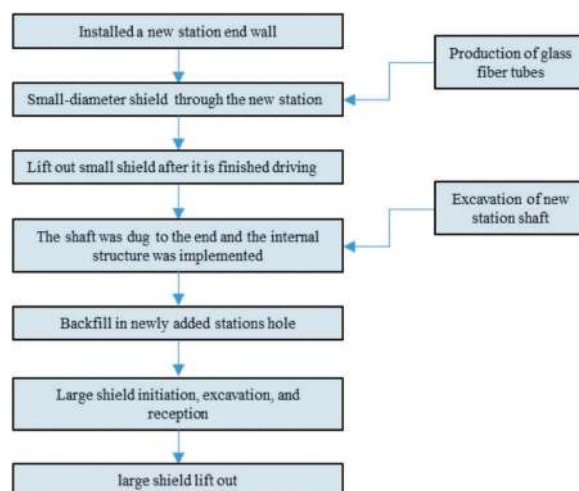

Figure 1. Construction technology flow for metro stations by use of large-diameter shield tunneling machines expanding small-diameter shield tunnels.

2.2 Construction characteristics

- (1) Safe and reliable. The shield tunneling machine is used to complete the station construction, which has higher safety performance than the underground excavation and open excavation.
- (2) High construction efficiency. Shield tunneling method is a fully mechanized tunnel construction method, which is used in both section tunnels and stations, and the construction efficiency is guaranteed.
- (3) Avoid long shutdown of shield, save the overall construction period. The small shield first adds the station, continues the subsequent excavation task, and synchronously carries out shaft excavation, which not only reduces the downtime of the shield, shortens the impact of the shaft on the total construction period, can greatly save the construction period and reduce the cost of large equipment idle.

2.3 Scope of application

This construction method is applicable to the situation that the new station scheme is stable and lagging behind, the ground environment and geological conditions of the station are poor, the overall construction period is tight, the existing station is not suitable for the transformation of the construction period is long, and the station cannot provide the starting conditions as scheduled.

Figure 2. Schematic diagram of construction steps for metro stations by use of large-diameter shield tunneling machines expanding small-diameter shield tunnel.

3 APPLICATION CASE

3.1 Project overview

Shenzhen Metro Line 14 Dayun Station, Baohe station and its intermediate air shaft have been completed, according to the project plan to carry out the

shield tunneling construction between the two stations. At this time, due to urban planning reasons, it was necessary to add Zhangbei station between Dayun Station and Baohe Station (Figure 3). Zhangbei Station is a side-platform station with a length of about 264m, and the newly added works include station platform, station hall, shaft, evacuation exit, etc. The project mainly passes through massive heavily weathered sandstone and partially through heavily weathered carbonaceous shale, soil-like strongly weathered sandstone and breezy limestone. The geological profile is shown in Figure 4. The massive heavily weathered sandstone is heavily weathered, the joint cracks are very developed, there are more moderately weathered rock blocks in the local area, and there are unevenly weathered interlayers in the layer, and the rock mass is broken into fragments. The standard penetration test measured 52 ~ 97 blows, with an average of 62.1 blows. Strong weathering carbon shale and earth-like strong weathering sandstone are easy to soften when exposed to water, and their strength decreases. The hammer number measured by standard penetration test is 71 ~ 113, with an average of 80.4 blows. The joints and fissures of breezy limestone are more developed, and the weathered fissures are more developed. The measured saturation uniaxial compressive strength is 63 MPa.

Figure 3. Plan of Zhangbei station of Shenzhen Line 14.

In order to ensure that the opening target of Metro Line 14 remains unchanged, the construction method and project planning adjustment of the new project are carried out, that is, the construction method of adding station sections through small shield tunneling is adopted first, and then the construction method of expanding and digging small shield tunnel segments to build stations is adopted. The feasibility of the construction scheme is established through model test research.

3.2 Key points of construction technology

(1) The small shield adopts glass fiber reinforcement segments in the station section (Figure 5). The normal design segment strength of this section is C50. In order to reduce the strength difference between the segment and the surrounding strongly weathered sandstone, and considering that the glass fiber segment is only a temporary structure, the

(a) Left line

(b) Right line

Figure 4. Section view of engineering geology of Zhangbei Station on Shenzhen Line 14.

empirical calculation uses C40 concrete with concrete impervious grade P12. The main rib of the annular tension is replaced by glass fiber rib of equal diameter. At the same time, considering the unified diameter type of glass fiber bars, the longitudinal tensile steel bars are replaced by glass fiber bars with a diameter of 22 mm, and the inner and outer main bars are connected by double rows of 14 mm U-type steel bars. The distribution bars are replaced by glass fiber bars with a diameter of 12 mm, and the inner and outer distribution bars are connected by 12 mm U-type steel bars. The joint between the glass fiber bar and the steel bar, and the glass fiber bar and the glass fiber bar should be fixed by binding both ends of the U-type steel bar. To facilitate subsequent removal and segment stability, the bolts are of a smaller specification class (normally M30), including sixteen M24 ring bolts and twelve M24 longitudinal bent bolts.

(2) Linear adjustment. The outer diameter of the small shield segment is 6.7 m, and the outer diameter of the large shield segment is 8.83 m. The line centers of the small and large shield segments are not completely coincident (Figure 6). If part of the small shield segment is not within the cutting range of the

(a) Segment segmentation diagram

(b) Segment reinforcement

Figure 5. Reinforcement diagram of small-diameter shield segment.

large shield cutterhead, the formation disturbance may be intensified during the excavation process, and the residual segments after cutting will accumulate and form a monolithic effect. Therefore, it is necessary to adjust the small shield route within the cutting range of the large shield cutter head. Theoretically, the small shield segment can be cut as a whole during expansion construction. In the scope of the small shield tunnel near the shaft, the plane adjustment of 46 cm (0.88cm/ ring) to ensure that the large shield cutter can cut the small shield segment as a whole.

(3) Backfill the hole. The amount of backfill is large, and a single line needs to be backfilled 5567 m³. A platform pump is arranged on the ground, and the mortar is pumped into the tunnel through the discharging pipe of A400 of the wellhead to the tunnel for backfilling. The backfill in the hole is divided into three layers (Figure 7). The first layer is 1.5 m, the second layer is 2.5 m, the third layer is 2 m, the first layer is not segmented as a whole, the second and third layers are divided into three sections of backfill, each section is 66 m, and forty-nine sealing walls are built in the middle, and the pump pipe is set up a pouring point every 20 m, and has an overall slope. Remove the bolt before backfilling,

Figure 6. Section diagram of large shield tunnelling.

remove the section by section, and set the convergence monitoring in the hole.

(4) Large shield type selection and cutter head preparation. The large shield equipment DZ512 and DZ513 of the expansion and excavation station were selected initially. The maximum propulsion speed of the shield machine was 4.8 m/h, the maximum thrust was 81905 kN and the rated torque was 17960 kN·m. Cutter head diameter of 8840 mm, using six spokes and surface plate design, equipped center disc cutter with six 17-inch double disc cutters, thirty-five 19-inch front disc cutters, thirteen 19-inch edge disc cutters, a total of eleven tracks, including the outermost two tracks have two each, seventy-six cutting knives, twenty-two pairs of scrapers. The center disc cutter spacing is 101.5 mm, the front disc cutter spacing is 78 mm, and the cutter-cutter spacing is 200 mm. The height of the disc cutter is 160 mm and the height of the cutter is 115 mm. There are six wear detection points (two disc cutters continuous wear detection, four disc cutters continuous wear detection) the maximum rock breaking capacity of 200 MPa. Cutter head opening rate is 34%, the center opening is about 40%. Screw conveyor adopts shaft screw, barrel body diameter is 1020 mm, the maximum passing particle size is 380 mm×570 mm, the maximum slag capacity is 550 m³/h, the maximum torque is 249 kN·m.

(5) Shield tunneling control. After the initial injection into the hole, it was found that there was basically no water on the palm surface, and 100~110 L of foam liquid should be injected into each ring in normal excavation. When the workability of residue soil was poor, the cutter head should be sprayed. After opening the warehouse, it was observed that the palm surface was stable, there was no clear water, and the top of the backfill in the hole was not dense. Under the premise of stable palm surface, the glass fiber bar cut by the cutter head will not accumulate at the bottom, and the small steel bar is not easy to wind the tool or the tool holder. The driving speed is 20 mm/min and the cutter speed is 1.5 r/min. The excavation site of large shield is shown in Figure 8.

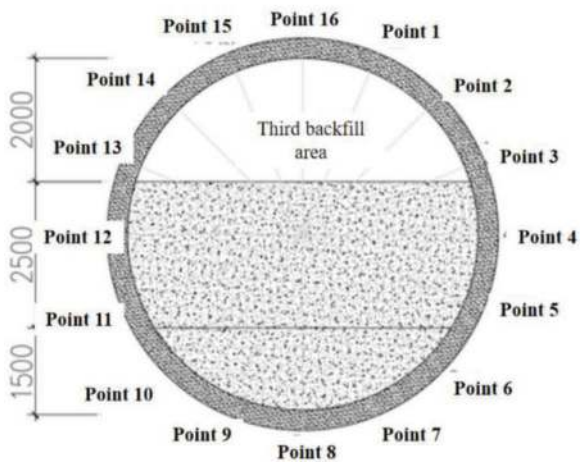

Figure 7. Schematic diagram of layered backfilling in the cave.

3.2 Benefit analysis

The direct economic benefits of large shield tunneling and small shield tunneling are mainly derived from the adjustment of the overall construction plan, greatly shortening the construction period, and reducing the idle cost of personnel and equipment for

(a) Before the large shield (b) After the large shield

Figure 8. Construction site.

a long time. The indirect economic benefits are derived from the implementation of the excavation task in advance, reducing the increase in construction costs caused by rush work in the later period, and ensuring that the overall opening operation target of Metro 14 is not delayed. Compared with the completion of the new station shaft, the small shield is hoisted out of the station, and then the large shield construction is carried out, which shortens the construction period of the whole project by ten months and ensures the construction period node of Shenzhen Metro Line 14, which is highly recognized by the supervisor and the owner.

The social benefits of this construction method mainly include two aspects. On the one hand, this process enriches the construction method of “tunnel before station”, and adopts large shield tunneling to improve the mechanization level of existing tunnel expansion and avoid the construction risk of underground excavation station. On the other hand, the small shield adopts a new type of glass fiber reinforcement segment, which provides a successful case for the engineering project that needs to use glass fiber reinforcement as the main reinforcement of the segment.

4 CONCLUSIONS

Generally speaking, subway construction adopts the construction sequence of “station first, tunnel later”, and the station shaft constructed first provides the receiving and starting conditions for the small shield tunneling in the section tunnel. However, due to special reasons such as line changes, new stations, and limited station construction sites, the following situations may occur: the small shield machine arrives at the station first, but the station construction progress is slow, and the shield lifting conditions cannot be provided. The construction method of large shield tunneling and small shield tunneling has become an effective solution.

- (1) The main construction procedures of the construction method include: the end wall of the shaft, the small shield through the station, the excavation of the shaft, the backfill in the hole, and the expansion of the large shield.
- (2) The construction method has the characteristics of safety and reliability, efficient construction and saving the overall construction period.

- (3) This construction method was first applied to the newly added Zhangbei station between Dayun Station and Baohe Station of Shenzhen Metro Line 14, which shortened the construction period of the whole project by 10 months, ensured that the overall opening and operation target of Metro Line 14 was not delayed, and achieved good economic and social benefits.

ABSTRACT: Accurately predicting the Penetration Rate (PR) in tunneling is crucial for evaluating the performance of Tunnel Boring Machines. However, a significant shortcoming of many existing studies is that the predictive models are developed using data from a single project, which limits their applicability to future tunneling projects. This research addresses this issue by examining whether the model can generalize to other tunneling projects and investigates the impact of an incremental learning strategy on its performance. In this study, the Extreme Gradient Boosting (XGBoost) model was initially trained and tested using data from one tunnel project and then generalized to a different tunneling project with similar geological conditions. To improve the model's generalization performance, an incremental learning strategy was used, which involved iteratively incorporating new data from the second tunneling project into the existing data from the first tunneling project to update the model. Additionally, the study analyzed how the generalization ability of XGBoost varies with the incremental size of new data. The findings indicate that there is a promising potential for enhancing the model's generalization ability using incremental learning techniques. However, additional research is needed to address the challenges related with skewed data and mitigating the effects of catastrophic forgetting.

Keywords: EPBM performance, Penetration Rate, XGBoost, Generalization, Incremental Learning

1 INTRODUCTION

The rapid urbanization and the need to reduce traffic congestion has led to an increase in underground construction projects. Tunnel boring machines (TBMs) have become a popular choice for tunnel excavation due to their efficiency, safety, and minimal impact on the environment (Huang et al., 2023).

To accurately predict TBM performance, many researchers have employed machine learning techniques using real-world data (Huang et al., 2023b; Shreyas and Dey, 2019). Several machine learning models have been employed (Mokhtari and Mooney, 2020), extreme gradient boosting (XGBoost) model (Zhou et al., 2021), artificial neural networks (Armaghani et al., 2019), deep learning (Pan et al., 2022). However, these models are constructed and tested using data from a single project. To establish confidence in these approaches and extend their

applicability, it is essential to validate these models across various projects (Sheil et al., 2020). Moreover, the environment in tunneling projects is subject to dynamic changes, necessitating the development of more intelligent models capable of continuous learning and adaptation. Traditional machine learning models are typically trained on static, identically distributed, and well-labeled data (He et al., 2016). Hyperparameter optimization and model selection are typically performed using the provided data before training begins. This process assumes that the data and its inherent structure remain static. However, these models often struggle to capture the dynamic characteristics of data collected in tunneling projects.

In sharp contrast to machine learning models, engineers have the capacity to progressively acquire new skills and expertise through the diverse range of projects they encounter throughout their professional careers. Incremental Learning refers to a learning

*Corresponding author: shuang54@stevens.edu

system’s ability to continuously assimilate new knowledge from fresh data while retaining the bulk of previously acquired knowledge. It aims to bridge the gap in incremental learning capabilities between natural and artificial intelligence (van de Ven et al., 2022). This approach empowers models to continually adapt and enhance their performance as new data becomes accessible. In the context of distinct tunneling projects, it is important to note that the underlying data distribution may undergo changes as construction progresses. Incremental learning serves as a valuable tool, enabling models to adapt to these shifts by seamlessly incorporating new data. This adaptive process plays a pivotal role in maintaining the models’ ability to generalize effectively across various projects.

The primary objective of this paper is to delve into the possibilities offered by incremental learning to enhance the model’s generalization performance in predicting penetration rate (PR) as tunnel construction progresses. Additionally, we seek to examine how the model’s generalization capacity will change with varying data incremental sizes which represent the amount of incoming new data. Our primary objective is to create a model that not only demonstrates excellent generalization abilities but also has the adaptability to respond to changing situations. This will pave the way for a more effective and intelligent tunneling system in the future.

2 DATA DESCRIPTION

2.1 Porto metro case

We obtained tunneling data from two segments of the Porto Light Metro Project in Porto, Portugal (Sousa and Einstein, 2012), to conduct and validate our study on TBM performance prediction. These two segments, Line C and Line S, traverse the city center of Porto in Portugal and are illustrated in Figure 1. Line C extends for a distance of 2.3 kilometers, stretching from Campanhã to Trindade. In contrast, Line S spans 3.7 kilometers, connecting Salgueiros to São Bento. Both tunnels were constructed using earth pressure balance shield tunnel boring machines (EPBMs) equipped with 300 mm thick segments. The outer diameter of Line C measures 8.7 meters, while Line S boasts an outer diameter of 8.9 meters (Centis and Giacomini, 2004). These EPBMs are engineered to excavate in mixed conditions, making them well-suited for the diverse soil compositions encountered in Porto. The soil conditions in the region exhibit significant heterogeneity, ranging from fresh granite to residual soil.

Before initiating the construction of the Porto Metro light metro project, an extensive geological survey was undertaken. This survey encompassed the drilling of over 500 boreholes to thoroughly assess the geological conditions in the area. The geological findings were categorized into seven distinct

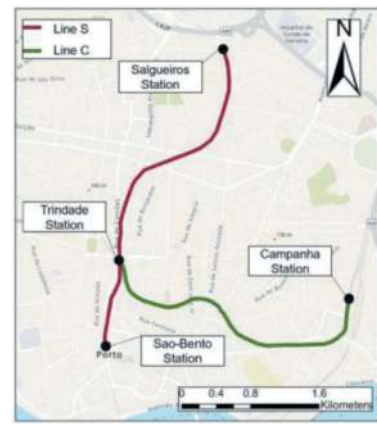

Figure 1. Top-down layout visualization of tunnelling projects.

geomechanical groups, denoted as g1 to g7. Groups g1 to g4 were indicative of rock-like materials, while g5 to g6 encompassed soil-like materials, including saprolite and residual soil. The seventh group, g7, included man-made materials and alluvial soils. Detailed longitudinal geological profiles and data pertaining to PR for both lines are presented in Figures 2 and 3.

Figure 2. Geological profile and penetration rate of Line C tunnel (Sousa and Einstein, 2012).

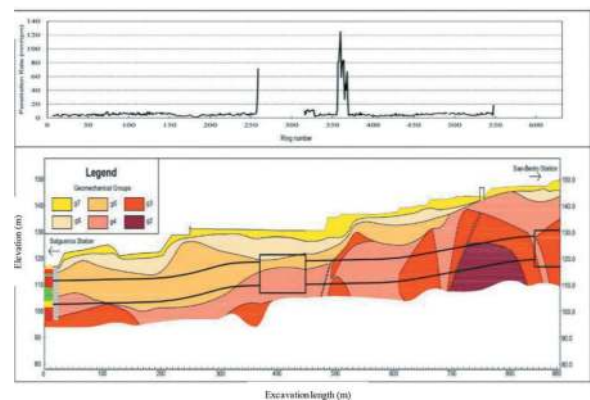

Figure 3. Part of geological profile and penetration rate of Line S tunnel (private communications with Transmetro).

2.2 Feature selection and processing

The EPBM deployed for the Porto Metro tunnel project was outfitted with an extensive array of sensors.

These sensors captured 195 variables at 10-second intervals during both excavation and stationary phases of construction. Only the data recorded during the excavation phase was utilized in the model to predict tunnelling performance. Additionally, parameters that held no relevance within this specific context, such as tank temperature and CH₄-monitoring, were disregarded for the analysis.

A systematic feature selection procedure was executed to accurately forecast the PR. This process was guided by insights drawn from previous research studies (Koopialipour et al., 2019; Pan et al., 2022; Yu et al., 2022) as well as practical knowledge garnered from industry expertise. Consequently, a set of nine parameters was chosen as features for the PR prediction task. These encompass attributes such as: torque cutting wheel, pressure force cutting wheel, thrust force, torque screw, cutting wheel speed of rotation, thrust pressure, excavated material flow, earth pressure, and foam lance pressure. PR, expressed as millimeters per rotation (mm/rpm), is adopted as the label, serving as the target variable that the models endeavor to predict. The PR distribution of tunnel Line C and Line S is depicted in Figure 4. It is worth noting that both projects produced skewed PR distributions. Commonly, the skewed points would be treated as outliers as they deviate dramatically from the main distribution and thus are removed. However, it is the authors' opinion that doing so would remove from consideration some important situations, such as drastic geology changes, encountering voids, or fault zones. Thus, in this paper, we consider both PR < 125 mm/rpm and PR < 25 mm/rpm.

Figure 4. PR distribution of tunnel Line C and Line S.

During the excavation of each 1.4-meter tunnel ring, an averaged representative value was computed for all features and the corresponding label. This approach was adopted to smoothen the data and enhance the robustness of the subsequent analysis. The purpose of this smoothing process is to counteract the inherent fluctuations present in the 10-second interval time series data. By mitigating extreme variations, this technique highlights the overall trends, which is particularly advantageous for the development of models. Furthermore, specific variables like earth pressure and foam lance pressure are measured through multiple sensors situated at various positions on the cutterhead. In this particular EPBM, seven sensors are allocated for earth pressure and four for foam lance pressure. For the purpose of model

development, the average of these sensors' values was used. Consolidating measurements from different sensors contributes to a more comprehensive and representative dataset for further analysis and modelling.

3 METHODOLOGY

The primary objective of this paper is to offer valuable insights into the generalization capabilities of models concerning tunneling performance prediction. To achieve this goal, the study places particular emphasis on exploring how the model's performance and its generalization ability varies with different incremental data sizes. By systematically updating the model using varying sizes of incremental data, this research aims to shed light on the intricate relationship between incremental learning and model performance, as well as its impact on generalization. Through this investigation, the paper seeks to contribute a deeper understanding of how incremental learning influences the overall performance and ability of models to generalize in the context of tunneling projects.

Figure 5 provides a detailed depiction of the incremental learning process employed in this study. Extreme Gradient Boosting (XGBoost), proved to be robust in generalization performance based on our previous research, was selected as the base model. The continuously acquired new data are segmented into sequential datasets through chronological order based on a predefined incremental size, which can be denoted as $\{T_1, T_2, \dots, T_n\}$. Here, T_i represents the i -th new dataset. The initial phase of the study involves training and validating the model using Line C data, with a training-validation stratified split of 70% for training and 30% for testing. Subsequently, the model is generalized to the entire Line S dataset. In each subsequent iteration, a new dataset T_i , corresponding to a newly excavated part of line S, is integrated with the previously existing data. For instance, during the first iteration, T_1 (first increment of data from Line S) is added to Line C data; in the second iteration, T_2 (second increment of data from Line S) is added to the combined dataset of Line C data and T_1 . It's worth noting that each T_i dataset is also divided into a 70% portion for training and a 30% portion for testing. This expanded and updated dataset is then utilized to retrain the model, fine-tuning its hyperparameters to enable it to accommodate the newly incorporated data. Ultimately, the model's predictions are generalized to encompass the remaining data from Line S, resulting in an iterative and progressively refined learning process. The model performance will be evaluated by coefficient of determination (R^2) and root mean square error (RMSE).

To assess the incremental learning performance on different incremental size, a range of different incremental data sizes was employed in this study. These sizes include 200, 150, 100, 60, 30, 10, and 5.

Figure 5. Flowchart of incremental learning process.

4 RESULTS

4.1 Model performance

Figure 6 illustrates the incremental learning performance of the XGBoost model, specifically developed for PR values less than 125 mm/rpm, with an incremental data size of 5. In this analysis, considering that the Line S dataset consists of 602 data points, the study investigates the impact of incorporating new data on both model performance and generalization. To do so, new data sizes ranging from 60 to 545 were examined. It's important to note that a few results are missing from the Figure 6 due to a technical constraint of stratified split. When dealing with imbalanced data, the common practice is to use the stratified split method to maintain a proportional representation of each range in both the training and testing datasets. However, this method may encounter difficulties when trying to create sections with zero instances, which can lead to the omission of these results in this analysis.

Figure 6. Incremental learning performance of XGBoost model on PR < 125 mm/rpm.

From Figure 6, it's evident that the XGBoost model demonstrates strong performance on both the training and testing datasets. This is substantiated by the R^2 values, with the R^2 for training exceeding 0.97 and the R^2 for testing surpassing 0.88. These high R^2 values indicate that the model is capable of explaining a significant portion of the variance in the data, reflecting its effectiveness in making accurate predictions for both the training and testing datasets. A noteworthy observation is made when incorporating more than 300 Line S data points into the model development process. At this point, the model's performance on the testing dataset exhibited instability. This phenomenon can be attributed to the increasing skewness of the data as more samples are added for model development. As

the model is exposed to an increasingly imbalanced dataset, it may start to overfit to the training data, attempting to fit it very closely. Consequently, this can lead to a degradation in testing performance as the model struggles to perform well effectively beyond the training set, ultimately resulting in the observed instability in performance. Another reason of downgraded performance could be "catastrophic forgetting", where the model forgets or degrades its ability to perform well on tasks it previously mastered when exposed to new data (French, 1999). That is, when XGBoost learns new knowledge on new sequential data, it adjusts its hyperparameters to minimize the loss on this new data. However, it may significantly modify its parameters, which can lead to a drop in performance on the knowledge it had previously learned.

Figure 7 illustrates the incremental learning performance of the XGBoost model, focusing on PR values less than 25 mm/rpm. In this analysis, PR values ranging from 25 to 125 mm/rpm were excluded, resulting in a dataset of 587 remaining data points. Despite of this adjustment, the study continued to investigate the impact new data sizes varying from 60 to 545. It's important to note that there is one missing result for the scenario where 65 Line S data points were integrated into Line C data. This omission is also due to technical constraints. In general, the XGBoost model exhibits strong performance for both training and testing, with the R^2 values for training consistently exceeding 0.85, and the R^2 values for testing mostly surpassing 0.7. However, it's observed that the model's performance becomes less stable in both training and testing when more than 200 Line S data points are incorporated for model development. This instability could also be attributed to catastrophic forgetting. In comparison to the previous scenario, the impact of the catastrophic forgetting is more pronounced when considering the model trained on PR values less than 25 mm/rpm.

Figure 7. Incremental learning performance of XGBoost model on PR < 25 mm/rpm.

The underlying reason behind this phenomenon is highlighted in Figure 8. Balanced data, referring to PR values below 25 mm/rpm, tends to exhibit a simpler structure compared to imbalanced data with PR values below 125 mm/rpm. When dealing

with balanced data, the model may not need to learn as highly complex patterns in the data. This simplicity makes it more vulnerable to forgetting when new data is introduced, as indicated by the significant structure change in upper right part of Figure 8. Conversely, imbalanced data is often more intricate, which in turn compels the model to learn a more intricate and robust representation of the data. This greater complexity in imbalanced data can contribute to a model that is less prone to catastrophic forgetting, as indicated by smaller structure change in lower right part of Figure 8.

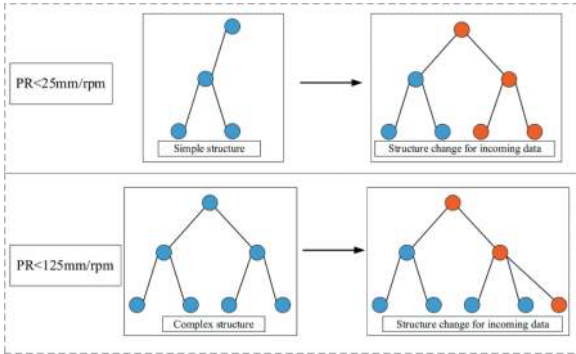

Figure 8. Catastrophic forgetting example of XGBoost model.

4.2 Model generalization

Figure 9 presents the model's generalization performance for PR < 125 mm/rpm with incremental data sizes of 60, 100, 150, and 200.

In Figure 9a, these plots reveal a noticeable trend: as new data is introduced, the model's generalization ability tends to deteriorate. This decline is evident through the decrease in R^2 and the increase in RMSE values. It's worth highlighting an interesting observation: there is a decrease in RMSE when the model begins incorporating 200 new data points, and this trend continues until 400 data points. This phenomenon can be attributed to the fact that the skewed data, which significantly deviates from the main distribution, starts to become part of the model development process. Figure 10 illustrates how skewed data are incorporated and how R^2 and RMSE vary during this process. Additionally, upon closer examination of the Line S data distribution, it becomes apparent that the second quarter of the data includes 10 skewed data points, as presented in Figure 11.

When we closely examine the model performance for incremental data sizes of 5, 10, and 30, several intriguing observations in Figure 9b and Figure 9c come to light. Firstly, it becomes evident that the model's generalization performance is inherently unstable as new data is introduced. Remarkably, even the inclusion of just 5 new data points can result in a significant drop of 0.15 in the R^2 value, indicating a notable impact on the model's predictive accuracy. Secondly, a noteworthy pattern emerges during the incorporation of new data, particularly

a. Model generalization performance on incremental sizes 60, 100, 150, 200

b. R^2 of model generalization on incremental size 5, 10, 30

c. RMSE of model generalization on incremental size 5, 10, 30

Figure 9. Incremental generalization performance of XGBoost model on PR < 125 mm/rpm.

Figure 10. Model generalization showing skewed data involved.

when the number of data points falls within the range of 240 to 300, instead of 400 which is concluded before from rough incremental size. During this phase, the model's generalization performance undergoes dramatic changes. Initially, R^2 values decrease, suggesting a decline in predictive power. However, RMSE exhibits a different behavior—it decreases initially due to the inclusion of skewed data but then increases in subsequent iterations. This fluctuation in RMSE is a result of the incorporation of data that initially deviates significantly from the existing dataset and subsequently affects the model's overall predictive accuracy.

Figure 12 presents the model's generalization performance for PR < 25 mm/rpm with incremental data sizes of 60, 100, 150, and 200. R^2 in most cases

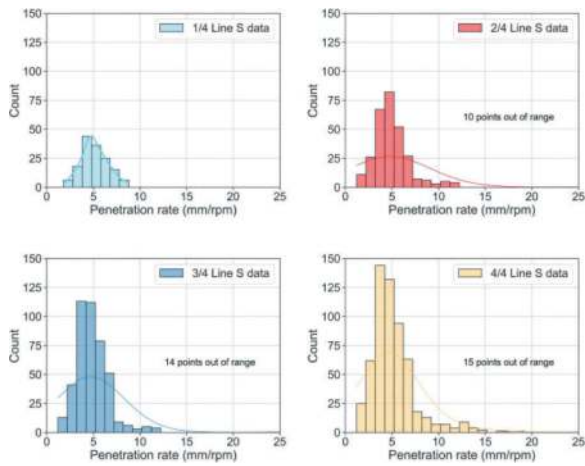

Figure 11. Incremental PR distribution of Line S data.

are larger than 0.5 and RMSE, compared to previous case, decreases significantly whose values mostly are between 1.5 to 2. The RMSE is much smaller than the one of the models built on PR < 125 mm/rpm, showing the robust performance of incremental learning on balanced data.

In Figure 12a, a noticeable trend emerges as new data is incorporated: the model's generalization ability shows slight improvement, as evidenced by the increase in R^2 from around 0.4 to approximately 0.8, while the RMSE remains relatively stable. An interesting observation worth noting is that beyond the inclusion of 500 Line S data points, the model's performance experiences a significant decline. This phenomenon could be attributed to the limited number of testing data points available for generalization. With only 47 data points remaining for generalization testing when 540 data points are incorporated, even a small deviation in one data point can exert a notable influence on the model's generalization performance, potentially leading to the observed degradation in performance.

Upon closer examination of the model performance with incremental data sizes of 5, 10, and 30, a general trend emerges: these plots consistently show improved generalization performance as new data is incorporated. However, it's important to highlight a remarkable observation when the model incorporates more than 500 Line S data points. During this phase, there are significant fluctuations in generalization performance, as indicated by the substantial variations in both R^2 and RMSE values. R^2 can reach values of approximately 0.88, with RMSE at 1.8, but it can also drop to as low as 0.13, with RMSE increasing to 3.5. These fluctuations can likely be attributed to the random nature of the limited number of remaining data points available for generalization testing. A poor prediction could result in much worse generalization performance than before.

5 CONCLUSIONS

This paper examines the generalization capability of the XGBoost model and explores the feasibility of enhancing it through the application of incremental learning. The research delves into the variance of model's generalization ability on various incremental data sizes. Recognizing that skewed data may hold valuable insights, the study considers two scenarios: one that includes skewed data where PR values are below 125 mm/rpm and another where skewed data is excluded and PR values are restricted to below 25 mm/rpm. Our conclusions are as follows:

1. In both scenarios, the XGBoost model generally demonstrates strong performance for both training and testing datasets. However, the model's performance can experience degradation as a result of incorporating skewed data and encountering the phenomenon of catastrophic forgetting.
2. Incremental learning has the potential to improve model generalization, as indicated by the increasing R^2 and decreasing RMSE. However, skewed data can significantly impact the model's generalization performance.

3. Incremental learning shows more promising results when applied after the removal of skewed data. However, further research is needed to explore the value of the information contained in skewed data and develop strategies that mitigate the impact of skewed data on model performance and generalization.

ABSTRACT: Controlling the rate of soil discharge is a key technology for earth pressure balance shield tunneling to maintain dynamic stability of the excavation surface. In order to ensure the safe excavation of earth pressure balance shield tunneling in rich water sandy stratum with large burial depth, the soil is classified into fluid state, hard plastic state, and transitional state between the two based on slump tests. Based on the II theorem, Darnell-Mol theory, and the discrete element numerical model of soil discharge, empirical formulas for soil discharge in three states are established. Finally, the three empirical formulas is coupled to obtain the empirical formula for soil discharge in the full state of the soil by using slump as an index, And verified through the monitoring data in practice. The results show that the theory of soil discharge in full state is reliable; The soil discharge rate increases with the increase of slump, pressure in pressure chamber, and speed of screw conveyor. For the construction of EPB shield tunneling with a buried depth of 30m, the reasonable range of slump for conditioned soil should be 102-192mm. This research can provide a theoretical basis for the application of earth pressure balance shield tunneling in deep buried stratum.

Keywords: earth pressure balance shield, slumps, soil discharge, soil condition, discrete element theory

1 INTRODUCTION

EPB shield tunneling is widely used in urban subway construction. In recent years, the overall construction trend of EPB shield tunneling has developed towards complex stratum such as deep burial depth and high water pressure stratum (Ma and Najafi, 2008; Qiao and Peng, 2016; Qiao et al., 2017; Zhao et al., 2016). The advantage of EPB shield tunneling is weak perturbation. In engineering, according comparison between the setting pressure of the pressure chamber and the monitoring pressure, the soil discharge can be controlled by adjusting the speed of the screw conveyor to achieve dynamic stability of the excavation surface support pressure, ensuring weak perturbation to the surrounding environment (Zhong, 2022). However, When the shield machine excavates in the deep buried depth, high water pressure, and cohesionless stratum, such as sand stratum and sand pebble stratum, it is difficult to control the soil discharge based on existing

experience, and the support pressure of excavation surface fluctuates greatly, which may cause the excavation surface to collapse. Therefore, it is urgent to establish the soil discharge theory, which can consider the engineering scale and guide shield tunneling (Borio and Peil, 2010; Liu et al., 2018).

During the shield tunneling, the soil is cut down by the cutter and enters the pressure chamber. Soil is transported to the screw conveyor by the blades, and finally transported to the conveyor belt. In the pressure chamber and screw conveyor, the soil is transported under pressure, and considering the properties of the conditioned soil, the soil discharge process is relatively complex. Therefore, it is difficult to establish a complete and scientific soil discharge theory. Maild (1995) proposed a diagram of the transport process and pressure distribution of soil in pressure chamber and screw conveyor, and analyzed the relationship between soil discharge and pressure difference, screw conveyor inclination angle, soil fluidity, and other factors; Merrit

*Corresponding author: 1013984090qq.com

and Mair (2006, 2008) assumed the soil as a solid and explored the effects of spiral blades and shaft size on the pressure gradient inside a screw conveyor. Based on above study, a soil discharge theory was proposed; Pena et al. (2007) established a 1:11 soil discharge model test, and studied the soil discharge law with different content of foam, bentonite slurry and other modifiers; Huang (2009) simplified the soil discharge, and established an soil discharge model using Fluent, and analyzed the influence of cutterhead opening rate on soil discharge and soil pressure distribution; Zhu et al. (2020) analyzed the velocity, motion trajectory, and mass flow rate of particles in sandy gravel stratum using the discrete element method, and obtained the flow characteristics of particles in the pressure chamber.

In summary, most soil discharge theories have a relatively small scope of application, which only assumed the soil as fluid or solid, these theories lack understanding of the conditioned soil state. Most of the soil is a semi liquid and semi solid body, and the description of the soil discharge in existing theories is far from sufficient. Therefore, it is significant to establish a comprehensive theory of soil discharge in all soil states considering deep burial depth engineering. Therefore, this paper conducts the following research work to address the above issues: 1) Based on self-designed soil discharge model test, we explored the influences of screw conveyor speed, pressure in pressure chamber, and conditioned soil state on soil discharge rate; 2) According to the slump test, the soil is divided into fluid state, hard plastic state, and transitional state between the two. empirical formulas were established for soil in three conditioned states, and verified with model tests; 3) Taking the slump of soil as an index, the empirical formulas of soil in three states were coupled, and the full state soil discharge considering engineering scale was proposed; 4) Based on the shield tunneling construction between Hengli Station and Panyu Square Station on Guangzhou Line 18, and combined with the empirical formula of full state soil discharge, a reasonable slump range in deep buried engineering is proposed to guide the soil condition plan and construction in practice.

2 MODEL TEST OF SOIL DISCHARGE

The soil discharge is the key factor affecting the excavation of shield tunnel. Therefore, in order to study the influence of screw conveyor speed, pressure, and soil state on the soil discharge, the model test of soil discharge was established, as shown in Figure 1.

The main part of the model test is the construction simulation system, which mainly consists of two parts: pressure chamber and screw conveyor. The inner diameter of the screw conveyor sleeve is 50mm, the length is 785mm, the screw diameter is 14mm, and the screw pitch is 35mm. The soil in the test is mainly fine sand, with a density of 1.585 g/cm^3 .

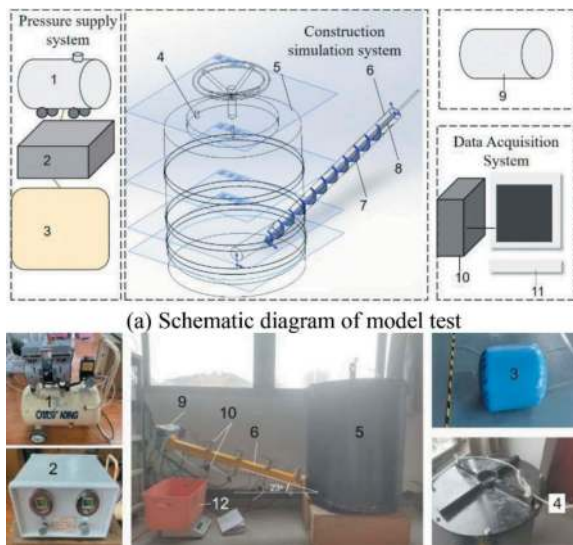

Figure 1. Model test of soil discharge. (a) Schematic diagram of model test (b) Model testing device. 1-Air compressor, 2-Pressure regulator, 3-Pressure airbag, 4- Pressure inlet, 5- Pressure chamber, 6- Sleeve, 7- Spiral blade, 8- Spiral rod shaft, 9- Rotating motor, 10- Data acquisition instrument (mainly including 4 soil pressure sensors and 4 water pressure sensors), 11- Computer, 12- Soil collection box.

The particle size distribution is shown in Figure 2. To investigate the influence of screw conveyor speed, pressure in pressure chamber, and conditioned soil state on the soil discharge rate, the following experimental conditions were designed: screw conveyor speed (2rpm, 4rpm, 6rpm, 8rpm), pressure in pressure chamber (20kPa, 40kPa, 60kPa), and soil state (dry sand, conditioned soil). The conditioned soil is modified by adding 15% foam by volume, 12% bentonite slurry by mass and 10% water by mass. Bentonite slurry is prepared in a ratio of 1:5 to water, which is fermented for 8 hours after stirred thoroughly. The concentration of the foaming agent mixture is 3%, and the foaming rate is 20 times. The slump of conditioned soil was measured to be 125mm, as shown in Figure 3. According to the above experimental conditions, the soil discharge rate is shown in Figure 4.

Figure 2. Particle size distribution of sand in the test.

From Figure 4, it can be seen that as speed and pressure in pressure chamber increase, the soil

Figure 3. Conditioned soil with a slump of 125mm.

Figure 4. Result of soil discharge.

discharge basically shows a linear increasing trend. However, for dry sand in high pressure condition (60kPa), the soil discharge rate is out of control, which basically does not meet the above rules. This is because sandy soil has poor workability and a large internal friction angle. Under high pressure, a tight soil plug is formed inside the screw conveyor, which greatly affect the soil discharge. The friction between the soil plug and the inner wall of the screw conveyor is extremely high. Before it reaches the outlet, it hinders the efficiency of soil discharge. However, once the soil plug moves to the outlet, the stress is instantly released, which causes a large amount of soil to spray, ultimately leads to a sudden increase in soil discharge rate. Therefore, the 60kPa/dry sand condition has no obvious pattern with the increase of screw conveyor speed. Under the same pressure and screw conveyor speed conditions, the soil discharge rate of the conditioned soil is basically higher than that of dry sand. This is because foam is added as conditioner, and foam is filled into the pores between sand particles, playing a “ball bearing” which can reduce friction between soil particles, and greatly improving the fluidity of soil.

3 STUDY ON SOIL DISCHARGE OF EPB SHIELD TUNNELING

According to the slump test, the fluidity of soil with different slumps is different, so the corresponding soil discharge rate will not be consistent. For example, when slump of fully fluidized soil is 300mm, compared to dry hard soil with a slump of 0mm, its soil discharge rate must be much higher than that of dry hard soil. Therefore, this paper divides the soil into hard plastic state (slump 0mm), fluid state (slump 300mm), and transitional state between the two states (slump 0-300mm).

3.1 Empirical formula for soil discharge in fluid state

In order to derive the empirical formula of soil discharge when soil state is fluid, this section uses the Π theorem and CFD to establish a numerical test for soil discharge, and fits the empirical formula for soil discharge when soil state is fluid. The specific details are as follows: the flow of fluidized soil inside the screw conveyor is essentially pipeline flow phenomenon. The inclination angle, pitch, and other physical structures of the screw conveyor all effect the soil discharge. However, in essence, these structural physical parameters effect the soil discharge by changing the pressure gradient dp/dx inside the screw conveyor, so the pressure gradient dp/dx is the first parameter involved in the soil discharge phenomenon. Similarly, the other involved parameter are: the diameter of the screw conveyor (D), the average velocity of the soil discharge (U), and the density of the soil (ρ), The viscosity of soil (μ) (To simplify calculations, Newtonian fluid is used to simulate the fluidized soil), and the speed of screw conveyor (ω). There are six parameters involved in the soil discharge. The dimensional matrix of the above parameters in the CGS unit system is as follows:

$$\begin{matrix}
 & D & \rho & U & \mu & dp/dx & \omega \\
 \begin{matrix} L \\ M \\ T \end{matrix} & \begin{bmatrix} 1 & -3 & 1 & -1 & -2 & 0 \\ 0 & 1 & 0 & 1 & 1 & 0 \\ 0 & 0 & -1 & -1 & -2 & -1 \end{bmatrix}
 \end{matrix}$$

In the above matrix, L , M and T are the basic variables of the CGS unit system, including length, mass, and time. The values in the matrix represent the dimensional indices of each involved variable. I. e, $\dim(\rho)=L^{-3}\cdot M$, \dim is a dimensional representation. The above dimensional matrix are converted into a row simplest form matrix, as shown below. From this, it can be seen that the diameter D , the average flow velocity U , and the density ρ are dimensionally independent. Pressure gradient dp/dx , fluid viscosity μ , speed of screw conveyor ω can be represented by these three dimensionally independent quantities, as shown in equation (1). Therefore,

based on the Π theorem, three independent similarity criteria can be established, as shown in equation (2).

$$\begin{matrix} D & \rho & U & \mu & dp/dx & \omega \\ \left. \begin{matrix} L \\ M \\ T \end{matrix} \right| \begin{bmatrix} 1 & 0 & 0 & 1 & -1 & -1 \\ 0 & 1 & 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 & 2 & 1 \end{bmatrix} \end{matrix}$$

$$\dim \mu = (\dim D)(\dim \rho)(\dim U)$$

$$\dim \frac{dp}{dx} = (\dim D)^{-1}(\dim \rho)(\dim U)^2 \quad (1)$$

$$\dim \omega = (\dim D)^{-1}(\dim U)$$

$$\Pi_1 := \frac{\rho U D}{\mu} \quad \Pi_2 := \frac{dp}{dx} \frac{D}{\rho U^2} \quad \Pi_3 := \frac{\omega D}{U} \quad (2)$$

where Π_1 , Π_2 , and Π_3 are the three independent similarity criteria for soil discharge. Π_1 , Π_2 , and Π_3 satisfy the Π theorem, then the three similarity criteria satisfy the relationship as shown in equation (3).

$$\Pi_2 = f(\Pi_1, \Pi_3) \Rightarrow \frac{dp}{dx} \frac{D}{\rho U^2} = f\left(\frac{\rho U D}{\mu}, \frac{\omega D}{U}\right) \quad (3)$$

From equation (3), it can be seen that as long as the form of the function f is determined, the relationships of Π_1 , Π_2 , and Π_3 can be obtained, and an empirical formula of the average flow velocity U can be derived. Now, based on fluent, a numerical model of soil discharge are established: 1) Model establishment. The screw conveyor model is shown in Figure 5. The length of the screw conveyor is 450mm, the diameter of the screw conveyor is 104mm, the diameter of the central shaft is 68mm, and the screw pitch is 90mm. The model is divided into 68768 grids by using unstructured grids. The inlet and outlet boundary conditions are set as constant pressure boundary conditions, while the rest, such as sleeves, blades, and screw conveyor shaft, are set as non inflow and non slip wall boundaries. 2) Parameter settings. In the model, Newtonian fluid is used to simulate the fluid state of the soil. The entire calculation is set to steady calculation.

In numerical calculations, it was found that the speed of the screw conveyor has little influence on the velocity. Therefore, it can be considered that the ω is not involved parameter of soil discharge. Therefore, equation (3) is modified to obtain a new Π theorem relationship equation:

$$\Pi_2 = \varphi(\Pi_1) \Rightarrow \frac{dp}{dx} \frac{D}{\rho U^2} = \varphi\left(\frac{\rho U D}{\mu}\right) \quad (4)$$

Equation (4) is a unary function related to Π_2 , with an independent variable of Π_1 . Therefore, as long as the $\varphi(\Pi_1)$ curve is obtained, Π_2 values of similar phenomena can be obtained, and the fitted function relationship can be used to obtain an empirical formula.

Figure 5. Numerical model of soil discharge.

Figure 6. Numerical models of slag discharge at different scales.

In order to study the same soil discharge phenomenon (i.e. similar phenomenon) at different scales, Figure 4 is taken as Condition 1, and it is magnified 10 times as Condition 2. The screw conveyor is lengthened to twice as Condition 3, as shown in Figure 6. The φ relationship of the different conditions under similar conditions is explored, that is, each working condition controls the Π_1 value to be equal, Ensuring that all working conditions are similar, and Π_2 is calculated at this time. The results are shown in Figure 7.

Figure 7. Numerical experimental relationship of Π_1 and Π_2 .

From Figure 7, it can be seen that the dimensionless values Π_2 of the three working conditions are basically equal, and decrease with the increase of Π_1 . So, according to Figure 8, the empirical formula

for soil discharge can be summarized when the soil state are fluid state. Firstly, the functional relationships φ of Π_1 and Π_2 are fitted. In order to facilitate subsequent solutions, the empirical formula adopts a linear fitting, as shown in equation (5). Further substituting equation (5) into equation (4), a cubic equation about the average flow velocity U of soil are obtained. For the concise of formula expression, the U^2 term is placed on the right side of the equation and represented by Π_1 . Finally, the empirical formula for flow rate Q is obtained based on the average flow velocity U , as shown in equation (6).

$$\pi_2 = \varphi(\pi_1) \Rightarrow \pi_2 = -1.026e^{-7}\pi_1 + 8.36 \quad (5)$$

$$\begin{aligned} U &= \frac{dp}{dx} \frac{D}{\rho U \phi(\pi_1)} \\ &\Downarrow \\ Q &= \frac{\pi(D_f^2 - D_s^2)D_f}{4\rho U \phi(\pi_1)} \frac{dp}{dx} \quad (6) \\ &= \frac{\pi(D_f^2 - D_s^2)D_f^2}{4\mu \frac{\rho U D_f}{\mu} \varphi(\pi_1)} \frac{dp}{dx} = \frac{\pi(D_f^2 - D_s^2)D_f^2}{4\mu \pi_1 \varphi(\pi_1)} \frac{dp}{dx} \end{aligned}$$

Where D_f is diameter of the screw conveyor, and D_s is the diameter of the screw conveyor shaft.

3.2 Formula for soil discharge in hard plastic state

When the soil is not conditioned or the condition effect is poor, the soil basically presents a hard plastic state. At this time, the slump of soil would be very small, the soil would hardly collapse. At this point, the soil can be regarded as a hard plastic solid in the screw conveyor. So, based on Darnell Mol solid transportation theory, the formula for soil discharge can be obtained as follows:

$$Q = \frac{(D_f^2 - D_s^2)}{4} \frac{\pi^2 D_f N \tan \varphi_f \tan \theta}{\tan \theta + \tan \varphi} \quad (7)$$

$$\theta = \arcsin \left(\frac{\sqrt{1 + K^2 - M^2 - KM}}{1 + K^2} \right) \quad (8)$$

$$\begin{aligned} M &= 2 \frac{H \mu_1 \sin \varphi_f}{l \mu_2} \left(K + \frac{\bar{D}}{D_f} \cot \varphi_f \right) \\ &+ \frac{\mu_2 \sin \theta}{\mu_2} \left(K + \frac{D_s}{D_f} \cot \varphi_f \right) \quad (9) \\ &+ \frac{H \sin \theta}{z_b \mu_2} \left(K + \frac{\bar{D}}{D_f} \cot \varphi_f \right) \ln \frac{P}{P_0} \end{aligned}$$

$$K = \frac{\bar{D}}{(\mu_1 \sin \phi_f - \cos \phi_f) D_f} \quad (10)$$

Where Q is the soil discharge per unit time; D_f is the diameter of the screw conveyor; D_s is the diameter of the screw conveyor shaft; N is the speed of

the screw conveyor; \bar{D} is the sum of the D_f and the D_s ; φ_f is the blade inclination angle of the screw conveyor; θ is the angle between the velocity of the soil and the x-axis is referred to as the conveying angle in this article; μ_1 is the friction coefficient between the screw and the soil; μ_2 is the friction coefficient between the inner wall of the screw conveyor and the soil; l is the height of the soil section inside the screw conveyor; P_0 is the pressure of the pressure chamber; P is the pressure at any position inside the screw conveyor.

3.3 Study for soil discharge in transitional state

Based on the above study, the soil discharge laws under the fluid state and hard plastic state of soil has been obtained. However, the soil generally is the transitional state between the two, so it is difficult to calculate the soil discharge through one of these theories. Therefore, based on the discrete element software EDEM, the soil discharge law of the soil in the transitional state were explored.

As the main conditioner affecting the fluidity of soil, foam content for a large proportion in the soil and has a significant influence on the soil discharge. foam, as an unstable system composed of bubbles, would produce defoaming phenomena such as drainage, consolidation, coarsening, etc. in the process of screw conveyor transportation of slag, which would further affect the fluidity of soil, so the soil discharge process of soil in transition state is very complex. In the whole soil discharge process, stability of foam will increase due to the existence of solid particles and the increase of internal pressure, so it can be considered that the foam of soil under pressure is more stable than the foam of soil in air. Therefore, according to the characteristics of foam in soil, a simplified foam-soil contact model and calculation scheme are proposed to simulate the soil discharge, which could consider defoaming phenomenon. The assumptions are made: (1) foam are regarded as particles, foam particles are incompressible in the whole soil discharge process; (2) Foam defoaming occurs instantaneously, without considering the process of drainage, consolidation and coarsening; (3) Material intrinsic parameters and conventional contact parameters of the foam particles are consistent with the soil particles, and the defoaming amount is only considered in post processing; (4) The foam defoaming in the pressure chamber is not considered. The radius of soil particles is 4mm, and that of foam particles is 2mm. The contact between all particles and the wall is Hertz-Mindlin contact model.

The soil is conditioned with bentonite slurry and foam. Therefore, the specific contact model is as follows: (1) Soil-soil contact model. Considering the bonding effect of bentonite slurry between soil and soil, the JKR contact model is adopted. (2) Foam-foam contact model. The Hertz-Mindlin contact model is adopted for foam and foam because of the smoothness of the contact liquid film. (3) Foam-soil

contact model. It can be seen from the defoaming process of foam during soil discharge that, with change of time and position migration, foam will defoaming due to liquid discharge and the increase of pressure difference between inside and outside the liquid film. At this time, there is a gap at the position originally filled by foam, and the surrounding soil particles will be immediately filled under the pressure. At this time, the lubricated effect of foam is weakened, and the internal friction of soil particles becomes larger due to contact, and the cohesiveness between particles is enhanced. In order to simulate this process, before foam particle defoaming, the JKR contact model is used for the contact between soil particles and foam particles. When the normal force is less than a predefined value, as shown in equation (11), foam are considered to be broken. At this time, in post-processing, foam particles are regarded as soil particles with the same volume, the foam particles that does not defoaming is considered as a particle with a mass of 0. At this point, the normal force is calculated according to equation (12). The intrinsic parameters of the material are defined (Zhu, H.H, 2020), and the contact parameters are calibrated by establishing a virtual slump test, as shown in Figure 8. Due to limited space, the virtual slump will not be introduced. The intrinsic parameters and contact parameters of the material are ultimately shown in Tables 1 and 2.

Figure 8. Virtual slump test.

$$F_n < F_{npre} \quad (11)$$

Where F_n is the normal force of foam and soil particles, F_{npre} is the threshold of normal force when defoaming.

$$F_n^* = -4\sqrt{\pi\gamma E^* \alpha^3} + \frac{4E^*}{3R^*} \alpha^3 - KA$$

$$\delta = \frac{\alpha^2}{R^*} - \sqrt{\frac{4\pi\gamma\alpha}{E^*}} \quad (12)$$

$$A = \pi R^{*2}$$

Where F_n^* is the normal force between foam particles and soil particles after foam defoaming, γ is the particle surface energy, A is the area of the contact surface between foam particles and soil particles, R^* is the radius of the contact surface between foam particles and soil particles, K is the adhesion

energy density, and E^* and R^* are both Hertz Mindlin basic parameters, which are calculated from the modulus and radius of the contact particles. The damping force and tangential force are consistent with the JKR contact model. Considering that the tangential rolling friction increases after the foam particles defoaming, the torque of the contact surface is used for explanation, as shown in equation (13).

$$T = -k\mu_r F_n R \omega \quad (13)$$

Where k is the friction amplification coefficient, set to 1.5 in this working condition, μ_r is the rolling friction coefficient, R is the distance from the particle center of mass to the contact point, and ω is the unit angular velocity vector of the particles at the contact point.

The established numerical model for soil discharge is shown in Figure 9, and the geometric dimensions of the screw conveyor are consistent with the model test in first section. A total of 140026 particles were generated.

From Figure 10, it can be seen that as the speed of the screw conveyor and the pressure of pressure chamber increase, the soil discharge rate shows an increasing trend, which is consistent with the law obtained from the experiment. In order to verify the rationality of the numerical model, the experimental results in the second section were compared with the numerical results, as shown in Figure 10.

Figure 9. Numerical model of soil discharge.

Figure 10. Comparison between numerical results and model test results.

It can be found that the numerical model has a good agreement under the working condition of 40kPa, and the numerical results under the working condition of 60kPa are greater than the experimental values. This is because during the test process, the soil consolidates under pressure, the effective stress increases, the internal friction of the soil increases, and the fluidity decreases. Therefore, compared to the slag discharge rate under the working condition of 40kPa, there is no obvious trend of increasing, and even a slight decrease. Therefore, it can be considered that the numerical model has certain rationality.

3.4 Empirical formula for soil in full state

The soil discharge largely depends on the fluidity of the soil. Slump is commonly used in engineering to evaluate the fluidity of soil. Therefore, slump can be used as an evaluation index to explore the relationship between the fluidity of soil and the soil discharge rate when it is in the transitional state. The contact parameters of soil with different slumps were calibrated according to the virtual slump test in Figure 8 (Due to the fact that the soil particles established in EDEM are spherical, There is friction between particles, so the complete collapse fo soil is impossible. Therefore, the maximum slump is taken

as 225mm, and the slump is normalized), and then based on numerical model in section 3.3, The soil discharge under different slump conditions can be obtained.

Figures 12, 13, and 14 show the variation of soil discharge with different slump . It can be seen that the soil in the transitional state has a fluidity greater than that in the hard plastic state and less than that in the flowing state. Therefore, the soil discharge of soil in transitional state is basically between the the hard plastic state and the flowing state, and increases with the increase of slump, which is basically in line with the actuality.

From section 3.3, it can be seen that soil discharge of soil in transitional state is based on laboratory scale, which is difficult to meet the engineering scale. Therefore, in order to overcome this problem, this paper combines the soil discharge theories in sections 3.1, 3.2 and 3.3, then couples the three soil discharge theories to obtain the full state soil discharge. From Figures 11, 12, and 13, it can be seen that the soil discharge rate of the transition state slag is between the other two types of soil discharge rates, and increases with the increase of slump. Therefore, the formulas in sections 3.1 and 3.2 can be modified using the slump as a variable, and the correction equation is:

$$Q^*(h) = f_1(h) \frac{\pi(D_f^2 - D_s^2)D_f^2 dp}{4\mu\pi\phi(\pi_1) dx} \Rightarrow Q_1$$

$$+ f_2(h) \frac{(D_f^2 - D_s^2)\pi^2 D_f N \tan\phi_f \tan\theta}{4 \tan\phi_f + \tan\theta} \Rightarrow Q_2 \quad (14)$$

Where Q^* is the soil discharge rate of soil in transitional state, Q_1 is the soil discharge rate of soil in

Figure 11. Full state soil discharge rate under 20kPa pressure.

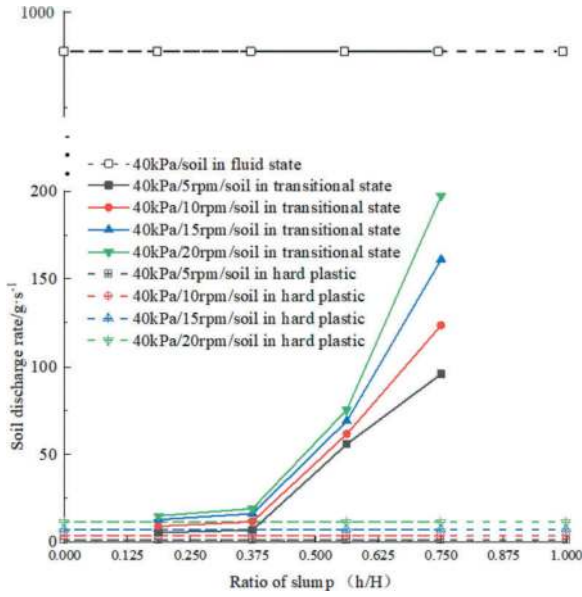

Figure 12. Full state soil discharge rate under 40kPa pressure.

Figure 13. Full state soil discharge rate under 60kPa pressure (In Figures 11, 12, and 13, h represents the slump of the soil, and H represents the height of the slump cone).

fluid state, Q_2 is the soil discharge rate of soil in hard plastic state, $f_1(h)$ and $f_2(h)$ are respectively the correction functions of Q_1 and Q_2 . h is the slump.

To determine the expression of $f_1(h)$ and $f_2(h)$, the slump ratio is used as the independent variable. So when h/H is 0 and 1, the state of the soil is in a hard plastic state and a fluid state, respectively, that is, when $h=0$, $f_1(h/H)=0$, $f_2(h/H)=1$. when $h=H$, $f_1(h/H)=1$, $f_2(h/H)=0$. Substitute the data from Figures 11, 12, and 13 to fit f_1 and f_2 functions..

From Figure 14, it can be seen that as the slump ratio increases, $f_1(h/H)$ decreases, $f_2(h/H)$ increases,

Figure 14. Correction function for soil discharge f_1 and f_2 .

which represents the change in the properties of the soil from a hard plastic state to a fluid state. So the function form of fitting curve is as follows:

$$f_1 = e^{-4.67214+54.81351\frac{h}{H}-0.14258(\frac{h}{H})^2} \quad (15)$$

$$f_2 = e^{-3.563\frac{h}{H}-7.0223(\frac{h}{H})^2}$$

The above equation is brought into equation (14) to obtain the empirical formula of soil discharge for the full state soil discharge considering engineering scale:

$$Q^*\left(\frac{h}{H}\right) = \left(e^{-4.67214+4.81351\frac{h}{H}-0.14258(\frac{h}{H})^2}\right) \frac{\pi(D_f^2 - D_s^2)D_f^2}{4\mu\pi_1\phi(\pi_1)} \frac{dp}{dx}$$

$$+ \left(e^{-3.563\frac{h}{H}-7.0223(\frac{h}{H})^2}\right) \frac{(D_f^2 - D_s^2)\pi^2 D_f N \tan\phi_f \tan\theta}{4 \tan\phi_f \tan\theta} \quad (16)$$

4 APPLICATION

To verify the reliability of equation (16), The shield tunneling between Hengli Station and Panyu Square Station on Guangzhou Line 18 has been used as the engineering background. The main crossing stratum of the right line are: medium coarse sand, muddy soil, fine sand, slightly weathered conglomerate, and strongly weathered granite. Geological longitudinal sections are shown in Figure 15. The burial depth of the shield tunnel vault is about 33.2 m, and the monitoring pressure of the pressure chamber is about 300 kPa. The engineering used 8.8 meter earth pressure balance shield to excavate, and the diameter of the screw conveyor is 1.02m, the length of screw conveyor is 13.321m, and the diameter of screw shaft is 0.285m, the speed of screw conveyor are 0~20rpm. Based on the dimensions of the screw conveyor and the monitoring data, the theoretical soil discharge is calculated using equation (16) and compared with the monitoring data, as shown in Figure 16.

From Figure 16, it can be seen that the monitoring data is within the maximum soil discharge rate based on equation (16) and the minimum soil discharge rate based on equation (16), which indicates that the equation (16) is reliable and can be extended to engineering applications.

The control of soil discharge is one of the key guarantees for the operation of EPB shield tunneling.

Figure 15. Geological section of shield tunnel crossing.

Figure 16. Comparison between soil discharge rate based on equation (16) and monitoring data.

In engineering, it is required that the theoretical soil discharge Q_s and the theoretical soil volume Q_0 determined by the excavation speed are basically equal. When $K = Q_s/Q_0$ is greater than 1, it indicates that the slump of soil is large, the properties of soil are soft and fluid, and the soil discharge is too large. Therefore, it is necessary to reduce the speed of screw conveyor. When K is less than 1, it indicates that the slump of the soil is small and its properties are dry and hard, and it is necessary to increase the speed of screw conveyor. It can be seen that for soil with different slumps, different speeds of screw conveyor are required to meet the excavation requirements. However, due to the different conditioning status of the soil, the actual soil discharge would differ from Q_s . This is because there is relative movement between the soil and the inner wall of the screw conveyor, which involves the soil discharge efficiency of the screw conveyor, which is related to factors such as the conditioning status of the soil and construction conditions. Based on the shield tunneling construction of the section from Hengli Station to Panyu Square Station on Guangzhou Line 18 as the engineering background, and the slumps of soil are used as evaluation index, the efficiency of soil discharge in different slumps is analyzed. The soil discharge efficiency is calculated according to equation (17).

$$Q_x = V_x N Q_0 = AVn_0 E_s = Q^*/Q_s \quad (17)$$

Where V_s is the theoretical soil discharge per revolution of the screw conveyor, N is the speed of

the screw conveyor, A is the cutting area of the cutter head, n_0 is the factor of loose, E_s is the soil discharge efficiency of the soil discharge, Q^* is the soil discharge based on equation (16).

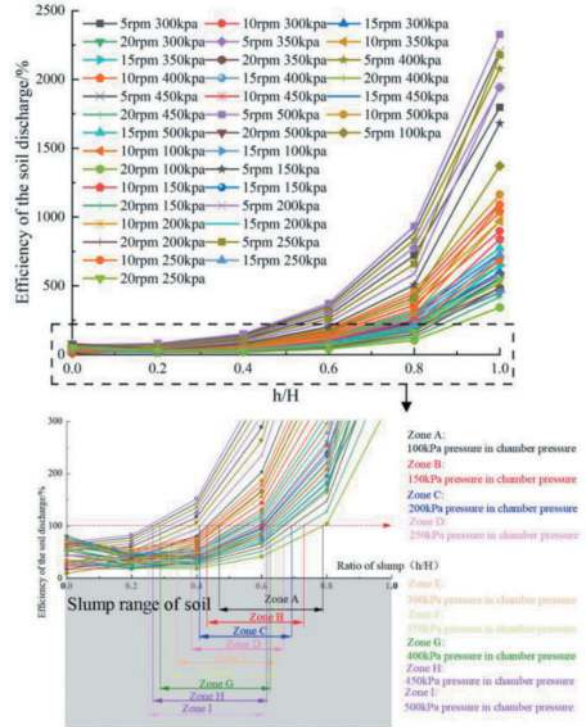

Figure 17. Efficiency of the soil discharge.

From Figure 17, it can be seen that as the slump increases, the efficiency of the soil discharge shows a non-linear growth trend, and the growth gradient becomes larger and larger. When the ratio of slump reaches 1, that is, the soil is in fluid state. Under the conditions of 500kPa pressure and 5rpm speed of the screw conveyor, the efficiency of soil discharge reaches 2326%. It is obvious that the soil discharge at this time is basically uncontrollable, which are greater than soil discharge calculated Q_s by equation (17). The efficiency of soil discharge further increases under high pressure, which requires the use of small slump soil in deep burial depth engineering, that is, the slump of the soil has a adaptability to the burial depth of tunnel. In engineering, it is necessary to ensure that the soil discharge is basically consistent with the actual soil discharge. the soil discharge efficiency of the screw conveyor is required to reach 100%, which is related to the burial depth of shield tunneling, the speed of the screw conveyor, and the slump of soil. Therefore, in order to provide a reference basis for similar projects, according to Figure 17, the suggested conditioned range for the slump of the soil under different burial depths can be obtained. Assuming that soil excavation and soil discharge is balance, earth pressure at rest can be used as the support pressure, and the pressure in pressure chamber basically follows a linear variation

relationship with burial depth. The monitoring pressure in pressure chamber is basically around 300kPa under the condition of burial depth of 30m, so it is not difficult to determine the earth pressure under other burial conditions. Finally, the suggested range for the slump of soil is shown in Table 3.

Table 3. Suggested conditioned range of soil.

Pressure in pressure chamber/kPa	Speed of screw conveyor/rpm	Slump range/mm	Burial depth of tunnel vault/m
100	5~20	141~237	10
150		126~216	15
200		121~208	20
250		117~204	25
300		102~192	30
350		93~186	35
400		87~183	40
450		81~181	45
500		75~180	50

5 CONCLUSION

This paper divides the soil state into fluid state, hard plastic state, and transitional state between the two. Empirical formulas and numerical models for soil discharge in three different states are proposed, and finally, the soil discharge theory of the three states is coupled by the slump to obtain the empirical formula for soil discharge in the full state of the soil, and the following conclusions are obtained:

- (1) The pressure in pressure chamber, speed of screw conveyor, and soil slump are the key factors that affect the soil discharge. The slag discharge is positively correlated with the pressure in pressure chamber, speed of screw conveyor, and soil slump.
- (2) Based on the Π theorem and CFD, an independent similarity criterion for the soil discharge phenomenon and the relationship between the similarity criteria were obtained when soil state is fluid. Based on the Darnell-Mol theory, the theoretical formula of soil discharge were obtained when soil state is hard plastic state. The discrete element numerical model of soil discharge considering foam defoaming was established when soil state is transitional state, and the soil discharge under different working conditions was calculated based on this numerical model, which was verified with the model test, and the reliability of the numerical model was verified.
- (3) This paper uses slump as an evaluation index of soil fluidity to couple the soil discharge theory of fluid state, hard plastic state, and transitional state, and then proposes an empirical formula for the soil discharge of full state soil, which can consider engineering scale. The shield tunneling construction between Hengli Station and Panyu Square

Station on Guangzhou Line 18 was taken as the engineering background, based on the monitoring data of soil discharge, the reliability of the theory of soil discharge in full state soil was verified.

- (4) There is a adaptability between the slump of conditioned soil and the tunnel burial depth. As the tunnel burial depth increases, the reasonable slump of the soil should be appropriately reduced. When the burial depth of the tunnel vault of 30m, the range of soil slump should be 75-180mm, which is more suitable.

ABSTRACT: The Earth Pressure Balance (EPB) shield Tunnel Boring Machine (TBM) ensures face stability of the face by introducing additives like foam and polymer to make excavated soils viscoplastic. The screw conveyor, serving as the muck discharge device in the EPB shield TBM, controls face pressure, impacting TBM excavation performance. This study aimed to construct a laboratory-scale model of the screw conveyor to determine the optimal muck discharge conditions for EPB shield TBM excavation. To create the model, the specifications of an 8m EPB shield TBM commonly used in road tunnels were analysed and scaled down by a ratio of 1:20. The torque measured for the conditioned artificial sandy soil in the lab-scale model were compared with the rheological properties assessed through the laboratory pressurized vane shear tests. The findings revealed that the screw blade torque decreases under moderate additive conditions and increases when over-applied. Furthermore, a relationship between the yield stress and screw blade torque was established, which is also linked to the slump value that measures the workability of the conditioned soil. These insights contribute to enhancing EPB shield TBM operations by predetermining more accurate injection of additives at the design stage.

Keywords: Earth Pressure Balance (EPB) shield Tunnel Boring Machine (TBM), additives, Screw conveyor, Torque, Rheological properties

1 INTRODUCTION

The Earth Pressure Balance (EPB) shield Tunnel Boring Machine (TBM) is a device designed for excavating the ground and filling its chamber, located at the rear of the cutterhead, with excavated soil. This process serves to support and stabilize the tunnel face. Typically, the excavated soil is discharged through a screw conveyor, and chamber pressure is regulated by adjusting parameters such as the rotational speed of the screw blades and the opening and closing of the discharge gate. The screw conveyor plays a crucial role in the excavation process, and it features a mechanism to reduce the pressure to atmospheric levels as the excavated soil travels along the screw toward the discharge gate.

The efficiency of excavation for an EPB shield TBM is highly dependent on the ground conditions at the tunnel face and the properties of the excavated

soil. Ideally, EPB shield TBMs perform optimally in ground conditions characterized by relatively fine-grained clayey silt, mud, and sand. These soils should have low permeability and high plasticity during excavation. These characteristics enable consistent transmission of support pressure to the tunnel face and allow for control over the transportation of excavated soil through the TBM. In addition to mechanical controls, soil conditioning is carried out by introducing additives into the tunnel face, chamber, and screw conveyor to maintain chamber pressure and to reduce pressure and torque on the screw conveyor. The application of additives is determined based on ground survey data collected before excavation, and the slump test results for muck during excavation. However, the slump test is conducted at atmospheric pressure and can yield different results depending on the operator. To address this limitation, it should be complemented by vane shear tests, which provide rheological properties that aid in designing

*Corresponding author: bh2917@korea.ac.kr

the injection of additives. Nevertheless, vane shear tests alone cannot fully assess the impact on the screw conveyor and the overall efficiency of the EPB TBM excavation process. Therefore, there is a need for research into the efficiency of excavation through reduced-scale model experiments. In this study, a typical EPB shield TBM was scaled down to a 1:20 ratio to create a laboratory-scale model. This model was used to evaluate discharge efficiency while using foam and polymer as additives.

2 ADDITIVES AND RHEOLOGICAL PROPERTIES

2.1 Additives

Soil conditioning involves the injection of additives, such as foam and polymer, to transform the excavated soil into a viscoplastic state (Lee et al., 2022). This method has broadened the spectrum of ground conditions that are suitable for EPB shield TBMs because the effective utilization of additives improves the properties of the excavated soil (Merritt et al., 2003). Additionally, it plays a vital role in maintaining face stability by decreasing the load on TBM equipment and minimizing the risk of face collapse.

2.1.1 Foam

As an additive, foam can effectively reduce surface tension and induce electrostatic repulsive forces, allowing soil particles to separate from each other and to fluidize the soil (Langmaack, 2000). Additionally, it can significantly alter the mechanical and rheological properties of the excavated soil, such as reducing internal friction angle, ensuring plasticity and workability, decreasing permeability, and minimizing wear on TBM cutters (Quebaud et al., 1998). Foam is typically composed of water, air, and a foaming agent. To produce foam, water and the foaming agent are injected into a foam generator at the desired concentration, where they combine with air. The injection process involves three key parameters: Foam Injection Ratio (FIR), Foam Expansion Ratio (FER), and Concentration of Foam (C_f), which are represented in Eqs. (1) – (3).

$$FIR = \frac{V_f}{V_{es}} \times 100(\%) = \frac{V_{lf} + V_a}{V_{es}} \times 100(\%) \quad (1)$$

$$FER = \frac{V_f}{V_{lf}} = \frac{V_{lf} + V_a}{V_{lf}} \quad (2)$$

$$C_f = \frac{V_t}{V_t + V_w} \times 100(\%) = \frac{V_t}{V_{lf}} \times 100(\%) \quad (3)$$

Where V_f is the volume of expanded foam (m^3), V_{es} is the soil volume (m^3), V_{lf} is the volume of aqueous foam solution (m^3), V_a is the air volume (m^3), V_t is the volume of foaming agent (m^3), and V_w means the water volume (m^3).

2.1.2 Polymer

Polymers serve the crucial function of maintaining uniform chamber pressure and preventing the collapse of the tunnel face. They also contribute to the enhancement of foam stability and a reduction in the permeability of excavated soil (Kwak et al., 2022). One crucial characteristic of polymers is their substantial water-binding capacity, enabling them to absorb moisture from the excavated soil upon injection and retain it even when subjected to external forces. These are particularly useful in highly permeable soils where foam alone is insufficient for effective soil conditioning. The polymers typically consist of water and a polymer solution and are applied in liquid form without air bubbles. There are two injection parameters for polymer injection: Polymer Injection Ratio (PIR) and Concentration of Polymer (C_p), which are expressed by Eqs. (4) – (5).

$$PIR = \frac{V_{lp}}{V_{es}} \times 100(\%) \quad (4)$$

$$C_p = \frac{V_p}{V_p + V_w} \times 100(\%) = \frac{V_p}{V_{lp}} \times 100(\%) \quad (5)$$

Where V_{lp} is the volume of aqueous polymer solution (m^3), V_p is the volume of polymer solution (m^3).

2.2 Rheological properties

To determine the optimal conditions for injecting additives into the target ground, it is essential to assess the rheological properties of the excavated soil after treatment with these additives. This assessment provides insights into the mechanical and rheological behavior of the treated soil, focusing on key rheological properties such as workability, peak strength, and yield stress.

Workability is closely associated with the transformation of the excavated soil, achieved through soil conditioning, into a state of plastic fluidization, which exists between the solid and liquid states. Enhancing the workability of the excavated soil, resulting in plastic fluidization, ensures uniform pressure at the tunnel face and facilitates the continuous discharge of soil through the screw conveyor. Typically, slump tests are conducted to evaluate the workability of conditioned soil.

Shear properties are assessed by deriving rheograms using raw torque data obtained from vane shear tests to determine peak strength and yield stress. The flow curve represents the relationship between shear rate and shear stress, both of which are rheological variables. These variables are calculated as described in Eqs. (6) – (7). The shear stress is calculated assuming that the surface is cylindrical in shape and that a uniform shear stress is applied to the surface (Karmakar et al., 2007). The shear rate assumes that the vane rotates in a cylindrical shape without upper and lower boundaries during the vane shear test (Meng et al., 2011).

$$\tau = \frac{2T_m}{\pi D_v^3 \left(\frac{H_v}{D_v} + \frac{1}{3} \right)} \quad (6)$$

$$\dot{\gamma} = \frac{4\pi D_c^2}{60(D_c^2 - D_v^2)} \omega_{vane} \quad (7)$$

Where τ is the shear stress (Pa), T_m is the measured torque value ($N \cdot m$), D_v is the vane diameter (m), H_v is the vane height (m), and $\dot{\gamma}$ is the shear rate (1/s), D_c is the chamber inner diameter (m), and ω_{vane} is the vane rotation speed (rpm).

3 LABORATORY TEST

3.1 Soil specimens

An artificial sandy soil was prepared by combining 30% illite and 70% silica sand for laboratory testing. Artificial sandy soil is classified as SM (Silty Sand) according to the Unified Soil Classification System (USCS). The particle size distribution curve of the samples is shown in Figure 1. This artificial sandy soil belongs to the ground conditions suitable for EPB shield TBMs, as proposed by Maidl (1995). The target unit weight of the soil specimens was set to be 1.8 t/m^3 .

Figure 1. Particle size distribution of artificial sandy soil.

3.2 Test setup and apparatus

The recommended foam injection parameters for optimal performance have been proposed as follows: FIR of 30-60%, FER of 5-30, and C_f of 0.5-5% (Oh, 2021; Shin, 2020). Foam injection parameters were determined by considering a range of slump values for optimal workability (i.e., 100-200 mm). Consequently, the selected parameters were 40% of FIR, 15 of FER, and 3% of C_f . Regarding appropriate polymer injection, it has been advised to utilize PIR values within 20% (Merritt et al., 2003). As indicated by the manufacturer, C_p was tested at 0.2 and 0.4% (Table 1).

After obtaining the target foam injection parameters (FIR, FER, and C_f) using the foam generator, the foam was injected into the sand soil specimens.

Table 1. Laboratory test cases and slump results.

No	FIR (%)	C_p (%)	PIR (%)	Slump (mm)
1	40	0	0	150
2	40	0.2	5	120
3	40	0.2	10	72
4	40	0.4	10	7

On the other hand, the polymer was mixed with water corresponding to the specified PIR and C_p targets. Afterward, it was stirred for 10 minutes in a small mixer before injection. The foam and polymer-infused artificial sandy soil were stirred for 2 minutes at a constant speed using a hand mixer.

3.2.1 Laboratory pressurized vane shear test

The rheological properties of conditioned soils were evaluated using a laboratory pressurized vane shear test apparatus developed by Lee (2021). This apparatus is designed to pressurize the soil specimen within a chamber, where a rheometer with a rotating vane applies shear to the soil specimen. In addition, the apparatus is equipped with a torque sensor that records the torque generated as the vane rotates. Two pressure gauges are installed to measure the pressure inside the chamber. The torque value can be monitored in real-time during the test. The apparatus adopted in the laboratory pressurized vane shear test is shown in Figure 2. In this test, a confining pressure of 200 kPa was applied to simulate TBM operation at a depth of 20 m.

Figure 2. Laboratory pressurized vane shear test apparatus.

3.2.2 Laboratory-scale model test of EPB shield TBM

The 8-meter EPB shield TBM was downsized to a 1:20 scale, and the screw blade featured an optimal shaft shape for sandy soil. The equipment was made of transparent acrylic to enable visual monitoring of the placement process. The scale model chamber had an inner diameter of 300 mm, a height of 500 mm, while the inner diameter of the screw conveyor casing measured 50 mm, with a total length of 460 mm. The

chamber was equipped with two pressure gauges, one at the top and one at the bottom. Similarly, the screw conveyor casing was equipped with three pressure gauges evenly spaced to facilitate real-time pressure measurement. Additionally, a torque sensor was installed to enable continuous torque measurement. The assembly of the manufactured equipment is shown in Figure 3, the adopted screw blade in Figure 4, and find detailed specifications in Table 2.

Figure 3. Laboratory-scale model of EPB shield TBM.

Figure 4. Laboratory-scale screw blade.

Table 2. Component and value of screw blade.

Component	Value
Total screw length (mm)	550
Screw shaft diameter (mm)	12
Screw flight diameter, D_f (mm)	46
Screw flight thickness (mm)	3
Number of pitches	16
Screw pitch, t (mm)	27.5
Pitch to diameter ratio, t/D_f	0.6

The conditioned soil specimen was placed in the chamber at a height of 400 mm, factoring in the 1:20 scale. Following this, the chamber was pressurized until 100 kPa, and it remained in a pressurized state for the discharge process. The screw blade rotated at a speed of 10 rpm, and real-time discharge measurements were recorded. In this study, the beginning of screw blade rotation marked the initiation of the experiment. The entire experiment lasted for 800 seconds, a duration standardized for each experimental case to ensure equitable comparisons.

4 TEST RESULTS

4.1 Rheological properties

The laboratory pressurized vane shear test was conducted for Cases 1 to 4 to examine the effect of polymer on the rheological properties of conditioned soils. Figure 5 presents a comparison of torque data over time, while Figure 6 illustrates the peak strength and yield stress for each case.

Figure 5. Torque results according to polymer injection.

Figure 6. Peak strength and yield stress.

In Cases 1, 2, and 3, injecting the appropriate amount of polymer resulted in a reduction of both peak strength and yield stress. Furthermore, due to the water-binding capacity of the polymer, the slump value also decreased. However, Case 4 demonstrates that excessive polymer injection led to increased torque and peak strength.

4.2 Screw torque and muck discharge rate

The laboratory-scale model test was conducted for Cases 1 to 4 to investigate the effect of polymer on the efficiency of muck discharge. The torque and pressure data over time are compared in Figures 7 and 8, respectively. In addition, the mass flow rate of muck discharge is illustrated in Figure 9.

Compared to Case 1, where no polymer was injected, Cases 2 and 3 exhibited lower torque measurements. The pressure results, analysed cell-by-cell, indicated a decrease in pressure as the muck moved from the chamber to the muck discharge gate. However, Case 4 showed very low workability and took a long time to stabilize. Notably, the injection of

(a) Torque data of Case 1

(b) Torque data of Case 2

(c) Torque data of Case 3

(d) Torque data of Case 4

Figure 7. Torque data of screw blade.

polymer resulted in a reduction in the amount of muck discharged per hour, similar to the observed slump results.

4.3 Discussion of test results

The average screw blade torque after stabilization is depicted in Figure 10. Similar to Cases 2 and 3,

(a) Pressure data of Case 1

(b) Pressure data of Case 2

(c) Pressure data of Case 3

(d) Pressure data of Case 4

Figure 8. Pressure data of screw barrel.

Figure 9. Mass flow rate of muck discharge.

injecting the suitable polymer reduced the machine's load. When comparing the torque results for each condition with the yield stress determined through the laboratory vane shear test, a correlation was identified, as shown in Figure 11. Conditions with optimal workability are marked with solid circles, while those with workability outside the optimal range are marked with solid triangles. The results of the laboratory-scale model test validate that proper conditioning can reduce the equipment load, even when it does not fall within the optimal workability range.

Figure 11. Torque and yield stress of conditioned soil.

5 CONCLUSIONS

The Earth Pressure Balance (EPB) shield Tunnel Boring Machine (TBM) is a device that maintains face pressure by filling the chamber with excavated soil, and controlling the screw conveyor is crucial for the machine's efficiency. Discharging muck through the screw conveyor significantly impacts the overall load of the equipment and the construction period.

This paper evaluated the efficiency of muck discharge from conditioned soil using a laboratory-scale model test and compared it with the rheological properties measured through a laboratory pressurized vane shear test. The correlation between the yield stress from the laboratory pressurized vane shear test and the torque of the screw blade was confirmed. The following conclusions can be drawn:

- 1) When the polymer was added to the conditioned artificial soil with foam, the slump value was lower than in the condition without polymer (Case 1), and both peak strength and yield stress were reduced. However, when the polymer content became excessive, as in Case 4, workability became very low, and peak strength increased.
- 2) Similar to the rheological properties, the proper application of polymer reduced the torque of the screw blade, while excessive application significantly increased the torque. Muck discharge decreased with increasing polymer injection, also similar to the slump results.
- 3) There is a correlation between screw blade torque and yield stress, and even in Case 3,

which had low yield stress but was not an optimal workability condition, it was identified that applying suitable additives can reduce equipment loads. Incorporating the results of the laboratory-scale model test into the construction process will improve constructability.

Use of biomass as soil conditioner to improve clay rheology in EPB tunneling

Muhammad Ishaq*, Benjamin Appleby, Jamal Rostami & Joseph Samaniuk
Colorado School of Mines, Golden, USA

ABSTRACT: Mechanized tunneling in soft ground presents inherent challenges, with clay clogging emerging as a particularly troublesome issue that leads to increases in downtime and project delays. The rheology of clay is influenced by several variables, such as its composition, mineralogy, groundwater chemistry, soil pH, and moisture content. This study focuses on clay conditioning with a biomass product made of glucose and oil, generated from industrial biomass production by algae. The objective of this study is to evaluate the impact of adding a solution containing varying concentrations of biomass on the rheology of clay at a laboratory scale. The observations made during and after tests on clay samples, each with different quantities of biomass agent, along with quantitative data obtained from a large-scale rheometer under constant moisture and rpm conditions, will be presented. The findings of this study confirm that the rheological properties of clay can be effectively modified, similar to drilling mud in the petroleum industry, to control and alter the rheological properties of clay, including its viscosity and clogging. Further testing and modeling efforts are currently underway to assess the optimal clay rheology achieved through the utilization of biomass in soft-ground tunneling.

Keywords: Clay Rheology, Biomass, Clay Conditioning, Clogging

1 INTRODUCTION

Mechanized soft ground tunneling projects often encounter material clogging predominantly due to clay content overloading the muck transportation-related components of tunnel boring machines, mainly in the excavation chamber and screw conveyor. Maintaining proper earth pressure balance at the tunnel face and operating the screw conveyor becomes challenging when the muck is prone to clogging (Feinendegen et al., 2011; Garroux et al., 2018; Hu., 2020; Sebastiani et al., 2022; Todaro et al., 2022; Yang et al., 2023).

“Clogging,” in the context of soft ground tunneling, refers accumulation and packing of clay particles in pore spaces of native soils making them difficult to transport (Mair, 2008; Zumsteg et al., 2013).

To facilitate consistent material flow and easy transportation, the muck should possess certain properties including workable viscosity, compressibility, and low permeability (Jeong et al., 2010; Dudhat et al., 2016; Sonebi and Perrot, 2019; Hu and Rostami, 2020; Xie et al., 2021; Zhang et al.,

2021). Achieving all the necessary properties in natural soil is nearly impossible. Therefore, the use of different soil conditioners is common in soft ground tunneling to adjust and improve its rheological properties and prevent clogging. Chemical additives and foaming agents are often used as soil conditioners to modify the rheological and mechanical properties of soils (Nelson and Miller, 1992, Puppala et al., 2006, Bhadriraju et al., 2008, Pedarla et al., 2011, Yi et al., 2016). In clay-rich soils, oil-based additives perform better at reducing the clogging phenomenon due to their inherent stability and easy integration with the soil than chemical and foam alternatives (Maidl et al., 1996; Mair, 2008; Vinai et al., 2008; Zumsteg et al., 2012; Hu and Jamal, 2020; Hu., 2020). Addressing environmental concerns related to chemical additives in muck disposal and the added advantages of oil-based additives, current research emphasizes testing eco-friendly additives and biodegradable materials. The goal is to alter the rheology of clay, a primary contributor to clogging in natural soils to avoid overloading or disruption in tunneling operation.

Clay is a term used to identify fine soil particles less than 2 microns in diameter (Adam and Hooper, 2001; Bleam, 2017; Brindley, 2006; Huggett, 2015; Matsui et al., 2022). Clayey soils are more prone to clogging due to the stickiness of clay particles caused by adhesion, inherent cohesion, composition, mineralogy, chemical setting, soil pH, and moisture content (Kooistra et al.1998; Bleam, 2017; Kang et al., 2019). Bentonite is a term used for commercially available clay often used as stabilizing fluid for drilling and laboratory tests (Cumaraswamy and Mohammed, 2020; Hua et al., 2012; Fernandez et al., 2021; Mat, 2023; Zhang et al., 2022a, b). In North America, commercially available bentonite clay is mined in Wyoming and South Dakota, where the biggest deposits of volcanic ash are found in the Black Hills of Wyoming and South Dakota and the Big Horn Mountains of Wyoming (U.S. Geological Survey, n.d.; Hannon et al., 2019, 2020a). In most of the laboratory tests related to clay rheology, bentonite clay is used as the base material (Chaudhuri, 2020, Jefferis and Merritt, 2013). This study uses Wyoming Bentonite to conduct small and full-scale laboratory tests.

Avoiding deeper discussion of clay chemistry, clogging links to various factors outlined in Figure 1. Two states, aggregation, and flocculation, decrease viscosity in clay-rich materials, while dispersion and deflocculation increase viscosity. The close packing of clay particles significantly decreases medium permeability, posing challenges in excavating soft ground mechanically. Figure 1 illustrates the clogging effect with a 25% moisture content bentonite mix for visual reference. Water serves as a widely-used technique employed by field crews to minimize clogging and enhance the workability of materials in soft ground conditions during mechanical excavation. Clogging intensity depends on clay plasticity, flow velocity, groundwater chemistry, and relative movement of working surfaces.

Figure 1. Clay particle state, Left: Four states of clay particles¹, Right: Clay mix with 25% moisture content.

Due to the many heterogeneities in clay soils including granular particles and large viscosities, traditional shear rheometers could not accurately characterize the fluid properties of real soils. Thus, there was a need to develop a fully capable rheometer

specifically designed to evaluate the mechanical properties of soil mediums, considering their varying particle size distribution. Consequently, modifications were made to an existing Soil Abrasion Index Unit at Earth Mechanics Institute (EMI), Colorado School of Mines, integrating the necessary attachments to measure the rheological properties of materials while preserving their original composition, particle size distribution, and moisture content (Hu and Rostami, 2020; Hu., 2020). In this paper, the device is referred to as a “Full-Scale Rheometer.” To compare against standard rheometers, a commercially available bench-top TA Instruments DHR-3 rheometer will be used.

This study investigates the use of a biomass product (commercially known as Encapso™) made from algae to modify the rheology of clay and reduce clogging during tunneling operations. The test matrix was designed to comprehensively assess the impact of the additive on the clay rheology and compare the results with measured values by the DHR-3 and Full-Scale Rheometer. Tests were conducted on clay samples with different moisture levels and biomass concentrations. Observations during and after these tests along with quantitative analysis of the data for each clay sample provided insights into how the biomass additive affects the flowability of bentonite clay.

2 EQUIPMENT AND MATERIALS

2.1 DHR-3 rheometer

The TA Instruments Discovery Hybrid Rheometer Series-3 (DHR-3) represents the latest advancement in a series of rheometers (shown in Figure 2). It is considered one of the world’s most advanced combined motor and transducer (CMT) rheometers. The DHR-3 rotational rheometers have a maximum torque capacity of 200 mN·m and can exert a maximum normal force of 50 N (TA Instruments, 2014).

Figure 2. DHR-3 rheometer.

¹ Figure retrieved from clay chemistry book (Bleam, 2017)

2.2 Full-scale rheometer

The full-scale rheometer is an industrial drill press modified with a Variable Frequency Drive (VFD) to control rpm, loadcells holding the sample chamber to measure torque, and a mixer attachment to become a rheometer, as seen in Figure 3. Due to its capability to characterize soil materials with large particle sizes and viscosities, covering many heterogeneities found in real-world geology and soil properties at various sites, it is referred to as the “Full-Scale Rheometer” in this manuscript.

Figure 3. Full-scale rheometer.

A full-scale rheometer consists of a cylindrical chamber with a 330 mm internal diameter and 450 mm height. A chamber lid is attached at the drive shaft under the adjustable head and impeller mount at the lower end of the spindle nose. The backup motor capacity powering the drive shaft consists of 3.7kW. The torque is measured using two sensors attached on opposite sides of the chamber and the chamber sits on a turn table mount so that it can freely rotate. A variable frequency drive is installed to the unit to control motor rpm. The unit is capable of driving shafts between 0 rpm to 1000rpm speeds. Detailed descriptions of the components can be found in the literature (Rostami et al., 2019; Gharahbagh et al., 2013b; Gharahbagh et al., 2014b, Hu and Rostami, 2020; Hu., 2020).

2.3 Impeller

There are two impellers used in the Full-Scale Rheometer given in Figure 4 and one impeller in the DHR-3 rheometer.

The auger impeller has a 148mm radius. The auger attachment was used to simulate the condition

within the screw conveyor of TBM. The Pin Rotor has a 296mm radius

The impeller used with the DHR-3 rheometer is a 4-vane aluminum rotor 42 mm in length and 15 mm in diameter.

Figure 4. Impeller, Left: Pin Rotor, Right: Auger.

2.4 Schematics of the mechanisms

Two different rheometers are used for testing the rheological parameters of mixtures, each featuring slightly different torque measurement mechanisms. The commercial rheometer directly measures torque by utilizing impeller force input, while the full-scale rheometer uses an indirect torque measurement method, utilizing load cells positioned on the sides of the material chamber. Refer to Figure 5 for schematics depicting the mechanisms in both rheometers.

Figure 5. Schematics of the mechanism, Left: Commercial rheometer, Right: Full-scale rheometer.

2.5 Base materials

This study uses two base materials: a) Wyoming Bentonite and b) Denver clay. Wyoming Bentonite (details in the introduction) was purchased from a local distributor, whereas, Denver clay was obtained from a construction site in Arvada, Colorado, shown in Figure 6.

Bentonite is used to compare full-scale and DHR-3 rheometer results. This determines the quality of data from a full-scale rheometer. Denver clay was used to investigate Encapso’s ability to change the rheological

Figure 6. Base material, Left: Denver clay, Right: Wyoming Bentonite.

properties of clay materials. Each test sample consists of around 60 kgs of wet batch of mixture. Table 1 shows the mineral characteristics and Figure 7 shows the particle size distribution curves of both materials (Anderson and Low, 1957; Hauser and Colombo, 1953; Hu., 2020).

2.6 Biomass

The conditioner, Encapso™, is a form of biomass derived from algae oil, characterized by particles sized

between 5-10 microns and coated with glucose. This particular coating renders Encapso™ highly effective in various extreme conditions, including elevated temperatures, high pH levels, increased calcium concentration, and the presence or absence of water. Its primary application lies in optimizing drilling processes by mitigating friction without inducing excessive greasiness or foaming. Furthermore, Encapso™ exhibits biodegradable properties, as confirmed by OECD 301B testing methods, thus it is an environmentally friendly soil conditioner. Customized packaging options are available for Encapso™. To ensure its integrity, protection from moisture is essential, and it has a shelf life of approximately 2 years. Storage requirements dictate a dry environment (humidity level below 70%) at a cool temperature (below 25°C). Detailed material characteristics are outlined in Table 2.

Table 2. Material characteristics of Biomass.

Description	Numerical Value
Total algae oil by weight	50-70%
Moisture	<4%
Bulk Density	240-360kg/m ³
Specific Gravity (Gs)	1.0- 1.1
Recommended Concentration	34-53 Kg/m ³
Cell wall stability	390°F
Lubricant stability	650°F

Figure 8. Biomass, Left: Dry material, Right: Micron-level².

2.7 Test matrix and sample preparations

The test matrix aimed to quantitatively analyse how the biomass agent affects bentonite, first employing the DHR-3 rheometer. Subsequent tests were carried out using a material mix with the same composition in a Full-Scale Rheometer. In the next phase, two distinct impellers were tested to comprehend their geometric influence on clay rheology. The final testing phase incorporated Denver clay into the matrix with

2 Image sourced from Corbion's Encapso product pamphlet.

a reasonable moisture content to further explore the impact of biomass concentration at lower effective shear rates.

Utilizing high moisture with bentonite was necessary due to the torque capacity limitation of the DHR-3 rheometer. In the case of Denver clay, the moisture content was initially selected to facilitate the hand-mixing process, which was challenging with lower moisture content. Later, a lower water content was considered to simulate in-situ ground conditions.

The mixing process involved hand-mixing all samples, varying in water content, for a minimum of 3 hours, followed by mechanical agitation using an electric drill with a mixing flat beater. All samples were allowed to hydrate for 24 hours before testing in a full-scale rheometer to ensure homogeneity. For the DHR-3 rheometer, approximately 80g of samples were extracted from large samples, with proper moisture content records. A detailed text matrix is given in Table 3.

Table 3. Test matrix.

Rheometer	Base Material	Water Content (%)	Biomass Concentration kg/m ³
DHR-3	Wyoming	200	0
	Bentonite	200	39
Full-scale	Wyoming	200	0
		200	38
	Denver Clay	500	0
		25	20
		25	30

3 RESULTS

This section is subdivided into two subsections to separately present results from the DHR-3 and full-scale rheometer.

3.1 DHR-3 Rheometer results

Two sets of tests were conducted (shown in Figures 9 and 10), each consisting of two tests, involving varied shear rates (both increasing and decreasing) using bentonite as the base material, mixed with a moisture content of 200 wt%. These tests were conducted using the DHR-3 rheometer.

The first set of tests aimed to establish a torque and viscosity baseline without incorporating biomass. The results indicated a torque of 4427 $\mu\text{N}\cdot\text{m}$ at a shear rate of 1 s^{-1} . However, as the shear rate increased to 400 s^{-1} , the torque rose to 5538 $\mu\text{N}\cdot\text{m}$. Concurrently, in this test, viscosity decreased from 1221 Pa . s to 8.25 Pa s as the shear rate increased from 1 to 400 s^{-1} .

In the same set of tests, where the shear rate decreased from 400 to 1 s^{-1} , the torque measurements

Figure 9. Test set -1 (Wyoming Bentonite with 200% Moisture).

Figure 10. Test set -2 (Wyoming Bentonite with 200 Moisture and 20 kg/m³ concentration biomass).

shifted from 5184 to 1905 $\mu\text{N}\cdot\text{m}$, and viscosity values changed from 8.25 to 1212 Pa . s. Refer to Figure 9 for a visual representation of the results of the first test set.

The second test set aimed to assess the influence of biomass on the matrix. The data shows less divergence between increasing and decreasing shear rate conditions. When increasing the shear rate from 1 to 400 s^{-1} , the recorded torque ranged from 2406 to 3726 $\mu\text{N}\cdot\text{m}$, while viscosity ranged from 1532 to 5.9 Pa . s. Conversely, in the scenario of reducing the shear rate from 400 to 1 s^{-1} , torque ranged from 3701 to 2225 $\mu\text{N}\cdot\text{m}$, and viscosity ranged from 5.9 to 1417 Pa . s, as illustrated in Figure 10.

3.2 Full-scale rheometer results

The first two tests were conducted on the same material sample which was tested in the DHR-3 rheometer, to validate the result and ensure the sensitivity of the Full-Scale Rheometer. In the first two tests, the Pin Rotor was used and only the increasing effective shear-rate scenario was recorded.

The results of torque shown in Figure 11 are in N.m. The first test using bentonite with 200 wt% water content without biomass shows 55 N.m torque at 0.08 s^{-1} shear rate, whereas 50 Pa . s was the viscosity. At 0.16 s^{-1} effective shear-rate torque increased to 59 N.m and viscosity decreased to 3.46 Pa . s.

In the subsequent test, biomass was introduced into the 200 wt% water content bentonite sample. This alteration resulted in torque fluctuation ranging from 25 to 38 N-m and a viscosity shift from 22 to 2.59 Pa . s, corresponding to an ascending effective shear rate of 0.08 to 0.16 s-1. The outcomes are shown in the accompanying Figure 12.

Figure 11. Full-Scale Rheometer test -1 (Wyoming Bentonite with 200 wt% Moisture).

Figure 12. Full-Scale Rheometer test-2 (Wyoming Bentonite with 200 wt% Moisture and 20kg/m³ biomass).

The third test using a Full-Scale Rheometer was to investigate how different impeller geometries affect the rheology of bentonite. The test involved using a Pin Rotor and an auger. Since the auger mimics the screw conveyor in an Earth Pressure Balance Tunnel Boring Machine (EPB TBM), incorporating geometric parameters into the test matrix was deemed essential for interpreting the results.

The bentonite mixture in this test had a water content of 500 wt% and contained no biomass. The primary goal of this test was to comprehend the relationship between impeller geometry and rheological properties. Therefore, efforts were made to maintain test conditions and preparation as consistent as possible. The results indicated a significant torque applied by the auger compared to the Pin Rotor, shown in Figure 13.

The recent series of tests aimed to replicate real-world conditions and assess how varying biomass concentration affects torque and viscosity in a material. Denver clay served as the base material, with water content reduced to 25%. Two specific

biomass concentrations were examined, utilizing an auger as an impeller to understand their impact on material behavior. Graphed in Figure 14 are the peak torque and viscosity results. At a biomass concentration of 20 kg/m³, the torque measured approximately 1200 N-m, and viscosity was around 10937 Pa . s. In contrast, a 30 kg/m³ biomass concentration yielded a torque of 956 N-m and a viscosity of 8552 Pa . s.

4 DISCUSSION

The use of biomass in tunneling operations offers a chance to offset environmental concerns linked to using alternative chemical soil conditioners. Integrating biomass with water as a soil conditioner provides an eco-friendly alternative, improving workability and addressing environmental concerns during muck disposal.

The test matrix was designed to analyze how Biomass affects clay rheology, and how beneficial in tunneling operations with EPB TBM. A precise method employing the advanced rheometer DHR-3 was initially utilized, followed by utilizing a Full-Scale Rheometer. The significant benefit of employing a Full-Scale Rheometer was to mitigate the challenges of characterizing the rheological properties of soil materials with large particle sizes and high

viscosities, that traditional steady-shear rheometers are not capable of measuring.

The initial testing phase aimed to establish baseline measurements using a mix of Wyoming Bentonite clay with 200 wt% moisture content. This same composition was then utilized with a biomass concentration of 20 kg/m³.

With the inclusion of biomass, the torque decreased by approximately 50 %, while viscosity increased by about 14 % in the DHR-3 rheometer. This notable reduction in torque highlights the biomass's efficacy in clay-rich soils.

Using the Pin Rotor on a Full-Scale Rheometer to examine the material's composition, the data revealed a significant reduction of 55 % and 56 % in torque and viscosity, respectively, for Wyoming Bentonite at a low effective shear rate. The discussion focuses on a low shear rate, which is feasible in the EPB TBM operation.

The Full-Scale Rheometer was used with geometry similar to a screw conveyor in EPB TBM. A comparative analysis of the Pin Rotor and Auger was conducted to understand the shear surface's influence on rheology. The findings revealed a 17 % difference in torque and a 15 % difference in viscosity at lower effective shear rates, underscoring the influence of impeller geometry. This signifies that soil muck with a significant clay content might affect the screw conveyor's efficiency if the geometry is altered for any reason during operation.

The last set of tests aimed to assess how varying biomass concentration affects the rheological properties of clay materials. Denver clay was chosen as the base material, and an auger was employed as an attachment in a Full-Scale Rheometer to closely mimic real-world conditions of tunneling in clay. The impact of biomass concentration was particularly noticeable at lower effective shear rates, with a substantial difference observed. Conversely, the viscosity of the mixture exhibited almost no variation at higher effective shear rates. The findings highlighted a 20 % reduction in torque at a biomass concentration of 30 kg/m³ compared to 20 kg/m³. Furthermore, a significant 22 % difference in viscosity was noted at an effective shear rate of 0.0011 s⁻¹. These results emphasize that a standardized biomass concentration is not universally applicable across all material types. Rather, tailored laboratory tests are necessary to determine the optimal biomass concentration for soil material at each tunneling site.

5 CONCLUSIONS

Incorporating biomass into tunneling operations presents the opportunity for an environmentally friendly solution to reduce mechanical workload in the cutting chamber and screw conveyor. Experiments investigated the impact of biomass on the rheological properties of clay, including viscosity and torque at varying shear rates, using advanced

rheometry (DHR-3) and a Full-scale rheometer. Tests with Bentonite clay having 200 wt% moisture showed ~50% torque reduction with biomass addition, confirmed in both small-scale and full-scale rheometers. After having the full-scale test results validated with advanced rheometry, a real-world simulation was designed using the Denver Clay at low moisture content which was deemed to be prone to clogging. Varying biomass concentrations in the Denver Clay mix further confirmed the impact of biomass on viscosity and torque requirement at a certain range of effective shear rates in a mix with 25 wt% moisture content. Site-specific full-scale testing is critical to determine optimal biomass levels, moving beyond a one-size-fits-all approach. This research highlights biomass's potential for decreasing clay viscosity and required torque, easing muck transportation and disposal.

ACKNOWLEDGMENTS

We gratefully acknowledge the generous support of Corbion company for providing the biomass Encapso™, to conduct this research endeavor. Additionally, we extend our appreciation to the Earth Mechanics Institute at the Colorado School of Mines and its staff for providing us with the requisite help in the successful execution of this research.

TBM jamming and statistical estimators: Case of a long and deep tunnel

Daniel Kasal, Alberto Flor*, Federico Amadini & Andrea Oss

Systra-SWS, Trento, Italy

ABSTRACT: TBM jamming events caused by caving can be difficult to predict and can cause significant delays and cost overruns. This study proposes a new method for predicting jamming events using aggregated quantities calculated on the TBM raw excavation data. These statistical estimators tend to reach extreme values when in proximity of recorded TBM blockages. By classifying each excavation section with a score based on the statistical estimator's deviation from normality, the TBM advancement can be monitored, helping operators and construction crew to anticipate difficult situations. The method is applied to three long and deep tunnels excavated through the Alps, where an extensive dataset is available.

Keywords: TBM, Excavation, Caving, Prediction, Statistical estimators

1 INTRODUCTION

In mechanized tunnel excavation, the unexpected stop (jamming) of the Tunnel Boring Machine (TBM) is one of the worst occurrences, in terms of cost, time and workers' safety. The ability to predict the likelihood of a TBM jamming event is therefore of paramount importance during the excavation. Early warnings of impending TBM failure (even just one ring ahead) are essential for implementing effective countermeasures.

There are many articles focusing on real time prediction during excavation, especially with Machine Learning techniques. For example: in Wu et al. (2021) a method is proposed to predict the encountered rockmass class, classified by their boreability, while Gao et al. (2019) describe the use of Recurrent Neural Networks able to predict the future values of important TBM operating parameters, by using in-situ monitoring.

Hasanpour et al. (2020), on the other hand, propose a method to predict the jamming risk at design phase by using artificial neural network (ANN) and Bayesian network (BN) trained on synthetic data that model ground convergence and the possibility of machine entrapment.

In this paper the case of deep and long tunnel is discussed, using the dataset of three TBMs, that encountered critical sections and underwent prolonged stops due to difficult geological conditions and severe

overburden. The jamming events were nine in total, eight of which caused by caving and one by squeezing.

The goal is to test whether these critical occurrences could be predicted by analysing the TBM data, such as Advance Rate or Torque, called Key Performance Indicator (KPI). These quantities, sampled at regular time intervals (every 3 seconds), tend to assume anomalous behaviours in the rings preceding critical sections.

This work aims to quantify the perceived spread and erratic trend of the TBM KPIs, proposing and discussing the usage of statistical estimators that can signal the upcoming critical phenomenon, showing that their extreme behavior is correlated to recorded jamming events.

2 PROJECT OVERVIEW

The Brenner Base Tunnel (BBT) will connect Fortezza (Italy) to Innsbruck (Austria). With total length of 56 km it will join the existing Innsbruck railway tunnel, reaching a total length of 64 km and becoming the longest railway tunnel in the world. This paper focus on the mechanized excavation with double shielded TBMs of the Mules 2-3 lot (Citarei et al. 2020), consisting of three parallel tunnels: an exploratory tunnel and two mainline tunnels. The distance between the main tunnels is 70 m, while the exploratory tunnel is located 12 m below them, as shown in Figure 1.

*Corresponding author: aflor@systra.com

Figure 1. Cross section of the BBT tunnels, modified from (BBT, 1999).

The overburden ranges from 595 to 1715 m. The alignment crosses a complex geology, passing through the Subpenninic core of the Tauern Window, which is wrapped by a stratified layer of Penninic and Austroalpine. The geological context is characterized by a great heterogeneity of the rock masses and by the presence of numerous faults. The main lithologies are phyllites, schists, granite, granodiorites and gneiss, as shown in the design and as-built geological profile in Figure 2. A complete geological description is presented in Schiavo et al. (2015).

Figure 2. BBT Lot Mules 2-3 as-built geological profile according to the Joint Venture (Pescara et al. 2020).

3 DATA

The datasets employed contain the measurement of TBM parameters for the three parallel tunnels. We will codename them T0 (the exploratory tunnel), T1 and T2 (the two main tunnels). At the time of writing, T0 and T1 are completed, while T2 is still under construction. Specifics of the three tunnels, and respective data, are reported in Table 1. The raw data samplings are the number of rows in the datasheet. The dataset is substantially larger than those reported in many other publications.

The dataset contains the measurement (sampled with a 3 second interval) of the TBM parameters, called Key Performance Indicators (KPI) (Maggio et al., 2022).

The KPI considered in the discussion are:

- Torque (T).
- Thrust force (TF).

Table 1. Tunnels details.

	T0	T1	T2
Total length [km]	14	14	11
Rings number [-]	9456	8130	6165
Excavation diameter [m]	6.8	10.7	10.7
Number of blocks occurred [-]	3	1	5
Raw data samplings	$9 \cdot 10^6$	$9 \cdot 10^6$	$6 \cdot 10^6$

- Rotational speed (RPM).
- Advance rate (AR).
- Penetration rate (PR).

A total of nine jamming events occurred to the TBMs in the three tunnels. Most of these were caused by caving, or face instability. One event was caused by squeezing, i.e., severe convergence of rock mass in plastic conditions (Working Group n°17, 2017). Some of these jamming events are described in detail in Amadini et al. (2021).

The events analysed and their causes are:

- T0.0 – caving;
- T0.1 – squeezing;
- T0.2 – caving;
- T1.1 – caving;
- T2.0 – caving;
- T2.1 – caving;
- T2.2 – caving;
- T2.3 – caving;
- T2.4 – caving and squeezing.

A caving event is induced by poor rock mass quality, high stress and, possibly, by water inflows. The excess of excavated material leads to a decrease in advance rate and rotational speed, with an increase in torque. When caving occurs, the TBM jamming is caused either by the machine reaching the maximum torque available or by problems to the material extraction's system, such as the backfilling of the cutterhead or the falling of excavated material from the conveyor bell.

A squeezing event is caused by the inability of the TBM's jacks to exert the necessary thrust force to contrast the friction between rock mass and shields.

3.1 Aggregated data vs raw data

To analyze the TBM functioning, it is common practice to consider aggregate values for each KPI (aggregated data), usually averaged on some length (every centimetre, every ring length, etc.). By looking at the mean per ring, one may anticipate whether some anomalies in the excavation are occurring. The main reason to use the ring-averaged values, instead of the more detailed time sampling (raw data), is twofold. On one hand the parameters behaviour inside a ring is wild and sometimes very difficult to analyse, therefore engineers or scientists may prefer to work with just the mean of the TBM quantity for

each ring (aggregate the information); these quantities are, most of the time, sufficient to summarize the situation. On the other hand, there is a computational and storage necessity: for a long tunnel, the datasheet with the recorded key indicators averaged per ring is of the order of thousands of rows times hundreds of columns. If one were to store the timestamped samplings (for example every 3 seconds) the rows can easily explode to the millions (the raw data are in the order of 10^3 per ring).

However, using only the KPI's average values per ring could lead to a significant loss of information. A comparison between two rings with a similar torque average is shown in Figure 3. In the second graph, it can be clearly seen that the average value is not representative of the whole situation. The goal is to quantify the extreme behaviour in the second graph, by aggregating the information with an estimator that could complement mean per ring.

Figure 3. Torque values during excavation of two different ring. Both images have the same mean value (red line), but they present two distinctively different situations.

4 PROPOSED ESTIMATORS

We present a collection of statistical quantities that may give a further understanding on the TBM's advancement, helping to describe KPI's anomalous readings.

Given a sample x_1, x_2, \dots, x_n of a measured quantity during the excavation of a single ring, the following statistical quantities can be calculated:

- **Mean:**

$$\mu = \frac{1}{n} \sum_{i=1}^n x_i$$

- **Standard deviation (SD):**

$$\sigma = \sqrt{\frac{1}{n} \sum_{i=1}^n (x_i - \mu)^2}$$

- **Max variation (MaxVar):** difference between 95th percentile and 5th percentile range

$$\max_{\text{var}} = P_{95} - P_5$$

- **Interquartile range (IQR):** the range between the 75th percentile (Q3) and the 25th percentile (Q1)

$$\text{IQR} = Q_3 - Q_1 = P_{75} - P_{25}$$

- **Coefficient of variation (CV):**

$$CV = \frac{\sigma}{\mu}$$

The previous statistical quantities will be called **statistical estimators** for the rest of the paper. These are aggregated quantities calculated for each ring using the raw data (3 seconds sampling) recorded during ring excavation.

A graphical representation of the statistical parameters chosen is shown in Figure 4 (applied to torque distribution), while a procedure chart of aggregating raw data to obtain the statistical estimator for three rings is depicted in Figure 5.

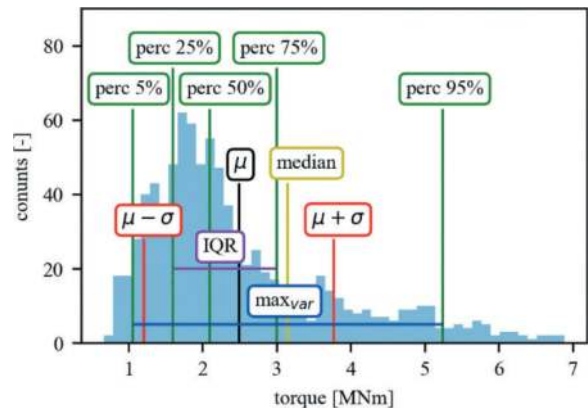

Figure 4. Graphical representation of the statistical quantities, applied to the torque distribution for the excavation of one ring.

In the following paragraphs, we will use the estimators as aggregate quantities per ring. Specifically, for each TBM parameter, we will calculate the estimators for each ring.

Figure 5. Example of the aggregating procedure, from raw data to statistical estimators, for three rings.

5 RESULTS

In addition to mean and standard deviation, we aggregate the TBM data during a ring excavation cycle by calculating the estimators described in the previous paragraph (max variation, interquartile range, coefficient of variation), for the TBM KPI's described in Paragraph 3 (torque, thrust force, rotational speed, advance rate, penetration rate).

As a preliminary step, the estimators' values are studied, looking for anomalous behaviours in the rings preceding a jamming episode. First empirical evidence is inferred by plotting the estimators' trends. Afterwards a scoring system to quantify the deviation of the estimators from their usual baseline is proposed, correlating this deviation with the occurrence of critical phenomena.

5.1 Estimators behaviour

The trends of the estimators in rings close to the recorded TBM's jamming events show that they tend to reach extreme values near the stops.

Among the aggregated quantities, the proposed estimators can alert of a critical section earlier than the mean, at least one ring earlier. IQR and MaxVar in particular, as shown in Figure 6 and Figure 7, signal the critical zone with one ring in advance. In both Figures the last 100 rings before the jamming events are plotted.

Figure 6. Torque mean value for each ring (above) and Torque maximum variation for each ring (below). Vertical line: the ring where T2.3 TBM stop happened.

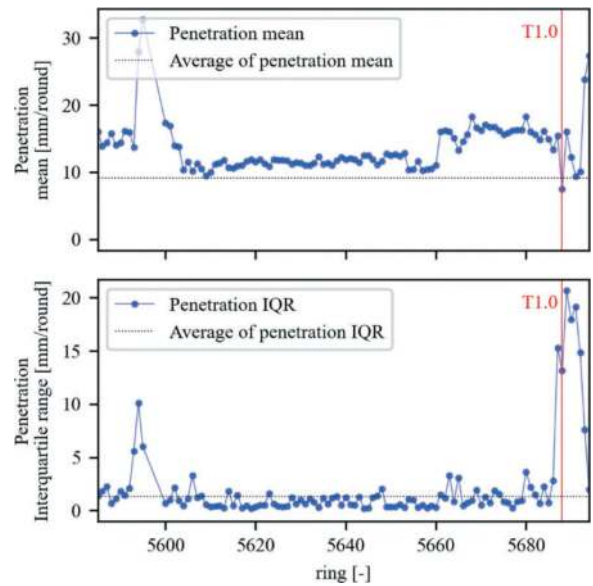

Figure 7. Penetration mean value for each ring (above) and penetration interquartile range for each ring (below). Vertical line: the ring where T1.0 TBM stop happened.

The comparison of the same estimator close to all jamming events can be plotted, by stacking the lines together for each critical event of the three tunnels. The curves show a positive trend in the 10 rings before the stops, for all nine cases recorded.

Torque – maximum variation (Figure 8): in the two rings before the jamming event, there is a relevant increase in torque maximum variation for the events T0.0, T0.2, T1.0, T2.3 and T2.4. In the jamming ring, for all the events analysed the quantity is at its peak, except for T0.1. The increase in torque maximum

variation seems to be correlated with the occurrence of caving, and T0.1 is the only event caused exclusively by squeezing.

Penetration – interquartile range (Figure 9): In this case, there is also a perceivable increase of the value while approaching the jamming event. The TBM stops showing the steepest trend in penetration IQR are the same of torque max variation, except for T2.4, where the variation is not that perceivable.

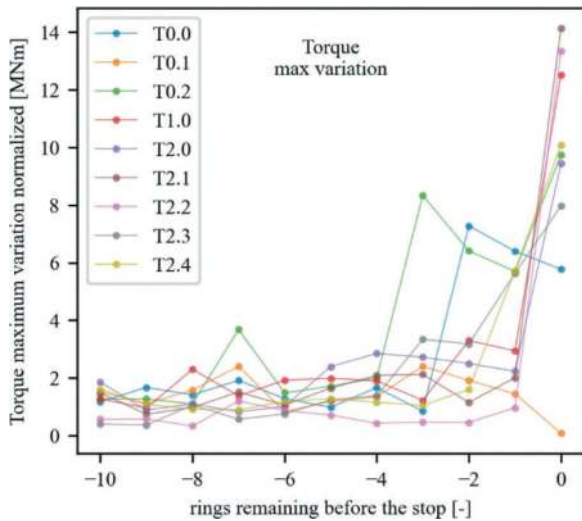

Figure 8. Trend of torque maximum variation in the last ten rings before the critical events. The estimators have been normalized for visibility, making results from the three tunnels comparable.

Figure 9. Trend of penetration interquartile range in the last ten rings before the critical events.

5.2 Scoring the estimators

Up to this point it has been shown that by employing statistical quantities of Paragraph 4, we can correlate their evolution during excavation with the presence

of critical sections. Graphically we showed that the estimators tend to spike when close to the ring of a recorded TBM stop.

This qualitative understanding must be formalized. The next step is to construct a scoring system, based on the statistical aggregations per ring, able to classify all excavation sections according to the likelihood of a jamming episode.

This next paragraph may appear complex at first glance, since we are going to construct a statistical distribution of statistical estimators. The core idea is that, once calculated for each ring, the estimators form a statistical population and, for each KPI, we have the collection of the estimator outcomes. Every new value of the estimator can be compared to said distribution and ranked accordingly.

By doing so, one can quantify the sentence “the estimators assume quite an extreme value”, by defining the extremity of the value compared to its other occurrences.

We assign the following score, called **variability score**, to each ring, based on the value of the statistical estimators:

- “H”: high variation compared to the estimator history, when the value is above the 99th.
- “M”: medium variation if the value is above the 90th percentile.
- “L”: low variation, all other cases.

With this scoring system we can classify the tunnel sections according to the severity of each KPI deviation from a “normal” behaviour.

As shown in Figure 10, the whole tunnel can be divided into three sections, according to the estimator variability score. The rings that have estimators with a score “H” are those that in the previous sections were described as anomalous and with extreme values.

Figure 10. Visual aid for the variability scores: variability score for the Max Var value of advance rate, calculated at each tunnel ring for all the recorded values. The rings for which the advance rate Max Var is above the 99th percentile of its distribution are ranked as “H” (High) score.

The intuitive idea in Paragraph 5.1 (see Figure 8) can now be formalized, by looking at the estimators score in the rings preceding a jamming event. Table 2 shows the highest variability score between the two rings before these events. For each recorded TBM stop (rows), we report the variability score of the statistical estimators (standard deviation, maximum variation, coefficient of variation, interquartile range) for the KPI (torque, thrusts, rounds per minute, advance rate, penetration).

An “H” value of the variability score means that either one or both rings before the critical section have a very unusual value of the statistical estimator. In many cases, the critical section is anticipated by an abnormal value, i.e. “H” score.

Table 2. Variability scores for estimators of KPI close to critical zone.

	Standard deviation					Maximum variation				
	T	TF	RPM	AR	P	T	TF	RPM	AR	P
T0.0	H	H	M	M	H	H	H	M	M	H
T0.1	L	H	L	M	M	M	H	L	H	M
T0.2	H	L	L	M	H	H	L	M	M	H
T1.0	H	L	M	H	H	H	M	M	H	H
T2.0	M	L	L	L	M	M	L	L	L	M
T2.1	L	L	L	L	M	M	L	L	M	M
T2.2	L	L	L	L	L	L	L	L	L	L
T2.3	H	M	L	L	H	H	M	L	L	H
T2.4	H	H	H	H	M	H	H	H	H	M

	Interquartile range					Coefficient of variation				
	T	TF	RPM	AR	P	T	TF	RPM	AR	P
T0.0	H	H	M	H	H	M	H	H	H	H
T0.1	L	H	M	M	M	M	L	L	M	M
T0.2	H	L	M	H	H	M	L	M	H	H
T1.0	H	M	M	H	H	H	M	H	H	M
T2.0	M	L	L	M	M	M	L	L	M	L
T2.1	M	L	M	M	M	M	L	M	M	L
T2.2	L	L	L	L	L	L	L	L	L	L
T2.3	H	M	L	L	H	L	M	M	H	H
T2.4	H	M	M	H	M	H	H	H	H	H

The statistical estimators that have a variability score between “H” and “M” in all the TBM stop events but one (T2.2) are:

- Maximum variation of the torque.
- Standard deviation, maximum variation, and interquartile range of penetration.
- Coefficient of variation of advance rate.

It is then important to point out that there are some critical events that did not show great variability of any statistical estimator before the ring of the jamming. This is the case of T2.0, T2.1 and especially the stop T2.2, which did not show any “H” or “M” behaviour in any parameter analysed.

5.3 Combining the scores

From previous section, the statistical estimators with variability score “H” on most of the jamming events are:

- Torque standard deviation (T SD);
- Torque maximum variation (T MaxVar);
- Torque interquartile range (T IQR);
- Advance rate coefficient of variation (AR CV).

This leads to the idea of highlighting only the rings where all these four statistical estimators have score “H”. As it turns out, many of this high-estimators rings are in proximity of jamming events.

The most important are those preceding the critical section (to be an information of practical use).

In Table 3 are reported the fraction of events that have 4 High-score estimators in the ring(s) preceding the stop. All the events for T0 and T1 tunnel were signalled by extreme estimators’ behaviour, while 2 out of 5 of the T2 events had this alert.

Table 3. Critical events in lot Mules 2-3.

	T0	T1	T2
Total caving events	2	1	5
Events with at least 4 estimators scored ‘H’	2	1	2

The 3D scatter plots in Figure 12, Figure 13 and Figure 15 show the estimators listed above (Torque SD, Torque MaxVar, Torque IQR and Advance Rate CV) for the three tunnels. The vertical red planes indicate the critical events. The markers colors are chosen as follows:

- Red: the rings where the jamming took place.
- Green: rings with all 4 estimators scored “H” and preceding the jamming event (these are the most important).
- Yellow: rings with all 4 estimators scored “H”, that are either following the jamming event or far from any event (false positives).
- Blue: all other rings.

Tunnel T2:

For the tunnel T2 the predictive capacity is limited. By highlighting the rings that have the 4 estimators scored High, one can see that only 2 out of 5 caving events have a warning. The highlighted dots can be seen in the 3D scatter plot (Figure 11), together with the 4 estimators’ behavior along the whole excavated tunnel (Torque SD, Torque MaxVar, Torque IQR and Advance Rate CV). In Figure 12 only one of the 4 plots has been chosen for clarity, but the colored marks still indicate rings with all 4 estimators scored ‘H’. One can see that only the two rightmost critical events have a green-colored ring preceding them.

For the T2 tunnel there are 15 rings exhibiting abnormal behaviour. These rings are as follows (from left to right):

- The ring where event T2.0 occurred;
- The ring where event T2.1 occurred and the ring after this;
- The ring where event T2.2 occurred and the ring after this;
- A ring approximately 30m after T2.2;
- The ring where event T2.3 occurred, the ring before and the ring after;
- 3 consecutive rings approximately 90 m after T2.3;
- The ring where T2.4 occurred, the ring before and the ring after.

These results show that, in two cases, it is possible to detect abnormal behaviour (green rings) before the critical ring (red). The other three events exhibited an unpredictable behaviour.

Moreover, there are two “false positives”. One of these (the one with three consecutive rings) was in fact a short jamming event, that was not included among the studied jamming occurrences since it did not require excessive effort to restart the TBM in that occasion.

Figure 11. The four estimators for the tunnel T2: Torque SD, Torque MaxVar, Torque IQR and Advance Rate CV. Vertical planes coincide with rings where critical events took place.

Tunnel T0 and T1:

For the tunnels T0 and T1, the estimators analysis works better. As for T2, the 3D scatter plots (Figure 13 and Figure 15), show the 4 estimators

Figure 12. Torque maximum variation per ring in T2, highlighting rings with large variation in the 4 statistical estimators. Rings antecedent to the events are green, the ring of the event is red, while all others are yellow.

Figure 13. The four estimators for the tunnel T0: Torque SD, Torque MaxVar, Torque IQR and Advance Rate CV. Vertical planes coincide with rings where critical events took place.

evolution along the excavated tunnel, with the red planes denoting the critical regions and the red-yellow-green points been the rings variability score “H” for all 4 estimators. In Figure 14 and Figure 16, a 2D slice of the previous graphs, with only one estimator (torque Max Var).

We see anomalies one ring before for T0.0 and T1.0, and for T0.2 up to three rings before.

Figure 14. Torque maximum variation per ring in T0, highlighting rings with large variation in the 4 statistical estimators. Rings antecedent to the events are green, the ring of the event is red, while all others are yellow.

Figure 15. The four estimators for the tunnel T1: Torque SD, Torque MaxVar, Torque IQR and Advance Rate CV. Vertical planes coincide with rings where critical events took place.

The T0.1 event needs to be studied separately, because it was caused by squeezing and the parameters behaviour in a squeezing event differ from those of a caving event.

In T0 there was a false positive, in a complex zone 100m before the squeezing jamming T0.1 occurred.

There were three false positives in T1: one 100 m before T1.0 event, where a minor stop of four

Figure 16. Torque maximum variation per ring in T1, highlighting rings with large variation in the 4 statistical estimators. Rings antecedent to the events are green, the ring of the event is red, while all others are yellow.

days occurred, and the other two in different areas. It should be noted that the excavation of these two rings was difficult, having taken about a day for each ring.

5.4 Results interpretation

While the proposed methodology demonstrated overall reliability, it underperformed in T2 predicting two out of five critical sections, as delineated in Table 3.

The challenges encountered in T2 can be attributed to its status as the last tunnel excavated. In brittle rock masses, T2 experienced detensioning induced by the prior excavation of tunnels T0 and T1. This, coupled with the presence of sub-vertical fault systems in the BBT project and the inherent unpredictability of TBM operation influenced by human factors, resulted in more abrupt TBM stops in T2.

It is crucial to recognize that, as expected with a predictive tool, the proposed methodology encounters difficulties in predicting such sudden events.

6 CONCLUSIONS

In this paper the use of KPIs statistical estimators is proposed. Their use can help monitoring the TBM advance to anticipate TBM jamming events, caused by caving. An extensive dataset has been analysed from the combined samplings of three long and deep rock tunnels (BBT railway project between Italy and Austria).

The statistical estimators avoid the loss of information that comes with using only the ring average of KPIs and are relatively simple quantities compared to the huge amount of the raw data samplings.

It has been proved that for some KPI, the statistical estimators tend to spike when approaching

a jamming event. By combining these quantities, a method is proposed that leads to the identification of excavation anomalies one ring (or even two rings) before, for 5 caving events out of 8, although some false positives were highlighted in other zones of the excavation.

It should nonetheless be noted that even in the false positive rings the TBM stopped for a short period of time and risked being jammed.

The scoring of rings based on the estimators can help monitoring TBM advancement, by being displayed on a dashboard in real time during excavation and serving as a supportive tool for decision-making, complementing human judgment.

Another application is to employ the estimators for automated data labelling for machine learning classification tasks. Most Machine Learning applications for TBM excavation are regressions and (time)series forecasting, see Flor et al (2023) and references therein. Classification would require the labelling of data and the proposed scoring system seems a good candidate to differentiate rings according to the value of IQR or Maximum Variation, as shown in Table 2.

The authors want to stress that this method requires some adjustments when applied to a real excavation case, when the full information of the whole tunnel is not available, since we still need to score the estimators based on their percentiles. The solution could be to use the z-score of the quantities calculated on the recent rings, i.e., on the moving statistics, as discussed in Amadini et al. (2023).

ABSTRACT: The Sotetsu-Tokyu-Link Line is a connecting line whose length is approximately 10 km in the city of Yokohama from Hazawa Yokohama-kokudai Station on the Sotetsu Line to Hiyoshi Station on the Tokyu Line. Shin-Tsunashima Station is a new intermediate station and locates on the fourth underground floor, approximately 35m deep (at the deepest) and 14 to 25m in width and 240m in length. Because there are several buildings on the surface at the 35m south of the station and eviction of tenants from those buildings was impossible, we decided to construct the tunnel by the square steel propulsion method, one of the trenchless method. Firstly, a series of square steel pipe boxes were constructed around the outer circumference of the tunnel to form the outer shell, and then the internal section was excavated. The cross section of the tunnel is a horseshoe shape (224m² internal area), and 42 square steel pipes were combined with each other. The method involved three critical challenges. (1) Accurate positioning in propulsion. (2) Closure of the steel pipes with minimum displacement. (3) Prevention of the inflow of groundwater into the launching shaft. To overcome these challenges, we adopted the following measures. (1) A new jack controller for on the propulsion machine (2) Newly developed steel shell joint structure which can tolerate construction errors (3) A double entrance packing waterproof device to be installed at the launching shaft. In this way, we are confident that these measures successfully coped with this difficult situation.

1 INTRODUCTION

The Sotetsu-Tokyu-Link Line from Hazawa Yokohama-kokudai Station on the Sotetsu-JR link line to Hiyoshi Station on the Tokyu Lines via Shin-Yokohama Station opened on 18 March 2023 (Figure 1). The length of the line is 10 km. Shin-Tsunashima Station is a new intermediate station and 240m in length, 35m of the north of the station (Tokyo side) is a trenchless tunnel. We report on the construction plan and results of this trenchless tunnel.

Figure 1. Route map of the Sotetsu-Tokyu-Link Line.

2 OVERVIEW OF THE CONSTRUCTION PLAN

2.1 Overview of Shin-Tsunashima Station

Shin-Tsunashima Station locates 7.8km apart from Hazawa Yokohama-kokudai Station, at the fourth underground floor, approximately 35 m deep (at the deepest part) and 14 to 25 m in width. Both ends of the station shaft were used as launching shafts for shield type TBMs. In addition, the first 34.5m portion of the tunnel requires a large cross-section with an inner space of 224 m² (Height:14m, Width:19m) to envelop a platform. Given the restrictions due to surface the (Figure 2) and geological conditions around the tunnel with thin solid strata above the tunnel and abundant groundwater, we constructed an outer shell with a small section of 1,000 mm × 1,000 mm in advance to minimize the impact on the surrounding ground during the excavation. The NATM and the shield widening method were denied due to concerns about the impacts on the surrounding area, such as ground surface subsidence and groundwater level lowering caused by loosening of the surrounding ground.

Figure 2. Aerial photograph of Shin-Tsunashima station.

2.2 Summary of geological features

The strata at this site are a solid upper stratum group with an N value of 50 or more and there are alternating layers of sand and mudstone. The distribution of the sand layer is unclear and abundant groundwater is observed (Figure 3).

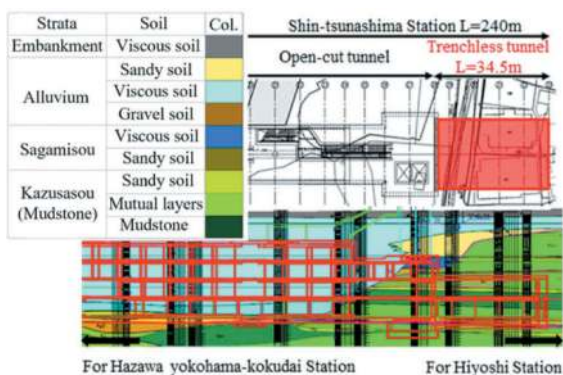

Figure 3. Ground plan and geologic cross section.

3 IMPROVEMENT OF PROPULSION METHOD

In this construction, we adopted a structurally improved version of the rectangular cross section used in previous construction of trenchless section. Figure 4 shows a cross-sectional view of the trenchless section of the Tsukuba Express Rokucho Station constructed in 2005, and the construction length of the section was about 15 m, and the N value of the ground to be excavated was about 1 through 10.

Figure 4. The cross section of Rokucho Station.

Improvement of this rectangular element propulsion method was studied for this paper's case because this section was constructed in relatively solid ground compared to previous construction results, the sandstone layer has abundant groundwater, the construction extension is long with large cross-section, and these elements can be used as permanent body.

Improvements of the construction method are as follows: (1) the propulsion machine is retrieved from the launching side because no reaching shaft was available, (2) a new joint structure to close the square steel pipe, (3) high propulsion accuracy including rolling measures was required for long-distance (35m) propulsion, and (4) prevention of joint work during construction under pressurized groundwater.

4 IMPROVEMENT OF ELEMENT JACKING METHOD

4.1 Retrieval from the launching side of the machine

Water cutoff on the arrival side was ensured by injecting chemical grout, and only the propulsion drive unit was retrieved while the outer shell of the propulsion machine was left in the ground. The machine could be reasonably and economically retrieved thanks to newly developed extraction device of the retrieval cart shown in Figure 5 and using the drive unit repeatedly. In order to ensure that water is blocked when retrieving the propulsion equipment, we decided to backfill propulsion equipment reaching area with cement bentonite after retrieving the propulsion drive unit, with the aim of stabilizing the ground in front of the face and preventing the inflow of groundwater.

Figure 5. The drive unit of the rectangular element.

4.2 Adoption of a new joint structure

We have developed a new joint that secures an appropriate amount of clearance so that it can be closed in any shape, and that can reliably stop flowing water during construction with shut-off valves and sealing materials (Figure 6).

In addition, the clearance inside the joint, which was traditionally 4 mm horizontally and 4 mm vertically, has been expanded to 28 mm and 9 mm respectively, which improves ability to cover construction errors during the propulsion, and makes it easier to clean and fill the inside of the joint with mortar. Furthermore, we decided to enlarge the joints because of ease of construction. To reduce the resistance during propulsion, the soil at the sites was replaced in advance with high-quality low-strength cement bentonite.

Figure 6. The joint between rectangular elements.

4.3 A new control mechanism for accuracy

Since the rectangular element was used for the main body and the position of the main body structure had to be fixed, strict propulsion accuracy was required. Rolling control was also important because the position of the joint installed at the edge of the rectangular element could be easily changed due to rolling. For this reason, a folding jack was installed on the propulsion machine, and new control jacks were installed on the top and bottom of the propulsion unit for adjusting the sled to correct the rolling (Figure 7).

Figure 7. The cross section of the propulsion machine.

4.4 Water influx during construction

As a measure against water leakage from the launching shaft, we developed new equipment to block water at the well-head with double entrance packing made of two types of rubber bonded together. A high-viscosity sealing material was also used to stop water between the double entrance packings (Figure 8). Since this was the first time of this construction method, a pre-construction test was conducted using a large-scale experimental device to confirm water blocking performance. In this test, it was found that the waterproof effect of the entrance packing was deteriorated and water leakage occurred due to vibration.

Furthermore, we decided to make improvements such as changing the shape of the rubber entrance packing according to the construction stage and confirm the improvement effect in additional tests before applying it. This is because it was necessary to improve the ability to follow the sway that occurs during propulsion.

Additionally, we improved the propulsion pipe joint with flange structure that can control the load during propulsion and extraction which is required in the control.

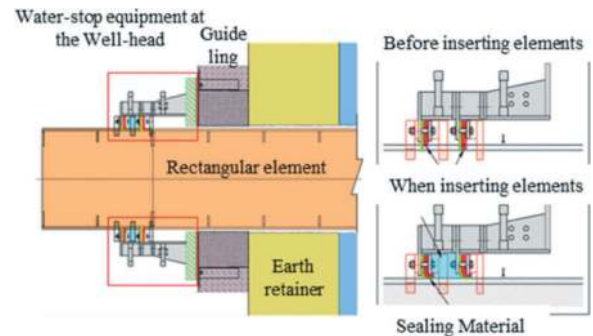

Figure 8. Water blocking equipment (Rectangular element).

In addition, since it is necessary for the water-blocking equipment to ensure waterproof in both directions of pushing and pulling in the propulsion of pipe and passing of flange, two lip-seal type rubber packings that are strong against turnover and have excellent water blocking performance when pulling in were used. By making the gap between the entrance rubber packings larger than the dented section (300 mm) of the joint, even when the joint passes through an entrance rubber packing, the other packing could stop water (Figure 9).

Figure 9. Water-blocking equipment (Joint replacement).

A feed water inlet was equipped between the two tiered lip seals to control fluctuations in water pressure and to fill the sealing material in an emergency.

5 CONSTRUCTION PLAN FOR TRENCHLESS TUNNEL

5.1 Construction procedure for trenchless tunnel

Figure 10 shows the construction procedure for the trenchless section. After completion of joint replacement, a standard element that serves as a guide was installed by the jacking method, and the external joints of the other elements to be installed subsequently were fitted to the internal joints of the installed elements, then sequentially pushed and connected. After above installation, concrete was filled inside the standard element and space between adjacent elements, and the inside of the fitted joint is cleaned.

Figure 10. Construction procedure for trenchless tunnel.

While repetitive cleaning and filling with mortar and filling concrete between and inside the elements, all square elements were assembled and closed and then excavated inside the large horseshoe shape section. The station platform was finally to be constructed.

5.2 Preceding replacement for joints

Prior to the construction of the rectangular element, the ground through which the joint passes was replaced with cement bentonite (low-strength) by a small-diameter jacking method ($\phi 600$ mm). Figure 11 shows the joints between the elements protruding from the excavation range of the rectangular propulsion machine to decrease resistance and secure accuracy. Several tests were conducted to confirm the solidification strength, fluidity, material non-separability, incompressibility, etc. of cement bentonite.

Figure 11. Preliminary joint replacement.

Table 1. Composition of cement bentonite.

A Liquid (Clay sand solution)		B Liquid Particular water glass	
Tackment (hardening agent)	TAC- α (aid)	Water	TAC-3G (plastic material)
120.2kg	60.1kg	929.9L	3L

5.3 Rectangular element propulsion

The main pushing-device in the launching shaft was extended to penetrate the ground (Figures 12 and 13), and the subsequent elements were connected in sequence.

Figure 12. Preliminary joint replacement (before propulsion).

Figure 13. Preliminary joint replacement (after propulsion).

High propulsion accuracy was required for rectangular element propulsion because the propulsion position determines the final body structure. Therefore, for the propulsion unit, a new rolling control jack was added to the front body of the propulsion unit so that not only

vertical and horizontal displacement but also rolling could be controlled and managed with a high degree of precision. A pressure-type water level gauge for vertical displacement and a target for horizontal displacement were installed on the propulsion unit and a gyro for rolling was installed on the subsequent elements (Figure 14). Table 2 shows allowance for location accuracy of the standard element and other ones. The propulsion machine used in the square element jacking work was retrieved and reused together with the propulsion drive unit. The structure of the water-blocking equipment was set based on a preliminary waterproof test, and maximum water pressure was assumed as 0.45MPa, 1.2 times of 0.35MPa considering safety factor for vibration of elements during propulsion.

Figure 14. Precision management of rectangular elements.

Table 2. Target value of elements.

Direction	Standard	Other
Horizontal	±10 mm	±25 mm
Vertical	±10 mm	±25 mm

5.4 Internal excavation

Ground might be loosened by installation of gable wall and rapid excavation of large section. Therefore, the process was divided into three parts (Figure 15). After removing the earth retaining wall at the end of the excavation section of the station, excavation was started from the top of the trenchless cross-section using a backhoe. Therefore, we set up measuring points for subsidence on the city road surface above the trenchless area, and proceeded with the excavation while checking the impact of the excavation on the surrounding ground.

Figure 15. Internal excavation of the trenchless tunnel.

5.5 Estimation by preliminary deformation analysis

In the trenchless section, after preceding replacement of the joint, the joint was connected from the top of the tunnel in sequence, and the square element was pushed forward to close it. Because this trenchless section was built with several methods, impacts from each work might accumulate into larger ground settlement. A step analysis was performed using the two-dimensional finite element method (FEM) to predict the ground deformation accompanying construction in advance which impacts on gas pipes on the city road above the trenchless section.

The deformation of the outer shell of the tunnel and the amount of settlement of the gas pipe were predicted by reproducing step analysis for the construction of a single-track tunnel, which was constructed simultaneously with the promotion of 42 rectangular elements in the outer shell of the tunnel and the excavation inside the tunnel. Figure 16 shows the analysis model, and Table 3 shows the analysis results. After internal excavation, the vertical displacement at the top of the non-excavated tunnel was 10.8 mm (displacement due to internal excavation: 5.8 mm). The analysis results were within the control values determined in negotiation with the surrounding facility owners.

Figure 16. Two dimension FEM analysis of internal excavation.

Table 3. Result of FEM analysis.

Status	Vertical settlement displacement (mm)	
	Gas pipe	General pipe
Completion (the upper half)	0.98	1.54
Outbound shield tunnel passage	1.70	2.67
Completion (the lower half)	3.23	4.86
Inbound shield tunnel passage	3.48	5.00
Completion (Internal excavation)	6.03	10.80

6 CONSTRUCTION RESULTS

Works for the rectangular element jack had to share the limited space of the vertical shaft with TBM works. In order to obtain space, as shown in Figure 17, a total of 42 rectangular elements were divided into two stages: 17 of upper half and 25 of lower half.

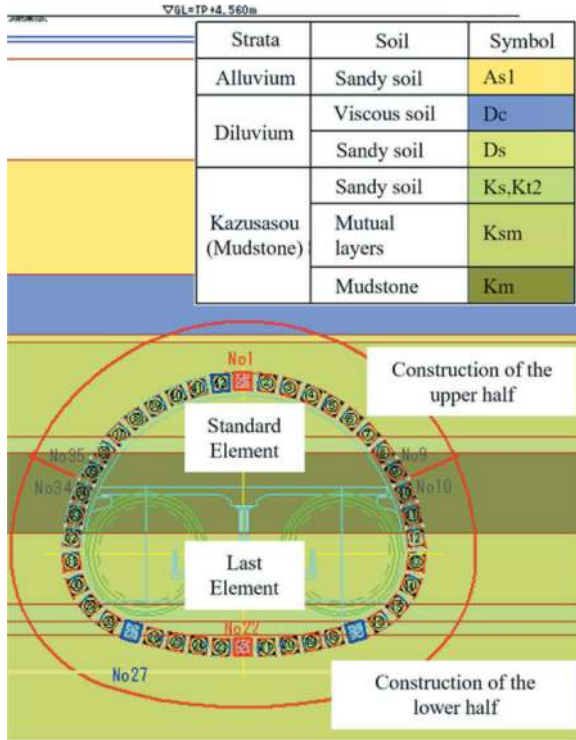

Figure 17. Two-phased approach of the propulsion.

6.1 Preceding replacement of joints

In the first half of the construction, the propeller tended to deviate downward at the sloping boundary between the sand layer and the mudstone alternate layer, so the propulsion speed had to be slowed down (Figure 18).

Figure 18. Descriptive sketch of the propulsion deviation.

Even if the above measures had been taken, it was still not possible to propel within the control target value (horizontal and vertical ± 50 mm). So it would be necessary to push and pull repeatedly and re-promote them.

At the same time, the overcut amount of the propulsion was reduced before the next replacement work from 11mm to 7mm, etc. so that the propulsion accuracy could be all within the control target in the end (Figure 19).

Figure 19. Result of preceding replacement.

In the preceding replacement work at the lower half, improved tunnel peripheral area was warped upward due to the grout lump involved under the propelling machine which exceeded the control target. It is thought that pieces of the shattered modified material, in lump form, went underneath the propulsion machine. By reducing the speed near the modified material to grind the modified material into small pieces, as a countermeasure, we were able to finally keep the propulsion accuracy within the control target value.

6.2 Rectangular element Propulsion

6.2.1 Result of the upper half

Figures 20 and 21 show the displacement generated in the propulsion machine and the rectangular element.

Figure 20. Result of horizontal displacement (upper half).

Figure 21. Result of vertical displacement (upper half).

The vertical displacement in Figure 21 is averaged number of measurements taken every 1m of the propulsion proceeding.

All horizontal displacements of the rectangular elements were within the control target of ± 25 mm. As for the tendency of the displacement, it was displaced to the side of the previously installed element.

It is presumed that ground was loosened due to early installation.

The average vertical displacement was about ± 15 mm, and the standard deviation was about 10mm. Basically, the propulsion accuracy and the finished shape accuracy of the elements showed the same tendency.

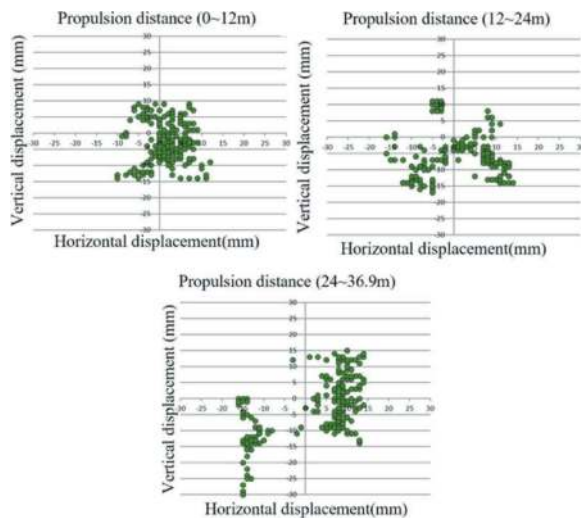

Figure 22. Displacements (every 1m of propulsion distance).

Figure 22 shows the result of classifying the displacement of the propulsion machine that occurred in every 1m of propulsion proceeding into three ranges.

This figure shows that the propulsion accuracy varies as the propulsion distance increases. In order to block the confined groundwater that acts on the pit mouth during propulsion, we tried to block the water by using two-staged entrance rubber packing and a high-viscosity sealing material filled between them. Nevertheless, water leakage occurred and the leakage was thought to be the cause of ground surface subsidence. In the lower half, it is lower than in the upper half construction due to higher water pressure, so prevention measures against water influx was required.

6.2.2 Result of the lower half

Figure 23 shows the horizontal displacement generated in the rectangular element, and Figure 24 shows the average vertical displacement of the excavator and the element.

It was within ± 25 mm of the control target value except for two closing locations. At the closing location, it was necessary to cover the displacement of each element on the left and right to fit the joint. To

Figure 23. Result of horizontal displacement (lower half).

Figure 24. Result of vertical displacement (lower half).

do so, we decided to increase the inner space of the internal joint and change the shape and length of the tip of the external joint so that the joint could be securely fitted (Figures 25 and 26).

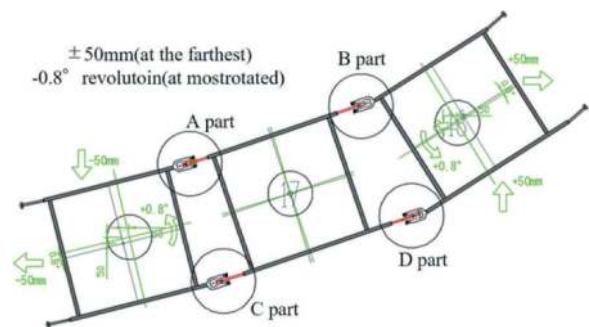

Figure 25. One of the closing locations.

Figure 26. Adjustment of the closing locations.

As a result, the propulsion of the closed section was smooth, but the displacement at the time of closing increased and slightly exceeded the control target value because restraint by the joint during propulsion was released and the flexibility increased. For No. 16 through No. 28, where the orientation of the element is almost horizontal, it was observed that there was a tendency to displace in the direction of the reference element that was installed earlier. For No.29 through No.34, no clear tendency was observed in the direction of displacement.

The average vertical displacement and standard deviation were generally within the control target values. As in the first half, the propulsion accuracy and the finished form accuracy of the element show the same tendency, and it is crucial to control the propulsion machine accurately.

As a result of classifying the displacement of the propulsion machine that occurred in every 1m of propulsion distance into three ranges according to the propulsion distance (Figure 27), there was a tendency for the displacement to increase as the propulsion progressed. The geology of the lower half is alternating layers of mudstone and sand layers, and it is presumable that the stratum boundary affected attitude control during propulsion, and displacement occurred regardless of the propulsion distance.

Figure 27. Displacements (every 1 m of propulsion distance).

Water leakage of about 20L/min occurred due to the change of the waterproof device at the wellhead and the outflow of the sealing material and the deformation of the steel guide ring installed at the wellhead. Most of these water leakages could be stopped.

6.2.3 Considerations on rotation of elements

Figure 28 shows the results of the rotation angle in rectangular element propulsion.

The average rotation angle of the rectangular element in the upper half was about -0.4° to $+0.6^{\circ}$, and the average rotation angle in the lower half was

Figure 28. Results of rotation of rectangular elements.

about -0.6° to $+0.7^{\circ}$ (positive direction: clockwise, Negative direction: counterclockwise), within the propulsion accuracy control value ($\pm 0.8^{\circ}$). The addition of a hydraulic roll correction jack to the front body of the propulsion machine made it possible to immediately correct rolling during propulsion. Thanks to these measures, the rolling angle could be controlled and managed within the control target value.

Figure 29 shows the completion of the upper and lower halves of the rectangular elements' propulsion.

Figure 29. Completion of upper and lower halves propulsion.

6.3 Excavation inside elements

After the rectangular elements were propelled and the joints were filled with mortar and the elements were filled with concrete, excavation inside elements was started from the crown. During the construction of the upper level, the displacement of the element was measured using a laser transit. The vertical displacement of the top of the tunnel (No.1 element) was 4mm from the start of measurement to the completion of the upper excavation, 7mm at the completion of the middle excavation, and 8mm before the completion of the lower excavation. This result approximates the prediction of 5.8mm in the FEM analysis for element excavation conducted in advance.

Furthermore, the ground surface subsidence was up to 13mm at its maximum after the commencement of the excavation inside elements and it has ceased and converged after the completion of the excavation. The reason why this value was larger than the displacement at the top of the tunnel is considered that it was influenced by fluctuations in underground movements.

Additional achievement is successful grouting during excavation in this work which waterproof was required at the horizontal joint surface of the end wall concrete and the boundary with the outer

shell. As a result, water leakage due to the elastic deformation of the rectangular elements during excavation was successfully prevented.

The fact that the ground surface subsidence was suppressed to about 10mm in the construction of a large-section tunnel with an inner space width of 19m and a height of 14m indicates that it is possible to minimize the impact on the surrounding ground when constructing a large-section tunnel by square element jacking was appropriate.

7 CONCLUSION

We could construct a large horse-shape tunnel with 42 elements by the rectangular element propulsion method with fine accuracy under the challenging condition of a large amount of pressurized groundwater. The deformation of the surrounding ground due to internal excavation was also well-controlled (Figure 30).

The results show that the propulsion method could be efficient and that the degree of flexibility

of the cross-sectional shape of the tunnel and the required accuracy can be attained. It is expected that this method will be adopted when constructing underpasses and underground spaces in urban areas.

Decision-making approach for parallel earth pressure balance machine advancements for tunnel construction

Niranjan Kumbhar* & Sanket Tirpude
MIT-WPU, Pune, India

ABSTRACT: Tunnel excavation with Tunnel Boring Machine is more systematic and safer due to in house deformation control by operator but when excavation done for parallel tunnels then tunnel construction became more slower because any one tunnel excavate entirely then go for 2nd tunnel to avoid this delay in tunnel excavation in this study highlights the influence of two parallel (||) TBM construction processes when this two TBMs Tunnel Boring Machine) which is used to excavate tunnel in numerical model . 7 construction sequences (decisions) where adopted for checking its feasibility in parallel tunnel construction simultaneously. In this study Excavation Cycle Sequence (ECS) introduced for representing excavation of tunnel and they are ECS-D1, ECS-D2, ECS-OEO, ECS-EOO, ECS-OM. All this ECSs complete tunnel excavation in different excavation cycles which are nothing but excavation for ring or rings as per ECS also installation and applicable for that particular ECS. This study shows that if adopt time dependent excavation (time=more or less installation of rings in numbers) make influence on deformation pattern between (ux=lateral deformation) parallel tunnels as well as in vertical deformation (uz). In tunnel advancement direction (uy= longitudinal deformation) as per excavation and installation of rings in Plaxis 3D model are constant (0.59mm) deformations because of application of constant thrust force which is required for the TBM movement in construction advancement direction (along +Y=axis) in Plaxis 3D model, we will suggest to implement variable thrust force models for further studies. This study shows that to minimize deformation use minimum excavation cycle such as ECS-OEO (Odd Even Order) and ECS-EOO (Even Odd Order), and if excavation cycle increases for more safer construction approach such in adverse geological sections in underground simultaneous excavation of parallel tunnels then increase drift (distance between excavation faces) to minimize deformation such as in ECS -OM (4.6m).

1 INTRODUCTION

Tunnelling works increase day by day and its need to provide a safe, rapid, and sustainable transport system to society. During the construction of metro tunnels, special awareness should be taken to minimize surface settlement and the safer foundation of high-rise buildings from the arching effect of the tunnels. To counteract this situation, more reliable machines deployed to construct a tunnel in urban areas call it as Earth Pressure Balance (EPB), the obvious reason for that is, it has the capability to maintain face pressure in terms of to avoid excess excavation in the face. Mechanized TBM (Tunnel Boring Machine) tunnelling method has been majorly used for constructing metros in many urban areas in the world is because this method has several advantages over the other methods, the advantages are, for example, reduced environmental impacts in relation to noise, dust, ground settlement, vibrations

and interruption to neighbouring infrastructure; reduced labour cost and danger to the existence of workers; improved tunnelling rate, majorly in soft soils

Fu et al. discussed that when new tunnel construction is done with existing tunnel max stress lining increases by 80 % to protect the existing tunnel stress monitoring done [1], relate to this study, in the present study ECS adopted to minimize the stress path during || simultaneous tunnel construction. Jiang et.al. discussed in two working conditions (excavation methods-1st up then down, 1st down then up) are 2 respective tunnel construction, which can affect the radial stress on the tunnel lining [2], on the basis of it in this study || tunnel construction sequentially modified in the form of ECS. Backer et al. discussed distance between horizontal twin tunnels plays a key role in settlement, previous study related to this shows that intermediate distance between two parallel lying horizontal tunnels

*Corresponding author: tunnelengineer123@gmail.com

increases then settlement decreases [3]. Raja Kanagaraju and Premalatha Krishnamurthy presented a tunnel depth-related settlement study in FEM to isolate its influence zone [4], in this study the influence zone isolated between two || parallel tunnels along the springline of parallel tunnels. As discussed by Ma et al. for TBM tunnelling effects on adjacent environment, several research has been carried out, numerical simulation, an examination of field data of settlement in soft ground tunnelling by indicating that a major proportion of total soil deformation occurs immediately after construction as well as Ma et. al. remarks deformation of the existing tunnel is relevant to the relative position of the TBM-EPB shield, the settlement development can be divided into three stages according to shield position change, shield approaching subsidence, shield crossing heave, and shield leaving subsidence [5], and this deformation characteristics are important in the present research study because with drift and ECS all above parameters can interact in || tunnel construction advancement. The ground movements associated with tunnelling and found that the main hazards related to tunnel construction in urban areas include poor ground conditions, the presence of a water table above the tunnel, shallow overburden, and tunnelling-induced ground settlement with potential damage to the existing structures and utilities on the top of the tunnelling area.

Taylor et. al discussed in his study about how stratification will affect the settlement [6]. Palassi et.al shows that face supporting pressure has more effect on settlements that grout injections [7]. Muhammed et.al. discussed construction advances during the construction stage for 1.5m of each stage were considered for analysis to check settlement using FEM software Plaxis [8], in this study the tunnel advancement is considered as 1.5 and for ECS it is different for the respective pattern of advancement. Bin-Chen Benson Hsiang describes that ground movement during excavation is mainly caused by the absence of sink in tunnel construction operations such as material discharge [9], and this study suggested that further data is desired to support their finding, so that a drift is introduced between simultaneous || tunnel construction Excavation Cycle Sequence [ECS] also some construction cycle patterns are suggested in this study. Shahriar et al discussed interaction of twin tunnels and adjacent structures are a complex problem because 3D software has significant power on the intensity of interaction and it can conclude that among TBM operation parameters face pressure influence [10].

Md Shariful Islam and Magued Iskandar [11] studied the important parameters of tunnel which is the construction sequence of twin tunnel, the settlement profile is directly influenced by the construction sequence and the position of maximum settlement shift towards the new tunnel [11], so that in this study included different construction sequence Excavation Cycle Sequence [ECS]. Daud et.al discussed that numerical analysis done in finite element for tunnels closely spaced settlement, and moments of tunnels are considered important [12], in this study || tunnels are

closed spaced to identify the deformation behaviour during ECS, the centre to distance of || tunnels is taken as $1.84D$ where D is external diameter of both tunnels. Liu et al. describes, the face support pressure doesn't have significantly influence on the 1st tunnel convergence [13], that is why in this study all || tunnel stimulations ECS are performed with the same face support pressure to check its impact on ECS. Previous study conducted by Adugna et al. tunnel-induced ground deformation in Plaxis 3D for EPB TBM and its control using grout pressure and pressure in their research [14], in the present study the face pressure is constant to check the drift effect during a || tunnel advancement, so it will help to better TBM excavation in the present study the face pressure is constant in ECS to normalize effect during || tunnel advancements and it will help to see drift effect in || tunnel construction. Suwansawat et. al. throw light in face pressure, shield element, grouting process, and lining element are most important parameters of mechanized tunnelling well described in previous studies along with the phases in Plaxis 3D FEM software for EPB-TBM tunnel [15], in this study throw light on the 5th factor which can control TBM excavation with is drift (face distance between two || simultaneous excavation along Y direction in global coordinate system in Plaxis 3D). Liu et al. describes excavation of the 1st tunnel shows greater surface settlement than that of the 2nd tunnel, especially for twin-tunnelling operations in which the excavation of the 2nd tunnel imposes a remarkable effect on the adjacent first tunnel [16].

2 MATERIALS AND METHODS

2.1 Materials

Instead of creating virtual new stratification, in this study included geotechnical data (Table 1) and TBM machine data (Tables 2 & 3) from a previous study. Geotechnical Materials (Data Set) and EPB (Earth Pressure Balance) TBM Properties taken from previous studies conducted in IIT, Chennai [14], to implement mix geological condition which is suited for Earth Pressure Balance machine TBMs for excavating tunnel. For Geotechnical properties Mohr-coulomb model assigned for this study because as per Plaxis 3D manual this model is suitable for preliminary studies so that 3 soil layers (Figure 1) along with a water head that is located -3m from the surface in the XZ plane and this will fulfil EPB TBMs working environment in Plaxis 3D model. In mix geological conditions EPB machine balance earth pressure Infront of cutter head to minimize excavation face collapse as well as minimizing surface settlement.

2.2 Methodology

2.2.1 Working environment in Plaxis 3D

In this study, we take half the portion of 2 TBMs because of its isotropic geometry (both tunnels have

2.2.2 Tunnel dimensions

In metro tunnels has approximate 6 m diameter to achieve standardization that's why in this study we take external diameter = 6.2 m [2]. Segmental lining thickness = 0.35 m [2] taken to avoid max deformation in parallel tunnel construction. Thrust force = 1166 kN/m² (assumed) which is applied in Plaxis 3D software without increment and decrement for all ECS for isolation of deformation check. As per International Tunnelling Association guidelines width Segmental lining width taken as 1.5 m each [10] and in this study total number of 10 rings constructed for each ECS. Distance between two tunnels = Overt of T1 to Overt of T2 = 5 m for checking lateral deformation between parallel tunnels [2].

Table 4. TBM concrete lining data for Plaxis 3D.

Sr. NO.	Global Coordinates	Length (m)
1	Xmin	-5.6
2	Xmax	5.6
3	Ymin	0
4	Ymax	54.6
5	Zmin	-26
6	Zmax	0

2.2.3 Tunnel orientation

Both Tunnels (T1 and T2) located the XZ plane in Plaxis 3D where Zmin = 12 m along the Springline (s) and the advance direction is Ymax parallel to the XY plane (Figure 2-e).

2.2.4 Tunnel advancement

FEM model constructed in structure mode (Figure 2) in the tunnel designer window with external diameter of the tunnel is 6.2m and the segmental lining thickness is 0.35m. It is assumed that both tunnels have constructed 25m, which is the initial advancement A (0) not monitored, next to it 10 segments of 1.5 m in width (A1=15m) are constructed with different Excavation Cycle Sequences (ECS) in the Ymax direction from the XZ plane. Tunnel advancement modelled in phase tab in Plaxis 3D. Initial phase software automatically calculates the insitu stress for the model and in phase 1 A (0) is assigned. From phase 2 construction, advancement of the tunnel for the next 10 rings begins manually (Figure 3).

Figure 3. Ring building methodology (a & b); after ring build (c & d).

2.2.5 Excavation Cycle Sequence (ECS)

A] Conventional approach

a. D1 represents the decision of advancement with no drift, simultaneously constructing 1 segment from each TBM, that is, from TBM 1 and TBM 2.

b. D2 represents the decision of advancement without drift, simultaneously constructing 2

segments from each TBM, that is, from TBM 1 and TBM 2.

B] Serpent approach (S)

a. *Version 1 (v1)* In this approach, the first segment constructed simultaneously from both TBMs and then one tunnel (T2) became a pilot tunnel with 1.5m drift.

b. *Version 2 (v2)* In this approach, the 1st segment constructed simultaneously and then both tunnels advance alternatively (sometimes T1 advance, and sometimes T2 advance with 1.5 m drift for respective phase).

Figure 4. Serpent Method of Tunnelling (SMT).

In SMT (Figure 4), Serpent (Snake) represents the directional advancement (snake head) T1 and T2 are Tunnel 1 and Tunnel 2 respectively. A (0) is initial advancement which represents area of tunnel before 10 segments constructions (snake tail). ECS is excavation cycle Sequence which decide number of segments installation and vertical distance (bold dash lines) between two ECS is referred as Tunnel advancement. Two different tunnel advancements which is nothing but tunnel construction methods (S-v1 and S-v2) are adopted to excavate tunnel. Serpent version 1 (S-v1) is site specific because if in site conditions found that T1 shows more ahead of face deformation (which found in early stage of modelling) after constructing 1 segment from each (T1 and T2) TBMs then don't overstress the situation let T2 advance 1st as a pilot tunnel with 1segment (1.5m drift) ahead of T1 in simultaneous excavation. Whereas in S-v2 when both tunnels construct 1 segment simultaneously then T2 achieve its 2nd ECS by installing 2nd segment then T1 will achieve its 2nd ECS at this situation T2 is stopped then T1 will construct its 2nd segment and achieve its 2nd ECS dame scenario follows and all 10 rings build done by using two vice versa TBM coordination.

C] Modified approach

a. *OEO* tunnels constructed in Odd Even Order like odd number of sets of linings (3 – 1.5 m each) from || TBM selected for installation (tunnel advancement), then go for even sets of linings (2--1.5 m each) from || TBMs likewise tunnel advancement(construction) go ahead.

b. *EOO* tunnels constructed in Even Odd Order like an even number of sets of linings (2–1.5 m each) from || TBMs selected for installation (tunnel advancement), then go for sets of odd linings (3-1.5 m each) from || TBMs likewise tunnel advancement(construction) go ahead.

D] OM

It is Observational Methods which includes the experience of the tunnel engineer during construction related to what that person experiences during advancement, this approach is adopted in Plaxis 3D by observing the output window, so for this consider 0, 4.5 and 6 m drift at various phases (ECS).

Figure 5. Horizontal c/s along || tunnel springline A-A* in Plaxis 3D output window.

3 RESULTS AND DISCUSSION

3.1 Results

Total deformation $|u|$, lateral deformation (u_x), longitudinal deformation (u_y), vertical deformation (u_z) represents the tunnel advancement effect during ring installation in global coordinate system, whereas lateral deformation u_x (s), longitudinal deformation u_y (s), and vertical deformation u_z (s) represent the tunnel advancement effect during ring installation along the spring line of || tunnels. Active = Segment installed or TBM advanced; pause = Segment already installed or TBM Paused. As per table 5 deformation values changes as construction sequence (ECS) change

Table 5. Last phase results of all ECS.

TBM Sequence	Phase No. (LAST)	Deformation [mm]							
		$ u $	$ u (s)$	u_x	$u_x(s)$	u_y	$u_y(s)$	u_z	$u_z(s)$

3.2 Discussion

In Figure 5 represents the cross section along springline which cut in horizontal plane of parallel tunnels to see lateral deformation u_x (s). In Figure 5 shows the

deformation of 10th ring build for each ECS.min and max deformation trends between parallel tunnels are varies ECS to ECS. In Figure 6 represents last phase lateral deformation (deformation between parallel tunnels along spring line) of 7 approaches of a parallel TBM advancement reveal different results from each other In parallel tunnel, overt to overt has a special connection in terms of stability especially during parallel (||) tunnel advancement. In D1, D2 approach, Figure 5 (a & b) represents the deformation for each advancement along springline of a || tunnels in D1 and D2 approach, respectively. In D1 the approach, the trend for the min lateral deformation for T1 is continuous, whereas in D2 it has a discontinuous min lateral deformation trend for T2. Figure 5 (c & d) represents all phases of u_x (s) for Serpent v1 and Serpent v2, respectively, during the advancement of tunnel. Min and max deformation trends are quite similar for both approaches which are continuous for min deformation and discontinuous for max deformation, and an important difference is that the min deformation trend changes from T1 to T2 when almost half the excavation done for Serpent v2 and max deformation effect reduced at early phases for a || tunnel advancement Figure 5 (e&f) shows OEO and EOO with the same criteria u_x (s), OEO shows less Max deformation coverage between a || tunnels than EOO. Figure 5 (g) represents the ECS-OM which shows the min and max lateral deformation along TBM drive for T1 and T2 || tunnel along TBM drive in springline which shows the min deformation trend is discontinuous for T2 tunnel and the max deformation trend starts with T2 tunnel advancement and shift towards T1 at end of the excavation cycle.

Figure 7 represents the deformations (whole model + along the springline of a parallel tunnels), which shows that the model deformation for the respective deformation is more than its relevant springline deformation. Serpent version (S-v1) shows

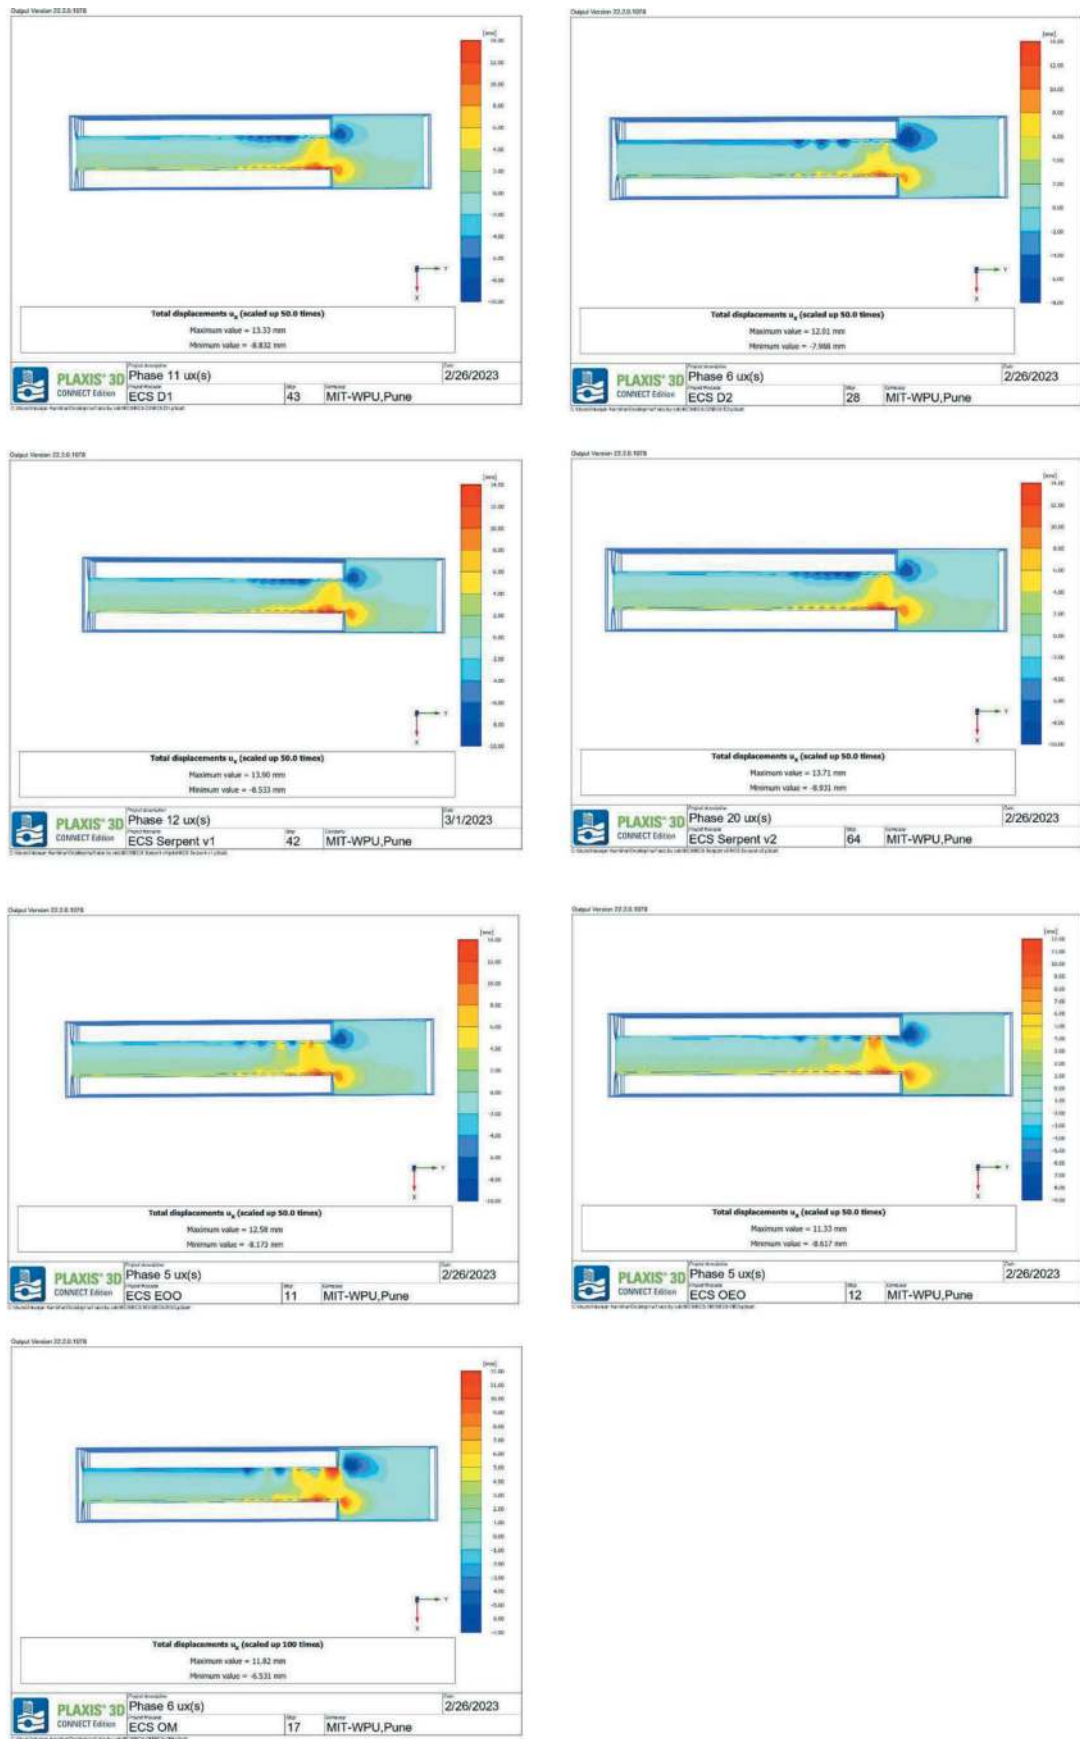

Figure 6. Top view of the final phase where the upper tunnel is T1 and the lower tunnel is T2, and (a) D1, (b) D2, (c) Serpent v1 (d) Serpent v2 (e) EOO (f) OEO and (g) OM that represents ECS.

the maximum total deformation $|u|$, whereas Odd Even Order OEO shows Min, Max deformation $|u|$.

Figure 7. The general deformation for the model is $|u|$, u_x , u_y , u_z , and the deformation along the springline for a || tunnels are $|u|(s)$, $u_x(s)$, $u_y(s)$, $u_z(s)$.

Figure 8. The general deformation for the model is $|u|$, u_x , u_y , u_z , and the deformation along the springline for a || tunnels are $|u|(s)$, $u_x(s)$, $u_y(s)$, $u_z(s)$.

During the construction of the || tunnel with TBM lateral deformation, the $u_x(s)$ is the key factor for a safe and efficient construction process. So that $u_x(s)$ behaviours need to be checked with vertical and longitudinal deformation. Figure 8 shows graphical representation of $u_x(s)$ and $u_z(s)$ along spring line for all construction approaching Excavation Cycle Sequences (ECS) show almost close linear deformation for vertical displacement in the horizontal direction whereas lateral deformation goes linearly decreasing toward the observational method (ECS-OM).

Table 6. Excavation sequence classes and its deformation for phase 1 (mm).

ECS	$ u $	$ u (s)$	u_x	u_x-s	u_y	u_y-s	u_z	u_z-s
D1	22.32	22.23	12.47	12.42	0.72	0.59	18.62	3.53
D2	22.32	22.23	12.47	12.42	0.72	0.59	18.62	3.52
S-v1	22.32	22.24	12.47	12.43	0.72	0.59	18.62	3.51
S-v2	22.32	22.24	12.47	12.43	0.72	0.59	18.62	3.51
OEO	22.32	22.23	12.47	12.42	0.72	0.59	18.62	3.52
EEO	22.32	22.23	12.47	12.42	0.72	0.59	18.62	3.53
OM	22.32	22.23	12.47	12.42	0.72	0.59	18.62	3.52

Figure 9. Deformation along the springline for a || tunnels which are $u_y(s)$, $u_x(s)$.

In Figure 9, compared to vertical deformation, OEO is more sensitive about vertical deformation, and it has more $u_y(s)$ than other ECS. $u_y(s)$ for D1, S-v1, S-v2 less than $u_x(s)$.

4 CONCLUSION

Plaxis 3D is a very useful tool to predict the effect of parallel tunnel construction simultaneously implemented in this study, showing a satisfactory and prominent result in || tunnel construction. This study will help to understand the behaviour of deformation during simultaneous excavation. By following the trend of ECS, one can choose the appropriate sequence for a particular geology as well as for critical sections such as D2, S-v2, OEO has the capabilities to divert the deformation effect from one tunnel to another by selecting an appropriate ECS which is relevant to ECS on site conditions, the adverse effect on a particular tunnel will be minimized in || simultaneous construction. From this study, with EPB TBMs in urban areas for surface and subsurface safety in undrained clay, the class (B)-subclass (III) has more capabilities. The response of || tunnel construction to different geotechnical properties, different tunnel diameter, and TBM properties is the scope of future studies.

*Conclusion is divided into 3 important outcomes obtained in this study;

I. Plaxis 3D and parallel tunnels

For Phase 1, as per Table 6, model deformation less than springline deformation (s) for all ECS and also model deformation shows consistency in deformation for all ECS, whereas for springline deformation, longitudinal deformation shows constancy for all ECS as well as longitudinal and vertical deformation shows fluctuation that is a sign of Plaxis 3D has potential to generate accurate results along springline of || tunnels. Reason behind Longitudinal deformation (uy) consistency is that constant thrust force is applied for TBM advancement and it totally depend on actual insitu geological conditions which diversify in nature whereas in this model layering is done while excavating tunnel cutterhead will cut constant layers ahead of face in longitudinal direction that means it does not cut another layer in another direction while advancing. Jointing, fracture, intrusion water ingress such geological features are cooperated in cutting layer in scope of future studies to study more longitudinal deformation and it is very precise and construction site specific.

II. Tunnel Industry Utilization (TIU)

Table 7. ESC for ECS to achieve min deformation in the respective direction, min deformation between sub-classes is taken as the final value for that particular class and for Class-D Min deformation check with Class-C because both have close results.

ESC	Scale	ECS	u	u s	ux	uxs	uy	uys	uz	uz s
A	I	D1	✓	✓			✓	✓		
	II	D2			✓	✓			✓	✓
B	III	S-v1	✓	✓	✓	✓			✓	✓
	IV	S-v2					✓	✓		
C	V	OEO	✓	✓	✓	✓	✓			✓
	VI	EOO						✓	✓	
D	VII	OM			✓	✓	✓	✓		

As per Table 7 Min deformation between sub-classes is taken as the final value for that particular class and for Class-D Min deformation check with Class-C because both have close results. () represents the decision of parallel TBMs advancement construction methodology to achieve minimum deformation specially in soil between two parallel tunnels (ux-s= lateral deformation along springe line) to avoid deformation during simultaneous excavation it will lead towards time saving sustainability tunnel construction approach along with improving safety.

III. With drift and without drift aspects in parallel tunnel construction

Table 8 and Figure 10 shows its graphical representation of drift its total phases in numbers of that particulate ECS numbers and it conclude that (Excavation cycle of S-v1 and OM have equal construction cycles with drift of 1.5m and 4.5,6 in certain phases, which shows that the continuation of drift will increase the deformation, so it needs to vary after a certain pattern

Table 8. Drift suitability in simultaneous parallel tunnel excavation

ECS	Phases	Drift[m]	u [mm]
D1	11	0	49
D2	6	0	49.48
S-v1	12	1.5	49.83
S-v2	20	0,1.5	51.29
OEO	5	0	46.63
EOO	5	0	46.83
OM	12	4.5,6	46.85

of excavation. In drift situation, the deformation will be higher when the increase of excavation cycle. From this study, it suggested that using 1.5 m drift for clay is not suitable instead of this suggested that use OEO or EOO approach during a || tunnel construction. Moreover, it notices that by comparing ECS-S-v1 from Phase 4 onwards in ECS-OM continuous drift with more than 1.5m such as 4.5m,6m gives satisfactory results for the same excavation cycle because Phase 4 onwards in ECS-OM values of |u| constantly reduce. For rapid and safe construction, the approach from this study suggested that in || simultaneous construction in case of drift 4.5 to 6 m and for non-drift excavation use modified patterns like ECS-OEO and ECS EOO. This graph concludes that if you need to increase excavation cycles for more safer construction approach then increase drift to minimize deformation (S-v1 < OM).

Figure 10. Drift aspects in ECS decisions.

ABSTRACT: The Mahaweli Water Security Investment Program (MWSIP) is a major project in Sri Lanka to provide water resources to the dry North-East of the country and enable two crops of rice per year. The current phase includes the construction of 76 km of waterway via canal, aqueduct and tunnel.

Contract UEC-ICB-2A is the biggest component of this current phase and includes the excavation of 27 km of underground waterway which will be the longest in South-East Asia when complete. The tunnels are being constructed by two, purpose built, Double Shielded Chinese TBMs of 7.6 m diameter. The construction is being carried out by China State Construction Engineering Corporation (CSCEC) for the Ministry of Mahaweli. The Engineer is a JV called the Project Management Design and Supervision Consultants (PMDSC) and the Client is represented by a Project Management Unit (PMU) and a Project implementation Unit (PIU).

During the economic crisis in 2022 the Country suffered many shortages including diesel and explosives. The original plan was to excavate a full launch chamber for the TBM from the bottom of the 23 m deep, 26 m diameter Northern Start Shaft. However, due to shortages of explosives and limitations on imports it was instead decided to launch the TBM in a short mode of only 65 m length and then to stop and complete the installation and commissioning of the TBM once the tunnelling had reached 200 m.

This paper will describe the actions taken to promote the tunnel progress and to achieve the best result for the TBM in very challenging circumstances.

Keywords: Tunnelling, TBM, short launch

1 INTRODUCTION

The Mahaweli Water Security Investment Program, financed by the Asian Development Bank and the Government of Sri Lanka, aims to complete the Mahaweli Development Program, started in the 1970s to improve farmer incomes, food security, equity between different parts of the country, public health, and domestic, municipal and industrial water supplies. Up to 900 million m³ of water will be transferred annually

through canals, reservoirs and tunnels from the Mahaweli River to the water-scarce north and north-west, where smallholder farmers have traditionally practiced single-season rice cultivation. The transfer will facilitate cultivation of a second, diversified, crop and must be shared with competing consumptive demands, as well as meeting daily peak energy demands through releases for hydropower (Chegwin and Kumara, 2018).

Phase 1 of the North Central Province Canal Project under the Mahaweli Water Security Investment

*Corresponding author: David.Lees@external.tractebel.energie.com

Program comprises three components – namely the Minipe Left Bank Canal Rehabilitation Project (MLBCRP), the Kalu Ganga – Moragahakanda Transfer Canal (KMTC) and Upper Elahera Canal Project (UECP), and the North Western Province Canal Project (NWPCP).

The objective of the 65.5 km long Upper Elahera Canal (UEC) is to transfer 100 MCM of Mahawelli water from the Morakahander Reservoir to the Yan Oya basin (Figure 1).

The UES is implemented in three program tranches:

1. Tranche 1 comprises the construction of the UEC from 0+100 km to 6+226 km (UECP-ICB1).
2. Tranche 2 includes the construction of the UEC from 6+226 km to 17+700 km (UECP-ICB3), UEC Tunnel 3 and Tunnel 4 from 27+509 to 55+600 km (UECP-ICB2A), and the Kalunganga-Moragahakanda Transfer Canal (KMTC) from 0+000 to 8+830 km (UECP-ICB2B).
3. Tranche 3 comprises the construction of the UEC from 17+700 to 27+509 km (UECP-ICB4), from 55+600 to 65+500 km (UECP-ICB5), and the transfer canal from the end of the UEC to the Mahakanadarawa Reservoir (UECP-ICB6).

Funding is provided by the Asian Development Bank (ADB) under all three Tranches.

The tunnels for UECP-2A consist of a short length of drill and blast excavation to be excavated under NATM principles (Tunnel 4) and two TBM drives one from the north and one from the southern portal (Tunnel 3). Access at the northern site is via a 26 m diameter vertical shaft and the intention was to excavate start tunnels for full assembly of the TBM from the bottom of the shaft.

However due to the economic situation that developed in Sri Lanka in 2022 where the provision of many resources became very difficult, due to a lack of availability of explosives for the drill and blast development it was necessary to consider an alternative methodology for commencing the TBM excavation namely a “Short Launch” option.

2 SHORT LAUNCH

The original concept was to excavate a launching pilot tunnel 370 (200+170) m long. However, due to limits on explosive availability it was decided to excavate 65 m in T4 and 15 m in T3.

Although the short launching method increased the working time of secondary assembly of the TBM, due to the low excavation rates achieved in the NATM excavation it was expected that the short launching method could expect to be completed up to 44 days ahead of the programme.

The original method proposed to excavate 170 m in Tunnel 4 of 1100 m and 200 m in Tunnel 3. Then to fully assemble the TBM in Tunnel 4 (except No 9 gantry) and push it forward 130 m into Tunnel 3, which would enable normal excavation to

start after an initial excavation of 70 m. This is presented in Figure 2.

Firstly, The No 5, No. 4, No. 2 and No.1 gantry were assembled and pushed back into the T4 Tunnel. Then the cutter head was lowered into the shaft and assembled at the head of the TBM. A special Crawler Crane had to be imported to lift the 150 tons cutter head, and due to import restrictions at the time in Sri Lanka, this had been arranged on a specific import/export permit. The total length of the first stage is 83 m as shown in Figure 4.

The next step was to push the TBM into the 15 m of excavated Tunnel 3 and install the first ring segments as shown in Figure 5.

Step 3 was initial tunnelling of 76 m. This is shown in Figure 6. The first 55 m using a temporary belt conveyor and gantry crane to lift muck from the shaft, and from 55 m to 76 m using bucket for mucking.

3 TBM 2ND ASSEMBLY

After completing 76 m of excavation the remaining gantries of the TBM (except No. 9 gantry which is the pipeline extension gantry) were assembled underground this gave a total length of the TBM of 153 m. The total available excavated length was 90 m in Tunnel 3 and 65 m in Tunnel 4 with 26 m for the shaft diameter giving a total of 181 m.

To perform this the gantries were moved back to Tunnel 4 removing them one at a time with the gantry crane, inserting the shotcrete bridge and reconnecting the gantries and moving the completed TBM back into Tunnel 3 as shown in Figure 7.

The next step was to excavate a further 98 m until the total length of Tunnel 3 reached 188 m. Then the No 9 gantry and belt conveyor system could be installed. When this was completed, normal tunnelling operation with full TBM launching could commence. This is shown in Figure 8.

4 TBM MODIFICATIONS

To facilitate the short launch a number of modifications were required to the TBM firstly the belt conveyor for the removal of the muck. The TBM belt drive was originally located in the No 8 gantry this was relocated to the end of the No 5 gantry and a temporary muck chute was installed.

The mucking conveyor was temporarily installed in Tunnel 4. The muck was first transferred to the shaft, and then lifted vertically to the ground by the gantry crane.

The mucking conveyor was temporarily installed in Tunnel 4. The muck was first transferred to the shaft, and then lifted vertically to the ground by the gantry crane as shown in Figure 11.

5 ELECTRICAL MODIFICATIONS

The cutter head transformer, ordinary transformer, capacitor compensation cabinet, power distribution

cabinet, frequency conversion cabinet, control room, etc. are all in place, and the main functions of TBM are ready for operation. Equipment not in place was powered separately.

The emergency generator on the right side of the No 5 gantry was removed and the transformer and capacitor compensation cabinet on the left side of gantry No.6 crane was modified.

Figure 2. Original concept long launch.

Figure 3. Northern access shaft and start tunnels.

Figure 4. First assembly - short launch.

Figure 5. Commence TBM excavation – short launch.

The TBM belt drive cabinet (MDO) needs was transferred from the left side of the No. 7 gantry to the top of the No. 5 gantry.

Due to the missing of shotcrete bridge and No. 3 gantry, there was a surplus of cables in the order of about 30 m, including the main drive motor cable, pump station motor cable and most of the control cables. These were protected from dust and damp and temporarily stored in the headroom space.

The pea gravel pump was removed and relocated at the shaft bottom. This was an independent system, so power was supplied from surface.

6 OTHER SYSTEMS

The TBM supply pipe route from the ground extends through the hose to the water tank located at the rear

The air compressor and gas tank are located on the surface at the shaft, from which a pipeline supplied compressed air to gantry No 5.

7 PROGRESS

The NATM excavation and support was completed on November 15, 2022.

First assembly of the 83 m of the TBM for the first launch commenced on November 16, 2022, and was completed on December 6, 2022.

The initial 90 m of TBM excavation commenced on December 27, 2022, and was completed on January 29, 2023. Excavation rate was slow due to the temporary mucking arrangement from the bottom of the shaft and due to commissioning work of some parts of the TBM during this period.

The second step in the excavation commenced on January 29, 2023, and finalized on 20 March 2023.

After that, was planned to prepare full commissioning of TBM, it was completed on April 10, 2023.

The TBM then excavated the initial 500 m of tunnelling to complete its full commissioning. This 500 m excavation was completed on May 9, 2023.

Engineers Team from PMDSC and the Contractor CSEC for their assistance in preparing this paper.

Adaptability design and application of TBM cutterhead in Beishan extremely hard rock geological conditions

JianFang Li*

China Railway Construction Heavy Industry Corporation Limited, Changsha Hunan, China

ABSTRACT: As a key part of rock TBM, the cutterhead bears great load during excavation and rock breaking. Under extremely hard rock geological conditions, higher requirements will be meant for cutterhead rock breaking efficiency and structural bearing performance. This paper analyzes the geological characteristics and project engineering difficulties of TBM long-distance spiral downhill construction in Benshan Laboratory, carries out adaptive design from the aspects of cutter selection and layout, disk structure, etc., analyzes and checks the balance performance and mechanical properties of the cutterhead, and designs and manufactures a TBM cutterhead suitable for Beishan extremely hard rock working conditions. The project engineering application results show that the tunneling efficiency and cutter usage of TBM meet the design requirements, which is of reference significance to the cutterhead design under similar extremely hard rock conditions.

Keywords: extremely hard rock, TBM, cutterhead, adaptability

1 INTRODUCTION

With the increasing acceleration of infrastructure construction in China, there are more and more large-scale projects in these fields as underground resource excavation, underground space development, nuclear industry laboratory and highway construction. As a major key technical equipment for human beings to carry out underground space construction in the 21st century, TBM is also widely used and its demand is constantly rising. Therefore, the R&D of TBM for applications under various complex geological conditions has become a technical key point that all manufacturing powers in the world focus on and compete to seize [1-4]. As the core component of TBM, cutterhead is in direct contact with rock surface and bears all rock breaking loads. Its adaptive design such as static analysis, cutter matching and balance calculation are necessary links and steps for cutterhead design [5-6].

Many scholars both at home and abroad have done a lot of design analysis on TBM cutterhead. Zhang Zhaohuang put forward the concept of curved cutterhead, which can reduce the vibration of cutterhead during tunneling by increasing the strength and rigidity, thus improving the service life of cutters and the rock breaking efficiency of TBM [7]. Zhao Zhenwei analyzed the plane, conical and spherical cutterhead structures under different tunneling conditions to

obtain the maximum deformation and equivalent stress of three types of cutterheads [8]. Sun Jianping analyzed the adaptability of related geological conditions, tunneling parameters, engineering construction, durability and safety [9].

The above studies mainly focus on the conventional TBM cutterhead, but there are few related structural research designs for spiral downhill tunneling cutterhead for extremely hard rock. Relying on the Beishan Underground Laboratory Project, this paper carries out adaptability research on the key technologies of cutterhead in view of the key and difficult problems in the process, and selects extremely hard rock cutterhead with strong geological adaptability, good comprehensive performance and comprehensive functions.

2 PROJECT INTRODUCTION

2.1 Project overview

The spiral ramp of the main project of Beishan Underground Laboratory is constructed by open TBM, with a total length of 7 km, an overall slope of -10% and R250 m horizontal turn. The rock mass is granodiorite, mainly Class I and II surrounding rocks. The uniaxial compressive strength of the rock is 110-260 MPa, with an average of 170 MPa. It is the tunnel project with the most complete rock and the highest strength in the

*Corresponding author: lijianfang@crchi.com

projects of the world under construction. The main difficulties in TBM design are spatial spiral downhill excavation and long-distance extremely hard rock construction.

2.2 Analysis of important and difficult points

The Project mainly faces the following technical difficulties:

1. Rock fissures are not developed. The core with RQD>90 accounts for 86.2% of the total core length, and the core with RQD>75 accounts for 93.4% of the total core length. The rocks generally have good integrity;
2. The uniaxial compressive strength of rock ranges from 110 MPa to 235 MPa, and the average uniaxial compressive strength is 170 MPa. The tensile strength of rock ranges from 6 MPa to 15 MPa, with an average tensile strength of 11 MPa. The rock friction index (CAI) is between 4.31 and 5.29, with high strength and abrasiveness;
3. The tunneling mode is spatial spiral downhill tunneling, which affects the service life of cutters.

Figure 1. Schematic diagram of rock core.

3 TARGETED DESIGN OF CUTTERHEAD

3.1 Structural design of cutterhead

3.1.1 Conical cutterhead design

There are plane, conical and spherical TBM cutterheads, as shown in the figure.

Figure 2. Schematic diagram of cutterhead structure.

The plane cutterhead is widely used due to its easy manufacturing, shorter cantilever length and good adaptability to various soft and hard surrounding rock conditions. In horizontal tunneling projects, the cutterhead is basically a plane cutterhead. Conical and spherical cutterheads are difficult to manufacture because the disk body composed of face plate and back plate is conical or spherical. The tapered surface or spherical surface of the disc body has a larger coverage area relative to the plane, so that the cutter spacing can be made smaller than that of the plane cutterhead. However, there is a free face between the conical and spherical cutterheads relative to the plane cutterhead hob during tunneling, so the rock breaking efficiency will be higher than that of the plane cutterhead. However, the crushed and peeling rocks at the upper part of the tunnel face are not easy to fall to the bottom during the process of horizontal tunneling. The smaller the cone angle and spherical diameter, the lower the ballast chute efficiency, resulting in secondary or more wear of the hob and cutter head, accelerating the wear of the hob and cutterhead and shortening the service life of the cutterhead. Therefore, the cone and spherical cutterheads are mainly used in inclined shaft and vertical shaft tunneling, but less used in horizontal tunneling.

The advantages and disadvantages of the three structural forms of cutterheads are shown in the table below.

Table 1. Advantages and disadvantages of cutterhead type.

S/N	Structural Type	Advantages	Disadvantages
1	Plane type	It is relatively easy to manufacture and is widely used, suitable for various soft and hard surrounding rocks	Rock breaking efficiency is lower than that of conical and spherical surfaces
2	Conical type	It is mainly used in inclined shaft and vertical shaft TBMs, with high rock breaking efficiency	Difficult to manufacture and low ballast chute efficiency
3	Spherical type	Less case of application, difficult to manufacture	Relatively difficult to manufacture and low ballast chute efficiency

According to the advantages and disadvantages of the three types of cutterhead structures, combined with the downhill extremely hard rock tunneling of Beishan Ramp Project, in order to improve the rock breaking efficiency of the cutterhead under extremely hard rock working conditions and take into account the smoothness of ballast chute, and considering the cutterhead height, cutter installation method and manufacturing difficulty, the cutterhead is designed as a conical cutterhead.

3.1.2 Design of high-load cutter head

The tunneling efficiency of TBM is related to the structural characteristics of the device itself, cutterhead, type of cutterhead used, cutter arrangement, geological conditions of construction and other factors. Among them, the bearing capacity and service life of cutter head structure are one of the key factors that could affect tunneling efficiency.

There are two types of cutter installation: back-mounted and front-mounted. The former is convenient for cutter operators to replace and inspect the cutters inside the cutterhead. At the same time, the hob holder is embedded in the cutterhead body, with better structural strength and higher stability. However, due to the embedded cutterhead body and limited by its large structural size, the cutter spacing of the cutterhead cannot be made smaller, and the strength of the cutterhead will be affected. Front-mounted cutter installation type, or the latter: The hob is disassembled from the tunnel face, so the size of the cutter head can be shortened from 630 mm to 520 mm. The strength and rigidity of the cutter head itself are better than those of the back-mounted type, or the former and the cutter arrangement is more symmetrical. Due to the reduction in structural size, the strength and rigidity of the cutterhead are better than those of the back-mounted type. However, there are some safety risks due to tool replacement in the tunnel face.

Figure 3. Back-mounted cutter head.

Figure 4. Front-mounted cutter head.

According to the characteristics of good integrity, high rock strength and extremely hard rock conditions, cutter installation form and cutter position in the Project, as well as the small space in the edge area and a certain inclination angle between the edge hob and the tunneling direction, the center and front side are front-mounted, and the edge hob is back-mounted.

3.1.3 Structural strength analysis

Taking the TBM cutterhead of Beishan Project as the research object, the cutterhead's structural strength is analyzed. The cutterhead is an integrated

cutterhead, which mainly consists of the front panel, rear panel, flange, rib plate, back plate and cutter. To ensure the feasibility of analysis and calculation, some chamfers and slight gaps are omitted in the solid modeling process, and grid division is carried out, as shown in the figure.

Figure 5. 3D model and grid model.

The static analysis method should be used to analyze the stress of TBM cutterhead. According to the installation method and movement requirements of TBM cutterhead, full displacement constraint should be applied on the bottom surface of flange plate of the cutterhead. In rock breaking, the blade penetrates into the rock and soil, causing cracks in the rock and thus spalling. Therefore, the hob cutter edge is stressed at some nodes. To better simulate the hob load, a rigid element is established to connect some nodes of the cutting edge so that the nodes on the cutting edge will be stressed at the same time. Considering the simultaneous action of vertical force, rolling force and lateral force on the hob, a local coordinate system will be established for non-horizontal and vertical hobs to facilitate loading.

After calculation, the structural stress and displacement nephogram of cutterhead can be obtained. It can be seen from the displacement diagram that the deformation at the center of the cutterhead is the largest, at 1.06 mm, and the degree of deformation gradually decreases from inside to outside. Due to gravity, the deformation at the bottom of the cutterhead will be greater than that in the surrounding area. The strain of deformation relative to the overall thickness of cutterhead is about 0.627%. The deformation of the flange and support plate is relatively small.

It can be seen from the stress nephogram that the maximum stress is 215.4 MPa and the statistical average of the maximum stress is 131.6 MPa. The stress of the cutterhead is mainly distributed in the support rib area, including six main support ribs and the connection position between each support rib and the flange.

3.2 Cutter and layout design

TBM tunnels in extremely hard rock strata and mainly breaks rock with hobs. Therefore, the

Figure 6. Cutterhead displacement Nephogram.

Figure 7. Stress Nephogram.

arrangement of hobs is a key factor in cutterhead design. According to different geological conditions and different cutter layout modes, the rock breaking efficiency of the cutterhead will be affected, which will impact the service life of the cutterhead and cutters.

The disc hob is the first part to contact rock on TBM and also a key part for breaking rock. Its main structure includes cutter ring, cutter shaft, cutter body, bearing, floating seal, etc.

Figure 8. Structure of disc hob.

The average uniaxial compressive strength of Beishan Ramp Project is 170 MPa, and the overall rock strength is extremely high. According to the most widely used disc hob stress CSM model proposed by Rostami^[10], the greater the compressive strength of rock is, the greater the force applied by the disc hob to crush rock will be.

Therefore, to improve the rock breaking efficiency of the cutterhead of Beishan Ramp Project, the cutterhead hob is designed as a large-load 20-inch hob. Compared with conventional 19-inch hobs, the inner diameter, outer diameter, inner width and outer width of the large-load 20-inch hob bearing are increased,

and the corresponding shaft diameter, end cover and installation size of the hob are increased accordingly, thus finally increasing the bearing capacity of the hob by 19% to 375 kN, as shown in the table.

Table 2. Parameters of hob bearing.

S/N	Parameter	20-inch hob	19-inch hob	Improvement rate
1	Bearing model	HH932132/HH32110	HH926749/HH926710	
2	Bearing bore diameter/mm	127	120.65	5.3%
3	Outer diameter of bearing/mm	304.8	273.05	11.6%
4	Inner width of bearing/mm	82.55	82.55	/
5	Outer width of bearing/mm	88.9	82.55	7.7%
6	Rated bearing capacity/kN	375	315	19%
7	Shaft diameter/mm	127	120.65	5.3%
8	Wear limit/mm	35	35	/

According to the geological conditions and actual layout of cutterhead, the final configuration of cutterhead is determined as shown in Table 3.

Table 3. Configuration of cutterhead and tools.

Name	Diameter of hob/mm	Quantity	Cutter spacing/mm	Cutter height
Central hob	457	4 (duplex)	100	145
Front hob	508	35	60	145
Edge hob	508	12	60 degressive	/
Number of buckets	/	6	/	105

3.3 Cutter spacing design

Disc hob spacing is defined as the shortest radial distance between two adjacent disc hobs, which is different from that the cutter layout must cover the whole section. The main requirement of disc hob layout is that the crushing area between adjacent disc hobs must be connected, and the related disc hob spacing becomes one of the most critical factors for disc hob layout. The spacing between the most important rolling hobs on the TBM cutterhead and the front disc hob is generally equal and a constant

value, which is 40-120 mm. The size is related to rock properties and tunneling parameters. Reasonable disc hob spacing can improve the tunneling efficiency of the cutterhead and reduce cutter wear.

The specific energy consumption for rock breaking by disc hobs is an extremely important indicator in the process of rock breaking by disc hobs, which is defined as the work done by disc hobs when crushing unit volume of rock. If the specific energy consumption is small, it indicates that less energy is required to crush unit volume of rock and the rock breaking efficiency is high. Therefore, the optimal cutter spacing between disc hobs can be determined based on the specific energy consumption^[11].

Simplified calculation formula for specific energy consumption improvement:

$$SE = \frac{W}{V} = \frac{F_R l}{V} = \frac{F_R l}{m/\rho} \quad (1)$$

Where: F_R is the average rolling force; l the cutting distance of hob; S the cutter spacing; p the penetration; A is the rock breaking area below; V the volume of rock debris $V=A \cdot l$.

The physical and mechanical parameters of rock specimens made with the standard method by using rock samples collected on site measured in the mechanical test center are shown in the table.

Table 4. Parameters of rock materials.

Rock Type	Density/ (g/mm ³)	Compressive Strength/ MPa	Tensile Strength/ MPa	Crushing Angle/(°)
Granite	2.97×10-3	156.2	26.5	120

First, the disc hob indentation test should be carried out to record the penetration of the disc hob and the length of the lateral crack when the rock lateral crack penetrates the free surface. The rock sample is loaded by a hob until the lateral crack penetrates the free surface and then unloaded, as shown in Figure 3. The maximum penetration of the disc hob and the width of broken rock (i.e. lateral crack length) are collected and analyzed.

Figure 9. Hob indentation experiment.

Considering the randomness of lateral crack length in the test, it is necessary to carry out multiple indentation tests and eliminate singularity data to obtain a trend curve between crack length and penetration, as shown in Figure 4.

Figure 10. Crack length at different penetrations.

In general, the lateral crack length increases generally linearly with increasing penetration. According to the fitting of measuring points, the first-order function of lateral crack length with respect to penetration is

$$L = 4.7p + 8.6$$

The specific energy consumption model of hob cutting the above rocks can be obtained as follows:

$$SE = \begin{cases} \frac{TR\phi P^0 \sin(\frac{\phi}{2})}{\lambda p S} & 0 < S \leq 9.4p + 39.2 \\ \frac{TR\phi P^0 \sin(\frac{\phi}{2})}{\rho^2 \tan \beta + Tp} & S > 9.4p + 39.2 \end{cases}$$

To compare the relationship between different penetrations, cutter spacing and specific energy consumption, the penetration is taken as 1, 2, 3 and 4 mm respectively. By substituting the above parameters into Eq., the calculation results of rolling force

Figure 11. Energy consumption change of different tool spacing ratio.

and vertical force under common tool spacing can be obtained.

It can be seen from the figure that with the increase of cutter spacing, the specific energy consumption gradually decreases and then increases gradually when it is reduced to a certain extent. With the increase of penetration, the excavation volume increases and the specific energy consumption decreases gradually. According to the geological conditions in Beishan, the specific energy consumption of hob rock breaking process can be calculated by using force prediction model. The analysis shows that under the geological conditions of Beishan, the cutter spacing is set to 60 mm.

3.4 Cutter balance calculation

The existence of overturning moment may cause the cutterhead to deflect through the center and perpendicular to the cutting direction, which will lead to uneven stress on the cutterhead and spindle, accelerate the wear of edges and some hobs, and adversely affect the rock breaking performance and service life of the cutterhead. When the cutterhead rotates for one circle, the overturning moment along X and Y directions is shown in the figure.

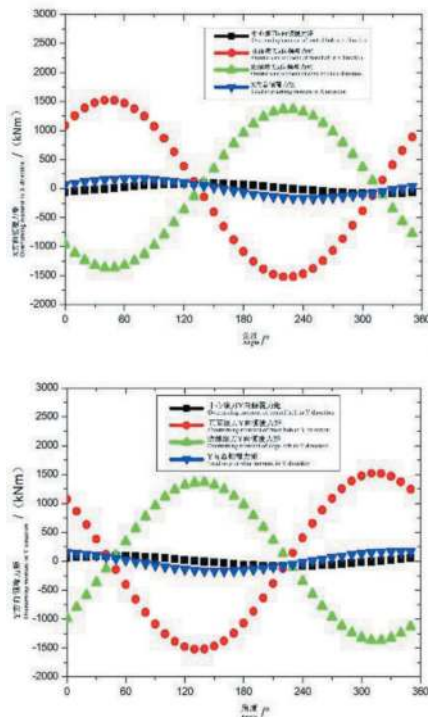

Figure 12. Overturning moments of cutterhead in X and Y directions.

It can be seen from the figure that the overturning moment generated by the front hob and the edge hob is obvious, which is related to the layout of cutters. The central hob has a small number and is located in the center of the cutterhead, so the overturning

moment is small; the overturning moment generated by the cutterhead in X and Y directions is 170 km, less than 3.3% of the overall torque, meeting the use requirements.

Figure 13. Physical cutterhead and tunnel formation.

4 PROJECT APPLICATION EFFECT

The Beishan underground laboratory project is under excavation now, with a maximum daily footage of 20.4 m and a maximum monthly footage of 340 m.

At present, the tool wear is normal and conforms to the wear law, with a low abnormal failure rate of tools.

In general, Beishan TBM runs steadily during tunneling and mucking is smooth. The cutterhead has good adaptability to project engineering geology and meets the construction requirements.

5 CONCLUSIONS AND SUGGESTIONS

- 1) For spiral downhill extremely hard rock tunneling, the conical cutterhead can realize free face and high rock breaking efficiency;
- 2) The knife spacing can better match the extremely hard rock tunneling conditions, with low specific energy consumption and high rock breaking efficiency;
- 3) By analyzing the geological characteristics of extremely hard rock in Beishan, TBM cutterhead is designed with targeted innovation, which can better meet the tunneling needs of the project and show good application effect.

In short, the selection and design of cutterhead are not determined by any single factor. On the basis of engineering geology, following the principles of technical reliability and economic rationality, it is necessary to comprehensively consider factors such as cutterhead structural type, cutter layout, cutter load characteristics, balance calculation, etc., so as to match more adaptable cutterheads and meet project requirements.

This paper relies on the actual project conditions to carry out targeted design and solve practical engineering problems. In the next step, more in-depth theoretical analysis and research need to be carried out on multi-objective optimization modeling and analysis.

ABSTRACT: Real time estimation and early warning of rock mass strength and integrity are very important for TBM safe and efficient tunneling. However, the previous research on the correlation model between rock core strength and FPI established without distinguishing the rock mass integrity has a large deviation in estimating the strength of jointed rock mass, and can't show the integrity of rock mass. In this study, firstly, based on the statistical analysis and fitting of field data collected at several tunnels with different geological conditions and different TBM diameters, a general correlation model between intact rock mass strength and FPI was established, and the concept of rock mass equivalent strength was put forward for the jointed rock mass. Then, a real-time method of estimating rock mass equivalent strength and integrity coefficient using FPI was proposed, the accuracy and applicability of which were verified in several project cases. Finally, based on the real-time estimated rock mass equivalent strength and integrity coefficient, the classification method and early-warning threshold of TBM digging rock mass was given, which can predict and warn the rock mass real-timely. The research provides a more practical and feasible idea and method for real-time estimation and early warning of rock mass strength and integrity in TBM tunneling.

Keywords: Tunnel, TBM, Rock mass strength, Rock mass integrity coefficient, Rock mass classification, Early warning

1 INTRODUCTION

In recent years, full face hard rock tunnel boring machine (TBM) has been rapidly developed in tunnel construction due to its advantages of fast construction speed, safety and environmental protection, gradually becoming the first choice. Rock strength and rock mass integrity, as the key parameters characterizing rock mass quality, are the main judgment

indexes for engineering rock mass quality classification and TBM driving performance. It is crucial to evaluate the rock strength and rock mass integrity of tunnel face timely and accurately during TBM excavating. However, limited by the TBM mechanical structure such as cutterhead and shield, the surrounding rock condition of tunnel face can't be observed directly, and the quality characteristics of surrounding rock can't be tested and evaluated in TBM

*Corresponding author: 1737459678@qq.com

tunnelling. At present, the traditional test method of rock strength and rock mass integrity can only be used after TBM stopped, lacking of real-time, which is difficult to provide TBM with online identification and early warning of surrounding rock. Therefore, according to the change of TBM tunneling parameters, establishing a real-time method of estimating rock strength and rock mass integrity to determine whether the rock mass is easy to boring or is broken, and to implement the real-time identification and warning of rock mass, is of great significance for ensuring TBM safe and efficient tunneling and improving the intelligent level of TBM construction.

Previous studies and engineering practices have shown that the TBM tunneling parameters are correlated with rock strength and rock mass integrity. In 1979, Hamilton and Dollinger (1979) proposed the concept of field penetration index (FPI). Subsequently, many scholars found that the relationship between rock strength and FPI was proportional through the laboratory analysis or the field measured data analysis respectively, and used this parameter to evaluate the rock mass (Nelson et al., 1983; O'Rourke et al., 1994; Hamidi et al., 2010; Farrokh et al., 2012; Saimi et al., 2017). Hassanpour et al. (2010, 2011, 2016) proposed and verified the relational model of rock strength, rock quality designation (RQD) and FPI based on several diversion tunnels in Iran. Du et al. (2015) analysed the correlation of FPI and main geological parameters through field data, and established a multiple regression model of FPI, rock uniaxial compressive strength (UCS) and rock mass integrity coefficient (K_v). Wu et al. (2020), taking the UCS, K_v and tunnel diameter as the main influencing factors and the FPI as the evaluation index, established an empirical prediction method of rock mass boreability and carried out the boreability classification by the analysis of measured data from five TBM tunnels.

According to laboratory test results, a rock strength estimation model based on TBM technical parameters (number and diameter of disc cutter) and tunneling parameters (thrust, torque and penetration) was put forward, the accuracy of which was verified by engineering examples, and an idea to solve the K_v was given (Fukui et al. 1999, 2003, 2006). Ma et al. (2017) and Zhang et al. (2022) proposed a rock strength estimate method according to the statistical analysis of measured data from TBM tunnel engineering, which has the same idea as the Fukui's method except for adding a parameter of tunnel diameter. Chen et al. (2017) analysed the correlation of tunnelling parameters and UCS based on the site data of N-J hydropower project in Pakistan, and found that the FPI had the best correlation with UCS, so as to put forward a fast evaluation model of rock strength based on FPI.

From all the research above, it can be found that a higher rock strength and integrity coefficient correspond to a smaller penetration and a greater

thrust, which means that estimating the rock strength by TBM tunneling parameters is feasible. However, there are some shortcomings in the current research: (1) some of the results are a semi-quantitative description on the basis of the laboratory test, without giving a general quantization formula for engineering; (2) some empirical models, based on the site data of a certain project, are only applicable to this project or similar projects, and are not universal; (3) the rock strength estimate models based on tunnelling parameters actually establish the relationship of the FPI with rock core strength, rather than with the excavated rock mass strength, which ignores the influence of rock mass integrity. The models have limitations in real application. In practical engineering, the rock strength is usually represented by rock core test strength (UCS). For the intact rock mass, the rock mass strength is close to the UCS, so the model estimated results have a good accuracy. But for the jointed rock mass, the rock mass strength is generally lower than the UCS. The tunneling parameters actually reflect the rock mass strength, so the model results estimated by the tunneling parameters are different from the UCS.

During TBM construction, the practical need is to estimate the rock mass boreability real-timely, that is, to know the rock mass strength as well as integrity. If the relation model of UCS and FPI is established without distinguishing the rock mass integrity, the model computing results will lack accuracy in jointed rock mass, which can't truly reflect the strength and integrity of rock mass. Therefore, this paper proposes a real-time estimate method of rock mass strength and integrity based on the TBM tunneling parameters. Firstly, different from previous studies, an empirical model between the intact rock mass strength (R_c) and FPI is established by the statistical analysis of field data from the intact rock mass sections with different lithologies in multiple projects. At the same time, considering that the rock masses with same FPI have same boreability, the concept of rock mass equivalent strength (R_{ec}) is introduced to reflect the model estimated results of jointed rock mass. Secondly, a real-time method to estimate the R_{ec} and K_v is established, the accuracy and applicability of which is verified by several project cases. Finally, based on the real-time estimated R_{ec} and K_v , the classification and early-warning method of rock mass in TBM tunneling is proposed, which can provide technical support for TBM safe and efficient tunneling.

2 CORRELATION MODEL BETWEEN INTACT ROCK MASS STRENGTH R_C AND FPI

2.1 *Project overview*

The research data in this paper is from 9 TBM construction projects (10 TBM in total). The main

Table 1. TBM specifications.

Project Name	TBM type	Cutterhead diameter/m	Number of disc cutter	Face cutter spacing /mm	Maximum thrust /kN	rotational speed /rpm

A water diversion project in Shanxi	23.28	Limestone, mudstone, shale	30~90	610
HJ tunnel project	37.69	Chorismite, breccia lava, granite porphyry	35~120	1000

technical parameters and geological conditions of each TBM project are shown in Table 1 and Table 2, respectively.

2.2 Data source of geology and tunneling parameter

To establish a more accurate and widely applicable model, the in-situ data of different projects and geological conditions are collected and sorted out. As shown in Table 1 and Table 2, the data used in this research, from different tunnel diameters, TBM types and rock types (including sedimentary

rock, magmatic rock and metamorphic rock, etc.), include tunneling parameter data and geological data. The tunneling parameter data, recorded in the field or copied in the TBM data acquisition system, mainly include the cutterhead thrust and penetration, which are used to calculate the field penetration index (FPI). The FPI is the ratio of single-cutter thrust to penetration, and the calculation formula is as Eq. (1). The geological data include uniaxial compressive strength (UCS) and rock mass integrity coefficient (K_v). Among them, the UCS is obtained from the uniaxial compressive strength test or point load test, and the K_v is

obtained from geologic sketch and analysis of volumetric joint count of rock mass, or from the calculation of geophysical exploration test.

$$FPI = F/(n.P) \quad (1)$$

Where, F is cutterhead thrust (kN); P is penetration (mm/r); n is the number of disc cutters.

2.3 Establishment of model between R_c and FPI

In TBM construction, the tunneling parameters actually reflect the rock mass strength. When the rock mass of tunnel face is intact with undeveloped joint or structural surface, the rock mass quality is mainly affected by the rock strength. At this time, the rock mass strength is approximately equal to the rock core strength, namely the test results of UCS. When the rock mass of tunnel face is broken with developed joints, the rock mass strength, affected by the rock strength and rock mass integrity, is generally lower than the UCS. At this time, the FPI actually corresponds to the jointed rock mass strength rather than the rock core strength (UCS). Therefore, the corresponding FPI and UCS under the intact rock mass in each project mentioned above are selected to fit the empirical formula of intact rock mass strength R_c (i.e. UCS) and FPI, so as to obtain a more accurate and widely applicable prediction model. According to the actual engineering surrounding rock classes and rock mass conditions, all the data of above projects are filtered. And a total of 165 valid data were selected for fitting. The UCS ranged from 10.2MPa ~224MPa, as shown in Table 3.

After fitting, the correlation model between the intact rock mass strength R_c and FPI is as follows (Figure 1):

$$R_c = 64.98 \ln(FPI) - 140.32 \quad (R^2 = 0.9146) \quad (2)$$

In this empirical model, the R_c increases with the FPI, and there is a good logarithmic relationship between them. The correlation coefficient of this model is 0.9146. The error between the actual R_c (namely the UCS) and the predicted R_c (calculated by FPI) is small, indicating that this empirical model can be used to predict the strength of intact rock mass.

3 REAL TIME ESTIMATION METHOD OF ROCK MASS STRENGTH AND INTEGRITY COEFFICIENT

3.1 Real time estimation of rock mass equivalent strength R_{ec}

In TBM construction, it is necessary to know the rock mass boreability, and to know the strength and broken degree of the rock mass.

Table 3. The practical data.

R_c (UCS)/MPa	Thrust /kN	Penetration/(mm/r)	FPI
224	4720	0.25	464.74

32.8	5214	7.1	14.79
...

Figure 1. The relationship model between FPI and R_c .

For the intact rock mass, the rock mass strength can be regarded as the UCS. In actual engineering, based on the proposed model (Eq. (2)), the strength of intact rock mass can be directly estimated using the real-time FPI calculated by the tunneling parameters from TBM data acquisition system, instead of rock core testing.

For the jointed rock mass, to describe the proposed model estimated result, the concept of rock mass equivalent strength (R_{ec}) is introduced, that is, the excavated rock mass strength

with the same penetration difficulty as an intact rock mass strength is called the equivalent strength of TBM excavated rock mass. In other words, some jointed rock mass with the same FPI has the same rock mass boreability as the other intact rock mass, that is, the boreability of a rock mass with higher rock strength and developed joints is similar to that of another intact rock mass with lower rock strength. In this way, regardless of the rock mass integrity, based on the proposed model (Eq. (2)) and the proposed concept of R_{ec} , the equivalent strength of rock mass (including jointed rock mass and intact rock mass) can be directly estimated using the real-time FPI.

To illustrate the accuracy of the real-time R_{ec} estimation method mentioned above, the estimated R_{ec} are compared with the quasi-rock mass strength. Quasi-rock mass strength (i.e. rock mass integrity coefficient correction method) is an empirical method to determine rock mass strength, which is to modify rock strength with certain simple test index as the estimated value of rock mass strength. The calculation formula is shown in Eq. (3).

$$\sigma_{cm} = (V_{pm}/V_{pr})^2 \sigma_{ci} \quad (3)$$

Where, σ_{cm} : uniaxial compressive strength of rock mass; σ_{ci} : uniaxial compressive strength of rock; v_{pm} : elastic longitudinal wave velocity of rock mass; V_{pr} : elastic longitudinal wave velocity of rock; $(v_{pm}/v_{pr})^2$: rock mass integrity coefficient, k_v . Joints, cracks and structural planes are the main factors affecting rock mass. Taking the product of UCS and k_v as the estimation value of rock mass strength avoids many subjective factors and is simple, which is one of the commonly used rock mass strength estimation methods in practical engineering.

Taking the field data of Northeast project and HJ project in China as examples (Table 4), the R_{ec} estimated by the FPI is compared with the results calculated by the Eq. (2) to verify the accuracy of the proposed method. The comparison results and error analysis are shown in Figure 2. The error analysis formula is as follows:

Table 4. The field data of projects.

Project Name	Lithology	UCS/ MPa	K_v
Northeast diversion project	granite	78~175	0.56-0.89
HJ project	migmatite	74~107	0.24~0.72

(a) Northeast diversion project (20 sets of data)

(b) HJ project (46 sets of data)

Figure 2. Comparison of results and error analysis.

$$E = \left| \frac{R_{ec} - \sigma_{cm}}{\sigma_{cm}} \right| \times 100\% \quad (4)$$

From the comparison results of above two projects, the R_{ec} estimated by the proposed model is close to the calculation results of the empirical formula (3), with the mean error of 6.53% and 16.76%. The errors of some results are relatively high, but the whole variant trend of the results estimated by two methods is identical with minor error. In addition, in the actual engineering the rock strength obtained through tests also have a certain discreteness, and the estimates of empirical method have a certain error.

3.2 Real time estimation of rock mass integrity coefficient K_v

The rock mass equivalent strength (R_{ec}) is a comprehensive reflection of rock block strength and rock mass integrity. The R_{ec} estimated by FPI in real time can reflect the rock mass boreability ahead of the tunnel face, but it can't reflect separately the rock strength and the broken degree of rock mass. Under the same R_{ec} , the condition of rock mass may be diverse. For example, the value of R_{ec} with lower strength and better integrity may be the same as that with higher strength and poorer integrity. Therefore, during TBM tunneling, it requires to know not only the boreability and equivalent strength of rock mass, but also the broken degree of rock mass, which is

crucial for identifying and warning the risk of TBM stuck in rock collapse and preparing appropriate support measures in advance. It's necessary to find a real-time estimation method for the rock mass integrity.

Applying the model to a practical project, the rock mass integrity coefficient (K_v) can be estimated real-timely based on the R_c under the intact rock mass with same lithologic measured in advance and the R_{ec} estimated by the model (Eq.2). The formula for the rock mass integrity coefficient estimation is as follows:

$$K_v = R_{ec} / R_c \quad (5)$$

The intact rock mass strength R_c can be measured by the rock core test in the stage of pre-geological investigation, or in the early stage of TBM tunneling under the intact rock mass.

However, affected by the sampling and testing error of the rock, the rock strength under the same lithology still has certain discreteness, so the mean compressive strength of the rock samples is taken as R_c . At this time, if the K_v estimated by the Eq. (5) is within a certain range, for example, the range of rock mass integrity classification as Table 5, it is enough to identify the risk caused by broken rock, and can be considered that the estimated results are accurate and effective.

Table 5. The correspondence between K_v and rock mass integrity.

K_v	>0.75	0.75~0.55	0.55~0.35	0.35~0.15	<0.15
Rock mass integrity degree (BQ)	Intact	Relatively intact	Relatively broken	Broken	Extremely broken

4 PROJECT APPLICATION AND VERIFICATION

In the following, the accuracy of the real-time estimation method above is verified through three application examples: Zhuxi reservoir diversion project, a diversion project in Guangzhou, and Gaoligongshan tunnel project. The predicted equivalent strength and integrity of rock mass will be compared with the exposed actual rock strength, surrounding rock classification and support, and analyzed in combination with the TBM driving thrust and penetration.

(1) Example 1: A tunnel section of Zhuxi reservoir diversion project: 15+916~15+716(200m).

In this tunnel section, the lithology is breccia fused tuff with the mean UCS of 145MPa (under the intact rock mass), and the class of surrounding rock is class II. The surrounding rock is intact with undeveloped joints and smooth surface, no water seepage and no rock support, except that the surrounding rock are partially broken in the mileages of 15+870~15+860 and 15+732~15+726, which is supported with mesh and shotcrete. The change of the model estimated results (R_{ec} and K_v) and the tunneling parameters (thrust (F) and penetration (P)) is shown in Figure 3.

Figure 3. Changes trend of R_{ec} , k_v , F and P of example 1 (176 sets of data).

From Figure 3, the thrust is basically maintained at 7 000kN, and the penetration ranges from 0.5 mm/r to 8mm/r, with great changes. The R_{ec} estimated by Eq. (2) is in the range of 50~250MPa, with an average of 114MPa. Among them, affected by the rock mass integrity, the R_{ec} of the sections (15+875~15+860 and 15+737~15+728) is lower than that of the intact rock mass sections, which is reflected in the relative increase of penetration and the decrease of thrust in TBM tunneling parameters. It can be seen that the R_{ec} is close to the UCS for the intact rock mass, and lower than the UCS for the jointed rock mass. In addition, at 15+784, 15+737 and 15+724, the UCS are 175MPa, 83.1 MPa and 162MPa respectively, corresponding to the penetration of 1.3mm/r, 6.3mm/r and 1.0mm/r, and the R_{ec} are 172MPa, 94MPa and 184MPa. The rock core samples are from the intact rock mass section, and the model estimated results (R_{ec}) are close to the rock core test results (UCS), so the model prediction is relatively accurate.

Under the same lithology, the ratio of R_{ec} to R_c (the mean UCS of this lithology is taken here) is the K_v . Therefore, the R_{ec} and the K_v estimated by the

model have the same variation. Under the sections of 15+875~15+860 and 15+737~15+728, the surrounding rock is partially broken, and the corresponding values of K_v are small, ranging from 0.25 to 0.55. Under the rest of sections, the K_v is relatively high, keeping above 0.55. The breccia fused tuff belongs to hard rock, which is complete or relatively complete in the surrounding rock II, and the K_v is above 0.55. Therefore, the K_v calculated in this paper is in line with the real situation, and the variation trend of K_v is basically consistent with the actual rock mass condition.

(2) Example 2: A tunnel section of Gaoligongshan tunnel project: 225+504~225+410(94m).

In this tunnel section, the lithology is granite with the mean UCS of 53MPa (under the intact rock mass). In the mileages of 225+504~225+419, the class of surrounding rock is class IIIa, and the surrounding rock is broken on the part of right side and weathered at 11 o'clock, with relatively developed fractures and developed groundwater in the section (225+504~225+477), and the surrounding rock is relatively intact with undeveloped crack and groundwater in the section (225+477~225+419). The bolting with wire mesh is carried out for the surrounding rock. In the mileages of 225+419~225+410, the class of surrounding rock is class IVa, and the surrounding rock has poor integrity, local strong weathering and quartz zone intrusion, which is supported with steel arch, systematic rock bolt and shotcrete. The change of the model estimated results (R_{ec} and K_v) and the tunneling parameters (F and P) is shown in Figure 4.

It can be seen from Figure 4 that the R_{ec} and K_v vary regularly with the actual rock mass conditions. The rock mass under the section of 225+504~225+421 is class IIIa. The section (225+477~225+421) has good integrity, so the values of R_{ec} and K_v are relatively high, with means of 47.25MPa and 0.89, respectively. The corresponding mean of thrust, penetration and FPI is 16 897kN, 10.74mm/r and 18.68, respectively, and the rock mass condition is good and easy to penetration. However, in tunnel section (225+504~225+477), the right side of surrounding rock is locally broken with developed cracks, so the R_{ec} and K_v are relatively low, with the means of 30.8MPa and 0.6. In terms of TBM tunneling parameters, the thrust decreases to 14 711kN, the penetration increases to 12.5mm/r, and the mean FPI is 14.5. The rock mass under the section of 225+421~225+410 is class IVa with poor integrity, so the R_{ec} and K_v are low, with means of 19.88MPa and 0.38. Correspondingly, the mean thrust is 11 202kN, penetration is 10.98mm/r, and FPI is 12.11. Compared with surrounding rock class IIIa, the penetration of class IVa remains basically unchanged and the thrust decreases, indicating that the rock mass is weak and broken with strong support. Therefore, the overall change trend of estimated R_{ec} and K_v is basically coincident with the construction practice.

Figure 4. Changes trend of R_{ec} , K_v , F and P of example 3 (109 sets of data).

The above two typical application examples show that the rock mass equivalent strength and integrity coefficient estimated by the method are in agreement with the actual rock mass conditions from the overall trend. There is a little error in some tunnel sections because the surrounding rock classification is to divide infinite rock mass sequence into several classes by the indexes of rock strength and rock mass integrity, which is no clear demarcation between the surrounding rock classes, so there may be some judgment errors in the classification of surrounding rock on site. From this, it indicates that the real-time estimation method of rock mass equivalent strength and integrity coefficient presented in this paper is feasible.

5 REAL TIME CLASSIFICATION AND WARNING OF ROCK MASS IN TBM TUNNELING

At present, the commonly used classification methods of tunnel surrounding rock stability are mainly proposed for the traditional drilling and blasting method, not TBM adaptability classification, and not online real-time intelligent classification. The intelligent identification and early warning of TBM tunneling rock mass is of great significance for judging the surrounding rock boreability timely and preventing the risk of tunnel collapse and TBM trapped. For this purpose, using the rock mass equivalent strength and integrity coefficient estimated by the real-time method in this paper, a classification and early-warning method of rock mass in TBM tunneling is established.

The rock strength is the key factor to measure the difficulty of TBM tunneling. For TBM, too high (i.e. extremely hard rock) or too low (i.e. extremely soft rock) rock strength is unfavorable for TBM tunneling. Too high rock strength means the rock mass boreability is poor, leading to the TBM tunneling difficult and the cutter replaced frequently due to serious wear,

which seriously affects the construction speed and increases the construction cost. Too low rock strength means the rock mass is weak and broken with poor stability, leading to an increase in corresponding support amount and time and a reduction in construction efficiency, which are often located in the bad geological zone and more prone to collapse, so that the TBM tunneling is blocked, or even stuck and trapped. At present, in the engineering circle, there is the underlying idea that the rock strength range of 30~150MPa is perfect for TBM tunneling. For the rock strength greater than 150MPa or less than 30MPa, the TBM construction efficiency is low, which is not conducive to TBM tunneling speedily. In addition, the existing studies (He et al., 2002; Li and Peng, 2006; Wang et al., 2020) and TBM construction practice analysis show that, for the rock strength greater than 200MPa or less than 15MPa, it is extremely difficult for TBM to boring. Based on the above analysis, in this paper, the 150MPa and 200MPa are used as the two levels warning threshold of extremely hard surrounding rock. And the 30MPa and 15MPa are taken as the two levels warning threshold of soft surrounding rock.

Rock mass integrity, measured by the K_v , is also a main factor affecting the efficiency of TBM construction. In general, the smaller the K_v is, the more developed the rock mass structural plane, and the higher the TBM tunneling speed is. However, when the K_v is too small, the surrounding rock integrity is very poor with especially well-developed rock mass structural plane and no self-stabilization ability. In this case, the TBM tunneling efficiency will be reduced due to the increase of surrounding rock support. From the TBM construction projects, when K_v is less than 0.35, the tunnel surrounding rock is very broken, mostly located in the fault fracture zone, and is prone to collapse and instability, which not only seriously affects the TBM construction speed, but also has the construction risk of TBM being stuck.

Based on the above analysis and the classification of rock mass basic quality in *Standard for Engineering Rock Classification of Rock Mass (GB/T 50218-2014)*, the rock mass boreability and safety risk during TBM excavating are classified by the real-time estimation of R_{ec} and K_v , thereby establishing a real-time classification and early-warning method of tunnel surrounding rock for TBM tunneling, as shown in Table 6.

For Table 6, the following explanations are given.

1. For the rock mass with equivalent strength of 30~150MPa, or 15~30MPa and integrity coefficient greater than 0.35, it is suitable for TBM tunneling, relatively easy to penetrate and safe, and the TBM construction will not have big risk even if there is occasionally local collapse. So, there is no need for warning.
2. For the rock mass with equivalent strength of 150~200MPa or greater than 200MPa, TBM tunneling penetration is very difficult. But even if there is local collapse, TBM construction will not pose a big risk. However, early warning can remind the operator that the rock is extremely hard, and attention should be paid to the inspection of cutter damage and appropriate adjustment of tunneling parameters. Therefore, two level rock extremely hard early warning are given.
3. For the rock mass with equivalent strength of 15~30MPa and integrity coefficient lower than 0.35, or rock mass lower than 15MPa, TBM tunneling penetration is very easy, but the rock mass may be broken or extremely broken or very weak at this time. Early warning can remind the operator of the risk of TBM being stuck due to collapse or deformation of surrounding rock, and attention should be paid to geological check and support adjustment. Thus, two level rock extremely soft early warning are given.

Table 6. Real-time classification and early warning of rock mass for TBM tunnelling.

Class	R_{ec}	K_v	Rock mass conditions	Boreability and collapse risk	Early warning
B-I	30~150	~	Suitable rock hardness and integrity	Easy or relatively easy penetration	No need for warning
	15~30	>0.35		Low or relatively low collapse risk	
B-II	150~200	~	Very hard rock and intact rock mass or occasionally local collapse	Difficult penetration	Second-level warning
	15~30	<0.35		Cutter wear fast and low risk Easy penetration Relatively high risk Extremely difficult penetration	
B-III	>200	~	Extremely hard and intact rock mass	Cutter wear extremely fast and low risk	first-level warning
	<15	~		Easy penetration High risk of collapse or deformation	

It should also be noted here that this paper focuses on the impact of rock mass strength and integrity, while the impact of rock burst and groundwater will be studied separately.

Compared with the previous surrounding rock classification methods for TBM construction, the proposed approach adopts the simple classification index parameters which is easy to get online. Using the R_{ec} and K_v estimated by the model in this paper can classify and warn the rock mass in TBM tunneling real-timely. According to the rock mass boreability and risk degree, the tunneling parameters and construction strategy could be adjusted timely, and the countermeasures could be made in advance to guide TBM safe and efficient tunneling.

6 CONCLUSIONS

- (1) Through the statistical analysis and fitting of field data under intact rock mass sections in a variety of lithologies from multiple TBM projects, a correlation model with general applicability of the intact rock mass strength (R_c) and the filed penetration index (FPI) is established, and the correlation coefficient reaches 0.914 6. The model prediction is close to the actual value, which can be used to predict the intact rock mass strength (i.e. rock strength).
- (2) For the jointed rock mass in actual TBM tunneling, the concept of rock mass equivalent strength (R_{ec}) is introduced. Then the real-time estimation method of R_{ec} based on FPI is proposed, that is, the FPI of excavated rock mass, calculated by the TBM cutterhead thrust (F) and penetration (P), is plugged into the proposed model to obtain the R_{ec} . Furthermore, the rock mass integrity coefficient (K_v) can be calculated via $K_v = R_{ec}/R_c$. In this way, the equivalent strength and integrity coefficient of rock mass in TBM tunneling can be estimated online instead of offline sampling and testing, thereby monitoring the boreability and broken degree of rock mass in real time.
- (3) Based on the model estimate results of R_{ec} and K_v , the real-time rock mass classification and bad geology warning threshold values are given. The research can predict the rock mass conditions real-timely and warn the bad geology timely in TBM tunneling, which provides the technical support for the TBM safe and effective tunneling.

In this paper, the real-time estimation method of rock mass strength and integrity coefficient for TBM tunneling is based on the relationship between rock mass strength and FPI, which is different from the previous models between rock block strength and FPI established without distinguishing rock mass integrity during sampling. In addition, the goal of

this method is not to calculate accurately the strength and integrity coefficient of rock mass, but to estimate its range real-timely using TBM tunneling parameters, intuitively know the boreability and broken degree of rock mass, and give the early-warning for TBM safe and efficient tunneling. Therefore, from the perspective of the TBM actual tunneling requirements, the method has good applicability.

ACKNOWLEDGMENTS

This research was supported by the Research Plan of Xinjiang EH Project of China (Grant No. EQ075/FY056) and National Key R&D Program of China (Grant No. SQ2022YFB2300029). The authors are very grateful for the huge support of all members of this research project.

Three-dimensional centrifuge modelling of the effects of TBM on adjacent piles

Xing Liang* & Stuart Haigh

Department of Engineering, University of Cambridge, UK

ABSTRACT: The demands of urban tunnel applications will continue to provide a major impetus to achieving improved understanding of the behaviour of piles due to TBM excavation. This research investigated the effects of new built tunnel by TBM method to the adjacent bored piled structures by applying a mini-TBM model. The novel miniature TBM designed in Cambridge geotechnical centrifuge has been proven successful in excavating soft clay. Results show that the undrained shear strength exhibits good agreements both in measurements by T-bar and estimations by Modified Cam-clay and SHANSEP method. Compared to tunnelling in softer clay, it shows a bigger settlement trough as expected and well agrees with the general understanding of longitudinal settlement trough, although limited by the size of strong box. TBM induced pore pressure variation can be perfectly explained as a result of thrust force and peripheral volume loss. Comparison with reported centrifuge tests presents the repeatability of the test and a larger settlement was obtained for smaller transverse distance from the tunnel axis. Recorded bending moments explains the influence of continuous tunnelling rather than simple change of volume loss. They were in a good agreement with previous reports but provided more details involving thrust and tapered shape of TBM. Finally, the capabilities of current mini TBM are discussed together with potential modifications.

Keywords: Mechanised tunnelling, reduced scale physical modelling, centrifuge, soil-pile interaction

1 INTRODUCTION

The growing population and extensive urbanisation of communities has led to a need for increased urban infrastructure inclusive of undergrounds. The overused infrastructures above ground left limited surface space in such dense urban area. Consequently, the construction of underground transportation (i.e., also known as tubes, metros, subways) has been undertaken in highly populated areas.

As the construction of urban tunnel develops rapidly, various tunnelling techniques were employed to maintain the ground safety. Among them, tunnel boring machines or TBMs were widely used due to its evident advantages of limiting the disturbance to the surrounding ground and producing a smooth tunnel wall. This significantly reduces the cost of lining the tunnel and makes them suitable to use in heavily urbanized areas. Like any other construction methods, however, tunnelling causes stress relief to the surrounding soil leading to ground movements around the tunnel which propagate through the soil to the ground surface. These movements might have an impact (e.g., axial load, bending moment, and pile capacity) on the piled structures. Researchers have been carried out investigating the damage caused by tunnelling to near buildings (Burland et al., 1977; Potts and Addenbrooke, 1997; Mair,

2011) but a relatively small amount of scholars worked on the effects of these ground movements on piled foundations and the resulting interaction with the overlying structures. As a result of the lack of knowledge and case studies, the behaviour of piled structured due to the tunnel excavations is not completely understood.

One of the most common techniques to study the tunnel-soil-pile interaction problem is by small-scale physical modelling, both at 1g (e.g., Lee and Yoo, 2006; Hu et al., 2022; Meguid and Mattar, 2009) and high g-level in centrifuge tests (e.g., Loganathan et al., 2000; Jacobsz, 2003; Marshall, 2009; Williamson, 2014; Franza and Marshall, 2018). However, the common limitations of above literature are that they considered the tunnelling process in a ‘two dimensional’ scenario rather than three-dimensional one, which is completely accurate in practical application. In such models, a latex membrane is wrapped around a metal cylinder, where the gap between them is filled with a fluid to achieve a pressure similar to the overburden pressure around the tunnel. A controlled volume loss can thus be obtained by adjusting extraction rate of the pressurised fluid. Ng et al., (2015) made an attempt to address the problem by splitting the tunnelling stages by applying multiple pressurised late membranes. However, such method still failed to capture the actual mechanism due to neglecting the continuity of TBM tunnelling. More recently,

Cambridge Geotechnical Group has made great efforts and designed a new mini-TBM system to simulate the TBM excavations. Based on the work of Viggiani et al., (2022) and Alagha (2023), the mini-TBM system has been assembled, successfully tested and some convincing data was obtained. This offers us to investigate the issue from a three-dimensional perspective. This research is aiming to provide a better understanding of the effects of TBM excavation on adjacent bored piles. This paper presents obtained data from recent centrifuge tests and discusses the effects of tunnelling on adjacent piles in soft clay.

2 EXPERIMENTAL ARRANGEMENTS BY CAMBRIDGE MINI TBM

The latest mini-TBM model was designed by Viggiani et al., (2022) and has been employed to conduct a series of tests. The machine is able to reproduce the mechanisms of shield tunnelling and to account for most sources of volume loss outlined above and has been proved to successfully investigate the effects of TBM tunnelling both in greenfield conditions and in scenarios where piled foundations exist (see Figures 1 and 2).

Figure 1. Conceptual drawing of Cambridge mini TBM (after Viggiani et al., 2022).

Figure 2. Model TBM system attached to tunnelling box.

The cutterhead has a diameter of 78 mm, while the diameter of the shield at the face is 77.2 mm. As the current mini TBM system aims to be operated in soft clay, a cutterhead with an opening ratio of 45% was employed. To imitate a tapering shield, a conical brass collar is placed at the front of the lining tube, with a diameter decreasing from 77.2mm at the cutterhead junction to 76.2mm at the tail. The inner

diameter of the chamber decreases from 70 mm to 50.8 mm, corresponding to the outer diameter of the inner tube. The soil is removed from behind the cutterhead by a horizontal auger with a diameter of 40 mm. The outer lining tube was carefully chosen to represent extremely stiff lining segments at prototype scale thus eliminating the contribution of lining deflection to the overall volume loss. The auger is driven by a servo motor and a 100:1 reduction drive gearbox that can provide a maximum torque of 27 Nm. The TBM is advanced into a strongbox filled with soil using a linear actuator that can provide a thrust of up to 20 kN. All tests were conducted in 50-g acceleration equivalent to a prototype of about 4 m. Specific details of the mini TBM system can be found in Viggiani et al., (2022) and Alagha (2023).

2.1 Experimental layout

2.1.1 Design of model pile

Model pile foundations were designed and fabricated to conduct a comprehensive study with respect to tunnelling effects on pile and further pile groups. The following sections provide a complete description of the design process in this study.

Based on works of Williamson (2014), two primary behaviours of a structural element, i.e., axial behaviour and flexural behaviour, are governed by their axial stiffness (EA) and bending stiffness (EI). In this regard, an equivalent model pile has to possess similar axial and bending stiffness to those of prototype so that the centrifuge model can represent the real structures. Under 50g level intended to adopt in this study, a 11 mm outer diameter and 1 mm thickness round aluminium tubes supplied by RS PRO were found to offer the best match in terms of piles within pile group. Here listed the detailed comparison between the properties of the model pile presented in Table 1.

The two significant behaviours of model piles used in this study are similar to the prototype. With respect to axial behaviour, the axial stiffness of model pile is slightly smaller than that of the prototype (around 16% less); In terms of bending behaviour, the bending stiffness of the model pile is larger than that of the prototype (around 37% more). The discrepancies could not be avoided due to the limitations of materials but would not exert great influences on a geotechnical problem.

2.1.2 Length and size for pile

All piles employed in this study are the same (235 mm in model dimension). The length corresponds to that the pile tip located at the tunnel centreline. In addition, the piles were distributed at a different distance horizontally to the tunnel axis.

As aluminium tubes have a quite smaller roughness than that of reinforced concrete, a thin layer of epoxy fine mixture was coated in the model piles to ensure that a rough pile shaft is modelled. Araldite rapid adhesive epoxy was used for its excellent adhesive strength

Table 1. Comparison between the properties of the model pile and prototype.

Property	Desired prototype pile	Prototype pile scaled down with 50 g	Selected model pile
Material	Reinforced concrete	Reinforced concrete	Aluminium
Cross section	Solid circular	Solid circular	Hollow tube
Outer diameter (mm)	550	11	11
Thickness	-	-	1
Young's modulus (GPa)	30	30	70
Axial stiffness EA (N)	7.13×10^9	2.86×10^6	2.40×10^6
Bending stiffness EI (Nm)	13.48×10^7	21.55	29.69

and waterproofing characteristics. Photographs of coating process are shown in Figure 3.

Figure 3. Details of coating process: (a) putting araldite cohesive to a clean plate; (b) pouring sands to another clean plate; (c) stick the model pile with sand by araldite cohesive; (d) leave the new coated pile for half a day.

2.1.3 Pile instrumentation

Single piles (piles A, B and C) were all instrumented with LVDTs to monitor their vertical movements during tunnelling. Strain gauges were installed in single piles to measure their bending moments (see Figure 3(d)). Pile A and pile B were employed with 7 strain gauges while the pile C was instrumented with 8 strain gauges (see Figure 4). Details and description of strain gauges system can be found in Williamson (2014) and Alagha (2023).

2.1.4 Clay property

Speswhite Kaolin powder, supplied by Imerys Performance Minerals, was chosen to model the clay samples in this study. This clay type has been widely used in previous studies (e.g., Elmes, 1985; Williamson, 2014; Lau 2015; Gue 2017; Garala, 2020) for its mineral homogeneity. In addition, the small permeability makes it suitable for modelling undrained geotechnical processes as tunnelling. The parameters reported by researchers have been listed in the Table 2.

Figure 4. Details of strain gauges in single piles (dimensions in mm).

2.1.5 Test layout

Figure 5 shows the experimental setup used in the centrifuge test. The inner dimension of the strong box is $780 \text{ mm} \times 460 \text{ mm} \times 620 \text{ mm}$. The buried depth of the tunnel centreline is $z_0 = 235 \text{ mm}$ (i.e., around three times of diameter with the cover-to-diameter ratio of 2.5). It is worth noting that the model TBM was inserted in the clay by a length of 110 mm, which is also the length of the shield body plus cutterhead. This is to ensure a tight fit between the porthole and the tunnel lining tube, resulting in the tunnelling length of 300 mm.

Thirteen LVDTs (L1 to L13) were used to measure surface displacement in the transverse (TS) and longitudinal section (LS) and pile head settlements. LVDTs L2, L6-L9 were employed in section TS and LVDTs L1-L5 were used in section LS. It is noted here that LVDTs were only placed on one side due to the symmetrical condition. LVDT L10 was used in the far field to measure surface settlement. LVDTs L11, L12 and L13 were used to measure the pile head settlements, namely Pile A, Pile B, Pile C, respectively. Six PPTs (P1 to P6) were performed in the test. PPTs P1 to P4 were placed around the mini-TBM to measure the pore water pressure variation due to tunnelling. Specifically, P1 and P4 were placed at both sides of the TBM while P2 and P3 were placed at the top and bottom of the TBM. P5 was placed at the tunnel centreline and in front of the cutterhead at the end of excavation. P6 was used to measure the pore water pressure in the far field. Single piles A, B and C were placed at the same side as that of LVDTs measuring transverse troughs. Piles B and C were at the same transverse section and Piles A and B were around 2D away from tunnel axis at the same longitudinal section. Pile group was placed on the other side with the edge around 1D away from tunnel axis.

*measured during clay preparation in this study.

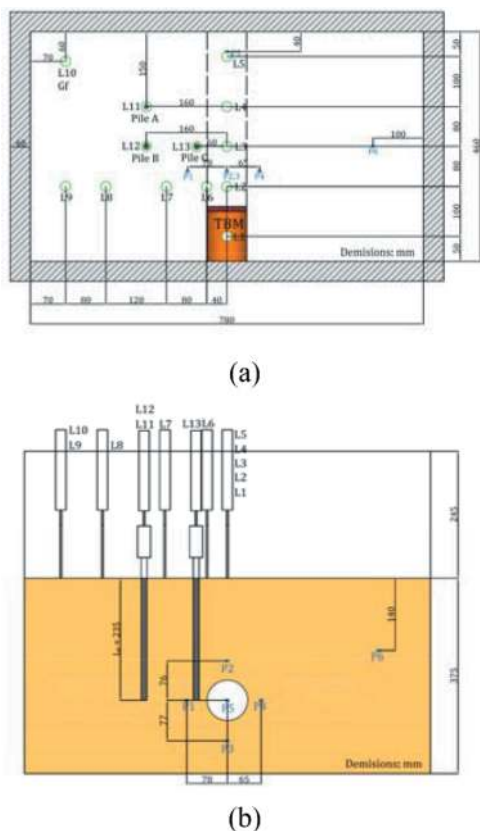

Figure 5. Layout performed in this centrifuge test: (a) plan view; (b) section view.

A T-bar test was performed during the flight after reconsolidating the clay to measure the undrained shear strength profile.

2.2 Experimental procedure

The centrifuge test was carried out following the procedures described as follows:

1. Prepare a normal consolidated clay;

2. Attach the mini-TBM to the tunnelling box;
3. Install pile/pile groups in the model clay;
4. Install monitoring instruments and assemble the centrifuge model;
5. Load the centrifuge package to the beam centrifuge;
6. Swing up to a centrifugal acceleration to 50 g;
7. Verify that the mini-TBM's drive system is operating well; if not, swing down and solve the issue;
8. Leave the clay reconsolidated for an hour under 50 g;
9. Activate T-bar at a rate of around 2.3 mm/s up to a maximum distance of 200 mm;
10. Operate the TBM to simulate mechanised tunnelling in the centrifuge;
11. Allow clay to post-tunnelling consolidate for approximately an hour;
12. Swing down and unloading.

3 EXPERIMENTAL RESULTS

All test results presented in this paper are in model scale, unless stated otherwise.

3.1 Undrained shear strength of clay

Determining the undrained shear strength profiles of clay is vital for analysing the force acting on the mini-TBM and understanding the physical behaviour of piled foundations during tunnelling. In-flight T-bar test was conducted to assess the undrained shear strength in this study. It should be noted that the T-bar performing rate should be such that the undrained penetration is achieved without causing any resistance increase due to partial consolidation. The T-bar undrained shear strength was calculated based on the T-bar penetration resistance, q_{T-bar} , which was computed by dividing the measured load by the projected area of the T-bar.

$$s_u = \frac{q_{T-bar}}{N_{T-bar}} \quad (1)$$

where N_{T-bar} is the T-bar bearing factor. Randolph and Houlsby (1984) concluded that the dimensionless load factor varied from 9.14 for a perfectly smooth pile (i.e., adhesion factor $\alpha = 0$) to 11.94 for a rough pile (i.e., adhesion factor $\alpha = 1$) and recommended an average value of 10.5 (i.e., adhesive factor α is around 0.4). Therefore, the value of 10.5 has been widely accepted to predict the T-bar undrained shear strength. Alagha (2023) carried out T-bar penetration test and miniature vane tests to verify the non-dimensional load factor. A total of six tests were performed and the results showed that all values have an average of approximately 11.6, which falls within the range reported by Randolph and Houlsby (1984) but is closer to the upper limit. This is also evidenced by the work of Gaudio et al. (2022). $N_{T-bar} = 11.6$ was used to compute the undrained shear strength as the test conducted in this investigation employed the same T-bar as that in the work of Alagha (2023).

The normalised soil parameter (NSP) concept, called “stress history and normalised soil engineering properties” (SHANSEP) can also be utilised to estimate the undrained shear strength profile of the soil (Ladd and Foott, 1974). The undrained shear strength, s_u of overconsolidated clay can be determined as follows:

$$\left(\frac{s_u}{\sigma'_v}\right)_{OC} = \left(\frac{s_u}{\sigma'_v}\right)_{NC} OCR^m \quad (2)$$

where m is a soil parameter indicating the relationship between over consolidation ratio (OCR) levels and s_u .

Based on the critical state soil mechanics by Schofield and Wroth (1968), Wood (1990) reported the calculation of soil parameter m as follows:

$$m = \frac{\lambda - \kappa}{\lambda} \quad (3)$$

Substituting the data from Table 2 to the Equation (3), the computed value of m is 0.84. This value compares well with the m values that result from the λ and κ values of Elmes (1985), Lau (2015) and Alagha (2023). Utilising these values, the estimated s_u profiles determined by SHANSEP and Modified Cam-clay were illustrated in Figure 6.

Overall, the undrained shear strength profiles measured using the T-bar results show a steady increase in s_u with depth, which can be expected due to the increasing OCR values. The T-bar test was capable of measuring up to a depth of 300 mm, which fully covered the thickness of the mini-TBM. Two approaches determining the s_u are quite accurate while s_u obtained from SHANSEP was larger than that attained from Modified Cam-clay. At a depth from 150 mm to 300 mm, the computed

Figure 6. Comparison for pre-consolidated clay.

undrained shear strength from MCC can be believed to represent the soil behaviour around the TBM. Meanwhile, it was verified that the T-bar was suitable for the measurement of the strength of soft clay.

3.2 Ground surface settlement

3.2.1 Vertical settlement trough

Figure 7 shows the extents of ground surface vertical settlement (S_v) measured by LVDTs 2,6-9 in this test. In addition, the result from a former test by the same machine but a softer clay ($s_u = 15$ kPa) was given (Viggiani et al., 2022). The transverse distance from the centreline of the TBM were normalized by the diameter of tunnel (D).

Figure 7. Surface settlement induced by tunnel excavation.

In this test, only half of the ground surface settlement trough was measured. At the end of the TBM excavation, the measured maximum settlement was 0.32 mm (0.41% D) above the centreline of the tunnel. At a distance of 1.5 D from the centreline of the tunnel, a surface settlement of 0.19% D was also measured. When it comes to tunnelling in softer clay, the maximum settlement was measured as about 0.46% D above the tunnel.

Equation (4) was used to fit the measured displacements induced by TBM excavation. As expected, the measured maximum settlement $S_{v,max}$ was located above the centreline of tunnel. The best-fitted curve using an i of 1.23 D (4.80 m in prototype) is shown in Figure 8.

$$V_s = \int_{-\infty}^{\infty} S_v dy = \sqrt{2\pi} i S_{v,max} \quad (4)$$

where V_s is the settlement trough volume, S_v is the vertical settlement at a certain distance from the tunnel centreline, $S_{v,max}$ is the maximum vertical settlement of the trough (i.e., usually to be above the centreline) and i is the horizontal distance to the point of inflection.

As proposed by O'Reilly and New (1982), i can be represented by Kz , where z is the vertical distance between from the centre of tunnel and ground surface. The deduced K value for the best-fitted curve is 0.41, which is within the envelop bounded by 0.4 and 0.6 suggested by Mair and Taylor (1997) for tunnelling in clay.

Figure 8. Settlement troughs induced by single tunnelling regressed by normal probability curves at various s_u .

3.2.2 Longitudinal settlement trough

Measurements from LVDTs L1 to L9 versus TBM advancement were shown in Figure 9. As TBM advanced, all LVDTs measured settlements increased. As discussed in Section 2.1.5, LVDTs L1 to L5 were used to measure the longitudinal settlement trough as illustrated in solid line. As L1 and L2 has been settled to some extents due to attaching TBM into the box, the slopes of these two curves decrease. In other words, the settlements in these two surface positions tend to be stable. On the contrary, the other three surface positions in front of the TBM measured by LVDTs L3 to L5 present rising trend due to tunnelling. The results well agree with the general understanding of longitudinal settlement trough (Attewell and Woodman, 1982 and Mair and Taylor, 1997).

It should be noted that the due to the limited strong box size, the settlements failed to reach an equilibrium, resulting in that we cannot get the final maximum settlement $S_{v,max}$. Another reason might be the continuous reconsolidation as a result of water level decrease. Nevertheless, we could build the three-dimensional settlements through all LVDTs data shown in Figure 10.

Figure 9. Settlements of L1 to L9 vs TBM advancement.

Figure 10. Three-dimensional settlement due to tunnelling.

3.3 Excess pore water pressures

Figure 11 shows the normalised excess pore water pressures during and after tunnelling as a function of time. Two indications of TBM positions are given at relevant times. The excess pore water pressures were normalised by the initial maximum pore water pressures measured by PPTs. Looking closely to Figure 11, just after TBM started excavation, all PPTs around the machine (i.e., P1 to P4) recorded positive pore water pressures due to the thrust force of the cutterhead. It should be noted here that P1 to P3 showed a decrease after the initial thrust effect, but the value measured by P4 remained increasing until face past the it. Once face past the PPTs, P1 remained almost constant until tail past PPTs; P2 suffered from flat variation before measured high positive excess pore pressure and persisted until the very end of tunnelling; P3, in contrast, recorded the pore water pressure remaining negative and gradually reducing until tail past PPTs; the pore pressure measured by P4 reduced to zero by the end of tunnelling; P5 remained low positive pore pressure but presented a rising trend. After the tail past PPTs, P1 remained positive pore pressure during the tunnelling and post consolidation; P2 kept increasing due to the tail gap; P3 reduced to zero by the end of tunnelling; P4 remained positive but gradually reduced to zero; P5, located at ahead of the final TBM face position,

began measuring significant positive excess pore pressure as TBM approached. This phenomenon was also reported in Viggiani et al., (2022) and Alagha (2023). Once the TBM stopped, the positive excess pore pressure turned into negative pore pressure very shortly due to the suctions of clay. As one would expect, PPT 6 positioned in the far field, did not exhibit any changes during tunnelling.

Figure 11. Normalised excess pore water pressure vs time.

3.4 Tunnelling effects on piled structures

3.4.1 Influence of transverse distance on piled structures

As mentioned above, the undrained shear strength of clay used in this study is 28 kPa. Figure 12 shows the settlement due to tunnelling. By comparing the normalised pile settlement with P2 and P12 in Alagha (2023), for piles at the monitoring section, a larger settlement was obtained for smaller transverse distance from the tunnel axis; for piles at the same transverse distance from the tunnel axis, the parallel curves exhibit the repeatability of the test. This is consistent with both previous centrifuge tests (Loganathan et al., 2000) and numerical studies (Jongradist et al., 2013). It should be mentioned that the settlements of piles A and B are not presented here as the LVDTs employed for them did not work well during the flight.

Figure 12. Normalised pile settlement versus normalised tunnelling distance.

3.4.2 Tunnelling induced bending moments along piles

Bending moments were taken to be positive if tensile stress was induced at the side facing the tunnel. As introduced in Section 2.1.3, seven strain gauges were used in piles A and B while eight strain gauges were installed in the pile C to measure the bending moments. Herein the strain gauges are labelled as the pile name plus number from the bottom to the top. For instance, the strain gauge at the bottom of pile A was labelled as A1. Figure 13 (a) (b) and (c)

(a)

(b)

(c)

Figure 13. Tunnelling induced bending moments: (a) bending moments on pile A; (b) bending moments on pile B; (c) bending moments on pile C.

illustrated the bending moments induced by mechanised tunnelling on single piles versus tunnelling distance.

As TBM approaches, the bending moments of all three piles increased. In terms of pile C, which is the closest to the tunnel axis, once face past the pile C, the bottom strain gauges recorded a rapid rise; while once tail past the pile C, a sudden increase was observed. The reason might be the volume loss of the tunnel increased due to the end of conical shield body. Similar observations also be captured in piles A and B as shown in Figure 13(a) and (b). Although the bending moment curves exhibit similar trend regarding piles A and B, the extent on pile A is apparently larger than that on pile B. This is because the existence of pile C blocked the horizontal soil movements due to tunnelling. Similar conclusions have been reported in Ng et al. (2015) and Alagha (2023). Figure 14 shows the summarised bending moments versus normalised depth.

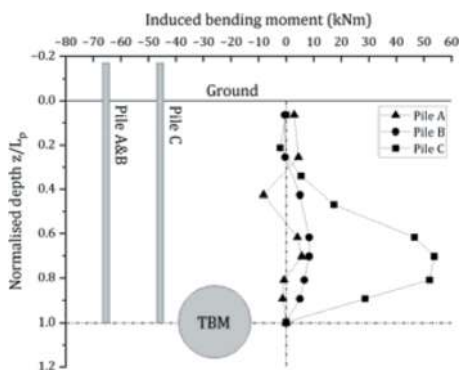

Figure 14. Bending moments versus normalised depth.

4 CONCLUSIONS AND PERSPECTIVES

The novel miniature TBM designed in Cambridge geotechnical centrifuge has been proven successful in excavating soft clay with an undrained shear strength of about 28 kPa. This work sets the foundation for further developments and improvements. In this paper, the undrained shear strength shows good agreements both in measurements by T-bar and estimations by Modified Cam-clay and SHANSEP method. Compared to tunnelling in softer clay ($s_u = 15$ kPa), this test results show bigger settlement trough as expected and well agree with the general understanding of longitudinal settlement trough, although limited by the size of strong box. The change of excess pore pressure due to continuous tunnelling was captured and analysed. TBM induced pore pressure variation can be perfectly explained as a result of thrust force and peripheral volume loss. A larger settlement was obtained for smaller transverse distance from the tunnel axis; for piles at the same transverse distance from the tunnel axis, the parallel curves exhibit the repeatability of the test. Recorded bending moments show the influence of continuous tunnelling rather than simple change

of volume loss. They were in a good agreement with previous reports but provided more details involving thrust and tapered shape of TBM.

Although the current design includes important features of an earth pressure balance machine, some features are still hard to simulate, like tail void gap. In addition, the size of the strong box limited by the centrifuge restricted the tunnelling length. But the size of TBM can be reduced to obtain a wider green-field whereas that of box is fixed. A smaller and sophisticated mini-TBM under higher g-level is on the way.

Geotechnical dimensioning of TBMs and new technological challenges

Giuseppe Lunardi, Giovanna Cassani, Martino C. Gatti* & Andrea Zimbaldi

Rocksoil S.p.A., Milan, Italy

ABSTRACT: The ever-growing need of transportation networks has led to considerable development in tunnelling works. Mechanized excavation is increasingly being applied, especially in the presence of high overburdens and squeezing rock-mass conditions. The advantages of the method are mainly to be found in an industrialization of the construction process, which enables greater excavation rates, as well as safer working conditions. The application of mechanized tunnelling in geotechnically complex contexts, however, forces to deepen the geotechnical dimensioning, considering the behaviour of the core-face, the face chamber-pressure and the interaction between the rock mass and the tunnel system, mainly the shield during excavation, to avoid jamming. These geotechnical analyses allow the design of the technical requirements for the TBM construction, in terms of chamber-pressure, shield conicity, over-excavation, and total thrust. The Authors will present a methodology approach to define in detail the correct technical specification for the TBM. A risk assessment must address the most critical aspects, towards which to choose the most appropriate risk mitigation interventions. The focus will refer to squeezing and geological complex conditions, where recent experiences have allowed projects to define very high-performance TBMs, according to the state-of-the-art. Numerical modelling is presented to analyse the problem and as a tool to help designers in defining with key technical specifications for the TBM advance. Based on monitoring data, specific “guidelines” will allow projects to calibrate operative parameters during excavation and to manage residual risks.

Keywords: geotechnical dimensioning, TBM, mechanized excavation, critical contexts

1 INTRODUCTION

The ever-growing need of transportation networks has led to considerable development in tunnelling works, with increasing excavation diameter requirements and facing adverse geological and geotechnical conditions. Mechanized tunnelling is increasingly being applied, not only in urban areas where it has always been preferred over conventional excavation, but also, nowadays, in the presence of high overburdens and, sometimes, in severe squeezing rock-mass conditions. The advantages of the mechanised system are mainly to be found in its industrialization of the construction process, which determines greater excavation rates, as well as safer working and better environmental conditions. However, the application of this excavation methodology in geotechnically critical contexts, by means of EPB-TBMs or hydro-shield TBMs, forces projects to carefully deepen the geotechnical dimensioning, considering in detail the behaviour of the core-face, according to the ADECO-RS Approach (Lunardi, 2008), and the interaction between the rock mass and the tunnel system, mainly the shields. The

definition of the correct pressure value, to be adopted in the excavation chamber to assure face-stability, as well as the TBM thrust, are crucial elements for the success of the advancement excavations. Jamming conditions must be especially avoided, which can lead to excavation stops or the shield’s ovalization.

In this paper, a methodological approach to examine the problem and to define the correct technical requirement for the TBM to be used is described. In the design stage, once the geological and geotechnical model has been defined (survey phase), a risk analysis must be developed in order to identify the critical issues regarding TBM excavation (diagnosis phase). Regarding each risk, the TBM design strategies must be identified, according to the potential offered by the TBM manufacturing market, and numerical analyses must be performed to size in detail the technical specifications to be envisaged (therapy phase). Finally, in the construction stage, specific “guidelines” should be adopted, to monitor the key parameters of the TBM advance with respect to each risk, and to calibrate the excavation system according to design variabilities.

2 GEOLOGICAL INVESTIGATIONS AND GDM MODEL

An accurate geological, geotechnical and hydrogeological model along the tunnel axis has to be constructed. This requires an investigation campaign with boreholes deepened 10 m down the future tunnel invert, in addition to desk studies of the area and relevant bibliographic research. All of the collected stratigraphic and piezometric data must be inserted in the GDM and used to produce an accurate predictive geomechanical profile considering geological sequences, contacts between formations, presence of faults or sliding structures and landslides. Lithological and geotechnical properties (strength and deformability parameters) of the rock-mass should be defined; it's also important to detect the presence of boulders or mixed face conditions. Finally, hydrogeological context should be assessed, that is to define distribution of aquifers, rock permeability values and groundwater levels.

3 RISK ASSESSMENT

Based on the GDM model, a risk analysis for TBM advance must be developed. The main typical risks, linked to geotechnical and hydraulic conditions, are described in the following and must be investigated with respect to TBM behaviour during excavation.

3.1 *Squeezing or swelling phenomena*

In poor rock-mass conditions, mainly in clays or argillitic shales, especially in the presence of high overburden (>80-100 m, with geostatic stresses greater than 2.0-2.5 MPa), it's very frequent to encounter the risk of squeezing conditions. These generate large convergence of the excavation profile, extensive plastic yielding around the cavity, and swelling phenomena due to the volume and stress variation in the rock-mass during excavation. The risk is the activation of high ground pressures on the TBM shields, which could exceed their static resistance, with ovalization and/or deformations. These high pressures on the shield, combined with the need to operate adequate balancing pressures at the face and to impart the cutters' energy to advance the excavation, can generate high thrust values for the TBM, exceeding the capabilities of the machine. The consequential risk is the TBM becomes trapped.

3.2 *Core-face instability*

When the state of stress in the ground is considerably greater than the strength properties of the material, even in the zone around the face, an unstable core-face condition occurs (category C, referring to ADECO-RS Approach), coupled by the risk of face collapses. Moreover, deformation of the core-face, in terms of extrusion and pre-convergence, could cause decay of the strength parameters of the ground, if it's

affected by "strain-softening" behaviour, further deepening the band of plastic yielding. So, it's necessary to enact pre-confinement operations at the core-face, by proper pressure in the TBM excavation chamber, minimising ground deformation and strength decay. This is clearly stated by extrusion tests, specifically applied to the sizing of the pressures to be maintained at the TBM face (Gatti, 2011 and Lunardi, 2013).

3.3 *Presence of boulders or mix-face condition*

Homogeneous face conditions, characterized by uniform stiffness and strength of the material to be excavated, allow regular and efficient advancement of the TBM. Otherwise, the presence of stone boulders, especially inside a weak rock-mass, or mixed face conditions characterized by different rock components can be critical for the TBM excavation. Some examples are reported in Figure 1.

Figure 1. Example of mix-face conditions.

Thus, the excavation tools of the TBM must guarantee adequate flexibility in relation to the variety of stiffness and strength of the excavated materials, providing suitable devices for their easy replacement in relation to the lithological variability of the rock-mass to be excavated.

3.4 *Landslides or existing superficial interferences*

The presence along the tunnel alignment of landslides or pre-existing interferences, such as buildings, roads or utilities, requires to limit the "lost volumes" during the excavation, in order to avoid subsidence at ground level and consequently damage to the pre-existing structures or accelerations to the movements of landslide. Generally, this risk occurs with low overburdens (with limited geostatic stresses), so that it is possible to maintain pressures in the TBM excavation chamber close to geostatic pressures, and drastically reduce deformations during the excavation phase. Similarly, care must be taken to backfill the segmental lining, in order to avoid settling at the tail of the TBM (Gatti, 2007).

3.5 *Water leaks and high hydraulic heads*

With reference to the hydrogeological context, the main risks are linked to the interception, during

excavation, of high-water inflows and to the presence of high groundwater pressure. The first risk can be mitigated through consolidation and/or drainage systems to be carried out at the face of the TBM and through the shield (dewatering system). For the second one, if the hydrostatic pressures exceed the static resistance of the concrete linings, drainage systems must be used, generally installed along the base of the sidewalls, so as to facilitate easy collection and disposal of the drained water (Figure 2).

Figure 2. Drainages systems.

The effectiveness of the drainage action can be verified, in the long term, by pressure monitoring systems mounted behind the segmental lining.

3.6 Presence of in-situ gas

The presence of in-situ gas can be identified through detailed analysis of the geostructural context (i.e., lithological and fault successions) and according to the results of boreholes that identify gas emissions. The gas risk is very high in mechanized excavations, considering that not all TBM equipment can be ATEX, such as the cutterhead. The Italian “Interregional Note 44” (NIR, 2009) provides useful advice to mitigate the risk of operating excavations with TBMs in a gas context. The TBM must be compartmentalized by sectors, to avoid the diffusion of gas in the different working environments. In the presence of gas, the excavation must be carried out with a full chamber (closed mode) to prevent possible formation of a “combustion chamber”, and a special gas-proof duct to enclose the top of the screw conveyor and the conveyor belt, for approximately the first 80 m, up to the protected tunnel sectors should be provided. Systems for monitoring and controlling the concentration of gas in the atmosphere must also be activated, coupled with ventilation systems (Lunardi, 2012).

3.7 Clogging phenomena

Clogging phenomena are linked to the presence of clayey soils, which are difficult to condition and subject to “cooking” and packing. The resulting risk is not allowing the correct pressures to be maintained at the face and the correct extraction of material from the screw. It may be necessary to use anti-clogging additives in addition to ordinary foaming agents.

3.8 Other risks

Other risks may be linked to structural geological conditions, such as the crossing of fault zones or highly fractured rock, as well as anomalous thrust conditions (for example of a tectonic nature or due to schistosity). These risks present similar problems to those already discussed in Section 3.1. Sometimes, in very sound rocks, problems may arise related to difficulties in penetrating and breaking the rock, with high wear of the cutting edges due to abrasiveness.

To identify the magnitude of the described risks, it is necessary to determine the frequency (F_E) of occurrence of the events identified above, evaluating the length of the tunnel sections in which they will have to be addressed. Furthermore, the impact (I_E) of each event must be assessed considering the possible consequences, in terms of health/safety, effects on the development of works to be carried out, economic and environmental impacts during construction. The risk will be identified as the impact for the probability of occurrence ($R = F_E \times I_E$).

4 DESIGN APPROACH AND TBM REQUIREMENT

The TBM design strategy is to consider mitigation measures, which will have the aim of mitigating the risks within residual acceptable values. With reference to risks of geotechnical nature, mainly linked to squeezing or complex geological conditions, it is necessary to adopt measures capable of governing the stress-strain distribution into the rock-mass all around the TBM, keeping the pressures on the shields below fixed values. This can be achieved by avoiding the relaxation of the rock-mass by applying counterbalancing pressures at the TBM’s face and along the contour of the shield, as well as by preparing a gap around the TBM by overcutting in order to accommodate the inevitable convergence of the rock-mass. It is therefore necessary to define the pressure value to adopt in the chamber pressure and choose the correct excavation diameter, coupled with TBM’s shield conicity. Modern TBMs can operate pressures at the excavation face of up to 5-6 bar, thanks to the maintenance of conditioned soil in the excavation chamber in the case of EPB or by means of bentonite slurry in the case of hydroshield. At the same time, they can inject bentonite along the gap between the shield and the excavation profile, using pressure injectors of up to 5 bar. Modern TBMs have also the possibility of modulating the excavation diameter during advance, to face different geotechnical contexts, and increasing the excavation diameter in the presence of squeezing conditions. This can be achieved both through the adoption of fixed “overcutting”, which is managed along the perimeter of the cutterhead, and through temporary “copy-cutters”, with hydraulic opening. Radial fixed overcutting values of up to 100-150 mm can be achieved, for single steps of 20-40 mm; additional copy-cutters can further increase the excavation radius by a further

50-60 mm. Typical shield conicities are between 50 mm and 130 mm. Considering that the shields, with a total length of 10-12 m, are generally divided into three sections (front, intermediate and tail shields), the conicity is guaranteed by providing a first step between the excavation diameter and the front shield (20-30 mm) and two reductions in diameter between the intermediate and the tail sectors (30-50 mm each), as represented in Figure 3.

Figure 3. Typical TBM shield conicity.

It follows that the maximum radial over-excavation can reach up to 250-300 mm. It is therefore necessary to equip the TBM with measures to facilitate driving if the expected convergences do not occur and the driving position may be lost. For example, 4 to 6 fin stabilizers are placed around the lower part of the shield and 2 to 4 round stabilizers in the upper part. It could also be useful to provide an “active articulation system” of the head, located in the front-shield, so as to manage the vertical guidance of the TBM. If a significant gap, between the excavation profile and the extrados segments is present, it’s necessary to make sure it is perfectly filled with bicomponent backfilling; the filling systems, carried out by 8-10 injection lines, must be able to guarantee an injection volume of 50-60 m³/hour.

The ground pressures, which will be active around the shield, will generate frictional forces that must be overcome by the thrust of the jacks. It is therefore necessary to size the overall thrust of the TBM to take into account all the necessary components: mainly the pressure to be maintained at the face, the force of the cutters for excavation, the friction forces along the shields, the weight of the machine and the back-up (Maidl, 1996 and Gatti, 2011). In the squeezing context, a total thrust in the range of 200-300 MN is recommended, depending on the TBM’s diameter. Numerical modelling must be performed to define in detail the proper chamber pressure, the excavation diameter (using overcutting and/or copy-cutter) and the total TBM thrust. A proposal is described in Section 5.

Another important strategy in managing mechanised excavations in squeezing conditions is to guarantee regular and continuous advances, avoiding

prolonged stops, which can generate the release of ground pressure on the shields and considerably increase the friction forces. This is the situation in which trapped TBMs most frequently occur. Some modern TBMs are equipped with the “continuous mining” system (CMS), which allows the installation of the segmental lining at the same time as the advancement. During the installation of a segment, the corresponding thrust cylinders must be temporarily retracted while the remaining pistons remain actively pushing on the rest of the ring; the TBM’s PLC manages the necessary redistribution of pressure in the active cylinders, to keep the centre of the thrust unchanged during the advancement of the TBM, as showed in Figure 4.

Figure 4. Redistribution of pressure in the active cylinders.

Another important tool is the “sliding continuous conveyor” system (SCC) and service extension. This solution consists of the installation of a single sliding belt of 1000 m in length with a bridge function between the machine belt and the ordinary tunnel belt, capable of advancing autonomously while following the TBM. Finally, it’s necessary to reduce as much as possible the maintenance interventions. This can be achieved by increasing the cutter positions of the cutterhead, adopting anti-wear protections on the cutterhead, on the edge of the shield and on the screw. It may be useful to install two high-pressure water injections of 300 bar (10 l/s) at the face to break up the rock-mass and foam injection points to lubricate the screw conveyor. With reference to the equipment for backfilling injection at the back of the segments, it could be useful to adopt a greater number of injection lines in the tail shield (10-12), with additional lines installed as spares. These can provide an automatic high-pressure washing system that will be activated on each line at the end of each excavation stroke of the TBM, to avoid blockage of the lines. The main TBM mechanical parts must be designed with a view to facilitating replacements and maintenance interventions.

5 NUMERICAL AXIAL-SYMMETRIC MODELLING

The interaction analysis between the rock-mass and the TBM shield during the excavation can be conveniently carried out with an axisymmetric model created with the software FLAC 2D ver. 8.0 by

Itasca. The result in terms of pressure on the shield can be considered as an upper limit because the axisymmetric model is not gravity oriented and the convergence along the tunnel boundary is the same on the whole circumference. In the analyses presented in the following, the mesh has a width of 50m and a height of 125m, to avoid boundary effects during the calculations of the stresses in the rock-mass; the mesh is composed of 25000 square elements, sized 0.5m. Excluding the boundary of the axisymmetric model, the geostatic load is applied on the other three boundaries from the initial phase of the model (the geostatic step), and, in the first excavation step, the lower boundary is fixed to avoid movements in the longitudinal direction of the excavation, due to the increase of stresses in that direction.

Figure 5. Axisymmetric model.

The model includes excavation steps of 1m each to simulate the advance of the excavation face from 15m to 80m, in the middle of the mesh. In each step, the geometry of the mesh is updated as a function of the calculated displacements, using the “set large” command in the software, to correctly evaluate the progressive contact between the rock-mass and the shield and the tunnel lining.

In each step, following the advance of the excavation face, one additional meter of the TBM shield, of the tunnel lining and of the backfilling is activated. The TBM pressure, which is constant at the face and decreases linearly to null pressure in the first 4 meters of the tunnel, is moved forward 1 meter too.

Mesh elements representing the steel TBM shield and the concrete tunnel lining, concrete class C35/45, are modelled with an Elastic behaviour. For the backfilling, the Mohr-Coulomb criterion is applied.

In Table 1, properties of the structural parts are reported. Mesh elements of the rock-mass and of the backfilling are fully connected (“attached”), while the interaction between the rock-mass and the shield is managed by an “interface” which is activated only in the case of contact between the two elements.

Figure 6. Detail of the FDM model for the high concicity TBM.

Table 1. Properties of the structural components.

Structural part	Thickness [m]	γ [kN/m ³]	E [GPa]	c' [kPa]	Φ [°]
TBM shield	0.05	78.5	200		
Tunnel lining	0.55	25	34		
Backfilling	≥ 0.1	20	0.5	0	25

The considered TBM shield has a typical length of 12 m and the nominal excavation diameter is equal to 10 m. Two types of TBM shapes are evaluated: one with “low concicity” (40 mm), for the excavation in good rock, and one with “high concicity” (130 mm), where relevant convergence is expected during excavation at the tunnel boundary (see Table 2). The evaluation of how far from the front face is the contact zone between the rock-mass and the shield and its extension is surely more reliable with respect to what can be

found with a simplified closed-form solution, such as the one used by Panet (1982). A geostatic isotropic pressure of 5.125 MPa is initialised in this application, for each of the cases studied below, considering a tunnel overburden of 200 m and a rock-mass unit weight γ equal to 25kN/m³. Three geomechanics contexts are analysed, with a different response of the core-face, as classified by the ADECO-RS approach (Figure 7):

- A – good rock, with “stable” behaviour
- B – fault zone with “short term stable” behaviour
- C – weak rock with “unstable” behaviour.

In the geomechanics context A, a TBM with a low concity (Model 1) is compared with a high concity TBM (Model 2), varying the TBM pressure from 1 bar (a) to 3 bars (b) and up to 5 bars (c).

Table 2. Geometry of the TBM.

TBM type	Low concity	High concity
Cutterhead		
R _{nom} [m]	5	5
φ _{nom} [m]	10	10
TBM Front shield		
R [m]	4.98	4.97
φ [m]	9.96	9.94
L [m]	6	6
gap from Cutterhead	0.02	0.03
TBM Middle shield		
R [m]	4.96	4.92
φ [m]	9.92	9.84
L [m]	3	3
gap from Front shield (m)	0.02	0.05
TBM Tail shield		
R [m]	4.96	4.87
φ [m]	9.92	9.74
L [m]	3	3
gap from Middle shield	0	0.05
gap from Cutterhead (m)	0.04	0.13
Tunnel lining		
R _{int} [m]	4.2	4.2
φ _{int} [m]	8.4	8.4
Thickness [m]	0.55	0.55
R _{ext} [m]	4.75	4.75
φ _{ext} [m]	9.5	9.5
gap from Tail shield (m)	0.21	0.12
gap from Cutterhead (m)	0.25	0.25

Figure 7. Radial tunnel displacement along the shield.

The analyses’ results are reported in Figures 8 to 11, representing:

- Radial displacement along the tunnel,
- Deconfinement rate, equal to the ratio between radial stresses at the tunnel boundary and geostatic pressure,
- Pressure along the interface between medium and shield, and
- Axial – circumferential stress in the TBM shield.

It can be noticed that different levels of pressure, always less than 10% of the geostatic load, have a slight impact on the tunnel convergence at the core-face and at the tunnel boundary. With the high concity TBM, bigger radial displacements are allowed and a lower pressure acts on the shield, even avoiding the contact with the middle and tail shield (Figure 10), thus reducing both the friction force on the shield and the thrust force required by the TBM to advance.

Figure 8. Geo-context A – Models 1 and 2 - Radial displacement.

Figure 9. Geo-context A – Models 1 and 2 – Deconfinement rate.

In Model 1, preconvergence at the tunnel face is around 1.5 cm and along the shield the entire gap of 4 cm, between the cutter-head and tail shield, is used. In Model 2, preconvergence at the tunnel face is around 1.5-2.0 cm and along the shield only 6 cm of the available 13 cm is used (Figure 8).

Figure 10. Geo-context A – Models 1 and 2 – Pressure along interface.

In the geomechanics context B, the high conicity TBM (Model 3) is compared with the same geometry but with the activation of a copy-cutter (Model 4), which increases by 5 cm the excavation diameter. The copy-cutter, allowing higher tunnel convergence, significantly reduces the contact zone between the soil and the shield, maintaining the average pressure along the interface around 1.5MPa (Figure 14), which means a maximum axial stress of about 150MPa at the end of the front shield and lower stress in the tail shield. Considering that the tail is the weakest part of the shield, it is difficult to put structural reinforcement in the inner part, where segments are to be placed (Figure 15). Even in this case, different front-face pressures have a small impact on the tunnel convergence and on the TBM shield, especially in Model 3.

Figure 11. Geo-context A – Models 1 and 2 – Axial stress in the shield.

Finally, in the geomechanics context C, the comparison is between the high conicity TBM (Model 5) and the same geometry but with an excavation diameter increase of 15 cm (Model 6), due to overcutting. With low pressure at the tunnel face (case a, Figure 16), the support given by the soil ahead the excavation face tends to be null causing a significant increase in the preconvergence at the tunnel face and subsequent tunnel convergence, with a higher risk of instability of the excavation.

Figure 12. Geo-context B – Models 3 and 4 - Radial displacement.

Figure 13. Geo-context B – Models 3 and 4 – Deconfinement rate.

Figure 14. Geo-context B – Models 3 and 4 – Pressure along interface.

The increase of the excavation diameter has a positive impact, reducing the contact zone between the soil and the shield (Figures 18 and 19). The contact zone has to be adequately evaluated to assure the feasibility of the excavation, even in terms of stresses in the shield and TBM thrust needed to advance.

Figure 15. Geo-context B – Models 3 and 4 – Axial stress in the shield.

Figure 17. Geo-context C – Models 5 and 6 – Deconfinement rate.

Figure 16. Geo-context C – Models 5 and 6 - Radial displacement.

Figure 18. Geo-context C – Models 5 and 6 – Pressure along interface.

6 GUIDELINES FOR THE CONSTRUCTION STAGE

Once the risks have been defined and the mitigation measures have been identified for the TBM project, it is also important to define “guidelines” for the management of the TBM advance and to calibrate the interventions during construction. The main design inputs, such as the chamber pressure at the face and the actual excavation diameter, can be varied during advancement and adjusted according to the evidence collected. Other parameters to be collected during advancement in order to verify the processes are being carried out efficiently, are the pressures on the shields, the annular gaps around the shield, the thrust values and the volumes of backfilling injected.

It should be noted that to record the annular gap around the shields and, in the event of contact, the acting ground pressures, it is necessary to equip the shields with fonti-meters and pressure cells. Generally, three control sections are arranged, one in the central position of each shield sector; 3 instruments are provided for each section, corresponding to the crown and the lateral sidewalls. The TBM control system allows the systematic recording of the pressures at different levels in the excavation chamber, the total TBM thrust, and the volumes of back-filling

Figure 19. Geo-context C – Models 5 and 6 – Axial stress in the shield.

injected for each advance stroke of the TBM. Furthermore, to ensure that the annular gap has been perfectly filled, the backfilling will be verified continuously by means of Pulse-Echo ultrasonic tomography based on the reflection of short pulses of elastic waves at the extrados of the tunnel lining segments, and by adopting the Ground Penetrating Radar (GPR) technique.

For each control parameter, a reference value (design value) and a range of possible excursions

must be set. The limits of this range represent threshold, attention and alarm values. For some parameters which refer to the most critical risks, such as for example the gap at the intermediate shield or the pressure on the tail shields to control the jamming risk, it is advisable to set a maximum limit, so as to implement urgent corrective actions in its proximity; warning and alarm values can be suggested at 70% and 90% respectively of the set value. The following scenarios can be identified:

1. If the values of the measured control parameters are consistent with the design value, within a minimum expected variability (+/- 10%), it's possible to proceed with the project operating parameters.
2. If the values of the control parameters are lower than expected, for example fewer thrusts, less convergence of the excavation profile and, therefore, less pressure on the shields, it will be possible to reduce the operating parameters (reduction of overcutting, pressure values at the front, etc.).
3. Vice-versa, if the values of the control parameters are greater than expected, or if there is a tendency towards greater difficulty in TBM advance, with thrust values higher than expected, higher ground pressure on the shields, it will be necessary to increase the operating parameters (increase in the excavation diameter with insertion of overcutting and/or copy-cutters, increase the pressure at the face, etc.).

Any change in the operating parameters must arise from an analysis of the monitoring data considering the trend over time on a significant number of readings and data collections. The analysis must therefore be conducted considering at least the values deriving from 2-3 strokes, before leading to variations during construction. If the planned actions are not able to resolve the problems, it's necessary to implement further measures to mitigate the residual risk, especially with reference to the risk of high pressures acting on the shields and therefore trapping the TBM. Some useful solutions to keep in mind relate to the use of the "clay-shock" mixture or hydro-demolition. To apply both solutions it is necessary to leave provisions in the shields for additional injectors. In the first case, a mud containing bentonite, fillers and additives is injected which has the property, when activated with a component B, of rapidly thickening so as to reduce, even partially, the convergences of the soil, and drastically reduce the friction of the shields facilitating the start/restart of excavation. In the second case, the hydro-demolition of the ground around the shields is carried out through the nozzles, to unlock the shields and allow the TBM to restart.

7 CONCLUSION

In this paper, a methodological approach to examine TBM excavation, especially in squeezing and complex geological contexts, is presented, to define the correct technical requirement for the TBM to be used. Once the geological and hydrogeological model has been defined, a risk assessment is necessary to address the critical issues to be carefully investigated in the design stage. The main parameters to be considered are the pressure to maintain in the excavation chamber and the modulation of the TBM diameter during excavation. Indeed, the nominal TBM diameter can be increased by overcutting and using copy-cutter systems, so as to calibrate the gap between the shields and the surrounding rock-mass and to control the ground pressure on the tail shield. These pressures and the correlated friction forces are responsible for the most important risk related to ovalization and/or deformations of the shield, and trapping the TBM. A proposal of using a numerical axial-symmetric model is presented, through which an understanding of the behaviour of the TBM excavation is gained and used to define the design aspects in detail. The examples presented allow focus to be placed on how different excavation radii can affect the static of the shields.

ABSTRACT: The Project for the Lima and Callao Metro Line 2 and a branch of Line 4 (Av. Faucett – Av. Gambetta) consists in the construction of an automatic underground metro line, on the East-West route of the city of Lima, with a length of 27 km (Line 2 of Red Base of Lima) and an 8 km section (Line 4) in correspondence with Elmer Faucett Avenue, from Óscar Benavides Avenue (Colonial) to Néstor Gambetta Avenue. The area of the city served by this new metro line will include approximately 2,4 millions of people.

The mechanized tunnel section will be 17,5 km long and located between 15 and 25 m with a maximum working pressure of 3 bar. The Project also contemplates the construction of 35 stations (no. 27 on Line 2 and no. 8 on Line 4) built with the Cut & Cover methodology and the construction and commissioning of two railway depots underway serving Line 2 and Line 4 of the metro. Due to the highly variable geological conditions, the tunnel will be executed by using two Tunnel Boring Machines (TBMs), one Earth Pressure Balance (EPB) and the other Variable Density (VD) TBM type. These two TBMs are manufactured by Herrenknecht (HK) and have the excavation diameter 10,27 m and 9,26 m the final inner diameter.

The geology along the tunnel alignment is particularly complicated, based on large alluvial deposits with low presence of fines and excavating sections under water table with high permeability ground.

The conditioning of the different types of soils encountered along the excavation of the tunnels plays a crucial role in the appropriate operations of the machines, for the correct maintenance of the pressure at the excavation face, the performance optimization, and the mitigation of the cutterhead wear.

Keywords: TBM, EPB, Variable Density, Underground, Conditioning, Metro

1 INTRODUCTION

This paperwork focuses on the various soil conditioning strategies implemented for the excavation of the Metro Lima tunnels, set after an extensive testing program performed prior to start tunneling but that have been continuously adjusted based on the results

in the field and to accommodate the different geological conditions encountered while tunnel boring.

One of the major challenges for carrying out the excavation of these tunnels in EPB mode, besides the adverse ground conditions, was dealing with the sudden ground changes that occur within small distances. Once the soil conditioning strategies were in

*Corresponding author: jlmagro@dragados.com; mcallejam@fcc.es; r.bono@webuildgroup.com; siacullo@ccmetrolima.com

place, it was crucial to pay close attention to any change of the excavation parameters and to assess the properties of the muck extracted from the excavation chamber.

Any delay to properly respond to these changes of geology by applying the correct conditioning strategy could be very detrimental for the excavation process and might lead to additional corrective measures, increasing costs and causing delay to the critical path of the overall project schedule.

2 PROJECT DESCRIPTION

The TBM bored tunnels of the Metro Lima project were divided in two stretches, according to the selected excavation method: 12.6 Km of pure EPB tunneling (including stations pass through) in Line 2, from the launching station E19 (San Juan de Dios) until the Switch Box in Parque Murillo, next to the station E11 and from there to the station E04 (Insurgentes). And 11.4 Km of VD tunneling, from station E04 to the Ventilation Shaft PV01Bis, by Callao Port in Line 2 and the 7.4 Km of Line 4.

Figure 1. Lima Metro Lines 2 and 4 under construction.

The alignment develops through the city of Lima, mainly below main roads, but also underneath various critical private buildings, some of them in poor structural condition, as well as below several live infrastructures, such as roads and railway, bridges and sensitive underground services, like two sewers of 1,4 and 2,1 m diameter, just 2,3 and 3,1 m above TBM path, one of them very old, installed through the excavation of an open trench, poorly backfilled. Ad hoc local ground improvements have had to be implemented as risk mitigation measures in some locations.

These challenging conditions have driven the TBM type selection and design. In particular, the tunnels to be excavated with the EPB TBM (from E19 to E04 of Line 2) are located above the water table with poorly graded and very dense sandy gravel, with high presence of boulders and minimum fine content.

On the other hand, the tunnels to be executed with the Variable Density Multimode TBM (from E04 to the end of Line 2 and Line 4) are quite like the other ones but under the water table.

The complex geological conditions of this tunnels are prone to cause overexcavation, especially in areas of bigger grain size gravel, embedded in a non-cohesive matrix, as well as clogging of cutterhead openings, blockage of screw conveyor and even difficulties to maintain face pressure within the planned range, because of high permeability.

On the other end, the presence of sand and boulders has caused high wear and damages by impact to the cutting tools, mitigated using a tailored soil conditioning for each case and customized cutting tools to accommodate the different conditions along the alignment.

The classic EPB excavation mode has been used so far, despite soil conditioning and TBM parameters having to be quickly adapted during excavation to adjust to rapidly changing conditions.

Other factors that may have enhanced the effect of conditioning the soil are mounting longer cutting tools, sticking out more from the cutterhead face, which allows an early remixing of the excavated soil with the foam injected in the front whilst keeping the high water pressure on within the excavation chamber from the bulkhead, to avoid damaging the sandy matrix of the face.

Moreover, the Variable Density Multimode TBM has mined in our preferred pure EPB mode too for the time being, assisted by a second in-line horizontal screw conveyor, to ensure the pressure drop from the excavation chamber up to the TBM conveyor when needed, such as when sudden pressure increase episodes.

3 GEOLOGICAL CONDITIONS

Both Line 2 and Line 4 tunnels run across the alluvial deposits of the Rimac River, below groundwater table for most of the alignment, up to 25 m above the tunnel crown, especially in the Callao Section. Some of the challenges of such ground conditions are the lack of fines in an always mixed face, featuring large boulders of up to 1 m in diameter and of high strength, and the great amount of gravel of 100 mm diameter and above. High permeability is also a factor, especially in Line 4 alignment, with up to 10^{-3} m/s in gravel.

The ground encountered so far while mining Line 2 is mostly large-size pebbles, from 150 to 400 mm size, and sand, with some stretches of clayey sand tongues or just clay.

The pebbles ratio in the soil matrix is also relevant, averaging 50% greater than 50 mm but, at a certain depth, it rises to 75%. The abrasion rate is also high, usually over 3.5 Abrasivity Cerchar Index (ACI) but with peak values up to 5.25 ACI. Permeabilities are between 5×10^{-6} m/s and $1,5 \times 10^{-4}$ m/s. The maximum water table height is 20 m above the tunnel invert.

On the other hand, the uniaxial compression strength tests on the extracted rocks gave values of 130 to 150 MPa, which could be considered as strong-medium resistance.

Figure 2. Grain size distribution considered at bidding phase.

Figure 3. Soil samples and excavated ground.

The main geological formations present in the project are summarized in the table below, where the following descriptions are provided: **R**: Backfilling/Top Soil contaminated and with a low level of compaction; **CL/ML**: Inorganic Clay with low/medium plasticity and silt with low plasticity; **SM**: Silty Sand; **GP-Ss**: Poorly Graded Gravel with sand, clay and silt with clayish/silty sand with low level of compaction; **GP-Sm**: Poorly Graded Gravel with sand, clay and silt with clayish/silty sand with medium level of compaction; **GP-Sf**: Poorly Graded Gravel with sand, clay and silt with clayish/silty sand with high level of compaction.

Table 1. Geotechnical parameters of the ground formations.

FORMACIÓN	γ_s kN/m ³	% Finos	C kPa	ϕ (°)	E carga MPa	G MPa	V_s (m/s)	V_s , adop. (m/s)	Gd MPa	Ed MPa
R	16,7	25	0	28	17	7	200	100	15	50
CL/ML	17,4	80	8	26	23	9	260	150	40	115
SM	16,9	34	5	30	35	14	280	225	85	250
GP-Ss	20	0	15	34	42	16	< 450	350	250	715
GP-Sm	21	0	25	36,5	82,5	31	450-600	500	535	1530
GP-Sf	22	0	32	39	183	70	> 600	650	950	2700

Their distribution in the excavation face varies along the alignment but in general, the stretch from the station E19 to E06 (EPB) is mainly GP-Sm, with lenses of SM that are generally very small, whilst in the portion from the E06 to PV01Bis (VD) is GP-Ss with layers of SM and CL/ML at the top of the tunnel

face in most of the stretch. The average granulometric distribution of this area is in Figure 4.

Figure 4. Grain size distribution (E19-E12 and E06-PV01Bis).

In Figure 5 there is a typical graph with the permeability and grain size distribution encountered so far during most of the excavation of the two TBMs. In particular, the first curve was taken from a sample where the geological formation is described as poorly graded gravel with high level of compaction (Average $V_s > 600$ m/s) with sand, clay and silt and clayish/silty sand. The second one was taken from samples where the geological formation is the same but with a low level of compaction (Average $V_s < 450$ m/s) and lenses of silty sand. Apart from the presence of fines, which is very low in the first one (fines 0,075 mm are about 2%) and higher in the second one (fines 0,075 mm are about 10%), the distribution of particles, which can be classified as pebbles and cobbles, is also different. For instance, cutting from the particles having size equal or greater than 100 mm, the percentage of the sample reaches in the first case 30% whilst in the second one is less than 20%.

Figure 5. Typical EPB and slurry mode application range with project grain size distribution.

It must be noted that where granulometry was discontinuous, with large amount of big grain sizes, mostly all TBM excavation parameters increased respect to those planned according to the previous lab tests, in which maximum grain size was restricted by the own limitations of the testing workbench.

Also, in the tunnel section to be excavated with the TBM 1 (EPB) from station E19 to station E11, random presence of larger boulders has been observed so far

from E19 to E16 stations, whose dimensions exceeded those represented in the graph (up to 400-500mm).

And again, the field experience during the tunnel excavation, particularly for the TBM S-973 stretch, has shown rapid changes of the ground permeability. This variability, especially during sharp transitions, has made the excavation more challenging. The permeability values measured before the excavation within the tunnel footprint have been found near the limit of what is considered suitable for the EPB application, as shown in Figure 6.

Figure 6. Ground permeability from E04 to PV01bis.

4 TBMS SELECTION

Both TBMs were selected based on the geological and geotechnical conditions defined in the Geotechnical Baseline Report (GBR), but also based on the risks of excessive ground settlement, efficiency and cost optimization and a general criterion of safety and environmental protection. As a result, one EPB and one VD TBMs were selected.

4.1 Analysis parameters before TBM design

TBMs type was selected considering all the information from geotechnical investigations and permeability analysis, grain size distribution, soil composition, abrasiveness, front face stability and presence of many boulders. A comprehensive review was performed, resulting in a risk assessment, including clogging potential, muck hauling and handling, performance, and TBM operation, as well as previous experiences.

From the granulometric analysis point of view, the operational area appeared to be more suitable for a Hydrosshield or Mixshield, but the presence of large boulders and big-size cobbles could have compromised the effective performance of the necessary stone-crusher, prior to muck extraction.

Also, higher equipment investment and operational costs of the slurry type TBMs were considered a factor for this decision.

Conversely, going with an EPB would be limited by the maximum boulder size the screw conveyor could handle. Also, the high permeability of the

ground in some sections of the alignment, together with the lack of fines, would compromise the ability to maintain and control face stability due to the difficulties to gradually drop the pressure from inside the excavation chamber, passing thru the screw conveyor, up to the extraction belt conveyor.

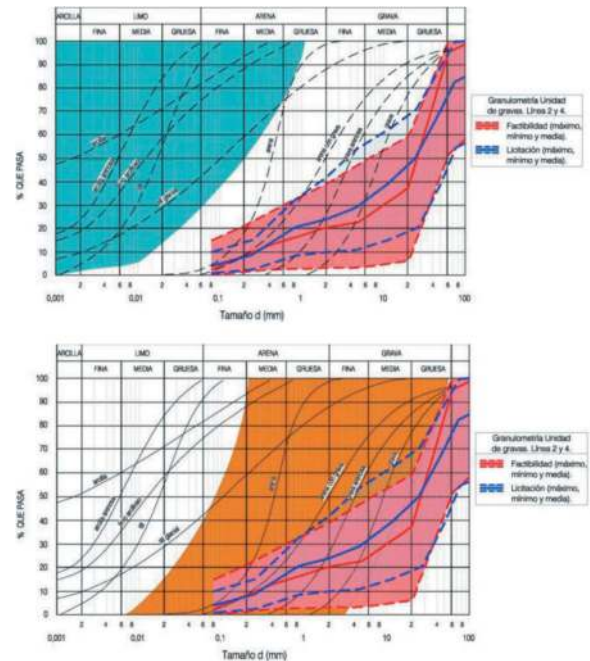

Figure 7. EPB (top) and Mixshield (bottom) application range according to granulometric distribution.

An assessment of the pros and cons of both technologies, EPB and Mixshield was performed, based on the commonly accepted application range for them, as follows:

Figure 8. EPB (top) and Mixshield (bottom) application range according to granulometric distribution and conditioning.

4.2 Summary of TBM design concepts

The TBM design was done considering the most reasonable assumptions that could be made with the data available at the time, with emphasis on the machine flexibility to leave options open to mitigate risks during the construction phase.

After a detailed assessment of all the risks, the following features were implemented to our TBMs:

Double screw conveyor to drop the pressure from the front to the discharge conveyor on the TBM, to deal with permeable ground.

EPB mode machines designed with slurry pre-chamber to be able to add fines quickly to the excavation chamber to compensate any sudden pressure drop caused by gravel, cobbles, boulders and porous ground in the face.

Strong anti-wear protection in cutter head and screw conveyors to protect them from highly abrasive granular soils.

Quick change of operations modes EPB/Slurry, to be able to deal with mixed face conditions.

Limit the boulder size passing through cutter head to 400 mm and maximize the dimensions of screw conveyors and crusher to deal with the many of them expected and prevent them from damaging the machine.

In turn, Cutterhead openings were narrower than those of a regular EPB TBM (less than 30%) and therefore, easier to clog than what would have been desired.

Those boulders were also considered a limiting factor for the excavation process (a lot of crushing involved) and for muck conveyance through slurry lines, due to their high resistance and abrasiveness, which was also an advantage for the EPB technology. Thus, we did select a first TBM to work over water level, to operate in EPB mode, with enhanced ground conditioning systems; and a second other TBM to work under water pressure, dual-mode (variable Density or VD) convertible to pure EPB or to Slurry mode, featuring two muck conveyance systems (conveyor belt, and slurry circuit and separation plant).

Figure 9. TBM VD at the factory and at site before launching.

5 TBM TYPE & CHARACTERISTICS

5.1 TBM 1 (“Delia”)

It is an Earth Pressure Balance machine manufactured by Herrenknecht in Germany, serial number

S-972, of 10,19 m excavation diameter, designed to hold 3 bar at spring line while mining. It weighs 1.750 T and its total length is 111 m with 5 backup cars. “Delia” was designed to mine up to 80 mm/min, with a maximum thrust of 107 MN at 350 bar hydraulic pressure and to rotate cutterhead up to 3 rpm, with 27,8 MNm maximum torque and 7.800 kW of installed power.

It does mount a 18,3 m long screw conveyor of 1,25 m diameter, shaft type; a vacuum erector to mount a 6+1 concrete segments ring and features all Hyperbaric Interventions means needed, including a man lock and a tool lock.

As previously said, it does have a slurry pre-chamber, to be able to quickly react to sudden pressure losses and mixed face conditions.

Figure 10. TBM EPB Herrenknecht S-972.

5.2 TBM 2 (“Micaela”)

It is a Variable Density (VD) machine manufactured by Herrenknecht too in Germany, serial number S-973, also 10,19 m excavation diameter and designed to hold 3 bar at spring line while mining.

“Micaela” was designed to mine up to same speed than its sister machine, 80 mm/min. It is heavier (1.980 T) and longer (148 m) than “Delia” because of a more stuffed shield and longer back up (7 backup cars) to hold systems for conveyor belt and slurry lines muck conveyance, but key parameters such as maximum thrust and torque are alike Delia’s.

Figure 11. TBM VD Herrenknecht S-973.

Unlike “Micaela”, it features a two in-line screw conveyor system, 18+14 m long, same 1,25 m nominal diameter and a jaw crusher within a slurryfier box, designed to crash rocks up to 1.200 mm size and features state-of-the-art Hyperbaric Interventions means too, including a man lock and a tool lock.

This TBM allows for mining either as an EPB, mucking out by means of one or the two in-line

Figure 12. Screw conveyor with slurryfier box and crusher.

screw conveyors onto a continuous conveyor belt; or as Mixshield, conveying muck out of the excavation chamber by means of a two in-line screw conveyors and a slurryfier box with a crusher inside and from them, pumping it out through the slurry circuit to the Slurry Treatment Plant (STP) overland, back in the staging area; and combination of modes (open, semi-closed and closed), according to the following chart.

Scope	Schematics of operation modes	Operation mode	Face support mainly by:	Muck transport	
S-972		Open mode	.	Conveyor belt	
		Semi-closed mode / face pressure by 2 nd medium	air		
		Semi-closed mode / face pressure by 2 nd medium	Foam and / or slurry		
	S-973		Active face pressure	slurry and / or foam	Conveyor belt & water circuit
			Active face pressure	slurry and / or foam	
			Closed mode	slurry	Slurry circuit

Figure 13. Operational modes of TBMs S-972 and S-973.

Both TBMs have cutting wheels designed for mixed-face conditions, including opening ratio of slightly less than 30%; 19" disc cutters, interchangeable with rippers; anti-wear plates 40mm + 20mm

bimetallic; extensive wear detection for cutting tools and cutting wheel structure; High Pressure Water (HPW) injection and 12 ground conditioning injection ports.

6 SOIL CONDITIONING

6.1 Preliminary tests during TBM design process

Initial tests were performed to determine and design an adequate conditioning system to operate the TBMs in EPB mode in a challenging geology as much as possible during the project.

Additional tests were performed later on, focused on ground water content for potential water ingress, to determine the impact of conditioning with foam on the cutterhead torque measured with a laboratory mixer and the capacity of the additives to reduce the ground permeability.

6.2 Tests while tunneling

More testing was performed prior to start tunnel boring and during tunneling. Samples were taken, representing typical particle distribution, making sure to also include the bigger size elements to truly replicate the actual ground conditions, even they had to be cut to a maximum particle size of 40 mm for slump tests.

The results showed that a FIR ranging from 30% to 50% gave good plasticity, depending on the water content added to the sample, which could be suitable for forming an EPB paste.

Additional tests were performed at the site using the TBM foam generators, calibrating the parameters and verifying the expansion rates by measuring before each test, in this case without removing the bigger particles from the sample. The materials for the soil conditioning used in these tests included, beside the foam, bentonite and polymer diluted in water.

Different recipes have been tested, finding the optimum results with the values indicated below, which anyhow are to be assessed considering real conditions, where the scale factor, temperature or pressure in the chamber can influence the actual results in the TBM.

It was observed that without removing the bigger particles (cobbles to boulders), Foam expansion rate (FER) and Foam injection rate (FIR) needed to be increased to achieve a proper EPB paste.

Figure 14. Sample of gravel with sand, clay, and silt before (left) and after conditioning (right).

Accordingly, the following parameters were set as a baseline to work in EPB mode: FER between 12 y 15, foam agent concentration up to 3% and FIR up to 90%. Moreover, it was anticipated that adding polymer to control ground water may be needed at some point in time.

6.3 Soil conditioning for TBM EPB S-972

Our soil conditioning program for the EPB TBM was focused on two main aspects: prevent cutterhead clogging when passing from very dense sandy gravel only to the same formation with large lenses of silt/clay and mitigate cobbles segregation in the excavation chamber, impeding muck extraction, which would cause performance issues, as well as accelerate screw conveyor and cutterhead secondary wear.

Figure 15. Water and gravel extracted by the screw conveyor.

Clogging prevention was managed mainly by adding high water pressure injection ports from the bulkhead and eventually, to the cutterhead.

And ground segregation by increasing FIR from 110% to 180% average with even higher peaks, with a 2,2 to 3% foam concentration and FER between 15 and 20.

In turn, stable face pressure, good consistency of the extracted muck, an excavation speed between 35 and 45 mm/min were achieved. Temperature measured in the bulkhead ranged from 32 to 45°C, cutterhead torque from 3,5 MNm to 4,5 MNm, contact force nominally from 4.000 kN to 6.500 kN (up to 12.000 kN in case of cutterhead clogging) and thrust force of circa 22.000 kN to 25.000 kN.

It must be noted that initially, bentonite was added from the bulkhead lines and through some of the foam lines in the cutterhead, to add cohesive particles into to the mixed material in the excavation chamber and to thicken the EPB paste, but no beneficial results were observed and as such, this practice was discarded from the soil conditioning plan.

On the other hand, having the right amount of fines in the ground improves the muck consistency but creates a fast-clogging effect of the cutterhead openings, which affects quickly to the main excavation parameters, like contact force or bulkhead temperature, reducing advance speed and jeopardized excavation face stability, specially above the shield, causing higher consumption of backfill grout and

Figure 16. FIR vs mined rings E19-E16 (TBM 1).

potential ground deformation. When this happens, conditioning parameters had to be quickly adjusted and increasing the volume of high-pressure water (an average of 4 m³ with peaks up to 10 m³ per excavation) in the cutterhead and reducing the FER were found highly effective. However, more liquified muck would alter the pressure balance, causing unsteady pressure drops along the screw conveyor and making muck more difficult conveying and disposal.

6.4 Soil conditioning for VD TBM S-973

The Soil conditioning with the Variable Density Multimode TBM can be divided in four different geological scenarios.

The first one being exactly like the one described for the EPB TBM tunnel sections and in particular, for the same geology but without groundwater; in this case, the recommended soil conditioning would be equivalent to the one previously mentioned.

Another case was where higher fines content appear (30%). When gravel size is smaller and compaction levels are less dense, being these either above or below the groundwater level, then FER and FIR had to be slightly adjusted. From the experience gained during excavation, in non-saturated ground like described above, FIR can go up to an average of 300%, foam concentration from 2% to 3%, FER from 18 to 20 and high pressure water injection volume over the 7 m³ per excavation.

However, if groundwater was present in most of the excavation face, FIR could be decreased to circa 170%, surfactant concentration from 2% to 2,5%, FER from 6 to 18 and high-pressure water volume would be maintained still within the same range.

Finally, the last scenario, which is probably the most critical for EPB mode, involved the presence of groundwater with water table roughly 10 m above the crown, high permeability (in the range of 2x10⁻³ to 8x10⁻⁴ m/s), low fines content (less than 30%) and high variability of particle size in a loose sandy gravel formation, with potential presence of cobbles and boulders. The challenges in this case are characterized by the increased risk of segregation of heavier elements on the bottom of the excavation chamber and high-water inflow if a proper

conditioning is not achieved. Excavation muck bleeding inside the excavation chamber may result in screw conveyor blockages, while excessive water ingress may lead to difficulties to maintain the pressure drop along the screw conveyor. Both these issues are addressed by adding a synthetic liquid polymer to the foam and high-pressure water we were using, injected directly into the excavation chamber in a percentage up to 0,04% of the excavated muck volume.

During the excavation in these geological conditions, it has been observed a drastic reduction of Foam Injection Ratio to values ranging from 40% to 80%, with a concentration of foam agent of 2,5% and FER of around 6.

It must also be noted that in these specific conditions, the foaming agent was enriched with a natural lubricating polymer that has thicker treated material.

Figure 17. FIR vs mined rings E04-PV01Bis (TBM 2).

In conclusion, these additives and proportions have allowed to maintain stable face pressures, good consistency of the extracted muck, an proper excavation parameters in very challenging conditions, while reaching 30 and 40 mm/min speed of mining, bulkhead temperature ranging from 32 to 42°C, cutterhead torque from 4,5 MNm to 7 MNm, Cutterhead contact force from 5.500 kN to 6.500kN and total thrust force ranging from 22.000 kN to 25.000 kN.

7 PRODUCTION RATES OF BOTH TBMS

Up to the date of this article (September 2023) the TBM1 (EPB) has excavated more than 2.4 Km from stations E19 to E16 and the TBM2 (VD) has excavated 4 Km, which is all its planned section of Line 2 and is about to be dismantled and reassembled at the Ventilation Shaft Gambetta to excavate Line 4.

TBM1 (EPB) has been able to mine 303 rings the best month, 69 rings the best week and 24 rings the best day while TBM2 (VD) did mine 378 rings the best month, 108 rings the best week and 23 rings the best day, considering a 6+1 precast concrete ring configuration, 1,7 m long and 32 cm thick.

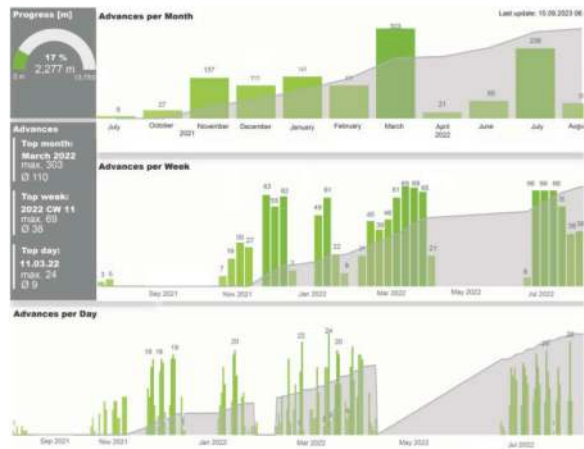

Figure 18. TBM 1 production summary (Oct-23).

Figure 19. TBM 2 production summary (Oct-23).

8 CONCLUSIONS & LESSONS LEARNED

Our TBM S-972 “Delia” is cutting the edge, proving that an EPB machine can successfully mine through granular soils, mostly gravels and above all, lacking what was considered the minimum amount of fines needed (30%) to mine in pure EPB mode, mostly thanks to the great development of conditioners in recent years, but also to a correct cutterhead and cutting tools selection and configuration and to a quick reaction to every change of conditions in the field.

As for the conditioning, it should be noted that it all started with extensive preliminary studies performed by conditioners manufacturers and Universities, but that they had to be flexible to accommodate site conditions and must be customized on site later on, in real time, according to the actual ground conditions the TBM is encountering at any given moment and the experience gained while mining through them.

To be able to work with an EPB in gravel and without fines and to do it safely, not only the Foam Injection rate (FIR) but the overall rate of ground treatment, including water, bentonite, or polymer,

shall be remarkably high, almost always above 100. And that accounts for both, the conditioning of the excavated ground and the saturation of the granular and unstable soils in the face and around the shield.

Ground conditioning must continue not only while mining but also during ring building and long stoppages, to prevent pressure losses that could compromise face stability, initiating overexcavation for the next ring. Conditioners shall be injected to the excavation chamber as needed to maintain it pressurized.

In addition, TBM must be sufficiently prescribed and dimensioned, especially thrust and torque, to be able to deal with an excavation chamber completely full of pressurized muck, which is the best way to prevent over excavating in unstable and crumbling ground conditions.

When pore water pressure adds up to the ground conditions depicted above, second screw conveyor helped to control and reduce the face pressure to atmospheric and to control the flow of muck and therefore, to ensure face stability. This was also successfully proven in similar circumstances in the excavation of the SR99 Bored Tunnel in Seattle, WA (USA).

Finally, full slurry mode is planned to be implemented when water pressure will be even higher, coming up next in the excavation of Line 4 and natural ground even more unstable than it has been so far, besides mining under and close to extremely sensitive utilities and structures, to ensure the finest face pressure control possible.

ACKNOWLEDGMENTS

Large diameter slurry TBM tunnels with very low cover: A comparison of approaches

Michael Mains*
AECOM, Burnaby, Canada

S. Sánchez, L. İçik & C. Mora
AECOM ECC Europe, Madrid, Spain

ABSTRACT: A critical aspect of the design of large diameter pressurized TBM tunnels in low-cover areas is whether the minimum required face pressure can be maintained below the maximum heave/frac-out pressure while accounting for TBM operational tolerances. In shallow tunnels, usually defined as having less than 1.5 times the excavation diameter of overburden, the minimum calculated pressure is typically very close to or exceeds the maximum permissible pressures as defined by frac-out or heave limit. Further, the available closed form solutions produce a wide variety of results making it very difficult to properly evaluate the risks and stability of a given low-cover alignment. The following paper provides a brief overview of some of the most common methods for determining the minimum confining pressures and frac-out limits for pressurized TBM tunnels including both closed form and 3D Finite Difference Modelling. The results of each method from a recent project in Latin America involving a Ø13.5m slurry TBM with less than 1.5 diameters of cover in a dense urban environment are presented for comparison. The paper concludes by emphasizing that 3D numerical modelling is essential for evaluating risk in these critical areas and that in all cases strong engineering judgement is required.

Keywords: Low Cover Tunnelling, Large diameter TBM, Slurry Pressure, Face Stability, Frac-out

1 INTRODUCTION

There is an industry trend in many parts of the world towards single bored tunnels rather than twin tube tunnels in the transportation sector. There are many advantages to the single bore option including a generally lower cost, faster construction schedule, and the deletion of several types of complicated structures like cross passages and cross-over boxes. One of the primary disadvantages, however, is that single tube projects require a deeper tunnel alignment and consequently deeper stations and shafts. Unlike tunnel excavation, the complexity and cost of station and shaft construction is quite sensitive to depth. Deeper stations not only require higher excavation volume, but all structural elements for both support-of-excavation and permanent internal structures become heavier and more costly. Construction of these deep station boxes also carries higher risk of impacting neighbouring buildings and infrastructure. These implications are especially true in soft ground projects

where slurry TBMs are commonplace. Consequently, an option to minimize these impacts is to place the tunnel alignment as shallow as possible near stations and shafts.

Placing large diameter tunnels in low cover areas (generally defined as having less than 1.5 diameters of cover) often triggers a whole host of additional risk analyses and often incurs additional costs associated with the tunnel rather than the station. However, the most critical aspect of the design is whether the minimum face pressure to maintain stability can be achieved without causing the ground to heave or frac-out. Only by first assessing this minimum feasibility requirement can other evaluations regarding safety, settlements, and the potential need for installation of pre-support and/or ground improvements be carried out.

The following sections provide a brief overview of some of the most common methods for determining the minimum confining pressures and frac-out limits for pressurized TBM tunnels including both closed form and 3D Finite Difference Modelling.

*Corresponding author: Mike.Mains@aecom.com

The results of each method are shown for a recent project in Latin America involving a Ø13.5m slurry TBM with less than 1.5 diameters of cover are presented for comparison.

2 MINIMUM CONFINING PRESSURE FOR FACE STABILITY

The calculation methods available to determine face stability and the minimum face pressures have not been covered in detail in any North American or European design codes or standards (For example AASHTO, FHWA, and EuroCode 7 do not cover the topic), nor has it been the subject of any ITA/AITES recommendation. Although specific to the German Context, DAUB's (the German Tunnelling Committee) "Recommendations for Face Support Pressure Calculations for Shield Tunnelling in Soft Ground" (2016) provides the closest thing to comprehensive summary of face stability calculations and seems to be the most referenced document on the topic in many projects in Europe and the Americas. France's Centre for Tunnel Studies (CETU) also issued a useful and informative document in 2022 on face stability, although not specific to pressurized TBM tunnelling and has yet to be adopted widely outside of France.

In practice, most face stability calculations are either executed using closed form approaches, the numerical modelling approach, or in critical areas a combination of both.

2.1 Closed form approaches

2.1.1 Drained condition without seepage

Pressurized TBM excavation can typically be categorized into either undrained or drained conditions. The choice between drained and undrained conditions can have a considerable impact on support pressure estimation. In the authors' experience, most soft ground tunnels fall into the "cohesive-frictional" soil category where the drained state is uncertain. In low permeability soils ($k < 10^{-6}$ m/s), the ground is probably in an undrained state if the TBM is advancing. In higher permeability soils or during TBM stoppages, drained or at least a partial drained is more likely.

For a drained condition in a cohesive-frictional soil, the calculation is done in effective stress according to a limit-equilibrium philosophy. First introduced by Horn (1961), the limit-equilibrium essentially models a failure wedge develops ahead of the excavation face and is surcharged by the overburden soils. The sliding of this wedge into the tunnel is resisted by friction and when this friction is insufficient a support pressure from the TBM is required to keep the wedge in place. The simple balance of forces approach is illustrated in the figure below.

Figure 1. Driving and resisting forces on an active wedge (DAUB, 2016).

To prevent seepage into the tunnel, the TBM support pressure also has to maintain hydrostatic equilibrium. Thus, the required pressure is equal to the minimum to support the sliding wedge plus the hydrostatic pressure. Typically, the support pressures for ground and water are factored by 1.5 and 1.05 respectively. The step-by-step procedure and all relevant equations are summarized well in the DAUB (2016) recommendation.

2.1.2 Undrained condition

Although it is much less common that the full face and overburden meets the criteria for an undrained analysis, it is nevertheless an important case to evaluate in cohesive dominant soils since it could be the prevailing failure mechanism. The undrained calculation is carried out in total stress using the undrained shear strength, C_u ($\phi=0$) and the stability ratio philosophy. The stability ratio is essentially expressed as the vertical stress at tunnel axis minus the support pressure, all divided by the undrained shear strength, as shown in the following equation.

$$N = \frac{\sigma_s + \gamma \cdot H - \sigma_r}{C_u} \quad (1)$$

Where N is the stability ratio, σ_s is the surcharge on surface, $\gamma \cdot H$ is the vertical stress at tunnel axis, and σ_r is the confining pressure exerted by the TBM.

If the critical stability ratio, N_{crit} , below which the face collapses is known, the minimum face pressure can then be back calculated from Equation 1. CETU (2022) provides an excellent comparative summary for N_{crit} as a function of the cover/diameter (C/D) ratio as calculated by the various approaches, project observations, and scale mode lab testing found in the literature.

This chart not only provides a quick and easy way to estimate face pressure, but also helps illustrate an important risk relating to low cover tunnelling. A large variability in N_{crit} exists for any given C/D depending on the method used. In deeper tunnels, a conservative approach is to simply use the lower bound line shown in Figure 2. However, in the low cover case even

Figure 2. Comparison of N_{crit} lines based on existing models (CETU, 2022).

the higher bound lines may produce pressures which approach or exceed the blow-up/frac-out limit of the ground thereby requiring a more sophisticated way of managing risk and defining operational pressures of the TBM.

3 MAXIMUM PERMISSIBLE CONFINING PRESSURE

The other principal failure mechanism that is critical in low cover is when excessive pressure heaves or ruptures the overburden soils, more commonly known as blow-up or frac-out. In low-cover, a small amount of heave can be expected and as long as it remains minimal, say below 5mm, it is not considered an issue in most cases. However, larger amounts of heave can cause damaging deformations for nearby structures. Even worse, frac-outs cause a “spill” incident with possible environmental issues and could erode/compromise nearby foundations. The TBM could also become stuck and require a rescue shaft. All of these risks are more prevalent in low cover areas and are much more consequential at larger diameters.

DAUB (2016) proposes the simplest method to estimate the limit pressure by recommending that the maximum permissible TBM pressure at the crown remain below 90% of the overburden stress. However, in shallow tunnels, it is relatively common that the minimum stability pressure exceeds the overburden stress. In this case, Hong Kong’s Geo Report No. 249 (2009) acknowledges that the factored shear strength of the ground can be mobilized to resist failure of the ground upwards in an ULS calculation. An example of this approach is Mollon (2013):

$$\sigma_b = \gamma D \cdot N_\gamma - C_u \cdot N_c \quad (2)$$

Where σ_b is the blow-up pressure, γ is the soil unit weight, D is the tunnel diameter, and C_u is undrained shear strength and N_γ and N_c are estimated from the below design chart.

Figure 3. Design chart for N_γ and N_c Mollon (2013) for cohesive soils.

However, in purely cohesive soils, maximum permissible pressure can be governed by the fracturing mechanism caused by high localized pressure which exceeds clay shear or tensile capacity.

A simple approach for purely cohesive soils is that provided by Soga et al. (2005) where the blow-up pressure P_f is calculated using Equation (3).

$$P_f = s_0 + n \cdot C_u \quad (3)$$

Where $n=1.25$ can be assumed (Atkinson et al. 1994).

There are however two major issues with relying on shear strength to set maximum operating pressures. The first is that although the factor of safety against rupture may be satisfactory, the maximum pressure limit may induce significant heave deformations. The second is that cohesive soils at low cover are often weathered and contain weaker seams which may have much lower shear strength than the representative value of the soil. Other preferential slurry paths may also exist such as existing boreholes, pipe bedding, or any other granular or weak zones that can be extremely difficult to detect prior to excavation.

4 NUMERICAL CALCULATIONS

As discussed in the previous sections, the available closed form approaches to calculate minimum face pressures produce a large margin of values. Further, the maximum limit pressure may generate large heaving displacements not captured in the closed-form calculation. Thus, it is clear that the available closed form solutions do not provide adequate information to properly assess risk in critical areas such as low cover zones, especially at large diameters.

3D finite element or finite difference modelling is an important method to add to the toolbox because it can account for all pressures in the excavation (face, around the shield, and grouting pressures), as well as account for mixed face conditions and complicated geometries.

By iterating the 3D model with varying excavation pressures, the deformation at face and surface can be traced as a function of pressure, creating a sensitivity curve which can be compared to an “admissible” zone relating to deformations. This allows an SLS approach for the definition of both the maximum and minimum TBM operating pressures. It is also the only method which allows for the extent of ground yielding to be investigated.

Figure 4. Example sensitivity curve (CETU, 2022).

Numerical modelling is however not without its limitations. For example, the risk of hydraulic fracture along weak zones or slurry loss through pre-existing or unknown paths are very difficult to model meaningfully in practice. It is still nevertheless a powerful tool which complements the existing analysis types and may even be necessary in critical locations of the tunnel alignment.

4.1 The settlement problem

The use of 3D numerical modelling often reveals a common issue seen in low cover scenarios. For example, we sometimes see large settlements generated at surface even though the TBM pressure is within the acceptable operational range. Peculiarly, this settlement can get worse if we increase the confining pressure which is the opposite of what we would normally expect for a deeper tunnel in more competent ground.

Consider a scenario where the TBM pressure is exactly equal to the vertical in-situ stress at the crown. The forces at node located in the crown of the excavation perimeter would be perfectly balanced. Now consider the nodes at spring line elevation for a soil with $k_0=0.5$ where the horizontal stress is about half of the vertical stress. the slurry fluid pressure will have increased as a function of its unit weight and the ground load will have decreased due to the k_0 condition. Thus, there is a nodal force

imbalance which pushes the sides of the tunnel outward to re-establish equilibrium. In soft ground, this effect causes the crown to “sag” which translates to settlements on surface and increasing the TBM pressure only makes deformations increase.

The effect is demonstrated in a FLAC Model shown in Figure 5.

Figure 5. Deformation trend in low cover for increasing TBM pressure.

5 COMPARISON BY EXAMPLE

As described in the previous sections, to adequately design large diameter alignments at low cover in soft ground, it is necessary to carry out both ULS and SLS analyses for face stability and frac-out/heave to define the TBM pressure operating window. An example analysis from a project in Latin America involving a Ø13.5m slurry TBM in soft ground is presented herein. The example shown is in mixed face conditions of predominantly soft cohesive soils with some weathered rock in the invert.

In mixed face conditions, the closed form approaches become even less reliable as they are only suitable for homogenous ground. In practice, mixed face conditions are usually handled by either averaging the soil parameters or taking the lower bound strength directly. If part of the face is in rock, the results can be skewed since rock strength is often an order of magnitude higher and could incorrectly imply that the face is stable when it isn't. Although these closed form approaches are important to understand what failure mechanisms may be governing, they must be supplemented by a numerical model to provide an adequate understanding of the problem.

5.1 Finite difference analysis

To address the aforementioned limitations of closed form calculation, finite difference modelling was used to further evaluate feasibility and risk of the Ø13.5m tunnel directly adjacent to one of the station boxes. TBM excavation would be excavated in mixed face conditions of soft fractured rock in the invert with the remainder of the face and overburden consisting of very soft fine grained and residual soils. The excavation cover is less than 1.5 diameters.

The analysis was carried out using FLAC 3D V7.0 and iterated by applying a steadily decreasing (collapse) and increasing (heave) face pressure,

starting from the operational minimum and maximum values initially estimated using the DAUB (2016) methodology.

Figure 6 shows an example of the displacement magnitude and vectors at one calculation stage with a high pressure value applied to the face.

Figure 6. FLAC 3D output showing displacement vectors during maximum pressure analysis.

The operational window can then be defined by plotting the displacements compared with the applied face pressure as shown Figure 7. Here the heave limit pressure is identified in the model by noting the pressure that triggers large displacements. A similar approach can be done for the minimum face pressure to maintain stability. The model also highlights importance of coupled analyses where the stress state is updated at every stage according with the compatible pore pressure.

Figure 7. Displacements at face and surface obtained in FLAC analysis.

5.2 Comparison of results

The comparison of results using various closed form methods as well as the 3D FLAC results can be found below in Figure 8.

We note that the numerical model correlates reasonably well with the lower bound stability limit pressures. However, the comparison of heave limits is much less clear. Numerical analyses suggest

Figure 8. Comparative analysis of face pressure.

a heave limit as much as 100kPa below the limit calculated using Mollon (2013) and about 100kPa higher the hydraulic fracture limit (Soga et al. 2005).

Additionally, iterations of the FLAC model all produced very large settlements on surface due to the phenomenon discussed in section 4.1 which ultimately led to additional risk mitigation measures being required. Thus, even though the FLAC analysis is the only method capable of capturing these large deformations, it was in this case is not capable of capturing the potentially more critical hydraulic fracture failure mode. This further underscores that no single calculation method is capable of analysing all probable failure mechanisms and that a combination of approaches should always be considered at critical locations of the alignment.

6 CONCLUSIONS

With shallow tunnels becoming an increasingly common means to lower the cost of stations and ancillary shafts, the particular problem of excavation stability in low cover requires special attention. The risks associated with a failure of the face, either from collapse or frac-out/heave, are significantly higher with larger diameter tunnels. The design of large diameter slurry TBM tunnels in low cover is not codified and recommendations are notably absent from the ITA/AITES working groups. The available closed form solutions provided in commonly referenced guidelines from Germany, Hong Kong, and France give varied results and are not sufficient to fully evaluate the risks associated with shallow excavation. Supplementing these calculations with finite element or finite difference modelling is essential but still doesn't capture all of the potential failure mechanisms. Thus, a healthy dose of engineering judgement and experience is always required regardless of how much computation has been carried out.

The mechanised excavation of the exploratory tunnel of the Brenner Base Tunnel: The major challenges

David Marini*

BBT SE, Bolzano, Italy

Andrea Lussu

BBT SE, Innsbruck, Austria

Giuseppe Venditti

BBT SE, Bolzano, Italy

ABSTRACT: The exploratory tunnel of the Brenner Base Tunnel was excavated for over 40 km in mechanised mode, using both double shield TBMs and an open TBM. The peculiar characteristic of this tunnel is precisely that its excavation occurs immediately before that of the main tunnels, with the primary purpose of providing greater certainty in terms of geological-geotechnical data for their excavation. During the excavation of the exploratory tunnel, some specific situations occurred which blocked the TBMs and required special measures to unblock them. This article describes the most striking construction challenges encountered, presenting the main interventions that were applied in the field to allow excavations to resume.

Keywords: Brenner Base Tunnel, exploratory tunnel, double shield TBM, open TBM, construction challenges

1 THE BRENNER BASE TUNNEL

1.1 Introduction

The Brenner Base Tunnel is a flat railway tunnel that connects two States and is the central part of the new Munich-Verona railway corridor, along the extended Scandinavian-Mediterranean corridor within the European TEN-T transport network. It stretches between Innsbruck (Austria) and Fortezza (Italy) for a total length of 64 km (including the Innsbruck bypass) and will be the longest underground railway link in the world.

The BBT is a complex system of tunnels with a total length of almost 230 km, of which 160 have been completed to date, the main ones being the two railway tunnels and the exploratory tunnel. It will offer a viable alternative for freight transport and will create a new travel opportunity for passenger traffic.

The main benefits of the project include the shift of freight and passenger traffic to rail, eliminating traffic congestion, to the benefit of people and the environment, greater safety from natural hazards and a significant reduction in journey times. Today,

travelling by train from Fortezza to Innsbruck takes 80 minutes for passenger traffic and 105 for freight traffic, while in the future, when the tunnel is completed, it will take 25 and 35 minutes respectively.

1.2 The purpose of the exploratory tunnel

The excavation of the exploratory tunnel extends from the Sillschlucht (at Innsbruck) to Aica (near Fortezza) and runs along the axis of the main tunnels for about 85 per cent of the route. By anticipating the excavation of the line tunnels, it considerably reduces geological-geotechnical and hydrogeological uncertainties and thus limits the risks in the excavation of the main tunnels.

Depending on the complexity of the rock mass to be excavated and on logistics, the excavation is performed either using traditional methods or with tunnel boring machines.

The most critical fault zones to cross were the Periadriatic Lineament in Italy and the Hochstegen fault zone in Austria, both excavated using traditional methods.

*Corresponding author: david.marini@bbt-se.com

Important stretches of respectively 24.5 km in Italy and 16.5 km in Austria were excavated by machine, and still provided useful and effective information of the rock mass in advance of the main tunnel excavation.

2 GEOLOGICAL FRAMEWORK

The Brenner Base Tunnel route is geographically located in the central part of the Eastern Alps and it crosses the Alpine arc from Innsbruck (Austria) to Fortezza (Italy), east of the Brenner pass.

From a geological point of view, the Brenner Base Tunnel crosses the major tectonic units that make up the Alpine chain. These units, which take the form of several overlapping strata, represent the remnants of the collision zone between the Eurasian (European) and Adriatic (African) plates, forming a dome at the centre of which the Penninic and Sub-penninic units of the Tauern window appear, the deepest tectonic units forming the core of the Alpine chain. The deepest structural sectors of the Tauern Window are represented by the central gneiss cores (Tux core to the north and Zillertal core to the south), which constitute the sub-Penninic parautochthonous basement, continental tectonic units of European origin, cloaked by the oceanic Penninic units of the Vizze and Glockner Plateau complex, on which lie the Austroalpine units of African origin (Adria). To the south, the important fault zone forming the Periadriatic Seam separates the Austroalpine from the Southalpine.

The current structure of the Alpine mountain range is the result of the polyphasic deformation process that occurred during Alpine orogenesis (see Figure 1).

3 THE EXPLORATORY TUNNEL IN ITALY AND AUSTRIA

3.1 The excavation of the exploratory tunnel in construction lots in Italy

3.1.1 Exploratory tunnel construction lots

In the construction lots B0021 'Aica-Mules Tunnel' and B0131 'Mules Lot 2-3', most of the exploratory

tunnel was excavated with TBMs. Mechanised excavation began in the Aica-Mules lot on 10/06/2008 starting from Aica northwards, and after 10,269 m of excavation the section was completed in November 2010. In the Mules 2-3 lot, the 'Serena' TBM began its journey on 25/05/2018 in the vicinity of the Trens emergency stop and after advancing 14,209 m northwards, it reached the end of the lot in November 2021 by the Brenner.

3.1.2 The TBM used in the mechanised sections of the exploratory tunnel

Two double shield TBMs with an excavation cross-section of 6.6 m and 6.8 m respectively were used for the excavation of the exploratory tunnel in Italy. The thickness of the tubing rings varies from 20 cm to 30 cm, as does the geometric arrangement of the segments and their performance characteristics (see Figure 2).

Advance surveys and geoseismic investigations, excavation front surveys during maintenance activities and interpretation of tunnelling data were systematically carried out.

3.1.3 Excavation difficulties encountered

In various situations, these advance investigations and the interpretation of real-time data made it possible to solve excavation difficulties with special interventions (over-cutting, advance consolidation by means of GRP anchors, foam injections, hydro-demolition and micro-loading behind the shield, etc.).

In the mechanised excavation of the total 24.5 km of exploratory tunnel in Italy, some unusual circumstances occurred, which forced the TBMs to stop and required special interventions to restart them.

The two most significant standstills are described below.

3.1.4 Exploratory tunnel section from km 49 to km 59 (Aica-Mules construction lot)

On 7 August 2009, after excavating approximately 6 km of the tunnel (at km 53+149, corresponding to km 6+190 from the Aica portal), during the TBM advancement phase, some cracks were observed in the left face at approximately 20 m from the face; 24 hours later, these had extended in the direction of the face, until they reached the TBM shield.

Figure 1. Geological profile along the axis of the Brenner Base Tunnel; legend with the structural units: brown-orange...Innsbruck quartz phyllite; blue-greenish...limestone schist; orange-blue...Hochstegen fault zone; pink...central gneiss, brown...paragneiss; red...tonalite with Periadriatic Lineament; pink...granite.

Figure 2. Model of the tubbing ring lining of the Exploratory Tunnel - Lot Mules 2-3.

The cracks and fractures moved in an exclusively horizontal direction and directly affected the body of the reinforced concrete cones even when they occurred near the joints. A resumption of the phenomenon limited to the approximately 10m portion of the tunnels occurred on 18/08/09 following the execution of a geognostic borehole on the left wall, which intercepted a pressurised water flow at a depth of approximately 20m from the wall itself. On this occasion, the cracks already present in the tubbing rings widened to the point of generating a real fracture, forcing four rings to protrude into the tunnel itself. (see Figure 3).

Figure 3. Damaged and shifted precast concrete segments.

Basically, in the last 150 m the rock mass surrounding the tunnel was generally good quality granitic rock (although it did cross two more fractured bands approximately 20 m thick located sub-vertical and sub-orthogonal to the route), though it was however almost tangential on the left wall to a sub-vertical fault sub-parallel to the route, 5-10 m thick, consisting of bands of very fractured rock and bands of completely transformed dark green tectonic breccias.

The position of the fault with respect to the direction of advancement made it impossible to predict through the tunnel face mapping, which had highlighted the sub-orthogonal fractured bands. On the other hand, seismic surveys systematically carried out during excavation are unable to detect reflectors parallel to the tunnel axis.

The additional investigations carried out allowed subsequent reconstruction of the geological situation.

Before the re-start, safety measures had to be taken consisting of radial bolts, retraction of the back-up wagons and installation of HEB100 profile ribs.

Restoration work then took place, consisting of:

- disassembly of those parts of TBM that had not been blocked by the shifted precast concrete segments,
- injections of expanding organic-mineral resin to solidify the areas subject to the most intense loosening, directly behind the precast concrete segmental rings on the left wall,
- injections of organic-mineral resins in a 3m thick strip on the left wall
- installation of RN32 self-drilling radial anchors, 3 m to 6 m long.
- cutting, demolition and replacement of the reinforced concrete segments with excessive displacement and/or breakage, for successive portions of reduced size with steel panels (see Figure 4).

Figure 4. Repaired stretch with steel panels.

These interventions made it possible to secure the precast concrete segmental rings, carry out the

necessary work on the TBM including back-up, and re-start excavation.

No special work was required at the TBM shield before restarting. After less than four months of downtime, it was possible to re-start excavation of the TBM.

For the following section, metal segments specially dimensioned to support high loads were laid over an extension of approximately 60 m (see Figure 5).

Figure 5. Stretch with steel ribs.

3.1.6 Exploratory Tunnel section from km 32 to km 46 (Construction Lot Mules 2-3)

On 27 March 2019, after approximately 4.2 km of mechanised excavation of the exploratory tunnel with the 'Serena' TBM (at km 42+007, corresponding to km 17+332 from the Aica portal), main piston thrusts of 21,000 kN were recorded, which required excavation to continue with re-gripping equipment and in single-shaft mode. On 30 March, the thrusts, still proceeding in single-shield mode, reached values of 70,000 kN, no longer allowing

advancement. The pressure cells on the front shield went all the way to the end of their scale, registering a pressure of 6 MPa.

A geological reconstruction shows a meta-archite rock mass with interlayers of quartz and mica schist in bands with horizontal schistosity. Due to the high overburden (1500m) and the horizontal schistosity, large blocks detached from the dome and on the left side of the TBM, favoured by the millimetric layers of mica with smooth, cohesionless joints, also causing an asymmetrical pressure on the shield.

In the first few days of the standstill, attempts were made to remove and lighten the material on the left side of the front shield by means of micro-charges.

The geological and seismic investigations carried out, and the reconstruction of the rock mass behaviour determined that the most effective approach to unblocking the TBM would be the construction of an approximately 13m lateral tunnel immediately behind the shield in order to decrease the pressures acting on around the shield.

The works that allowed the re-start of the tunnel boring machine were designed by the construction contractor, based on the specific solutions aimed at solving TBM standstill situations which had been presented in the technical section of their bid during the tender procedure.

This lateral tunnel was built on the left wall (west side of the TBM) and secured mainly with ribs and steel sheets placed on steel arches which are driven upwards and outwards into the rock at a flat angle until a new steel arch can be placed underneath (see Figure 6). More specifically, the following interventions were carried out:

- preparation of the 1.5mx2m side opening on the left face of the precast concrete segmental ring behind the shield: injection with epoxy resins, installation of 2m radial anchor bolts, installation of UPN 140 beams around the opening (see Figure 7);
- cutting and removal of precast concrete segment;
- drilling and micro-loading;

Figure 6. Diagram of the repair works.

Figure 7. Junction to the lateral tunnel.

- Securing with HEB 120 ribs and the above mentioned steel sheets on steel arches, with 0.75m spacing along the entire length of the shield (see Figure 8).

Figure 8. Lateral tunnel parallel to the TBM shield.

In addition to freeing the shield along the left wall and in the dome, it was necessary to lower the lateral tunnel, to further decrease the contact between rock and shield.

A special metal push frame was constructed to perform re-start attempts. It was then necessary to backfill the exploratory tunnel with pea-gravel and cement mortar, after properly protecting the shield.

After 44 days of stoppage, excavations could be resumed.

3.2 The excavation of the exploratory tunnel in construction lots in Austria

3.2.1 Exploratory tunnel construction sections

In Austria, the exploratory tunnel was excavated in 3 sections. A first section in the northernmost area, i.e. in the Innsbruck quartz phyllite, had already been excavated conventionally by blasting in 2009. A 16.5 km long section in the central area between the Innsbruck emergency stop and St. Jodok was excavated between 2015 and 2019 using an open gripper TBM.

3.2.2 Mechanical excavation of the exploratory tunnel section from km 8 to 23

The decision to drive the section between km 8 and 23 with an open gripper TBM was based on the acknowledgments from the first conventionally driven exploratory tunnel section in the quartz phyllite and the geological explorations from the surface. The decision to use an open TBM was made in order to guarantee best possible documentation and sampling of the open area behind the shield in order to obtain accurate geological - geotechnical information for the main tunnel tenders. Furthermore, an open TBM was put out to tender in order to be able to react more flexibly during excavation through predicted fault zones, the location of which was not known. Appropriate supporting measures such as injections and drilling shields for difficult sections were also included in the tender.

During excavation between September 2015 and July 2021, a total of 9 relevant fault zones were encountered, which led to collapses and delays.

The first relevant fault was encountered about 1 km after the start of driving at project kilometre 9. In this section, a rock structure with shallow dipping, poorly interlocked schistosity was encountered in conjunction with clustered shear traces and a fault zone with a thickness of approx. 10 m. This unfavourable combination and the shallowly dipping course of the fault zone led to a large-volume collapse above the TBM shield with a cavity volume of approximately 750 m³ (see Figure 9), and lead to

Figure 9. Fault zone progression at km 9.000; legend: green...foam; yellow...concrete; orange...cement injections.

notable deformations of the primary structure in the area behind the shield (see Figure 10).

Figure 10. Deformation of the steel profiles in the top heading.

At the beginning, collapses and advance fractures were recorded around the drill head; the belt scale recorded the production of significantly higher tonnage of excavation material compared to the theoretical excavation volume. First smaller collapses, so-called “Zipfelmützen (jelly bag caps)”, were overcome by “controlled spoil removal” without significant driving disturbances. In the area of the damage zone, despite intensified constructive measures behind the shield to prevent outbreaks, further collapses and an enlargement of the cavity occurred due to the spoil removal. When it became foreseeable that a cavity would expand backwards over the shield, the excavation process was stopped for safety reasons and the following immediate measures were initiated:

- a barrier was created with radially bored and injected IBO anchors in the area behind the finger shield to prevent the cavity from spreading to the rear;
- intensification of deformation measurements to keep the effects of the cavity on the tunnel lining under control.

Before further crossing of the cavity, the project team identified, planned and evaluated various solutions and options (pipe shield, bypass) for crossing the areas of fault zone interference. The greatest challenge here was to ensure worker safety behind the finger shield. As excavation continues, the collapse in the area of the crown moves backwards beyond the finger shield. Finally, it was decided to apply the “continuous steel profile” solution. In the “continuous steel profile” solution, UNP 180 special profile ribs were installed shoulder-to-shoulder between the existing shotcrete shell and the finger shield in the “open area” with the required shotcrete backing (double metal grid mats and fleece insert or expanded metal) (see Figure 11).

Figure 11. “Continuous steel profile” solution UNP 180 profiles set shoulder-to-shoulder.

These special profiles have the same steel cross-section and therefore the same axial resistance as the tendered TH ribs; like the TH ribs, the UNP 180 profiles were equipped with adjustable clamps to allow deformation at very high support pressure. Compared to the TH profiles, the UNP 180 profiles have a lower modulus of resistance, at the other hand they have the advantage that they can be additionally secured with IBO anchors. The holes for the IBO anchors were designed as slotted holes to ensure that the ribs can deform inside each other.

The excavation was continued slowly and the UNP 180 profiles were positioned shoulder-to-shoulder under the protection of the finger shield. After placing 6-7 UNP-180 profiles, metal grid mats were placed and the whole section was covered with a sprayed concrete layer to reinforce the steel structure. This strengthened the tunnel lining and ensured safe working in the A1 area.

After 3-4 work fields (i.e. 4-5m) had been excavated using this method and there was still no stable rock in the drill head area, the tunnel lining behind the finger shield was additionally reinforced for safety reasons by injecting and poring a concrete slab over the UNP 180 profiles to provide additional protection against collapse for the workers. Concrete was pumped into the cavity above the TBM via backfill pipes that had already been installed during tunnelling. To prevent the concrete from penetrating into the drill head, it was sealed and stabilized with silicate foam before starting the concrete casting process (see Figure 9).

The casting took place under constant monitoring of the deformations. After the concrete had hardened, driving was continued using UNP-180 profiles positioned shoulder-to-shoulder until the drill head had reached stable rock again and there was therefore no danger of jamming or caving. Before restarting regular driving, the remaining cavity above the lining was filled with concrete and injected in a controlled manner via the backfill pipes. A total of 26 days was required to excavate through and secure

the fault zone. Jamming of the TBM was avoided thanks to the quick action of all parties involved.

At project kilometer 16.6, another collapse occurred in the Bündner Schiefer section. Shortly before the drill head entered the major fault zone, the excavation encountered folded alternating sequences of limestone phyllites and limestone schists. The main fault dipped steeply at about 70° obliquely against the excavation direction and entered the cavity from the right-hand side (about 25° to the axis). When the formation of a collapse was detected, the measures that had been tried and tested up to that point and successfully used in several collapses (analogous to the collapse described above) were immediately initiated. However, this time the fault zone progression was very steep. The thickness of the core zone was similar in size to the previous collapses, at about 4-5m, but this time the cavity spread further and further upwards as driving continued (see Figure 12).

Figure 12. Laser scan of the cavity above the finger shield at the beginning of the collapse.

At a certain point the laser measurements showed heights up to 17 m and more. Subsequently fractured material fell on the shield and, in combination with lateral pressures due to the lack of vault action, led to jamming of the TBM. Despite several attempts, the TBM could not be started. Therefore, it was decided to drive two lateral side tunnels (see Figure 13) by means of micro-blasting and the use of a small excavators in order to free the drill head.

To the excavation of the lateral side tunnels lead to a decrease of the lateral pressure on the cutter head and allowed to continue the excavation process. Estimates of the mucked excavated material have revealed a cavity volume of over 5,000 m³. Due to the large amount of loose material above the lining and the shield, it was also not possible to refill or inject the cavity from the TBM as in previous collapses. The excavation through the fault zone at km 16.6 required 45 working days. Since the safety was ensured and the static load capacity of the exploratory tunnel was guaranteed by the lining and the concrete cover above it, the TBM excavation continued even without the complete refilling of the cavity.

Figure 13. Excavation of one lateral side tunnel to free the cutter head.

Even though the load-bearing capacity for driving the exploratory tunnel was ensured, an impact of the cavity on the main tunnel tubes still to be excavated above the exploratory tunnel could not be excluded, due to the great height of the collapse and the still present cavity. For this reason, after TBM driving had been completed it was decided to access the cavity by means of a ramp dug from the exploratory tunnel using the conventional drill&-blast excavation method, to backfill and ensure the cavity professionally. Furthermore, it was decided to use the ramp required for backfilling to excavate the sections of the main tunnel tubes through the fault zone conventionally at main tunnel level in order to prevent future jamming of the TBMs and thus delays in the further construction lots (see Figure 14).

Figure 14. Ramp to the main tunnel level and excavation through the fault zone.

This measure led to significant risk reduction in the main construction lots, as it was possible to avoid the TBM stuck and excavation delays in these areas. The measures were carried out parallel to other ongoing construction activities, thus minimising the impact on the overall time schedule.

4 CONCLUSIONS

Despite various difficulties in excavating the exploratory tunnel, average advance rates of 10-12m/day could be achieved. The usefulness and necessity of an exploratory tunnel in deep-lying tunnel systems was confirmed, as it was possible to explore the geologically relevant areas in advance, with a smaller diameter excavation.

Not only did this provide valuable knowledge for the excavation and the further tender procedures of the main tunnels, but the advance excavation of the exploratory tunnel also allowed construction measures to be taken to secure fault-zones in the main tunnel tubes, from the exploratory tunnel, which led to a significant reduction in risk as well as cost and time.

On the basis of the knowledge gained during excavation of the exploratory tunnel, it was possible to redesign and move positions of assembly caverns, other necessary caverns and cross-passages before excavation of the main tunnels. In some cases, as shown, it was advantageous to anticipate the construction of singular tunnel sections, to reduce jamming risk of the main tunnel TBMs.

Last but not least, the continuous exploratory tunnel can also be used during the operational phase of the BBT to maximize the availability of the tunnel

system by allowing time-relevant maintenance and servicing work on the rail tunnels to be carried out from the exploratory tunnel via shafts without impact on the rail operation.

ACKNOWLEDGMENTS

We would like to express our sincere thanks to BBT SE CEOs Martin Gradnitzer and Gilberto Cardola, both for their willingness to share the technical experience of the Project and their support of our active participation in international events in our sector.

Excavation management system for mechanized tunnelling in urban areas

Massimo Marotta*, Jeyatharan Kumarasamy, Alvin Sim, Chee Keong Poh & Kin Boon Chang
Land Transport Authority, Singapore

ABSTRACT: The Land Transport Authority (LTA) of Singapore has been planning and constructing the expansion of the rail networks since 1995. Bored Tunnelling by Earth Pressure Balance (EPB) and Slurry Pressure Balance (SPB) TBM have been extensively used to build up the network. Apart from monitoring the tunnelling operation parameters and ground related movements using monitoring instrumentation, Singapore has developed and implemented a comprehensive Excavation Management System (EMS) to ensure improve the accounting and reconciliation of the excavated soil and rock. Excavation management is a major risk mitigation measures as it allows for early identification of over-excavations which, if undetected, will potentially impact the surrounding area with risks of large settlements or sinkholes. However, the muck reconciliation is complex is nature as affected by several factors such as the variable nature of the geological conditions, the effect of advance speed, the effects of accuracy of the instrumentation used to measures flow and density, and more. For this reason, a more holistic approach is necessary where different methods based on volume or mass are employed to provide sufficient data to the tunnel engineers. This paper will the describe different muck reconciliation methods, and will discuss practical application of the Excavation Management system using Slurry and Earth Pressure Balance Boring Machines in Singapore.

Keywords: Mechanized Tunnelling, Excavation Management, Muck Reconciliation

1 INTRODUCTION

In conjunction with Singapore’s vision to have sustainable, efficient and extensive Mass Rapid Transit (MRT) system across Singapore Island, more and more underground rail tunnels are being planned and constructed.

A total of 148 TBMs, both Slurry type and Earth Pressure balance, have been extensively used for tunnelling for the variuos MRT lines, from the North East Line (NEL), to the Circle Line (CCL), the Downtown Line (DTL) and the Thomson East Coast Line (TEL).

Table 1. TBM used in Singapore MRT from 1995 to 2017.

MRT Line	EPB	Slurry	Open Face
Phase 1-2	1	0	1
NEL	14	0	2
CCL	19	8	0
DTL1/CCLe	3	0	0
DTL2	8	11	0
DTL3	29	0	0
TEL/TELe	28	24	0
Total	102	43	3

Tunnelling under densely populated and developed cities and towns has been gathering momentum over the last two decades in Asia and other parts of the world.

With growing scarcity of land space, tunnels for transportation, conveyance of clean and wastewater and utility services are being located under public roads, buildings, and other infrastructure.

As such, any ground movement associated with tunnelling activities has to be carefully estimated and controlled in order to prevent damage or disruption.

In Singapore, mechanised tunnelling started with open shields during the nineteen eighties, supplemented by compressed air as face support mainly to deal with ground water, moved on to earth pressure balance TBMs in the nineties and to slurry machines in the new millennium which have contributed to the improved control of ground movements and ground-water control.

In Singapore, the continued use of slurry TBMs, starting from Circle Line MRT, then Downtown Line MRT followed by the East-West-North-South Power Cable Tunnels, the Thomson East-Coast MRT and the Deep Tunnel Sewage System (DTSS) phase 2, has contributed to progressive improvements to slurry TBM technology, slurry transportation systems as well as separation systems.

*Corresponding author: marotta_massimo@lta.gov.sg

In addition to these, another major advance is the way excavated spoil is quantified and compared to the theoretical excavation quantity at the tunnel face.

This allows early and accurate reconciliation to detect and deal with any over excavation during tunnelling, although the methods deployed for measurement of the excavated soil/rock are different under EPB and Slurry machine respectively.

The objective of Excavation Management System (EMS) is therefore to early identify potential over-excavation and take appropriate actions promptly when necessary.

This is achieved by reconciling the measured quantity of excavated volume and mass with theoretical values estimated based on geometry of excavation and expected ground condition.

An allowable deviation from the theoretical values is set and follow-up actions should be taken once limit is exceeded.

However, it is important to understand that the reliability of the Excavation Management System is highly dependent on variation of geological conditions at the tunnel face, the accuracy of the measuring instruments and other operational factors, and therefore it is essential to understand that an holistic assessment is required, often comprising the assessment of other relevant TBM parameters, i.e. variation in face pressure, torque, etc.

2 SOIL PHASES

In soil or rock skeleton, it consists of solid particles, water and air. Figure 3 below represents the schematic phases diagram of the soil and rock composition by both mass and volume.

Figure 1. Soil phases diagram.

In Excavation Management, the Dry Volume V_{dry} refers to the volume of the solids (V_{solid}), while the Dry Mass M_{dry} refers to the mass of the solids (M_{solid}), and following equation express the relationship between the two:

$$M_{dry} = V_{dry} \rho_{solid} \quad (1)$$

With reference to the equations included in the paper, the following abbreviations are used:

- ρ_{bulk} = bulk density of the soil
- ρ_{solid} = solid (particle) density
- n = porosity
- S = degree of saturation

3 EXCAVATION MANAGEMENT FOR SLURRY TBMS

3.1 Slurry transportation system and solids separation

Mode of transportation of excavated materials from TBM is through bentonite flow via Slurry Transport System (STS) to Separation Treatment Plant (STP). During excavation, bentonite-based slurry is delivered from the STP to the TBM excavation chamber via slurry feed line. At the same time, excavated materials are transported from the chamber, via slurry discharge line to the STP for the separation of solid particles. Not every particle size is separated at the STP. As the STP is designed to retain bentonite, fines from the excavation (i.e. silt/clay) are also be retained in the system, causing an increase in the slurry density and a decrease in the slurry rheological properties.

Figure 2. Schematic of slurry transportation and separation.

As the Excavation Management System is affected by the interpretation of geological information and by instrumentations accuracy, LTA has, in the recent years, required for provision of secondary reconciliation systems to be done at the Slurry Treatment Plant. Additionally, LTA has introduced rigours check on slurry physical and rheological properties using Key Performance Indicators and stringent testing regime since Circle Line projects (Marotta, 2010).

3.2 Assumptions and limitations

Excavation management is based on a comparison between theoretical and actual values of excavated volume or mass.

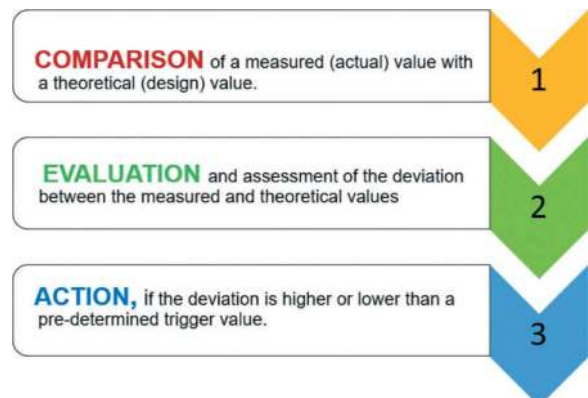

Figure 3. Excavation management process.

For the excavation management to be as accurate as possible, an important assumption is operating in a closed system where the difference in volume or mass between the slurry discharge and slurry feed can be used to determine the actual volume or mass of the excavated material. For slurry TBMs, the above is achieved when tunnelling with a membrane model at the tunnel face, where the formation of an impermeable filter cake can prevent major slurry losses into the ground. In reality, a overlap of both models can be assumed to govern the interactions at the tunnel face. Especially in highly permeable ground conditions such as coarse gravel, the penetrating filter cake model becomes more dominant.

Figure 4. Schematic membrane model.

A closed system implies no major water seepage into the excavation chamber during tunnelling. Seepage cannot be measured and if present would drastically affect the results of the Excavation Management System.

For tunnelling in Singapore, the membrane model is generally achievable based on the characteristics of the local geological formations. However, minor losses or ingress in the system could still be one of the many factors contributing to the accuracy of the Excavation Management System.

3.3 General approach on excavation management

Muck reconciliation is done by volume and by weight. As described in Yee et al (2018), the traditional reconciliation method is by Volume, as its theoretical value is very simple to be calculated based on TBM cutting area and the advance length, with the actual Volume measured by the instruments (flowmeters) installed in the slurry feed and discharge line.

However, the experience with over 40 Slurry TBMs confirm that a reconciliation by volume only is often not sufficient, due to several reasons. Firstly, there are risks that an Over Excavation by Volume may not be captured by the system if the void if filled with slurry from the feed line.

Figure 5. Schematic over-excavation.

To be accounted for, any void created by over-excavation shall remain empty. If filled by slurry, the volume of slurry filling the cavity will offset the over-excavated volume measured through the discharge line. That's why it is important to assess all the other available data such as variation in the Slurry Tank Level, variation in Face Pressures, Deviation Flow, which would help assessing if an over-excavation has occurred.

Figure 6. Slurry treatment plant active tank.

Additionally, as explained in the previous paragraph, any alteration to the system volume may occur in case of seepage in the chamber, filtration outside the chamber or even seal water introduced to the slurry pumps.

Therefore, to rely only on muck reconciliation by volume has its own limitations and having muck reconciliation by Mass can allow for a better assessment. Mass measurements are done using Density Meters installed in the slurry the feed and discharge lines. Additionally, further measurement by mass can be taken for verification purpose at the Slurry Treatment Plant, if equipped with compartmentalized muck pit and measuring weighing system on the conveyor belts.

3.4 Excavation management by total volume

The Theoretical Excavation Volume depends on the TBM cutting diameter and the excavation length of the advance, and can be calculated as:

$$V_{\text{theor}} = \frac{\pi d_{\text{T}}^2}{4} L_{\text{advance}} \quad (2)$$

where d_{tbm} is the cutting diameter of TBM and L_{advance} is the length of advancement, which is typically 1.4 meters to 2m for TBM size used in Singapore MRT construction projects.

The actual excavated volume can be measured using flowmeters installed at the feed and discharge slurry line.

The comparison between theoretical and actual excavation volume can be tracked in real time:

Figure 7. Real time visualization of EMS by total volume.

3.5 Excavation management by dry mass/dry volume

As described in Yee et al (2018), different TBM suppliers used different equations for the calculation of the theoretical dry mass/dry volume, and it may not be so evident that some of the equations were written for tunnelling in Saturated soil (S=1). To avoid errors in muck reconciliation, it is advisable to use equations which are applicable to soil of any degree of saturation, such as:

$$M_{dry} = V_{tot_th} \frac{(\rho_{bulk} - \rho_{water} \times S)}{(\rho_{solid} - \rho_{water} \times S)} \rho_{solid} \quad (3)$$

$$M_{dry} = V_{tot} \rho_{dry} \quad (4)$$

$$V_{dry} = V_{tot_th} (1 - n) \quad (5)$$

The theoretical dry mass/ dry volume is highly dependent on the density of the soil/rock at the tunnel face.

Therefore, when tunnelling in rock soil mix face conditions, the calculation of the theoretical mass can be challenging.

As shown in the figure below, for a Metro tunnel size the variation in Dry mass for a 1.4 m excavation length can range from 63 to 130 Tons.

While having sufficient Soil Investigation can help, there are always possible deviations between the expected and the encountered ground conditions. Common practice is therefore to analyse the ground conditions encountered in the previous ring to estimate rock and soil distribution for the following ring. During excavation, the gradient of dry mass/dry volume graph will be monitored and compared with excavated materials collected. This is possible

Figure 8. Variation of Dry Mass in mix rock/soil conditions.

Figure 9. Abrupt soil/rock interface observed at the tunnel face.

as the Slurry Treatment Plant is equipped with compartmentalized pits, belt weigher and density meters to measure the quantity of rock chips, sand, and fines remaining in the system.

Measurements of Dry Mass and Dry Volume is done using both flowmeters and density meters installed along the slurry feed and discharge lines.

As described by Yee et al (2018b), most of the flow meters available in the market is of electromagnetic type. Location of flow meters would affect their accuracy. It is generally recommended to position the magnetic electrodes perpendicular the direction of steady flow and reasonably distance away from density meter so to avoid interference.

To measure the corresponding density, density meter is also recommended to install at vertical pipe position where the soil particles are better evenly distributed across the pipe as compared with horizontal pipes position. Wear in the slurry pipe would affect its accuracy over time. Density meter of radioactive type has higher accuracy as compared with electromagnet density meter. (Yee et al, 2018a)

To have better accuracy of the density meters, it is advisable to perform multiple points calibration prior

to commencement of tunnelling. The calibration should be done with water and with sample of drilling fluid of a density equal or higher to the maximum expected density on discharge line during tunnelling.

A quick check on the accuracy of the density meter can be done during by-pass operation when slurry circulation is done outside the excavation chamber with no solid ingress. Under this by-pass mode, the density in feed and discharge should be equal. However, it takes some time to reach a stable reading once the slurry in the system is homogeneous. Should a major deviation be observed, it is advisable to engage the density meter supplier or agent for a re-calibration (Yee et al, 2018b)

3.6 Secondary muck reconciliation

The secondary reconciliation measurements are carried out with weigher installed at conveyor belt transporting soil from STP to muck pit.

Figure 10. Muck Pit for gravel.

Figure 11. Muck Pit for sand.

However, belt and muck pit would collect only the relatively large solid particles that are successfully separated in the Slurry Treatment Plant (STP), and not the fines (including bentonite) which are below the STP separation capacity (usually defined as d50 of the cyclones). Therefore, for accounting purpose, the fines in the system need to be estimated by comparing the difference in the total slurry

volume and density at the start and at the end of each excavation cycle (Yee et al, 2018)

Figure 12. Automatic measuring of fines in the system.

3.7 Evaluation and assessment

With many data available, it is important to understand that assessment on the occurrence of a potential over-excavation shall be done holistically with the understanding that muck reconciliation method has his own limitations.

In general, the allowable limits of under or over excavation (i.e. +/- 15%) do not represent an acceptable variation in the excavated quantity, but are set to reflect the reliability of the excavation management as a comparison between a measured and a theoretical value, where both are affected by a large number of external factors as described in this paper.

For instance, when tunnelling in rock/soil mix face, great variation on dry mass/dry volume is expected. In this case, accounting by total volume may be more reliable than accounting by mass.

When tunnelling in ground with very high content of clay, the soil separated at the STP and collected in the muck pit (gravel/sand) may only be a small percentage of the excavated one. In this case the estimation of fines in the system is very important for the secondary muck reconciliation at the STP.

Where multiple methods are used, analysing trends and outliers can be a better methodology than simply rely on individual measurement as number. Having this approach, and executing holistic assessment, has proven to be effective in identifying potential over excavations.

4 EXCAVATION MANAGEMENT FOR EPB TBMS

4.1 Muck reconciliation by volume (EPB)

Traditionally and for a long time the quantity of spoil excavated by an EPB TBM has been measured by volume based on the number of muck skips.

The reliance only on the volume can lead to inaccuracies related to computation of the bulking factor of the spoil, injection volume of soil conditioning, sticking of spoil to the interior of the muck skip and the like.

Unlike for Slurry TBMs, it is more complex to reconcile the excavated spoil for EPB TBMs. For a start the injection of ground conditioning foam to the cutterhead and excavation chamber leads to

Figure 13. Muck skip for soil disposal (EPB TBM).

accumulation of air in the chamber. Often this accumulated air is not purged. As a result, the excavation could proceed with a partially full chamber thus leading to significant fluctuations in the volume and weight of the spoil removed from the chamber for individual rings. This can be avoided by releasing any air that has accumulated in the excavation chamber at periodic intervals during tunnel boring or once every advance towards the end of the boring cycle, for example 300mm before completing the advance.

Other than using the muck skips, muck reconciliation by volume can also be done using scanner, measuring the soil on the conveyor belt and providing real time visualization (Veenuganan et al (2023)

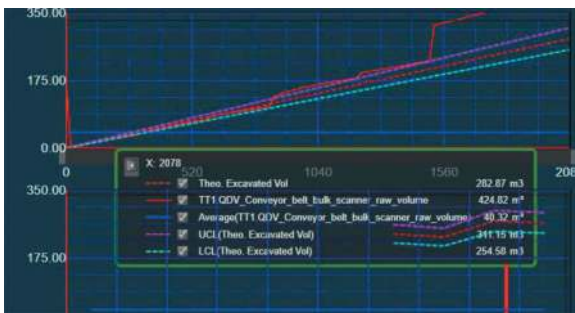

Figure 14. Volume scanner real time visualization.

The belt scanners principally scan the profile of the spoil which is carried on the belt using special laser devices installed on top of the conveyor belt at a specified height.

As shown in Veenuganan et al (2023), recent Singapore experience in large diameter TBM in alluvial soil has shown the measurement by the scanner largely be within the allowable limit.

It is important to understand that any muck reconciliation by volume is affected by the quantity of water/foam injected, by the air content as a result of soil conditioning. The quantity of water or condition-

Figure 15. Belt scanner results (% of theoretical).

ing injected shall be therefore accounted for in order to determine the net excavation volume

4.2 Muck reconciliation by Mass (EPB)

Muck reconciliation by Mass can be executed by different means depending which muck transportation method is used. Generally, weighers are installed at the conveyor belts transporting the soil out of the TBM (TBM belt). For long drives where conveyor belt is used for soil transportation to surface, additional weighers can be installed along the tunnel belt.

If muck skips are used and gantry crane employed to lifting the skips for soil disposal into muck pit, the excavated total mass can be calculated by measuring each skip before and after it is loaded by the excavated soil.

The advantage of muck reconciliation by Mass, is that it is not affected by the tunnelling bulking factor, including by the presence of air as a result of soil conditioning. The measurement by mass can be relatively accurate as long as any fluid added during excavation (water, conditioning) is accounted for and is subtracted from the measured total mass in order to derive the net excavated mass.

4.3 On Board Muck Weighing System (OBMWS)

The OBMWS is an enhanced version of weight measurement, introduced and developed by the Land Transport Authority and currently adopted in some of the Cross Island Line tunnelling project.

It follows the same principles of the Gantry Crane method, where muck reconciliation by Total Mass is done by measuring the weight of skips. However, instead of measuring the weight of the skips when they reach the gantry crane, load measurements of the skips are done directly using load cells embedded on the flat bed of the rolling stock, as seen in Figure 15.

The load cells can transmit data in real time and can be integrated directly into the PLC system, allowing for real time visualization (Veenuganan et al, 2023) for each skip as it the soil come from the EPB Screw conveyor.

Figure 16. OBMWS Real Time Visualization.

Figure 17. Flat car equipped with load cells for OBMWS.

5 CONCLUSIONS

The paper has outlined the principles, limitations, and applicability of various muck reconciliation methods, for tunnelling using Slurry and EPB Boring Machines.

The aim of Excavation management System is to detect potential over-excavations so that actions can be taken before escalating into large ground movement or sinkholes.

Nevertheless, it is important to understand that the system is influenced by various factors as outlines in the paper, and therefore the Excavation Management System should consist of a holistic interpretation of the various measurements by volume and mass measurements and their comparison with their theoretical “expected” values based on tunnel dimension, advance rate and ground conditions.

This systematic approach to excavation management is especially beneficial when tunnelling in urban environment where the allowable tunnel induced ground movement are often limited and governed by serviceability limits. Tunnelling in Singapore has developed a state-of-the-art approach on Excavation Management thanks to the contribution of all industry partners, from Contractors to TBM Manufacturer to consultants. The continues development of more advanced software solution in this field would, is and will continue to be highly beneficial.

Advancing mechanized tunneling through integrated digital design, simulation, and data-driven techniques

Günther Meschke*, Yaman Zendaki, Abdullah Alsahly & Ba Trung Cao
Ruhr University Bochum, Bochum, Germany

ABSTRACT: Towards the digitalization in tunneling industry, interactive digital planning as well as model and data driven steering support during construction is at the forefront of modern tunnel projects. Project stakeholders are then possible to collaboratively explore and visualize various design alternatives in a virtual environment in real-time, which leads to optimized tunnel design and reduced construction risks. For this purpose, a digital interactive platform has been developed for collaborative planning and construction in tunneling projects, in which digital data, numerical simulation, and the damage assessment of existing infrastructure, is integrated and visualized in real-time. In this work, firstly, an interactive tunnel alignment design example utilizing the digital platform is presented. Secondly, a simulation-and-monitoring-based example, which adopts risk-oriented models for the steering of Tunnel Boring Machines considering interactions with the built environment, in association with monitoring and process data to enable an informed real-time adjustment of the construction process, is also illustrated. This contribution provides an insight into the latest advancements in the field, focusing on digital design, integration of Building Information Model and numerical simulation, interactive planning, and real-time steering support during tunnel construction.

Keywords: Real-time prediction, Numerical simulations, Interactive design, Tunnel alignment, TBM steering

1 INTRODUCTION

With the move toward digitalization in the tunneling industry, data from different sources in a tunnel project are required to be digitally transformed, efficiently stored, processed and displayed. Digitalized data is then used to collaboratively explore, to process and to visualize in a virtual environment, which leads to not only optimized tunnel design but also reduced construction risks.

With respect to the design task, the development of a real-time interactive digital platform for planning and design of tunneling projects, particularly in urban areas, provides a valuable tool to support the decision-making process in the design phase, such as the tunnel alignment design problem. In this paper, a simulation-based interactive platform, which allows to quickly investigate different possibility of planning the tunnel alignment in real-time, is introduced to better enrich the alignment design process. The platform is established based on a combination of several approaches, such as the Building Information Model (BIM) (Borrmann

et al., 2015), Finite Cell Method (FCM) (Düster et al., 2008) and surrogate models. Similar to the Tunnel Information Model in (Koch et al., 2017), a BIM-based data management model, which contains four essential components in mechanized tunneling including a ground model, a TBM model, a tunnel model and a built environment model, has been generated in Revit software. In (Alsahly et al., 2020), a BIM-to-FEM concept has been introduced and developed to properly transform necessary data from the digital model to numerical simulations based on the Finite Element Method (FEM). This concept has been extended in this paper namely BIM-to-FCM approach in order to connect the BIM-based model to a 3D FCM model for the simulation of tunneling processes in soft soils, which can efficiently simulate different tunnel alignments. The simulation results are then utilized to create a surrogate model using a combination of the Proper Orthogonal Decomposition (POD) and the Radial Basis Functions (RBF) to substitute the time-consuming FC model (Zendaki et al., 2023). The POD-RBF model has the capability to quickly

*Corresponding author: guenther.meschke@rub.de

provide the system responses (e.g. surface settlement, risks of building damages) with respect to an arbitrary tunnel alignment created by the design engineer in an interactive environment.

Simulations and data-driven techniques are employed not only to assist the design tasks but also to enhance the tunnel construction process. The process-oriented 3D FC model is also used together with the POD-RBF model in a concept of combining simulation and monitoring data to support the TBM steering. In this approach, the operation of TBMs is suggested for future construction steps based on the possible system responses (e.g. surface settlement and risks of damages on existing buildings). Similar to the alignment design problem, a bunch of simulations is carried out using the FC model to generate a dataset, which can be learned using the POD-RBF model. During the construction process, corresponding to each configuration of operational parameters, the POD-RBF model can quickly provide the surface settlement as well as the associated risks of damages on building.

The paper is structured as follows. Section 2 presents the methodology of the FCM, the BIM-to-FCM approach, and the POD-RBF method. Section 3 describes the concept of interactive tunnel alignment design and simulation and monitoring supported TBM steering. Section 4 is devoted to the illustration of digital design, simulation and data-driven techniques in mechanized tunneling through two respective application examples. Finally, the work is summarized and some conclusions are drawn in Section 5.

2 METHODOLOGY

2.1 FCM for the simulation of tunneling processes

To accommodate for the flexibility in varying the tunnel alignment in analysis and design, a tunnel analysis model based on the FCM is proposed (Bui et al., 2022).

FCM allows for the use of one structured background mesh for all simulations, which removes the need to create a custom mesh for each track alignment in every simulation. This is particularly important for the generation of synthetic data where thousands of simulations are needed. The soil domain is discretized using the structured background mesh, whereas the other tunnel components like grouting and lining are discretized with a boundary-fitted mesh and tied to the background mesh. Different soil layers are modeled using a boundary representation that completely cuts through the background mesh. The material properties are then assigned to integration points depending on their position with respect to each of the soil layers' boundary representations. Figure 1 shows a tunnel section simulated with the FCM model for the Wehrhahn Linie Düsseldorf reference project. More details about the simulation model can be found in (Bui et al., 2022, Zendaki and Meschke, 2022).

Figure 1. FCM model for tunneling processes in soft soils.

2.2 BIM-to-FCM approach

For the assessment of the impact of various tunnel alignments or steering scenarios of the TBM (e.g., settlements, damage criteria), the process-oriented FCM model is coupled with a BIM model to automatically exchange data between the two models. This coupling allows automatic extraction of all relevant information needed for the numerical model and subsequently performing a numerical analysis for the tunnel drive.

A BIM model including information of geology, alignment, lining, existing infrastructure, material, and process parameters in a tunnel project is developed in Revit. The varying parameters (e.g. the tunnel alignment or the operational parameters) are parameterized using Dynamo. After defining expected parameters of an arbitrary scenario of the tunneling process, the corresponding simulation model can be quickly obtained using the developed automatic framework. Figure 2 presents the BIM model in Revit of a reference tunnel project with the information of geology, alignment, lining, TBM, existing buildings, material properties, and process parameters. For a better description of the BIM to numerical analysis concept, readers are referred to the work of Alsahly et al. (2020) and Ninic et al. (2021).

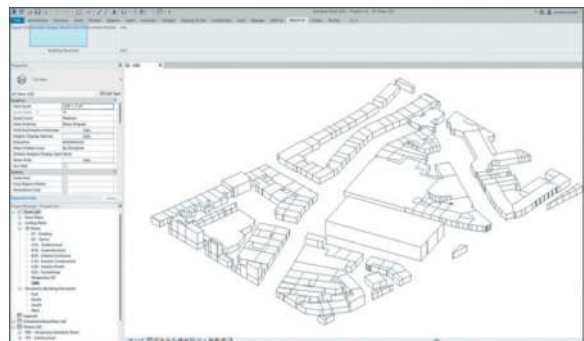

Figure 2. BIM model of a reference tunnel project with all relevant information.

2.3 POD-RBF model

Instead of the time consuming FCM simulations, the POD-RBF is employed to efficiently substitute the

numerical model in order to enable the real-time predictions for different purposes in tunneling.

The data obtained from M simulations (e.g. settlements and building damages) is arranged into a matrix \mathbf{Q} (N rows \times M columns). N output values in each column represent the number of settlement points and maximum principal strains in all buildings corresponding to a specific scenario (a tunnel alignment or an operational scenario). The POD basis vectors Φ (Smith et al., 2005), which characterizes the matrix \mathbf{Q} , can be obtained by solving the eigenvalue problem of the sample covariance matrix \mathbf{C} of \mathbf{Q} . A reduced basic functions of K ($K \ll M$) dimensions are kept to approximate \mathbf{Q} . The reduced or truncated POD basic matrix $\hat{\Phi}$ then consists of the first K POD modes. The original snapshots matrix \mathbf{Q} is approximated by

$$\mathbf{Q} \approx \hat{\Phi} \cdot \hat{\mathbf{A}} \quad (1)$$

Where, the truncated matrix $\hat{\mathbf{A}}$ contains constant values associated with the given matrix \mathbf{Q} . Here, only snapshots, which were included in the given \mathbf{Q} , can be approximated. To obtain responses with an arbitrary snapshot, a nonlinear interpolation function of input parameters needs to be integrated into the matrix $\hat{\mathbf{A}}$. Therefore, an expression of $\hat{\mathbf{A}}$ using interpolation functions \mathbf{F} of input parameters and an unknown matrix of constant coefficient \mathbf{B} is as follows

$$\hat{\mathbf{A}} = \mathbf{B} \cdot \mathbf{F} \quad (2)$$

In this work, a type of Radial Basis Functions (RBF), the inverse multi-quadric radial function (Hardy, 1990) has been adopted as the interpolation function. Finally, an approximation of responses corresponding to an arbitrary input is obtained by

$$\mathbf{Q}^a = \hat{\Phi} \cdot \mathbf{B} \cdot \mathbf{F}^a \quad (3)$$

More details about the POD-RBF algorithm are given in (Cao et al., 2016, Zendaki et al., 2023).

3 SIMULATION-SUPPORTED-TUNNELING CONCEPTS

3.1 Interactive tunnel alignment design

A schematic illustration of the interactive tunnel alignment concept is presented in Figure 3. In the first step of the procedure, a number of possible tunnel alignments are generated. The process-oriented FCM model is then used to simulate the mechanized tunneling processes with various tunnel alignments. The inputs in each simulation are the coordinates of alignment points, which represent the tunnel alignment. Afterwards, a POD-RBF model is

established using these coordinates of points as inputs and strains in buildings in all alignment scenarios as outputs.

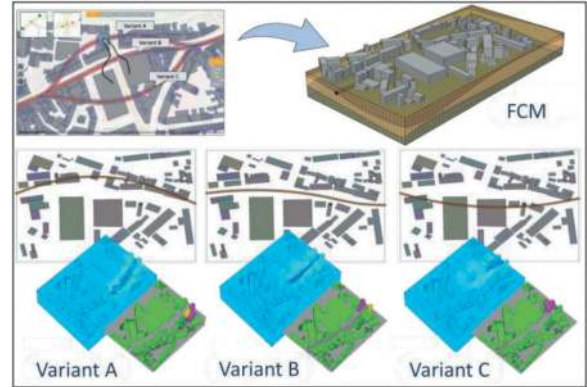

Figure 3. Scheme of interactive tunnel alignment design.

Considering predefined design criteria and constraints with respect to tunnel serviceability, e.g. fixed position of stations and curvature tolerance according to the design speed of the train, a tunnel alignment can have different shapes. In this work, a set of twenty-one control points following a cubic function are chosen to represent the alignment. For a general case, where an arbitrary number of points is used to represent the alignment, the proposed strategy is still valid. Figure 4 illustrates a collection of possible tunnel alignments in 3D space within an investigated area. The coordinates of all alignments scenarios, which are regarded as inputs of the POD-RBF surrogate model, are then sent to the FCM model to execute the simulations.

Figure 4. Possible three-dimensional tunnel alignments.

3.2 Simulation-monitoring supported TBM steering

This concept employs the advantages of simulations and monitoring data to support a possible extreme scenario occurring during the tunnel construction in

an urban area, which encounters a soil layer change between two soft soil layers (see Figure 5). In this case, designed steering parameters for the second half of the tunnel section are required to be adapted to the new geological condition.

Figure 5. TBM operation support in a scenario of soil layer change between 2 soft soils layer.

In general, numerical simulations considering the new geological condition can be executed to roughly estimate soil-structure interactions; however this approach is not realistic for a practical application during the tunnel construction due to the expensive computation time from simulations. Therefore, the POD-RBF surrogate model is utilized to substitute the numerical model. Figure 6 presents the operation concept exploiting simulation data as the basis of surrogate models for real-time predictions.

To construct the surrogate model, a number of operation scenarios, which can be applied to the new situation, are firstly simulated using the FCM model to generate the necessary data. During the real-time application, i.e. the construction stage, engineers can investigate different steering possibilities before making a decision by adjusting process parameters with arbitrary scenarios. Quick evaluations of multi-output quantities from the POD-RBF provide engineers suggestions on the decision-making process. To better support the steering decision, real-time predictive simulation models will be continuously updated with monitoring data during the construction.

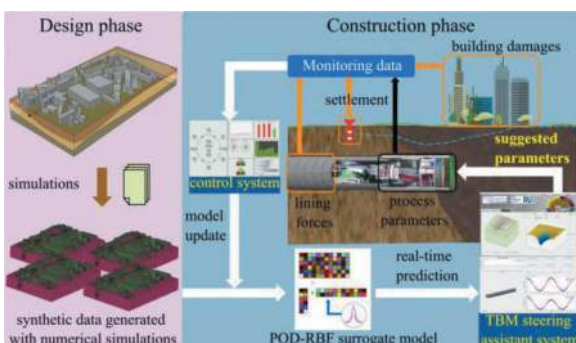

Figure 6. Concept of simulation-supported TBM steering.

4 APPLICATION EXAMPLES

4.1 Interactive tunnel alignment design

This section presents the application of the digital design approach in a scenario of tunnel alignment design in an urban area. A section of 400 x 300 meters inspired by the tunnel project Wehrhahn Line Metro in Düsseldorf, Germany is generated. A tunnel with an excavation diameter of $D = 9.5$ meters, see Figure 7, is assumed to be constructed using the shield tunneling method. The length of the computational model is 400 meters. The bottom surface of the model is fixed in both horizontal and vertical directions since it is assumed that deformations in deeper soil layers can be neglected. Buildings located at the ground surface are modeled depending on the Level of Details (LOD) (Ninic et al., 2019). The LOD varies from a simple substitute model using shell elements with equivalent thickness and stiffness; 3D block volume elements; or a detailed structure with connected walls, columns, and slabs. To efficiently simulate the problem, an adaptive searching algorithm, which assigns higher LOD to critical buildings based on their position with respect to the tunnel alignment, is employed to reduce unnecessary degree of freedoms of less important buildings, see Figure 7.

Figure 7. Simulation model of a section with buildings.

A total of 85 buildings at the top surface used in this application example are illustrated in Figure 7. The design task is to interactively create an arbitrary tunnel alignment and visualize immediately the possible associated damages on all buildings. In a way similar to (Cao et al., 2022), the building damage assessment is performed by estimating the principal tensile strains in each building individually. A POD-RBF model, which considers the coordinates of the alignment control points as the inputs, is used to predict the tensile strains in 85 buildings.

Quality of the POD-RBF model is evaluated using the 5-fold cross validation with the data from a total number of 2000 simulations of three-dimensional tunnel alignments. In this example, the 2000 samples are generated with a constraint such that in each alignment the Y coordinates of any alignment points are within the range from 50 to

250 meters. On the other hand, to maintain the design of a shallow tunnel with a cover depth in the range of 1.2D to 3.3D (D as the excavation diameter), the variation of Z coordinates of alignment points is kept between 16 meters and 36 meters. Table 1 summarizes the mean L_2 norm errors of all validation cases in each fold of the 5-fold cross validation for the prediction of maximum tensile strains in buildings as compared to the reference solutions from FCM simulations. It is shown that with an average error of only 2.7% and similar prediction accuracy in all 5 folds, the POD-RBF surrogate model can efficiently substitute the FCM simulation model to predict the maximum tensile strain in the buildings.

Table 1. Prediction performance of the POD-RBF model: L_2 norm error (in [%]).

5-fold cross validation	Building strain error [%]
1	3.8
2	2.0
3	3.4
4	2.2
5	2.0
Average	2.7

Based on the proposed computational strategy, an interactive real-time simulation software namely “TunAID” (Tunnel Alignment Interactive Design) is developed to support the decision-making of tunnel alignment selection during the design phase of a tunnel project. With the help of TunAID, a real-time prediction of TBM-soil interactions, i.e. the surface settlements and the associated risks of damage on buildings, are enabled for an arbitrary tunnel alignment design. A screenshot of the developed software is depicted in Figure 8. In an interactive design manner, corresponding to each movement of the pointer an alignment following a predefined criterion is created and visualized immediately. Consequently, the associated risks of damages on all existing buildings are quickly estimated and shown in the developed software package.

Figure 8. A screenshot of the TunAID application.

4.2 Simulation-monitoring supported TBM steering

This section is devoted to the application of the simulation-support TBM operation concept. The simulation model generated in this example represents a tunnel section of a reference project, where the tunnel is excavated underneath an urban area with a large number of buildings. The target to operate the TBM in this example is to minimize the possible damages on existing buildings in the area. The computational domain, the tunnel alignment, the associated buildings, and the geological conditions of the section are depicted in Figure 9. The shield tunneling method is used to construct a tunnel with a diameter of 11.34 m. The cover depth in this section varies from 17 m to 20 m. The simulated tunnel alignment consists of 57 concrete lining rings, each with a length of 2 m and a thickness of 0.4 m. There are in total 108 masonry residential buildings, which are typically two to three-story buildings, taken into consideration in the simulation. However depending on their locations to the tunnel alignment, different LODs are used to model the buildings, see Figure 9(a).

Figure 9. Simulation model of the section with buildings: (a) Computational domain with 108 buildings; (b) Geological conditions of the simulated section.

Along the simulated tunnel section, three soil layers including a filling layer, a medium sand layer, and a dense sand layer exist as depicted in Figure 9(b). In the Y direction, the soil layers are assumed to be horizontal. In the first half of the section, the TBM advances in the dense sand layer (with a modulus of elasticity $E_3 = 66$ MPa), while in the rest of the alignment, the tunnel is constructed in the medium sand layer ($E_2 = 37$ MPa). A soil layer change situation with the transition zone of 30 m appears in the area from ring 21 to ring 36, i.e., in the range of 42 m to 72 m from the left boundary of the computational domain.

A total number of 324 operation scenarios considering different face support pressures in two tunnel sections and the steering time (i.e. where starting to adjust the pressure) are created and used as inputs to execute corresponding FCM simulations. The respective POD-RBF models take these operational parameters as inputs and the simulated settlements at 931 surface points and the simulated

damages on 108 buildings as outputs. To estimate the risks of damages on buildings in practice, categories of damages converted from associated strain values (Boscadin and Cording, 1989) are usually used, therefore the POD-RBF models in this example will predict the tensile strains on multiple positions of buildings. The building strains are then converted to categories and visualized as shown in Figure 9 to indicate the building damage levels. Table 2 shows the prediction accuracy of POD-RBF models for both surface settlements and strains.

The settlement can be excellently predicted using the POD-RBF model with a L_2 norm error of only 2.4% as compared to FCM results. The prediction of non-linear strains on buildings also shows a great agreement between the two models (FCM and POD-RBF). The overall L_2 norm error of 5-fold cross-validation for the strain prediction is 7.52%, while the computation time is significantly reduced from 10 hours to only 1 second.

Table 2. Prediction performance of POD-RBF models in TBM control example with buildings: L_2 norm error (in [%]).

5-fold cross validation	Settlement	Tensile strain
1	2.4	7.40
2	2.39	7.10
3	2.51	7.59
4	2.32	8.10
25	2.39	7.27
Average	2.4	7.52

The presented simulation-based strategy has been integrated into a real-time simulation software called SMART (Simulation and Monitoring based Assistant for Real-time steering in mechanized Tunneling) to support the TBM operation during the tunnel construction (Cao et al., 2016; Zendaki et al., 2023). In this paper, the SMART application focuses on the possibility to quickly estimate the surface settlement and the risk of building damages.

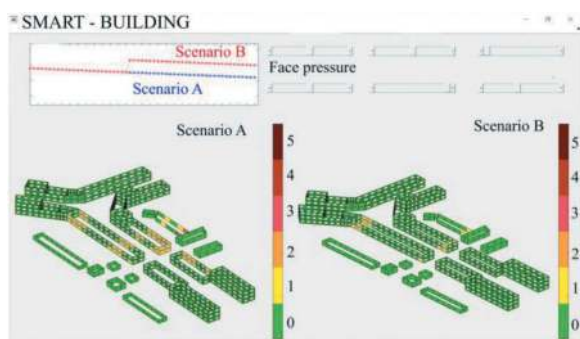

Figure 10. A screenshot of the SMART application illustrating the simulation-supported TBM steering.

Figure 10 shows an application of the SMART app for an investigation of TBM process control in an urban area. Two investigated scenarios: scenario A with the blue line and scenario B with the red line, are shown in the top left of the panel. In scenario A, the relative change of face pressure is kept constant, while a moderate increase of 40 kPa for the face pressure is applied in scenario B. The resulting damage categories are plotted respectively at the bottom of the application panel. The results show that the pressure adjustment in scenario B will lead to a safer situation with lower damage categories in critical buildings in this area. Generally, by changing the sliders of model inputs on the top right panel (i.e., the relative change in support pressure), the associated damage categories of buildings can be quickly estimated and visualized, which provides a real-time assistant tool for site engineers to make a decision on how to select the face pressure in next excavation steps.

5 CONCLUSIONS

In this paper, a framework for advancing TBMs in mechanized tunneling through the support of digital design, numerical simulations and data-driven techniques has been presented. The digital BIM-to-FCM concept has enhanced the data exchange between a BIM-based data management system and a FCM simulation model. The FCM simulation model serves as the main investigation tool for the numerical analyses in tunneling process, both in design stage and tunnel construction. To activate the interactive alignment design and the real-time TBM steering support in construction stage, surrogate models based on POD-RBF method have been utilized.

In both application examples, the POD-RBF models have proven to be able to substitute efficiently the FCM simulation model. The associated computation time is substantially reduced from 7 to 10 hours (using FCM simulations) to only several seconds (using POD-RBF model), while the prediction capability remains. Two user-friendly applications namely TunAID and SMART have been developed to support the tunneling work. The TunAID software allows to interactively determine (in real-time) optimized tunnel alignments resulting in minimal settlement-induced damage within a predefined section of a tunnel project. On the other hand, the developed simulation-based SMART application can be used as an assistant system for real-time TBM operation support in practical tunneling.

TBM design and special features for boring through highly squeezing ground

Maurizio Monina*
Webuild, Milan, Italy

Marco D'Ambrosio & Fabio Del Rossi
Seli Overseas, Rome, Italy

ABSTRACT: The Italian railway network systems is under rapid expansion and several new railway lines are under construction in the Country. Most of these new lines in Italy include numerous long tunnels and more than 40 TBMs will be in operation simultaneously to complete the works in the tight schedule imposed by the European Community that, through the Next Generation EU funds, contributes to finance these infrastructures. However, many of these tunnels cross clayey formations in extremely poor local conditions, with strongly converging and squeezing behaviour in presence of gas. The difficulties posed by such geological conditions could not be faced by the “standard” TBM designs available on the market. Indeed, without the introduction of substantial innovations, the mechanical excavation of these tunnels would have been impossible. At the same time the execution of these tunnel by conventional excavation would have required extremely long times, not compatible with the challenging schedule foreseen. To deal with these criticalities and ensure at same time high productions of the TBMs, specific and innovative technical and design solutions have been developed, such as: excavation with variable diameter, accentuated shields conicity, redundant cutting tools arrangement on the cutterhead, dynamic hydrodemolition “on the go”, static hydrodemolition, continuous mining system, reinforced shields, extended sensors for preventive maintenance and gap monitoring, exceptional thrust, active articulation, high viscosity lubricant injection capability. The muck transport and the services along the tunnels have also been improved to reduce the TBM stand by times for the extension operations. Some of the mentioned design features have been tested in previous and on-going projects while some others have been developed for these applications. The article will describe the adopted solutions and innovations, the rationale for their introduction and the first outcomes from the project sites where the TBMs have already started the excavation.

Keywords: convergence, gas, clay, thrust, hydrodemolition, innovation

1 INTRODUCTION

The rapid expansion of the Italian railway network has ushered in a wave of construction projects that demand the creation of an extensive network of tunnels. To meet the ambitious schedule imposed by the Client Rete Ferroviaria Italiana (RFI) and to be fulfilled by Webuild as main contractor, more than 40 Tunnel Boring Machines (TBMs) are planned to be in operation at the same time.

These projects span the entire Italian peninsula, with a notable concentration in southern Italy. Notably, they involve the Naples-Bari and Salerno-Reggio Calabria connections, and the new Messina-Catania-Palermo railway line in Sicily.

A substantial portion of these tunnels, especially those in Sicily, cross clayey formations marked by

exceptionally challenging geological conditions. These include pronounced convergence and squeezing behaviours, particularly in presence of gas. Conventional TBM designs proved to be insufficient to address these formidable challenges, necessitating the introduction of substantial innovations to enable mechanical excavation within the strict project timelines. To overcome these geological hurdles while ensuring optimal TBM productivity, a collaborative effort between Webuild Group engineers and the TBM's manufacturers has resulted in the development of pioneering technical and design solutions. This article provides an in-depth exploration of the innovative solutions and design features adopted to overcome the geological challenges posed by clayey formations. It elucidates the rationale behind their integration and presents initial outcomes from

*Corresponding author: m.monina@webuildgroup.com

project sites where TBMs have commenced excavation. Some of the described design features have been tested in prior and ongoing projects, while others have been developed specifically for these demanding applications. These innovations not only enable the successful completion of tunnels in adverse geological conditions but also contribute to the efficiency and reliability of TBMs in the ever-expanding Italian railway network.

2 METHODOLOGIES AND SOLUTIONS

In this chapter are described only the main innovations introduced on the TBMs, that supplement the general improvement of other well-known systems, such as extensive probe drilling facilities, grouting and increased dewatering capabilities, not part of the current focus.

2.1 Excavation with variable diameter

Acting on the excavation diameter can be one of the most effective actions to prevent the TBM from being blocked when it must face highly squeezing ground. At this purpose during the TBM's design phase a package of "special features" has been defined to make it possible the adaptation of the excavation profile, when necessary. A combination of main drive vertical displacement and enlarged cutting profile with additional and extended tools in the most peripheral positions, are effectively a good practice to let the TBM passing fast through the highly squeezing ground tunnel zones.

The sequence to increase the final boring diameter includes first the use of a copy cutter which creates empty space in the crown so that the cutting wheel can bore into a larger diameter. Once enough room is created, the gauge cutters can be shimmed out and installed at the most peripheral positions into the empty spare housings. The cutting tools are commonly shimmed out in subsequent steps up to a final total exposure of 130 mm (case of ripper tools) with respect to the nominal boring diameter. In addition, there is the possibility of the main drive displacement, commonly executed in two increasing steps, up to 65 mm each, for a total amount of 130 mm extra bore on radius. These features are activated in the most critical situation, where an extra bore exceeding the 80 mm on radius is required, to guarantee the steerability of the TBM even with high overcut. Moreover, the main drive can be designed with an initial offset between cutting wheel and center of shield, in the range of 10÷20mm, which gives an additional possibility to extra-bore.

Here below a schematic representation of the steps to increase the bore diameter:

In such case the total overcutting TBM capacity at crown is 260 mm, resulting from the combination of 130 mm of the main drive displacement and 130 mm of the gauge cutters shimming out.

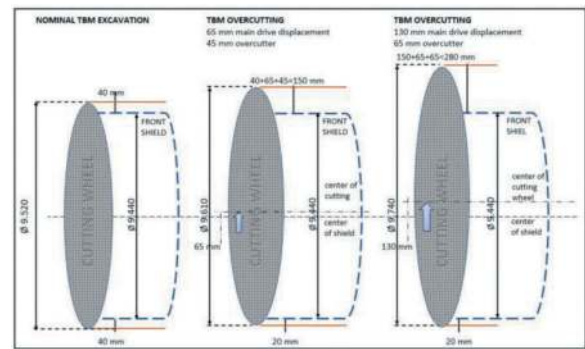

Figure 1. PA-CT maximum overcutting.

2.2 Accentuated shields conicity

In addition to the possibility of varying the excavation diameter as described in the previous paragraph, the TBM must have an adequate conicity or stepped geometry and the shortest possible length (compatible with the dimensions of the internal elements of the machine) to reduce friction with the ground.

In these regards, all the TBMs that will be used in the mentioned new projects, are designed with a much more accentuated conicity and a more stepped geometry compared to common practice. This allows for a greater gap between the ground and the shield and reduces the influence of the rock squeezing against the shield in terms of friction and load.

The proposed mitigation measures, aimed at addressing all the risks, therefore have a particular focus on those related to deformations and poor rock mass conditions in presence of high coverage, both in the excavation phase (problems related to the TBM and excavation management) and in the long-term phase (lining design).

In the figure below is included a schematic representation of the typical shield's conicity that has been applied in the recent TBM design development.

Figure 2. Shield conicity in Palermo-Catania Project Lot 1+2.

Particular attention was paid to maintain an appropriate gap between the tail shield and the extrados of the tunnel lining ring. This gap was estimated at 140 mm as shown in the figure below (case of TBM of Circonvallazione di Trento Project).

Figure 3. Tail shield gap in Trento Project TBM.

2.3 Increased wear resistance

On the cutterhead, the installation of an additional cutting line, for a total of 3 lines (long rippers/cutters, short rippers, scrapers), guarantees an extended protection against wear of the face and especially of the gauge part of the cutting structure.

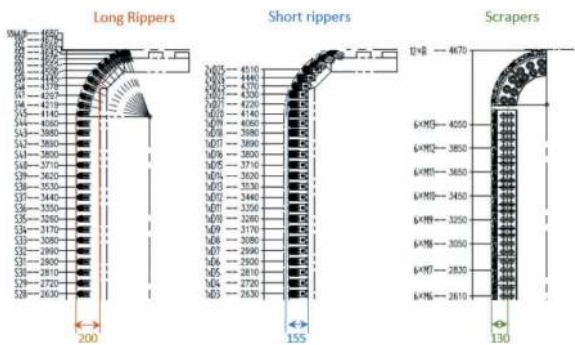

Figure 4. Cutting lines protrusion in mm on ME-CT lot 2 - forza d'agrò TBM.

The excavating tools, provided with a massive amount of tungsten carbide inserts employed to increase hardness and wear resistance, reduce the frequency of replacement in hyperbaric conditions and often in presence of gas.

Special passive protection, like Vautid or similar on the gauge, are foreseen as well.

To avoid clogging phenomena, water nozzles in the center can inject water up to 300bar, while a minimum opening of 38% of the center optimizes the muck flow.

On the tail shield, the adoption of special wear resistant brushes with Teflon inserts and the employ of an additional grease chamber, has proved to be an effective measure to extend the sealing life.

2.4 Static and dynamic hydrodemolition

In case of shields blockage, there have been already successful experiences of application of the hydrodemolition system with high pressure water (up to 1600 bar) through holes arranged along the shield, to achieve the disintegration of the pile resting on the TBM. Nevertheless, in case of extended and extremely quick squeezing conditions, the single application of the system might not be decisive. Therefore, an enhanced version of the system while

advancing, called “hydrodemolition on the go” or “dynamic hydrodemolition”, has been developed. Such system, first employed by the Webuild group’s company Seli Overseas on Cociv Radimero Project, allowed to halve the thrust required to advance the TBM. The spacing of the nozzles, together with a 12° slope of the jet with respect to the surface of the shield, is essential to provide a connection between the fractures created by two adjacent nozzles, creating a continuous and more effective fracture surface along the tunnel kidneys and reducing the compression of clay material on the TBM shield.

The coming TBMs, are all factory provided with pre-drilled holes for hydrodemolition to cope with these exceptional conditions, designed for cases where thrust values around the shields are excessive.

Figure 5. Nozzle detail and distribution on the shield in cociv radimero TBM.

2.5 Continuous mining system

One of the main limitations in the performances of the single shield TBMs is that its cycle of advance foresees to alternate the excavation with the segments erection. The Continuous Mining System instead allows the segments erection of the ring during the boring stroke, with a consequent decreasing of the cycle time. This requires the TBM to be equipped with adequate thrust cylinder stroke (about 3.1-3.2m for 1.8m long segment) and an intelligent steering control system that keeps unchanged the position of the center of thrust of the TBM. This is possible thanks to the PLC adjusting the pressure of the cylinders when some are retracted for ring building. The number of segments installed while the TBM is boring may vary from 3 segments to the full ring depending on the penetration rate of the machine. The Continuous Mining system, as prepared, allows the ring assembly to begin when the TBM has excavated about half of its advance stroke, installing part of the segments simultaneously with the excavation of the second half of the stroke. The decision to begin ring installation only in the second half of the excavation stroke made it possible to

contain the elongation of the thrust cylinders and thus the length of the machine shields.

The number of segments the TBM is able to mount “in shade” at the excavation stage varies according to the TBM’s speed; the slower this is, the more segments can be installed. The hourly output of the TBM increases in terms of meters/hour of advance by a percentage ranging typically from 20% to 30%.

In addition, the shorter TBM standby time between excavations allows for more continuous shield advance, a very important factor in crossing critical areas to avoid shield entrapment and to reduce face instabilities.

In conclusion, the combination of higher productivity and shorter stand-by times significantly reduce the operating hours of the TBM and consequently the working hours of its electromechanical parts, reducing the need of maintenance of the parts themselves.

2.6 Reinforced shields

Another critical factor for the TBMs operating in clay as the ones of Palermo-Catania project, is to accommodate the special condition of anisotropic loads on the shields, with anticipated pressures reaching up to 15 bar under static conditions.

Three distinct scenarios, as illustrated in Figure 6, have been meticulously examined and designed for the shields, with particular focus on the tail shield.

In Scenario 1, we have considered the potential presence of horizontal thrusts surpassing vertical thrusts. The value under consideration is $K0 = 1.5$, representing the maximum value observed in hydraulic fracturing tests.

Similarly, in Scenario 2, we have considered the possible existence of voids in the crown area and/or along the excavation profile. In this scenario, thrust

does not engage certain sections of the shield. Due to the presence of these voids, the shield will remain unconfined, allowing for free outward deformation.

Lastly, in Scenario 3, we have accounted for the potential presence of voids in the crown area and/or along the excavation profile. Here, the thrust does not affect specific portions of the shield. As with the previous scenario, the shield is not constrained due to the presence of voids, permitting unrestrained outward deformation.

The three load conditions described above led to the joint choice with the TBM manufacturers for a Q690D type steel (yield strength ≥ 690 MPa, ultimate tensile strength 730-940 MPa) with a tail shield thickness of 70/80 mm, reinforced with 30 mm thick ribs, arranged both longitudinally and in cross-section as depicted in Figure 7.

Figure 7. Tail shield: in yellow highlighted the internal reinforced ring 30mm thick.

Figure 6. Three different load scenarios for shield dimensioning .

2.7 Extended sensors for preventive maintenance

The TBMs will be provided with an extensive amount of sensors, controlling critical components such as main bearing seals, lubrication oil, main drives reducers and electric motors, VFDs, hydraulic pumps, cutting tools, critical parts of the belt conveyor system. The information provided by these sensors, will be elaborated by a specific software (named “S.M.I.L.E.”), that is being introduced by Webuild with the target of facilitating the maintenance of the TBM and conveyor systems and automatically elaborates a complete planning of the maintenance interventions based on the actual operating cycles and sensors data of the machine.

Making use of the most recent technologies of the digital world (Internet Of Things, Digital Twin, Big Data, Artificial Intelligence and Machine Learning) is able to provide a practical and simple tool that allows to schedule daily, medium-long term and extraordinary maintenance, reducing drastically the failures that stop the production process. The software is used for the maintenance of the TBM and Backup System, the Tunnel Conveyor and the Cutterhead. A full integration with the already existing Weview web platform (also developed by Webuild) is guaranteed, from

Figure 8. Main families of sensors on the TBM and belts: 1-cutting tools; 2 gear and lube sensors; 3 void detection; 4 belt system; 5 gas sensors.

which to collect the operating & sensors data of the TBM and to which send the maintenance reports for the creation of the database and the relative inspection and maintenance sheets.

The three types of maintenance can therefore be properly planned and by doing so anticipate/prevent the failures that could stop the entire excavation process:

- Preventive Maintenance: programming of Interventions performed at regular time intervals or when a certain usage threshold is exceeded;
- Predictive Maintenance: correct/fine tune the preventive maintenance program considering the operational and sensors data of the TBM;
- Corrective or extraordinary maintenance: by analysing the operational and sensors data will also detect when a component is near to fail and automatically instruct an extraordinary maintenance intervention before of a catastrophic failure occur.

2.8 Gap monitoring

During mechanized excavation operations in the geological formations being traversed, an important feature planned in the shields are extensometers (fontimeters) and additional pressure cells in the three shields that make up the entire TBM.

Three pressure sensors and three extensometers are equipped on each shield - front, middle, and rear - to provide crucial data to the machine operator or the supervising engineer during excavation phases, such as monitoring over-excavation (through the extensometers) and increasing pressure on the shields (via the pressure cells).

In each shield, three extensometers are positioned just behind the excavation chamber: one in the center at 12 o'clock, the second on the right at 2 o'clock, and the third on the left at 10 o'clock. The extension of each individual piston is 500mm in the front shield. The extension of the extensometers in the middle and tail shield is 150mm because at this distance from the excavation face, a less extensive void presence is expected as increasing the distance from the excavation face results in reduced over-excavations.

The additional pressure cells, three for each shield (front, middle, and tail shields), are placed near the extensometers, in the positions previously mentioned.

Figure 9. Fontimeters along the shields and detail.

2.9 Exceptional thrust and active articulation

To facilitate efficient and uninterrupted excavation operations with TBMs in the planned squeezing clay soils, particularly those in Sicily, as well as all other machines used in Webuild projects throughout Italy, we have specified two levels of primary thrust from the TBM suppliers. The first level is intended for standard operation, while the second level is meant for unlocking the TBM in case it becomes stuck due to squeezing on the shields.

Additionally, each TBM is equipped with an active articulation system for the front shield. This system serves to enhance the machine manoeuvrability and, when required for inspection or replacement of excavation tools like cutters, rippers, or scrapers, allows for the retraction of the front shield and the cutting head.

In the Palermo-Catania project (excavation diameter 9.32/9.48m), for instance, the primary thrust is distributed among no.42 thrust pistons (no.21 pairs) with diameters of 300/240mm (casing/rod) and a stroke length of 3200mm. These pistons act upon the 7 segments comprising the precast ring, with 3 pairs assigned to each segment. As for the active articulation, it comprises 16 cylinders with diameters of 420/300mm (casing/rod) and a 350mm stroke.

The total thrust values are summarized below:

- Total Thrust at maximum operating pressure: 118792 kN @ 400bar
- Total exceptional thrust for shield unlocking (Emergency): 163201 kN @ 550bar
- Maximum Articulation Thrust Cylinder Force: 77584 kN @ 350 bar.

2.10 High viscosity lubricant injection capability

In order to minimize the risk of the shield entrapment due to downtime, a further enhancement has been considered through the possibility of lubrication of the shield mantle with bentonitic mixtures, improved in terms of effectiveness and redundancy through three sections of nozzles uniformly distributed along the circumference, able to limit soil convergence in place, especially at soils that have a particular predisposition to this phenomenon.

Studies and tests have been carried out together with La Sapienza University of Rome to use a high

viscosity lubricating mixture and with the TBM manufacturers to set up the necessary injection systems. This solution ensures better lubrication of the shield by further decreasing the friction and counteracts subsidence, as far as possible, before the injection of the backfilling mortar.

Figure 10. Tests on high density lubricating mixture.

2.11 Services extension time reduction

Together with the “special features” designed to let the TBM passing through the tunnel sections, where a high squeeze ground behaviour is expected, there is a series of improvements on the extension of the services lines which contribute to reducing downtime.

Those are related to:

- Increase of the capacity of the conveyor belt cassette up to 1500 m belt storage
- Increase of the capacity of the ventilation duct cassette at the TBM’s back up, up to 200 meters duct storage
- Optimization of the HV cable extension in the way to install the fixed cable that feeds the TBM together with the temporary cable of the back up cable reel
- Increase of the capacity of the hose reel at the TBM’s back up, up to the double of the standard storage capacity
- Introduction in the back up of a dedicated platform that allows the extension of the tunnel pipes easier, faster and safer by means of lifting hoist.

The above measures have the target to avoid impacting heavily the TBM production cycle and reduce the downtime specially in the most critical zone, where the ground have highly squeezing behaviour and the TBM needs to pass through quickly.

2.12 Dealing with gas

In consideration of the geologic formations and the risk associated with the presence of gas, it has been necessary to design the TBM and other tunnel equipment in an ATEX configuration and in accordance to local Italian regulations (NIR 44), which defines the specifications for the advancement of mechanized excavation in presence of gas in the rock mass. Based on Cociv Radimero experience, a dual aeration and air intake system is foreseen. The aeration

system enables uncontaminated pressurized air to converge inside the excavation chamber and into the frontal area of the TBM, allowing dilution of the methane concentration.

Figure 11. Air circulation in atex TBM.

The suction system is designed to extract contaminated air no longer into the tunnel belt duct (which often causes the TBM to stall) but directly outside the tunnel via an isolated and dedicated pipe. This solution ensures room compartmentalization by creating a flow path in the tunnel that is hydraulically isolated from the surrounding environment.

3 CONCLUSIONS

The paper highlights several significant innovations that have been introduced, often based on recent experiences within the Company Group. These innovations are designed to mitigate the risk of machine blockages in challenging conditions, such as those arising from soil squeezing, high overburden, and gassy soil. However, the success of the upcoming projects, which must be compliant to the tight schedule mandated by the European Community, will also heavily rely on effective project management.

Engineers, geologists and specialists on site, armed with machine data and geological information, will be tasked with meticulously planning the advance of the Tunnel Boring Machine. This includes identifying the most suitable areas for planned stoppages and harnessing the additional features integrated into these new-generation TBMs.

ABSTRACT: Tunnel boring machines (TBMs) have gained considerable attention in recent years due to an increased demand from investors and mine owners to deliver mining operations at the earliest possible timeline, along with increasingly demanding environmental restrictions and global health and safety trends. The TBM has been used to address different objectives in mining projects, such as access to ore bodies or mining areas, water supply and exploration. Several technical and financial parameters should be considered in the selection of the right TBM type and method statement. One of the most important design parameters is the gradient of the tunnel, especially in access tunnel planning and development. In circumstances where ore bodies occupy either a high depth from the surface or in mountainous areas, the vertical alignment of planned mine access tunnels may have a relatively high gradient. Addressing the issues around these high gradient requirements creates unique TBM design and planning challenges. This paper briefly reviews several recently executed and studied tunnelling projects using current TBM technology. The findings will assist mining industry clients, consultants and contractors when evaluating TBM applications in future projects.

Keywords: Tunnelling, TBM, Mining, High gradient

1 INTRODUCTION

There is currently an increasing focus amongst investors and mine owners to consider the utilisation of Tunnel Boring Machines (TBMs) in mining projects. This can be explained by the capacity of this tunnelling system to deliver rapid and safe ore body access, which in turn can secure early project revenue generation.

Table 1 presents a list of projects where TBMs have been used to construct tunnels for access, conveyance, drainage, exploration and water diversion purposes for new and existing mines (Brox, 2013).

The application of TBM tunnelling systems requires that the following technical areas be investigated to achieve the benefits of rapid TBM excavation. These areas include:

- Geological and hydrogeological conditions
- Site access roads

- TBM assembly and disassembly
- Tunnel alignment and gradient
- Contractor experience
- Project schedule and procurement
- TBM size
- Tunnel support and lining
- Muck disposal and transport system
- Logistics

Tunnel alignment and gradient remain one of the most important technical areas in mining project evaluation. In circumstances where ore bodies occupy either a high depth from the surface or in mountainous areas, the vertical alignment of planned mine access tunnels may have a relatively high gradient.

This paper briefly reviews several executed and recently studied tunnelling projects using current TBM technology. The findings may assist mining industry clients, consultants and contractors when evaluating TBM applications in future projects.

2 SOME EXAMPLES OF EXECUTED PROJECTS

The history of TBM tunnelling for mine exploration and access tunnels started more than fifty years ago with the Step Rock Iron Mine in northwestern Ontario, Canada. After the earliest applications and attempts of TBMs in mining operations (often using machines not originally or specifically designed for mining projects), the mining industry has witnessed more successful TBM applications. A significant amount of experience has been gained over the last three decades, with an increasing willingness of the

* Planned TBM excavation.

manufacturers to design TBM machines specifically suited for mining operations. Some more recent TBM applications are considered below;

2.1 The grosvenor decline tunnel, Australia

The Grosvenor Decline Tunnel is a metallurgical coal project owned by Anglo American in Moranbah, Central Queensland, approximately 180km southwest of the coastal port city of Mackay and about 1,000km north of Brisbane (Scialpi, Ofiara, 2013).

The Grosvenor Coal Mine considered two decline tunnels, creating mine access to the shallowest coal seam depth at 130m. Longwall panels are 300m in width with lengths up to 6,200m. The first decline tunnel is used for the transportation of coal from the longwall to the deposit area on the surface, while the second decline tunnel is designed to transport staff and machinery (Figure 1).

Both decline tunnels are approximately 1,000m in length with a gradient of 1:6 or 16.7%, see Figure 2 (Tunnel Talk website), approximately 9.5° for the conveyor drift and 1:8 or 12.8%, approximately 7° for the transport drift. Except for the vertical curve (400m radius) between the assembly area on the surface and the launch tunnel, there are no curves along both drifts' alignments.

Figure 1. Plan view of conveyor and transport drifts.

Figure 2. Long access tunnel is at 16.7% incline.

Each drift has an internal diameter of 7.0m and consists of a steel-fibre-reinforced concrete segmental lining (universal ring in 5+1 segments).

The TBM decline tunnels at the Grosvenor Coal Mine are designed to be “blind headings”, i.e., excavation ceases when the TBM reaches the coal seam. The TBM developed one tunnel at a time and must be retracted back up the slope through the pre-cast concrete-lined tunnel it has just completed. The TBM must be retracted quickly so that continuous mining machines can access the coal seam to begin the follow-on mine development work. The TBM is also needed to begin excavation of the second drift as soon as possible. Both drifts need to be completed and cleared to allow effective mine development work to proceed.

The Grosvenor Earth Pressure Balance (EPB) TBM design incorporated special features to allow quick demobilisation in a “blind heading” without the need for a large disassembly chamber. Underground disassembly on the steep gradient would have been difficult, costly and time-consuming due to the mine’s strict roof support requirements for such a large chamber.

The Grosvenor Project was successfully completed and proved that TBMs are well-suited in mining operations for main access and conveyor haulage tunnels as well as ventilation tunnels, offering numerous advantages compared to drill and blast or road header excavation tunnelling methods, such as

- improved personnel safety;
- higher advance rates;
- better precision and control;
- improved ventilation;
- smoother tunnel profile; and,
- reduced ground disturbance and ground support.

2.2 *The Monte Giglio incline tunnel, Italy*

This tunnelling project involved the construction of a 9,500m tunnel for the installation of a conveyor belt linking the “Colle Pedrino” quarry to the new cement production factory of Calusco D’Adda in Bergamo (Busillo et al., 2006). The tunnel portal was located in the area of the Monte Giglio quarry near the cement factory. The tunnel route has a gradient of 6.2° for approximately 850m, a shallow rise of 0.5° to 1.25° for approximately 5,800m and a final sharp rise with an ascending slope of up to 11.86° for approximately 2,900m. The tunnel was bored using a double-shielded Robbins TBM with a diameter of 4.88m and was lined with 200mm hexagonal-type pre-cast reinforced concrete segments.

2.3 *Parbati H.E. incline tunnel, India*

The project consisted of boring two inclined pressure tunnels of the Parbati-II Hydroelectric project by one double shield TBM. The project consists of 1,546m

twin tunnels with a finished diameter of 3.5m, each with an incline of 30° (Khali et al., 2013). The TBM could excavate through rock at steep inclinations but also install the tunnel lining with hexagonal-shaped pre-cast concrete segments mechanically. Figure 3 shows the breakthrough (ITA newsletter, 2008).

Figure 3. Breakthrough in inclined pressure shaft with TBM.

2.4 *“Linth-Limmern” (KLL), Switzerland*

The AXPO power station Linth-Limmern built between 1957 and 1968, is located in the Swiss Alps, at Glarus” south of Zürich (Burger, 2012). The existing plant, approximately 300 MW, was modified and extended to a pump storage plant with an additional capacity of approximately 1,000 MW at peak power. The new underground powerhouse was positioned close to the existing dam reservoir at 1,850m above sea level and connected to the natural but now extended lake Muttsee, at approximately 2,450m above sea level. Part of the connection was the two new, 1km long inclined pressure shafts of 5.2m excavated diameter at a gradient 40°. The Gripper TBM was assembled in the horizontal position and moved to the launch position onto a ramp with a 14° incline. The final shaft inclination, 40°, was then achieved by a TBM-bored vertical curve with a radius of 150m (Figure 3).

2.5 *Snowy 2.0 project, Australia*

Snowy 2.0, a major pump-hydro expansion of Australia’s renowned Snowy Mountains Scheme, is underway, with tunnelling to commence. The majority of the tunnels on Snowy 2.0 will be constructed by TBMs, including a pre-cast segmental lining support system (Snowyhydro website). Figure 5 shows a schematic profile of the plan (Energymatters website).

The remainder of the underground works, including the access tunnels, shafts, and power station complex, will be constructed by a drill and blast method. Future Generation, the client, has procured

Figure 4. A view of gripper TBM.

three single-shielded TBMs for the construction of the Snowy 2.0 underground works, including two open-mode and one dual-mode machine. The TBMs will have a nominal excavation diameter of 11m and will be compatible with a common concrete segment geometry.

Whilst relatively similar in this regard, the challenges faced by each TBM differ substantially due to the respective tunnel arrangements, construction strategies and anticipated ground conditions. The second TBM to commence excavation is supplied by Herrenknecht, and will excavate a 2.7km long emergency, cable and ventilation tunnel, which will access the power station complex parallel to the main access tunnel. Beyond this point, the TBM will continue its drive up a 25° inclined pressure shaft to the upstream surge shaft before continuing into the western portion of the headrace tunnel.

Figure 5. Snowy 2.0 scheme.

3 SIMILAR TBM PROJECTS BY SOUND MINING GROUP

Sound Mining Solution (Proprietary) Limited (Sound Mining), in collaboration with Project Managers and Design Engineers Limited (PMDE), assisted two different clients by providing professional consulting services for Preliminary Feasibility Studies (PFS) which considered orebody access by TBMs. The two case studies are considered further.

3.1 TBM for twin decline access tunnels

Inspired by the Grosvenor decline tunnel in Australia, mechanised tunnelling by means of a TBM has been considered for developing twin decline access tunnels in an underground Iron Mine Project.

In consideration of the design approach, the geometry and dimensions of the orebody, including shape, size, dip, strike, depth and extent of the orebody, are critical parameters for mine design purposes. An oblique view of the orebody under consideration is presented in Figure 7. It shows views looking northeast (almost perpendicular to the strike) and a side view with approximate dimensions. Sublevel caving (SLC) was selected as the preferred underground mining method.

All required TBM studies have been completed at a Preliminary Feasibility Study (PFS) level. The TBM tender has been awarded, along with the selection of the EPC Contractor to execute the project.

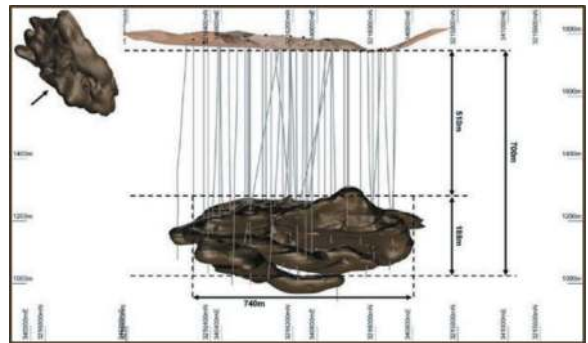

Figure 6. Generalised views of the underground orebody.

3.1.1 Tunnels geometry and alignment

Different alternatives were considered to access the underground orebody. One of the alternatives considered was implementing a twin decline tunnel system. An alignment (route) of the decline system was designed and is presented in Figure 8.

Figure 7. Plan view schematic of twin decline.

In order to design the decline route, the following parameters were carefully considered:

- geometry and location of the orebody;
- stope and development designs;
- crusher(s) position;

- position of the existing portal; and,
- Maximum gradient of 16% for the decline tunnels.

It should be noted that the start coordinates of the declines were considered fixed points due to the previously excavated tunnel portal.

Different options for designing the twin decline tunnels were investigated and considered in the following steps:

- development of the mine design criteria;
- design of the stopping (production) area in the orebody;
- design of the underground infrastructure to link all the underground tunnels and excavations;
- design of the access underground from the surface.

The twin decline's cross sections are illustrated in Figure 9.

Figure 8. Cross section of twin decline tunnels.

This consists of a conveyor decline equipped with a conveyor belt and a maintenance roadway adjacent to the conveyor belt. The maintenance roadway is wide enough to accommodate a utility vehicle which will transport conveyor belt spares, tools, equipment and maintenance personnel. The conveyor decline will transport the rock from the mining area to the stockpile area on the surface. The second decline tunnel (service decline) will be designed at a 7m diameter to transport personnel, equipment, machinery logistics and support ventilation requirements.

Figure 10 Provides a profile view of the declines.

Figure 9. Profiles of the decline tunnels, mechanized section.

3.2 TBM for an incline ore conveyor tunnel

Inspired by several incline tunnels worldwide, TBM tunnelling has been selected for an Ore Transfer Tunnel excavation. This was a separate project in a very different international locality, and the project scope focused on providing the shortest possible access route to transport the mined ore from the deposits down from higher elevation mountainous areas to lower elevation areas where the ore would be discharged onto the designated stockpile areas. In order to navigate the environmentally sensitive areas on the surface, it was decided to investigate the use of an underground tunnel between the deposits at the top of the mountain and the low-lying areas.

The selected access design is a 7.5 m internal diameter underground tunnel equipped with a conveyor belt to transport 34 Mtpa (Million tonnes per annum) of mined ore from the deposits at the top of the mountain to the low-lying area. It has been assumed that all heavy-duty and large equipment would be transported on the surface via the construction roads.

Various technical areas were identified during the scoping of the PFS and formed the basis of the scope of work. These included:

- Tunnel geometry and cross-section
- Geology and geotechnical studies
- General method statement
- Portal designs
- Tunnel Boring Machine (TBM)
 - o TBM selection
 - o TBM backup system requirements
 - o TBM launching structure design
 - o TBM ventilation system
 - o TBM assembly and disassembly plans
 - o Muck handling
- Tunnel lining and inlay segments design, including waterproofing
- Tunnel Services
 - o Tunnel power supply
 - o Compressed air supply
 - o Industrial water supply
 - o Tunnel drainage system
 - o Tunnel ventilation
- Site mobilisation plan
- Risk assessment

3.2.1 Tunnels geometry and alignment

Several alternatives for the tunnel alignment were studied, and the finally selected characteristics at the PFS design stage are as follows:

- The tunnel will be a single tube with no transfer point or cross passages along the route.
- The tunnel length is about 5km.
- Vertical alignment will be according to the variable gradients from the Lowland's Portal 0.5°, 6° and 15°, see Figure 10.

Figure 10. Longitudinal profile of the tunnel.

- Horizontal alignment will be rectilinear with no curves at the ends.
The final cross-section of the tunnel is presented in Figure 11. According to execution and operational requirements, the final diameter and excavation diameter will be 7.5 m and 8.3 m, respectively.

Figure 11. Cross section of the tunnel.

3.2.2 General method statement

Three principal alternatives for the method statement were identified as described below:

- Alternative I: Tunnel construction by one shielded TBM (Length = 5,030m). In this alternative, a dual-mode TBM, which can work in closed soil, will be the optimal choice.
- Alternative II: Tunnel construction from two working faces by one shielded TBM (Length = 3,645m) from the tunnel inlet and conventional method (Length = 1,385m) from the tunnel outlet.
- Alternative III: Tunnel construction by one Gripper TBM (Length = 5,030m). Depending on waterproof requirements, two sub-alternatives with or without cast in place for concrete lining is considered

A study was compiled on these alternatives for the method statement describing and discussing key comparisons. For this exercise, no constraints around the project were assumed. This approach assisted the project team to consider all possible method statements at the PFS level. The TBM was assumed to be the main excavation equipment for the tunnel. A Multi-Criteria Analysis (MCA) was used to compare the alternatives and select the optimal option.

The following principal goals have been targeted to select the optimal alternative:

- Minimise the construction time
- Minimise the total project costs
- Minimise the impact of the construction on the environment
- Maximise the technical adequacy (directly related to the reduction of the construction time)

As a preliminary result, Alternative I was selected as the basis for further studies at the PFS level.

4 CONCLUSIONS

The main advantages of TBM tunnelling compared to drill and blast or road header excavation (conventional/traditional methods) are:

- Higher advance rates by TBMs;
- Successful excavation through heterogeneous and loose rocks by using the correct TBM type;
- Successful excavation of hard to very hard rocks like Quartzite;
- Their optionality to manage groundwater control at the tunnelling face through closed-face TBMs and heavy-duty drainage pumps in the tail shield area;
- Improvement in health conditions for workers by providing a safe place in the shield, along with the support benefits of concrete segmental lining erection;
- Better ventilation control; and
- Smoother tunnel profile and clean working environment.

The main disadvantages of the use of TBMs for mining projects are as follows:

- High initial investment for the TBM purchase or for the modification requirements for the second-hand TBMs, along with their supporting logistical systems, including concrete moulds and transport systems, etc;
- TBM tunnelling should be considered as a separate project itself within the mining project programme, which needs to be carefully managed by specialists with TBM insight;
- Long lead times are required for TBM projects; this includes site establishment at the job site (12 to 14 months), TBM installation (2 to 3 months) and finally, TBM commissioning (1 to 2 months);
- The circular shape of TBM excavations creates their own design constraints when compared to conventionally excavated tunnel shapes.
- In circumstances where one TBM is being used to excavate two tunnels, it is necessary to consider two separate assembly and disassembly operations;
- Similarly, when using one TBM to excavate two declines, it is necessary to order a spare set of TBM shield skin due to burying the first set into the

ground if using one TBM only to excavate the twin declines.

TBM tunnelling systems can be viable technoeconomic alternatives to conventional tunnelling approaches in mining projects. The TBM must be designed for the tunnel route's ground conditions.

ACKNOWLEDGEMENTS

The authors thank Sound Mining Solution (Pty) Ltd (Sound Mining) for their support of this project.

ABSTRACT: Soil conditioning is critical for optimising the performance of Tunnel Boring Machines (TBMs), especially in complex ground conditions such as those experienced at the Silvertown Tunnel Project, a 1.4 km long twin-bored tunnel under the Thames in London, excavated with a 12-meter diameter Earth Pressure Balance (EPB) machine by Herrenknecht. Mixed geology, which consists of various soil types with different properties, poses significant challenges to TBMs due to variations in soil composition, strength, and water content along the tunnel alignment. Soil conditioning techniques are employed to enhance the properties of the soil and improve its excavation properties. Foaming agents, or “Foams” are branded by type, some are dedicated for excavation through cohesive soils, while some foam types are relatively more efficient for heterogeneous ground. Other polymers can be considered emergency measures for the optimal management of mixed geology mining. Foams are injected into the soil to reduce its density and permeability, making excavation operations more efficient by reducing the resistance encountered by the TBM’s cutting tools. Selecting the appropriate foam for soil conditioning is crucial to optimise TBM performance, meaning that the best results are obtained with efficient cooperation between the chemical supplier and the contractor. This study highlights the critical role of foam additives for soil conditioning in optimising the TBM performance for the Silvertown Tunnel Project, by comparing the adaptation of two different foams in specific geological conditions. Valuable insights have been gained regarding their effectiveness in reducing soil resistance and improving the overall performance of the TBM. The findings emphasise the importance of selecting the most suitable foam and adaptable strategy for each geological section of the tunnel alignment. The success experienced in the Silvertown Tunnel project is thanks to foam conditioning strategies, enhanced by support from supplier’s collaboration since the preliminary stages of the project.

Keywords: Soil Conditioning, Tunnel Boring Machines, Tunnelling, Silvertown, EPB-TBM

1 INTRODUCTION

TBMs play a pivotal role in underground infrastructure construction, permitting efficient excavation through various geological conditions. One of the central factors influencing EPB operation performance is soil conditioning, a process aimed at developing the properties of the excavated soil, enabling improved extraction, transportation, and disposal. This paper discusses and explores the role of soil conditioning regarding performance, particularly the use of foaming agents in assisting TBM performance, with a specific focus on data from the Silvertown Tunnel Project. The complex geology with diverse properties encountered during the drives posed unique challenges for soil conditioning, requiring a dynamic approach and constant input from contractors and support from the chemical supplier.

The Silvertown Tunnel Project, a new twin-bore road tunnel under the Thames, will be the

first in London in over 30 years. Serves to improve cross-river public transport, improving the reliability and resilience of the wider road network. Data from this project functions as an ideal case study for investigating the effectiveness of different soil conditioning agents and related strategies to enhancing TBM performance in diverse geological conditions.

The research presented in this paper aims to contribute to the knowledge base of TBM performance optimisation and soil conditioning techniques. It provides an in-depth analysis of the performance of four different foams from two suppliers in the application at Silvertown Tunnel Project’s specific geological conditions. Valuable insights are gathered from this comparative study, shedding light on the effectiveness of these foams in reducing soil resistance and enhancing overall performance.

Figure 1. Silvertown break through southbound.

Soil conditioning is an essential element in the successful execution of tunnelling projects employing TBMs. Its significance arises from the intricate practice of modifying soil properties using various agents, such as foaming agents, polymers, or water, to facilitate excavation. The capacity to significantly diminish soil resistance is at the core of its importance, by modifying the soil's characteristics, particularly its density and permeability, flowability and also compressibility (Herrenkecht et al, 2011) should be taken into consideration, inevitably conditioned soil becomes more susceptible and responsive to excavation.

This reduction in resistance minimises the wear and tear on the TBM's cutting tools. Substantially enhancing the tunnel construction efficiency and allowing progress to run more smoothly and faster is advantageous on multiple fronts, reducing project timelines and curtailing energy consumption, resulting in reduced operational costs. Additionally, soil conditioning plays a pivotal role in extending the operational lifespan of TBMs and, in turn, reducing maintenance requirements. Given these machine's intricate nature and costliness, this aspect is of utmost importance and can translate into considerable financial savings over a project lifespan.

2 SILVERTOWN TUNNEL GEOLOGICAL CONTEXT

The geological profile along the alignment of the Silvertown Tunnel exhibits significant variation in ground conditions. It is composed of River Terrace deposit, a medium dense to dense slight clay, sandy to very sandy, angular to rounded, fine to coarse flint gravel with occasional cobbles; London Clay, a 100% clay mineral, plastic, stiff and sticky; Harwich formation, silty sand with gravel and cemented beds, fine-grained sand with varying proportions and pebble beds. Finally, the Lambeth Group includes Woolwich Formation laminated beds, lower shelly clay, and Reading Formation with lower mottled clay (Figure 2).

In summary, the varying geological scenarios along the tunnel alignment demonstrate a complex

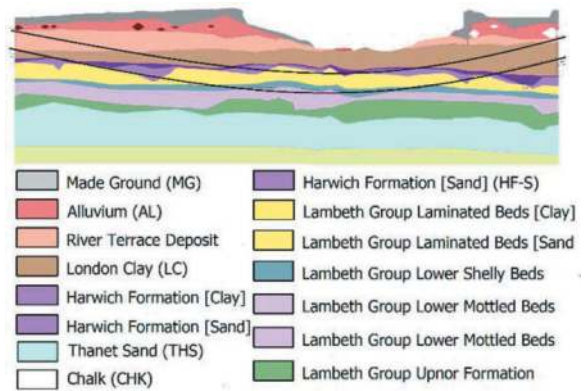

Figure 2. Geological cross section.

interplay of soil types and properties for the different formations. These diverse ground conditions necessitate careful consideration and selection of soil conditioning techniques, including the use of foaming agents, to assist the TBM operations.

2.1 Geological scenarios

The varying proportions have been categorised into distinct scenarios along the tunnel alignment. The scenarios have been strategically considered to align with the changes in soil composition, consistency, and the presence of specific geological profiles along the chainage. This deliberate approach serves a twofold purpose; facilitating a more precise interpretation of the data for the study and enhancing our understanding of the performance within the specific geological context. The data was analysed across six studies to capture the difference in foaming agents across the twin tunnels, by further tailoring the scenarios to match the geological conditions, we can draw more meaningful insights and conclusions about how the TBM behaves in response to the variations in the geological profile.

2.1.1 Scenario 1

Chainage 1240 – 1340, there is a predominance of River Terrace Deposits, with a lower amount of London Clay, this scenario features sandy gravel with low cohesive fraction and high permeability conversely, the presence of cohesive soil with excellent permeability values add complexity to the ground condition.

2.1.2 Scenario 2

Chainage 1340 – 1420, As we move into Scenario 2 the ground conditions become more mixed with a progressively decreasing presence of River Terrace Deposits, increasing presence of London Clay, and lower presence of Harwich Formation and Woolwich Formation.

2.1.3 Scenario 3

Chainage 1420 – 1530, London Clay becomes the dominant geology feature, accompanied by Woolwich

Formation Laminated Beds, the Harwich Formation is less prominent in this scenario, further emphasising the transition towards London Clay-dominated ground conditions. This section exhibits stiff and sticky silty sand with clay and is characterised by angles of shearing resistance and cohesion intercepts within specific ranges.

2.1.4 Scenario 4

Chainage 1530-2250, is marked by the predominance of Woolwich Formation Laminated Beds. This geological formation is composed of silty sand with clay, with relatively high angles of shearing resistance and minimal cohesion intercepts. However, the presence of the Harwich Formation and Woolwich Formation lower shelly clay introduces variability in ground conditions within this section.

3 IMPACT OF MIXED GEOLOGY ON TBM PERFORMANCE

Mixed geology in tunnelling projects introduces various challenges, through ranges in soil composition, strength, water content etc (Oliveira et al., 2017; Shirlaw, 2016). The soil composition can undergo significant shifts along the tunnel alignment, encompassing clay, sand, gravel, or combinations of geological ratios. Each soil type unique properties impact the TBM performance differently, requiring the careful selection of soil conditioning techniques, products and approaches to address the encountered soil types effectively. Additionally, merged variations in soil strength present shifting circumstances, with some sections featuring cohesive soils possessing high shear strength and others holding weaker or less stable soil layers. Managing these fluctuations in soil strength requires dedicated real-time monitoring and operational adjustments to maintain face stability (Anagnostou et al, 1996) and excessive wear issues.

Mixed geology can naturally affect the content of water and bring about dramatic changes, varying between well-drained, drier soils to submerged or saturated sections. Excessive water content presents difficulties, such as over-excavation, settlement and instability, requiring careful control and management of pressure differentials to uphold excavation efficiency and assist soil transportation and storage (Pixoto et al, 2017). TBMs deployed in such conditions must be capable of managing these challenges to maintain operations, for the geology encountered by adapting the parameters and soil conditioning strategies. Certainly, successful navigation of mixed geology hinges on multiple factors, such as real-time monitoring and effective planning, however, the importance of soil conditioning adaptation cannot be emphasised enough for successful TBM operations, inevitably ensuring the integrity of the project.

4 SOIL CONDITIONING WITH FOAMS

Soil conditioning on TBMs encompasses several critical aspects. Firstly, it involves modifying the soil's inherent properties, including cohesion, density, and permeability, to render it more suitable for extraction, thus, effectively transmitting the pressure in the excavation chamber and along the screw conveyor (Herrenknecht, 1994; Anagnostou and Kovari, 1996; Nomoto et al., 1999). For example, loose or granular soils may be compacted to support stability, while sticky cohesive soils are treated to alleviate adhesion and enhance ease of disintegration (Zumsteg et al, 2012). A principal component of soil conditioning is the reduction of soil cohesion, this has the potential to restrict TBM progress substantially. As cohesive soils are characterised by their tendency to adhere together, appropriate soil conditioning strategies must be adapted this includes the use of chemical agents, such as foaming agents or polymers, to diminish cohesion to transform the soil properties into a more easily extractable state. This transformation prevents the TBM from becoming clogged and immobilised and additionally minimises excessive wear on its cutting tools.

Benefits can also be observed from enhancing soil permeability, particularly relevant in instances where developed drainage and prevention of water ingress into tunnels is crucial. Soil conditioning agents are utilised to promote the permeability of the soil, assisting challenges during tunnelling associated with water ingress. Adapting to geological profiles is fundamental to this process, as different conditions demand tailored approaches to mitigate risk and manage the desired soil properties for efficient excavation. Therefore, soil conditioning agents and techniques are distinct to the unique geological characteristics encountered in each tunnelling project.

4.1 Silvertown foaming agents

During this project, two specific foaming agent types were employed, Foam 1 and Foam 2, utilised for the primary purpose of soil conditioning. These foams have been carefully selected and tailored to address the unique geological conditions encountered along the tunnel alignment. Foam type 1 enhances excavation efficiency in granular and heterogeneous ground conditions, where soils may mix sand, gravel, and other granular materials. Designed to reduce soil cohesion, allowing for smoother TBM advancement by mitigating resistance and wear on cutting tools.

Foam type 2 is for cohesive ground conditions, typically characterised by sticky and adhesive soils, such as clay-rich substrates. This foam is engineered to break down soil cohesion effectively, making the soil more workable and less adhesive. Facilitating efficient TBM progress in such challenging geological environments by reducing stickiness and enhancing soil properties. Choosing the appropriate

foam type for soil conditioning is a critical decision that impacts TBM performance significantly. This paper explains the beneficial partnership between the chemical supplier and the contractor in selecting the most suitable foam for each geological section of the tunnel.

Many other foam types are available such as high-expansion and low-density foams, environmentally friendly, biodegradable foams (Dal Negro et al, 2022), and polymer-based foams, each one addresses specific soil conditions as needed and offers adaptability and flexibility in soil conditioning strategies. This paper focuses on the use of Foam 1 and Foam 2 types along with the personalised strategies selected to assist the tunnel excavation and related performance in the distinct geological scenarios encountered along the tunnel alignment with respect to the project.

5 IMPACT OF FOAM SELECTION

The importance of selecting the appropriate foam type for soil conditioning in tunnelling projects cannot be overstated, as it significantly influences the efficiency and overall success of excavation endeavours. Several critical factors related to foam selection highlight its significance, Principal the foam concentration should be considered a central figure in determining how effectively the foam and related consumption alters the soil properties. Next, the expansion characteristics or foam expansion ratio (FER) is important for achieving the optimum soil conditioning effects without causing over-expansion that could lead to ground instability. Additionally, the appropriate foam injection ratio (FIR) or total foam volume proportional to the treated soil, supports efficient conditioning while curtailing waste and cost. However, it is also important to recognise the foam types are not standardised across suppliers thus, each supplier entails a unique formulation that impacts overall performance in different geological conditions. Therefore, specific factors are related to suppliers and foam type, such as foam stability, which is essential to maintain the conditioned soil properties over time, inhibiting soil reaggregation. The ability to control water content is also crucial, finding a balance with soil conditioning parameters ensures the stability of the ground and minimises the associated risks.

Furthermore, the flexibility to change foam selection to support the different geological conditions along the tunnel alignment can be beneficial for efficient extraction. This holistic approach to adapting foam selection contributes to cost-effective and safe tunnelling and can also align with environmental requirements to minimise the ecological footprint for soil conditioning activities. In summary, the educated selection of foaming agents and appropriate strategy for geological encounters is a multifaceted decision that directly impacts the outcomes of TBM tunnelling works.

6 COLLABORATION WITH CHEMICAL SUPPLIER

The relationship between the chemical supplier and the contractor in implementing soil conditioning strategies for tunnelling works is a beneficial and communicative process that develops across multiple phases. It begins during the tender phase, where the contractor seeks to collaborate with the chemical supplier. During this initial stage, the chemical supplier engages closely with contractors to understand the project's specific requirements, geological complexities, and performance objectives. This early involvement ensures that soil conditioning strategies are considered from the project's initiation, setting the requirements for bespoke solutions.

A key stage of developing this collaboration is a comprehensive laboratory testing phase. Here, the chemical supplier and the Contractor work together to propose and conduct rigorous tests, as discussed by EFNARC (2005), Peila (2016) & ASTM (2017) simulating the project's geological conditions. These tests evaluate the performance of various soil conditioning agents, such as foaming agents, in modifying soil properties. Collaborative data analysis and interpretation help the Contractor make informed decisions regarding selecting the most effective conditioning agents in the field.

Once the project is in construction, the chemical supplier provides valuable on-site support and training. This entails close cooperation with the Contractor's on-site team, including TBM engineers and operators, to ensure that selected foaming agents are applied correctly and at the appropriate parameters. Recommendations and training include equipment setup, safety protocols, and contingency measures to address unforeseen challenges during tunnelling. This continuous support and guidance foster a collaborative environment that ensures the effective implementation of soil conditioning strategies throughout the project's duration, ultimately contributing to its success.

Finally, effective soil conditioning often requires collaboration between the project's engineers and chemical suppliers. Chemical suppliers bring their expertise to bear in selecting the most appropriate agents and techniques tailored to the specific soil types. This collaborative effort ensures that the conditioning process aligns seamlessly with the project's objectives, schedules, and successful execution.

7 SOIL CONDITIONING EVALUATING PERFORMANCE

Advancement operations for TBMs are performed and guided by numerous parameters: speed, thrust, main-drive torque, screw torque, contact force and EPB pressures, as these values are indicative of the TBM advancement, they provide insight into the overall performance. Comparing this average data

for these parameters across geological scenarios may correlate results, highlight trends, and identify variations.

Relationships can also be identified between the TBM parameters and the soil conditioning parameters to indicate TBM performance, specifically with respect to the proportion of foam to soil, indicated by FIR percentage. Understanding this impact of FIR on the excavation advancement illustrates if higher volumes of foam are associated with enhanced progress for the geological conditions. Establishing the optimal foam-to-soil ratio should generate performance increases whilst supporting efficient excavation effects. Acquiring this balance is the objective, as this assists in minimising resistance and the efficient use of foam resources, noting that in the situation finding the balance is key it should be recognised for foam conditioning “more” does not always translate to an improved situation establishing an equilibrium is essential for excavation efficiency and foam consumption for well-conditioned soil (Figure 3).

Figure 3. Conditioned soil southbound drive.

To further illustrate the performance differences within the range of TBM and Soil conditioning parameters, calculations can be made to demonstrate normalised performance indications (NPIs) in the context of TBM advancement, resistance reduction and excavation efficiency. The use of these NPIs, in conjunction with direct observations, to assist with each performance assessment, emphasises how foam conditioning strategies can be tailored to different geological scenarios. TBM advancement NPI can be defined as the difference between thrust and main drive torque, used as an indication of resistance. Moreover, the ratio can

indicate how effectively the TBM is advancing through soils with reduced resistance, higher thrust and lower torque would be observed, and conversely, lower thrust and high torque may suggest increased resistance in the geological profile. An NPI for resistance reduction incorporates thrust, main drive torque and contact force, likewise providing value associated with resistance relative to the applied force providing a measurement of resistance reduction relative to applied force, a Lower ratio indicates reduced resistance reduction and contrariwise. An NPI for excavation efficiency includes values from multiple parameters to illustrate excavation efficiency, considering the cutterhead diameter, TBM speed, thrust and torque from the main drive, A Higher NPI may suggest that the TBM is achieving greater excavation progress for the energy and cutterhead size used.

8 COMPARATIVE STUDY OF FOAM TYPES

The paper uses data from both drives of the TBM, northbound nine hundred metres and southbound nine hundred metres, capturing the average TBM and related soil condition values across the opposing tunnel chainage for each advancement, divided into six studies enabling a systematic comparison of the foam types and suppliers in different instances. The data set captures 1.8 kilometres of tunnelling across the six studies, studies 2 and 4 are further divided into scenarios to give additional comparison with reference to the change in geology, we can also consider the difference in foam type and supplier (Table 1).

Table 1. Key study data.

Study	South Bound Advance	North Bound Advance	Scenario	Chainage
1	Supplier 1 - Type 2 (S1T2)	Supplier 2 - Type 1 (S2T1)	1	1252.6-1316.8
2	Supplier 1 - Type 1 (S1T1)	Supplier 2 - Type 1 (S2T1)	1 & 2	1316.8-1368.8
3	Supplier 1 - Type 1 (S1T1)	Supplier 1 - Type 2 (S1T2)	2	1368.8-1398.8
4	Supplier 1 - Type 1 (S1T1)	Supplier 2 - Type 1 (S2T1)	2, 3 & 4	1398.8-1756.5
5	Supplier 2 - Type 1 (S2T1)	Supplier 2 - Type 1 (S2T1)	4	1756.5-1872.5
6	Supplier 1 - Type 1 (S1T1)	Supplier 2 - Type 1 (S2T1)	4	1872.5-2154.3

All the results within the data sets have been analysed against one another, to obtain a clear

understanding and representative comparison, we can consider the data to have two areas of interest to directly associate to arrive at a performance-related conclusion in the comparison. Data values from the soil conditioning system; Consumptions of water and foaming agent, foam expansion ratio (FER) and foam injection ratios (FIR) and the data values from the TBM systems; thrust, main drive and screw torque, advance speed, penetration, cutterhead rotation contact force, EPB crown pressure.

9 CASE STUDY FINDING & DISCUSSION

Analysis of the data from the advancement average, NPIs and larger analysis values all show the same general trends associated with the FIR regarding the TBM parameters, namely thrust, main drive torque, speed, and pressures. Increasing FIR values show reductions in the discussed parameters, and, conversely, decreased values of FIR show increased values in the TBM parameters. This can also be demonstrated when comparing FIR, thrust and main drive torque values against the geological profile, in scenario 1, the average thrust and torque were the lowest, increasing when advancing into scenarios 2, then 3 and finally highest at scenario 4, the associated FIR values decreasing against this trend as the Thrust and Torque increase see Figure 4.

Figure 4. Average NPI 1 vs FIR, Study & Scenario.

As discussed, geological scenario 1 demanded a larger volume of water to support the extraction the EPB pressures were lower in this case, lower FER values were adopted, and given the lowest values for thrust, torque, and contact force, the related FIR

values were observed to be higher. As the geology changes to scenario 2, FIR values peaked along with the foam and water consumption, but this translated to the highest values in the screw conveyor torque. thrust torque, and contact force values, on average, increased. Moving into scenario 3, these values peaked, and FIR values dropped along with water and foam consumption. In scenario 4, contact force peaked, thrust and torque remained level, but the water consumption was at the lowest along with the screw torque. It is essential to keep in mind that this summary is a generalisation of the values across the different geological scenarios. Therefore, variability is an inherent aspect of these results due to a multitude of variables and factors that can influence these results in such complex conditions. It is important to recognise that data organisation can be a valuable tool to reduce variability, additional in the evaluation of the scenarios, the data was deliberately arranged by advancing speed, such as, 40mm/min by refining that narrowed data set, it was possible to carefully scrutinise the effect of the TBM parameter within the specific scenarios, allowing for a more precise evaluation.

Comparing the average data sets from each study and related scenarios given northbound and southbound advances, we see the variation in all parameters, a difference of the FIR ranging 8-35% is observed, and commonly the higher this difference, the higher the difference in TBM parameters (Table 2). Across the average data sets for the study and scenario, mostly, TBM parameters show differences however we do see some isolated cases where individual parameters are similar, but not all parameters within the set are the same. For example, in study two scenario one, north and southbound advances are the same for an average torque of 8.46MNm corresponding soil conditioning values show a 16% difference for FIR and a 56% difference for concentration, giving an extra 195 litres of foaming agent. In this case, the entire TBM parameters only vary by 10%, considering this, it would be expected that northbound with increased concentrations to show favourable results in performance, but this is not the case. We see an average thrust increase of 24% and an average increase of contact-force of 9%, albeit the advance speed is 4mm higher, this case illustrates, given that the foam type is the same, better performance can be seen from adjustments in the soil conditioning parameters and foam supplier, leading to an optimum balance translating to benefits in the TBM performance.

The trends clearly reflect how geological conditions cause variations in the TBM parameters and related performance. The soil conditioning strategy is intern adapted to support these variations; thus, the performance of the said strategies should be the difference between the northbound to southbound trends in TBM parameters, not the effect of the change in geology. The distinction in the difference can be directly attributed to the performance of these strategies, as the geological conditions are the same. If we deliberate the specific challenges posed by

mixed geology at Silvertown Tunnel, it is clear from the data that as the geology changes from study to study and, more importantly, across the scenarios, adapting the conditioning parameters is essential.

While different soil conditioning strategies were implemented from Northbound to Southbound drives, a consistent trend in TBM parameters emerges across the geological scenarios. Focusing on studies 2, 4 and 6, we see the same foam type 1 used opposingly, but from different suppliers in relation to the drives, supplier 1 for north-bound and supplier 2 for south-bound. Consider that these three studies are also representative of all the geological scenarios from 1 to 4, from the average data for these cases, the soil conditioning strategies vary from north to southbound. For the Northbound drive, the water used for the foam system was approximately 24-45% lower until geological scenario 4 was reached at this point, it remained 28% higher compared to the South. The foaming agent concentration followed a similar trend to the water consumption, given a 0.6% difference across the geology leading to a foam consumption average ranging from 336 to 714 litres per advance. The average FER values remained similar across all the scenarios at a 4.2 to 4.9 ratio, Hence, FIR followed the same trend as the water utilised, ranging on average from 69 to 44%. For the Southbound drive, we see a larger variation in the parameter values, with an average range in the water consumption of 14,837 to 42,877 litres, the trend showing a reduction in water consumption moving from scenarios 1 to 4. The concentration varied by

0.8%, with an average total foam consumption varying from 232 to 519 litres. Across the geology, the average FER and FIR varied by 52% and 68%, respectively. The approach to increase FER for granular profiles not only aids the increased FIR but is crucial for maintaining EPB pressure, face stability, water control, etc.

All the average TBM parameters apart from the screw torque are all lower for the southbound drive until study 4, scenario. 4, given that the speed was also lower until this instance, it is difficult to make an assessment for the respective drives and associate the variations in soil conditioning parameters and associate these changes to the difference in the TBM parameters across the two drives.

However, a unique situation presents to draw firm conclusions over a period of 114 advances, in study 4, scenario 4 and can give us an interesting insight into the soil conditioning strategies and related foam parameters as the average data for the TBM is almost the same in this occurrence, the TBM parameters align given very similar values apart from the screw torque. Given this situation, we isolate the supplier for foam type 1 and soil conditioning parameters to indicate contributions to performance. Table 3 indicates the average values across this instance, 28% difference in water consumption, 34% difference in foaming agent, 12% difference in FER, and 16% difference in FIR.

Considering these differences and the general trends discussed earlier for the association of FIR and TBM data, it would be presumed that an increased FIR and average additional foaming agent

Average Foam Water Pump [l]	20829	15770
Average Foam Consumption [l]	329	234
Average FER	4.8	5.4
Average Concentration	1.6%	1.5%
Average FIR	49%	42%

consumption of 95 litres would yield better performance for the Northbound drive, however this is not the case with reduced foaming agent consumption and FIR percentage but higher FER ratio for the geology in scenario 4 supplier 1 - foam type 1 resulted in equivalent performance apart from screw conveyor torque which showed a 30% improvement in performance. This ultimately illustrates that a better balance was achieved in the southbound drive as the data for the foam-to-soil ratio and consumption has provided the same performance from significantly reduced consumption and a more adaptive strategy form to the geological condition given the supplier and foam type.

10 CONCLUSIONS

The data analysis consistently shows a relationship between soil conditioning parameters and TBM advancement parameters, more specifically, the association of FIR can be related to thrust, main drive torque and face pressures. The increased FIR relates to reductions in TBM parameters, for some scenarios, this influence can be attributed to the predominance of cohesive soil. However, the question of improved performance for a given advancement is struck with a balance of the FIR to reach an optimum for each geological situation and the importance of the ability to adapt a tailored strategy. The FIR value is a figure based upon all the conditioning

parameters and this optimum value is dynamic in its approach within changing geological conditions.

As the performance of the TBM relies on the soil conditioning systems, generally, it is difficult to substantiate the related performance increase to a given foam, as there's more than one way to arrive at increased FIR and other soil conditioning parameters are important and must be deliberated. Therefore, the contributing factors should account for the required change in soil properties to enable efficient extraction. This approach is evident in the different strategies adopted for Northbound and Southbound drives. Considering the same TBM performance in the same geological profile but significant reduction in the soil conditioning consumption with on average 34% less foaming agent for 114 advances on the Southbound drive with foam type 1 from supplier 2. The challenges posed by mixed geology as Silvertown Tunnel highlights the significance of adapting the soil conditioning parameters to the condition of the geological profile. Moreover, the key understanding should be focused on the point of balance between TBM and conditioning parameters and proactively adjusting and fine-tuning the foam concentration, water consumption, and FER to reach the optimum FIR for a given geology to support extraction and enhance TBM performance.

Strategies for foam soil conditioning and related parameters should first consider geological conditions so that the appropriate foam type can be selected, it may be where multiple foam types should be considered in the case of mixed geology. Secondly, the selection of soil conditioning parameters should be constantly reviewed and optimised based on the geological situation and the required TBM performance. This process can be significantly improved if the suppliers and contractor take a collaborative approach, as each party has specialised knowledge that can contribute to beneficial outcomes. From laboratory testing, knowledge of technology and site support, the supplier's input can substantially bolster the contractor's operations.

Various factors guide the effectiveness of a foam's influence on this balance, and this complexity that develops is even more evident when we consider the mixed geology experienced in projects like the Silvertown Tunnel. To negotiate these challenges effectively, it is imperative to accept a customisable strategy, one that prioritises a holistic understanding of geological conditions and proactively regulates soil conditioning systems to reach the ideal soil properties for each instance along the tunnel alignment.

ACKNOWLEDGEMENTS

We extend our gratitude to the Riverlinx CJV tunneling department for facilitating analysis and cooperation in the development of this paper.

Tunnel excavation with EPB: Development of new conditioning agents to reduce the amount of water required for soil conditioning

Enrico Dal Negro, Alessandro Boscaro* & Enrico Barbero
Mapei S.p.A., Milan, Italy

Carmine Todaro & Daniele Peila
DIATI - Polytechnic University of Turin, Turin, Italy

ABSTRACT: Tunnel excavation with TBM requires large amounts of water that are necessary for several different applications. When EPB machines are used, an important contribution to the water consumption is due to the soil conditioning, in particular when the excavation is in cohesive formations. The proper amount of liquids necessary for the soil conditioning depends on several aspects (such as geology, type of conditioning agents used, configuration of the TBM, earth pressure applied at the tunnel face, etc.), however values of WIR (Water Injection Ratio = Volume of pure added water/Volume of soil excavated) in the range of 10%-30% are common.

The development of new conditioning agents allows to significantly reduce these amounts of water. The laboratory of the University “Politecnico di Torino” carried out a thorough campaign of tests using a reference clay, whose results show that new conditioning agents allow to save water in a range between 20 and 33% compared to the traditional products. This reduction of the WIR means thousands of tons of water saved for tunnel excavation, with consequent advantages under several points of view: technical, economical, and environmental. The reduction of water means lower volume of tunnel muck, less trucks necessary to transport the muck to its destination, which means lower CO₂ emissions due to downscaled logistics, etc. All these advantages are more and more relevant nowadays, especially in those countries where water has become a precious and scarce resource.

The paper describes the tests carried out and obtained results. The advantages of these new conditioning agents are presented in detail and contextualized in the view of a sustainability approach in tunnel construction.

Keywords: Tunnelling, TBM, EPB, Soil conditioning, New products, Water, Environment

1 INTRODUCTION

Mapei S.p.A., is at the forefront of innovation in sustainable TBM operations by developing new products capable of reducing the environmental impact of mechanized tunnelling. This has resulted in a wide range of products dedicated to reducing the amount of CO₂ emissions and the overall environmental impact of a TBM project.

As is well known, water is a very valuable resource and an increasingly rare commodity, which in the later years is demanding an increase in sensibility regarding the way it is utilised, especially in territories where its scarcity makes it even more of a precious asset to be carefully managed.

TBM tunnelling, similarly to many other industrial processes, requires a massive amount of water to be performed. The non-contaminated portion of water employed in mechanized tunnelling jobsites is continuously re-used during the activity, such as the water used for the cooling systems of the TBM. Part of the water is instead lost into the muck, such as the groundwater extracted during the excavation or the large water quantities which are necessary for soil conditioning during the excavation itself, especially when cohesive grounds are excavated.

The main issue stands in the fact that some soils, in order to be excavated with EPBs, require large amounts of liquid to be added, either as pure water (defined by the parameter of WIR = Water Injection

*Corresponding author: boscaro@utt.mapei.com

Ratio) or in foam generation. Moreover, greater values of WIR are generally required in order to condition cohesive soils with particularly high stickiness, such as clays, mudstone, shale, etc.

Since soil conditioning constitutes the greater part of the water needs of these jobsites, reducing the environmental impact of soil conditioning can also be linked to reducing the amount of water used in TBM tunnelling projects.

1.1 *Creating a new type of soil conditioning agent*

As part of Mapei's Water Saving Program (WSP), a new range of products have been specifically introduced to allow for a reduction of the WIR parameter.

In this paper we will describe the experimental phase of Polyfoamer ECO WSP and Mapedisp ECO WSP when applied in comparison with a reference soil conditioning product.

In detail, the following chapters have been produced to describe the operational methods for carrying out laboratory tests aimed at the characterisation of a clay extracted from a quarry near Reggio Emilia, in accordance with the technical partnership between DIATI of the Politecnico di Torino and Mapei S.p.A.

The new generation products were designed and manufactured with a view to achieving good conditioning of the clays by reducing the amount of water required by the soil to be conditioned.

The laboratory tests performed are:

- Mini flow test.
- Mini slump and flow table test.
- Slump test.
- Dynamic adhesion test.

1.2 *Reference nomenclature*

The following nomenclature for technical parameters has been adopted throughout the entire experimental phase.

w_n (%) – natural water content, computed on the dry weight of the soil;

w_{add} (%) – additional water content, calculated on the dry weight of the soil;

w_{tot} (%) – total water content, calculated on the dry weight of the soil;

$c\ w/w$ (%) – concentration of the solution calculated as weight of conditioning agent per 100 g of soil;

$c\ v/v$ (%) – volume concentration of foaming agent on volume of generating liquid;

ϕ_{BJ} (mm) – base diameter of the sample in the mini slump test, before application of the jolts;

ϕ_{AJ} (mm) – base diameter of the sample in the mini slump test, after application of the jolts;

h_{BJ} (mm) – height of the sample in the mini slump test, before application of the jolts;

h_{AJ} (mm) – height of the sample in the mini slump test, after application of the jolts;

w_{saved} (%) – amount of water saved. Percentage value computed on the w_{add} value of the considered

conditioning and the w_{add} value of the reference soil conditioning;

T (Nm) – average torque value, calculated in the dynamic adhesion test.

For the calculation of water contents, percentage values are rounded. Values with a decimal part greater than or equal to 0.5 are rounded up, values with a decimal part less than 0.5 are rounded down.

2 UTILIZED MATERIALS

The purpose of the experimentation described in this report is to study, by means of laboratory tests, the conditioning of “Reggio” clay using specific conditioning agents for clays. Specifically, 3 different soil conditioning agents supplied by Mapei S.p.A. have been tested, defined as follows:

- reference conditioning agent - “REF”;
- next-generation conditioning agent - “Polyfoamer ECO WSP”;
- next-generation additive - “Mapedisp ECO WSP”.

Both the soil conditioning products as well as the clay used in the experimental phase will be described thoroughly in the following paragraphs.

2.1 “Reggio” clay

The clay soil used for the experiments was supplied to the Tunnels & Underground Space Research Center of the Turin Polytechnic University directly by Mapei S.p.A., in hermetically sealed containers carrying a total of approximately 400 kg of material. The mineralogical analysis, certified by the supplier (Movimento Terra e Trasporti Ruggi) of the clay and carried out semi-quantitatively by XRD spectrometry showed the following composition:

- Clay Material: 43%
- Feldspar: 19%
- Quartz: 35%
- Other: 3%

The Atterberg limits are instead:

- Liquid limit: 54%
- Plastic limit: 30%

Figure 1. Thewes graph for “Reggio” clay.

Further analysis based on the Atterberg limits and the natural water content equal to 13%, shows that “Reggio” clays could be classified as prone to clogging risk, as shown in Figure 1.

The material was then processed in order to make it suitable for the planned tests.

Specifically, two different types of clays were produced:

- dry crushed clay ($w_n = 0\%$), hereinafter referred to by the acronym “DCC”
- chip clay ($w_n = 12.6\%$), hereinafter referred to by the acronym “NCC”.

Figure 2. Clay samples used in the laboratory for the test campaign. DCC (left) e NCC (right). The difference in color is due to the different water content in the samples.

The two variants of clay material employed in the tests can be seen in Figure 2, while their particle size distributions are shown in Figure 3.

2.2 Conditioning agents

Conditioning agents play a key role for the correct conditioning of soils, expressly in clayey ones (Peila et al., 2016). For this testing campaign, three

different specific conditioning agents for clays were used in addition to water taken from the water network of the metropolitan city of Turin. Specifically:

- a) “REF” (reference) conditioning agent. “Traditional” foaming agent, formulated with anionic surfactants of the SLES (Sodium-Lauryl -Ether-Sulphate) type, characterised by the following chemical composition reported on the safety data sheet in section 3: alcohols, C12-14, ethoxylates, sulphates, sodium salts; CAS number: 68891-38-3, 500-234-8; Concentration: $\geq 10\% - < 20\%$;
- b) “Polyfoamer ECO WSP” conditioning agent. Next generation foaming agent, formulated with the aim of reducing the amount of water required in comparison to ‘traditional’ foaming agents;
- c) “Mapedisp ECO WSP” additive. A next-generation dispersing additive, to be used in combination with foam to further reduce the amount of water required for conditioning.

3 LABORATORY TEST CAMPAIGN

The two types of tests carried out on the conditioned samples, namely Mini Flow tests and Mini Slump/Flow Table tests, will be described in detail in the following paragraphs.

3.1 Mini flow tests

The mini flow test campaign was performed according to the procedure described in the article published in an international scientific journal: C. Todaro, A. Carigi, L. Peila, D. Martinelli, D. Peila, Soil conditioning tests of clay for EPB tunnelling, Underground Space, Volume 7, Issue 4, 2022, Pages 483-497, ISSN 2467-9674.

Figure 3. Grain size distributions of the clay samples used for the test campaign.

Mini flow” tests have been recently introduced into the scientific literature and laboratory experimental practises for the characterisation of conditioned clays. These tests involve the use of a mini-cone (Figure 4), a scale reduction of the one used for slump tests (CEN 2009).

The cone base diameter is 44 mm, while its height is 66 mm.

Table 1. Mini flow tests results for “Reggio” clay.

ID	Conditioning agent	w_{add} (%)	flow (%)	slump (%)	w_{saved} (%)
6	REF	90	16	24	/
7	Mapedisp ECO WSP	90	126	84	0
8	Polyfoamer ECO WSP	90	126	83	0
9	Mapedisp ECO WSP	70	43	56	22
10	Polyfoamer ECO WSP	75	61	69	17

Figure 4. Mini flow cone front and from-above views.

3.1.1 Mini flow test results

The obtained results are shown in Table 1, while pictures of performed tests can be seen in Figure 5. Flow and slump values refer to height and diameter of the conditioned material downstream of the cone lift (computed on the dimensions of the mini-flow cone) and are shown in percentage value. The amount of conditioning agent, which remained constant for all

tests (ID 6-10), is 0.5 g, equivalent to a dosage on the treated soil in concentration w/w equal to 0.5%.

Regarding results on “Reggio” clay specimens, given the same dosages used in terms of the amount of water added and the amount of conditioning agent (ID 6, 7 and 8), adopting the new generation products results in flow values increased by around 8 times and slump values were more than three times as much. Polyfoamer ECO WSP in the ID 10 test shows flow and slump values approximately 4 and 3 times higher than in the ID 6 comparison test, despite the fact that the amount of water added is approximately 17% less than in the reference test.

The specimen treated with Mapedisp ECO WSP (ID 9), although made with a w_{saved} of 22%, shows values for flow and slump respectively about 3 and 2 times higher in relation to those obtained in the reference (ID 6).

Figure 5. Mini Flow tests for “Reggio” clay. IDs are labelled.

3.2 Mini slump tests

The tests performed by using the mini slump (geometries shown in Figure 6) involve the use of NCC “Reggio” clay, which is characterised by its natural water content. The mixing of the soil with the correct amount of water and foam is carried out until a homogenous material is achieved. The conditioned material thus obtained is then placed inside a mini slump cone, using the surface of the flow table as a base support. A first slump test is thus performed, and the values of the base diameter (φ_{BJ}) and height (h_{BJ}) are measured. Fifteen jolts are then applied at a height of 25 mm after which base diameter (φ_{AJ}) and height (h_{AJ}) are measured.

Table 2. Mini slump and flow tests results.

Test ID	Conditioning agent	w_{add} (%)	w_{tot} (%)	φ_{BJ} (mm)	h_{BJ} (mm)	φ_{AJ} (mm)	h_{AJ} (mm)	flow (%)	slump (%)	w_{saved} (%)
1	REF	45	58	114	57	171	104	71	31	/
2	Polyfoamer ECO WSP	45	58	160	75	211	104	111	31	0
3	Polyfoamer ECO WSP	35	48	116	49	174	96	74	36	22
4	REF + Mapedisp ECO WSP	45	58	145	70	202	104	102	31	0
5	REF + Mapedisp ECO WSP	38	50	141	63	195	104	95	31	17

The cone base diameter is 100 mm, while its height is equal to 150 mm.

The density value of the “Reggio” clay $\gamma = 1.786 \text{ kg/L}$ was used as a constant for all mini slump test campaign.

The conditioning parameters, which have been kept constant for all tests, are:

- $c(\%)$: 2.0
- FER(-): 8
- FIR(%): 60

Figure 6. Mini-slump tool.

3.2.1 Mini slump test results

The results are summarized in Table 2, while images of the test for ID5 are shown in Figure 7 as example. The values for flow and slump are referring to height and diameter values measured after the jolts, calculated in comparison to the original mini slump dimensions. ID 4 and ID 5 tests have been carried out with a conditioning procedure which made use of Mapedisp ECO WSP with a fixed dosage of 0.8 g over 1500 g of clay, corresponding to a dosage of 1 kg of polymer over 1 m^3 of soil in situ. The additive dosage, in the range of one tenth of a gram, is negligible for the calculation of water content. For the calculation of w_{saved} , ID 2-5 refer to ID 1.

Considering the use of Polyfoamer ECO WSP, while keeping the water content and conditioning parameters constant (comparison between test ID 1 and 2), the flow percentage increases by about 1.5 times, from a value of 71% to a value of 111%. Considering instead tests ID 1 and 3, equivalent results in

terms of flow are obtained by conditioning the soil with a w_{saved} of 22%.

If, on the other hand, we consider the conditioning obtained by adding Mapedisp ECO WSP to the REF, keeping the water content and conditioning parameters constant (comparison between test ID 1 and 4), the flow percentage increases by about 1.5 times, from a value of 71% to a value of 102%. Considering instead tests ID 1 and 5, similar results in terms of flow are obtained by conditioning the soil with w_{saved} equal to 17%.

The “slump” parameter is irrelevant, with values in the range of 30-36% regardless of the conditioning they were subjected to.

Figure 7. ID5 mini slump test pictures before jolting (left) and after (right).

3.3 Slump tests

he slump test is probably the first that was used for characterise the conditioned soil even if it was originally applied to cohesionless soils (Peila et al., 2009; Borio abd Peila, 2011; Peila et al., 2013). The slump test campaign has been performed in compliance with the procedure described in the article published in the international scientific journal: C. Todaro et al. (2022).

The slump tests foresaw the use of NCC “Reggio” clay, which is characterised by its natural water content.

3.3.1 Slump tests results

The results obtained are summarised in Table 3 while images of the tests performed can be found in Figure 8, Figure 9, Figure 10, 11 and 12.

Test ID 5 was carried out with a conditioning which employed Mapedisp ECO WSP with

Table 3. Slump test results.

Test ID	Conditioning agent	w_{add} (%)	w_{tot} (%)	Slump A (cm)	φ_A (cm)	Slump B (cm)	φ_B (cm)	Slump C (cm)	φ_C (cm)	w_{saved} (%)
1	REF	32	45	19	28	11	25	25	49	/
2	Polyfoamer ECO WSP	22	34	13	27	0	20	17	34	33
3	Polyfoamer ECO WSP	26	38	17	34	5	22	22	41	20
4	REF	26	38	12	23	1	20	18	38	/
5	REF + Mapedisp ECO WSP	26	38	16	30	7	21	24	46	20

a fixed dosage of 2.02 g on 12000 g of clay, equivalent to 0.3 kg of polymer on 1 m³ of soil in situ. The amount of additive, in the order of one gram, is negligible when calculating water content. For the calculation of w_{saved} , ID 2-3 refers to ID 1, while ID 5 refers to ID 4.

The analysis of a slump test is not only based on the numerical value of the slump at the cone. In all materials, but especially in clay materials, other parameters must be considered such as the overall homogeneity of the sample, its pulpy consistency and stickiness. Only from the careful evaluation of all these

parameters can an overall judgement of the slump test be considered reliable. The writers, in order to facilitate reading, introduced a simple scale of pulpy consistency (1 - not very pulpy; 5 - very pulpy) and stickiness (1 - not very sticky; 5 - very sticky). The evaluations in terms of pastiness and stickiness were made after the execution of slump B and C.

Further comments for direct comparisons of "REF" tests and the other conditioning combinations are listed below:

ID 1 vs ID 2: Slumps A are comparable in terms of pulpy consistency and stickiness. Slumps B are also comparable, although ID 2 is characterised by a w_{saved} of 33%. It should also be considered that ID 1 - slump C is an unacceptable slump as it is excessively fluid. In fact, the conditioned soil leaked abundantly from the plate downstream of the execution of the shots, whereas ID 2 - slump C shows a slump at the cone in the ranges, without any material leaking from the plate.

ID 1 vs ID 3: Slumps A are comparable in terms of pulpy consistency and stickiness. Slumps B are also comparable, although ID 3 is characterised by a w_{saved} of 20%.

ID 3 - slump C shows a slump value at the cone in the range, with no material escaping from the plate.

Figure 8. ID 1 slump tests.

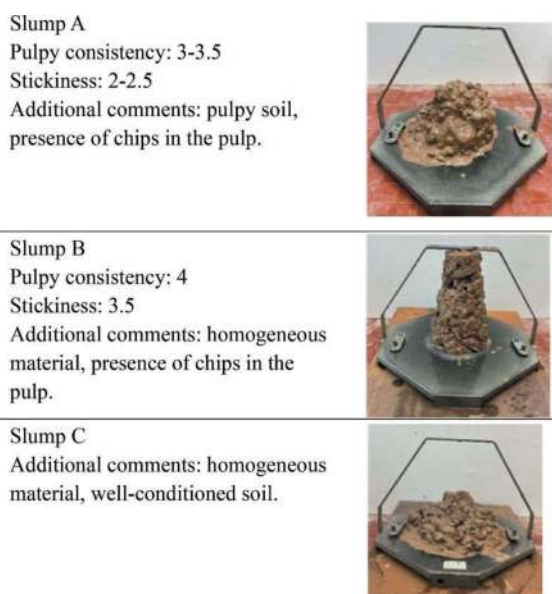

Figure 9. ID2 slump tests.

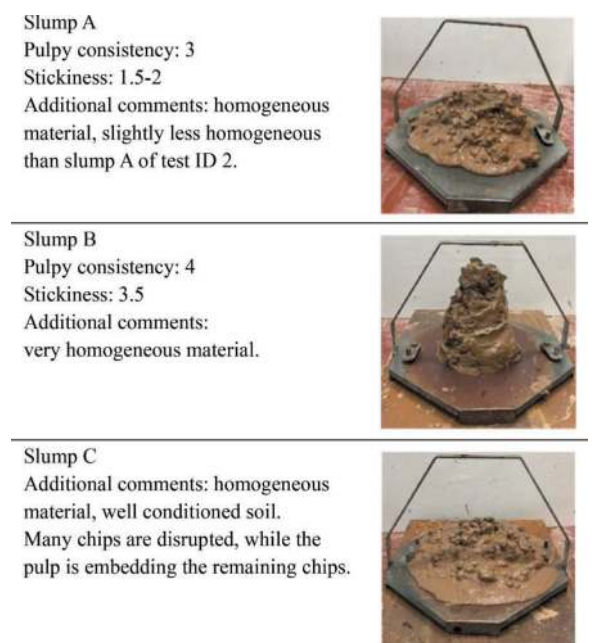

Figure 10. ID3 slump tests.

ID 4 vs ID 5: Conditioned soils with equal water content. Comparing Slump As, the better result obtained in ID 5 in terms of pulpy consistency is evident. ID 5 - slump B was less stiff than the corresponding ID 4 - slump B (with slump values at the cone of 7 and 1 cm respectively), as well as showing a more limited stickiness. ID 5 - slump C slightly off the plate but with fewer chips and more paste than ID 4 - slump C.

ID 3 vs ID 4: Conditioned soils with equal water content. ID 4 - slump A is slightly stickier than ID 3 - slump A. ID 3 - slump C was much pulpier than ID 4 - slump C. It should be noted, however, that ID 4 - slump C exhibited a high degree of stickiness during lifting of the cone, which was not the case in ID 3 - slump C.

<p>Slump A Pulpy consistency: 2 Stickiness: 3.5 Additional comments: less homogeneous material, the creamy outside hides the chips, which are still hard to the touch.</p>	
<p>Slump B Pulpy consistency: 2.5 Stickiness: 4 Additional comments: less pulpy yet very sticky material, the cone would not detach easily from the conditioned material.</p>	
<p>Slump C Additional comments: homogeneous material, scarce presence of non-disrupted chips.</p>	

Figure 11. ID4 slump tests.

<p>Slump A Pulpy consistency: 3.5-4 Stickiness: 2.5 Additional comments: homogeneous material, creamy paste.</p>	
<p>Slump B Pulpy consistency: 3.5 Stickiness: 2.5 Additional comments: homogeneous material, creamy paste.</p>	
<p>Slump C Additional comments: Homogeneous material, well conditioned, chips present but with small. Slight excess of fluidity, with limited material falling out of the plate downstream of the jolts.</p>	

Figure 12. ID5 slump tests.

3.4 Dynamic adhesion tests

The dynamic adhesion test campaign was carried out on the basis of the procedure described in Todaro et al. (2022) and Carigi et al. (2023).

The dynamic adhesion test is based on the rotation of an aluminium disc, 120 mm in diameter and 10 mm thick, placed in contact with the clay material under specific conditions in order to assess the developed adhesion. The test, specifically designed for the study of clays, involves placing the disc in rotation within the material to be tested, with a constant rotation of 90 rpm (Figure 13). The clay material then adheres to the surface of the disc and the contact is ensured by applying a pressure of 1 bar to the conditioned material. The pressure is applied by means of a plate which, pushed by 2 hydraulic pistons, moves downwards in contact with the soil, thus making sure that the intended pressure is applied to the conditioned soil. The test provides important information about the resistance exerted by the clay soil to the rotation of the disc, due to the adhesion/clogging forces typical of clay soils. During the test, the torque required to ensure a constant disc rotation speed is constantly measured and recorded.

Dynamic adhesion tests foresaw the use of NCC “Reggio” clay, conditioned by its natural water content.

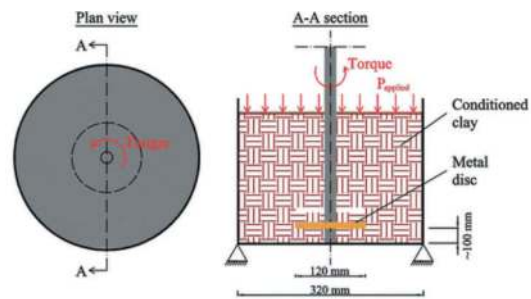

Figure 13. Schematic diagram and picture of the dynamic adhesion test apparatus. 1. steel container; 2. torque transducer; 3. hydraulic pistons; 4. steel cover; 5. hydraulic unit.

Table 4. Dynamic adhesion tests results.

Test ID	Conditioning agent	w_{add} (%)	w_{tot} (%)	c (%)	FER (-)	FIR (%)	T (Nm)	w_{saved} (%)
1	REF	27	40	2	8	45	4	/
2	Polyfoamer ECO WSP	23	35	2	8	45	3	17
3	REF + Mapedisp ECO WSP	23	35	2	8	42	4	17

3.4.1 Dynamic adhesion test results

The conditioning parameters of the tests and the results obtained in terms of average torque T (Nm) and w_{saved} are shown in Table 4 while Figure 16 shows the trends in torque as a function of time. The average torque was calculated over the 300 s of the actual test, after the pressure stabilisation transient phase which lasted an average of 120 s for all 3 tests. This reduction in FIR was evaluated in agreement with the commissioning company’s technicians in order to maximize adhesion phenomena during the test, consistent with obtaining good conditioning results.

Figure 14. Torque over time graph for dynamic adhesion tests.

The reference test, i.e. ID 1 is highlighted in grey color. ID 3 was carried out by conditioning using Mapedisp ECO WSP with a fixed dosage of 2.55 g per 15000 g of clay, equivalent to 0.3 kg of polymer per 1 m³ of soil in place. The amount of additive, in the order of a gram, is negligible for the purpose of calculating the water content. For the calculation of w_{saved} , ID 2-3 refer to ID 1.

Figure 15 shows some shots of the significant phases of the dynamic adhesion test. For illustrative purposes only, the images shown refer to ID 1.

Figure 15. Dynamic adhesion test ID 1. Material completely poured into the steel container (left), material at the end of the test (right), extraction and visual analysis of the disc (right).

An analysis of Figure 14 shows that the 3 torque trends as a function of time are very similar, despite the fact that IDs 2 and 3 were carried out with a w_{saved} of 17%. Regardless of the test considered, the torque values never exceeded the value of 7 Nm, an indication that the conditioning used ensures that adhesion/clogging phenomena are controlled. The T values, between 3 and 4 Nm, also show a high degree of similarity in the behaviour of the materials tested with dynamic adhesion testing.

4 FINAL CONCLUSIONS

The study of the conditioning of clays is a complex analysis which is difficult to carry out using a single type of laboratory test. In the present study, the conditioning of the “Reggio” clay was evaluated by means of tests considering both homogenised clay (obtained from the DCC sample) and clay in chips (NCC sample), conditioned with products specifically designed and manufactured for the conditioning of cohesive materials.

The different conditioners adopted, adjusted each time depending on the type of test carried out, highlighted the effectiveness of Polyfoamer ECO WSP and Mapedisp ECO WSP (the latter used as an additive alongside a reference conditioning agent) in guaranteeing good conditioning, comparable to that obtained with REF, while using reduced quantities of added water.

Specifically speaking, mini-flow and mini-slump tests denoted a potential water saving ranging from 17 to 22 % when comparing samples conditioned with Polyfoamer ECO WSP to the ones conditioned with the REF conditioning agent. Similar results ($w_{saved} = 17-22\%$) for the same tests were observed by comparing the samples treated using REF with an addition of Mapedisp ECO WSP with the ones conditioned using REF only.

With Slump tests, the best results highlighted a potential water saving between 20 and 33% using Polyfoamer ECO WSP.

Dynamic adhesion tests evidenced samples treated with next generation products, which are the ones conditioned with either Polyfoamer ECO WSP or with a combination of REF and Mapedisp ECO WSP result in a potential water saving of 17%.

In conclusion, with regard to technical performance parameters, a potential water saving of a minimum of 17 % has been consistently observed, denoting a great potential for the reduction in water

demand for TBM jobsites which would result in a significantly lower environmental impact as well as an economical advantage.

ABSTRACT: The opening of the East Rail Line (EAL) Cross-Harbour Extension has re-shaped the public travel pattern and metro network in Hong Kong. The history of the century old EAL has also been rewritten as a direct rail link, connecting the city boundary and the Northeast New Territories with the Central Business District area on Hong Kong Island. It brings people from the Northeast New Territories closer to the city's financial hub with one railway line. Variable density TBM was first used in Hong Kong for this project to minimize the inherent risk for one of the TBM drives with very shallow ground cover and within heterogenous soil in reclaimed land. Advanced obstruction removal and protection of existing structures was carried out to mitigate the tunnelling risks. Rigorous numerical analysis has been carried out to predict the ground behaviour and design the confinement pressures. Performance of the TBM drives and the Variable density TBM has been reviewed based on the monitoring data from a suite of comprehensive geotechnical instrumentation.

Keywords: Tunnel boring machine (TBM), Variable density (VaD), Shallow ground cover, Tunnelling risk, Performance prediction

1 INTRODUCTION

The opening of the East Rail Line (EAL) Cross-Harbour Extension in 2022 has re-shaped the public travel pattern and metro network in Hong Kong. The history of the century old EAL has also been rewritten as a direct rail link and the city's fourth railway cross-harbour tunnel, connecting the city boundary and the Northeast New Territories with the Central Business District area on Hong Kong Island. It brings people from the Northeast New Territories closer to the city's financial hub with one railway line. The new connection also helps alleviate the congested sections of the railway corridor as well as road traffic via the vehicular Cross-Harbour Tunnel.

Hong Kong is densely populated with 1,110 km² of land mass. Its mass transit system operated by Mass Transit Railway Corporation Limited (MTRCL) is one of the main modes of transportation for the public. The 6km long EAL Cross-Harbour Extension, situated between the Kowloon Peninsula and the central business district on Hong Kong Island, includes an Immersed Tube Tunnel (IMT) below Victoria Harbour, an overrun tunnel below the hills in Admiralty, modification, and extension of the existing Hung Hom Station and Admiralty Station and four TBM tunnels connecting the IMT to Admiralty Station via the brand-new Exhibition Centre Station (EXC). Figure 1 shows alignment and connectivity of the EAL Cross-Harbour Extension.

*Corresponding author: ngneil@mtr.com.hk

The EAL Cross-Harbour Extension alignment features various engineering solutions to overcome complex geology, varying topography and many other site constraints. There exist various and distinct inherent risks for one of the TBM drives with excavation below only 6m of ground cover in reclaimed land. The possibilities of uncontrolled ground collapse due to compressed air leak during TBM cutterhead maintenance, compressed air blowout due to excessive confinement pressure, loss of confinement pressure if encountering underground obstruction which can result in over-excavation as the TBM attempts to drive through the ground at shallow depth necessitated detailed review of the risks and implementation of advanced mitigation measures.

One of the key successes to the shallow cover TBM drive was the use of a hybrid variable density slurry TBM combining Earth Pressure Balance (EPB) and Slurry (Mixshield) processes. The slurry density inside the excavation chamber was adjusted based on the geology and TBM operation mode. This mitigated the chance of pressurised slurry leaking onto the ground surface while minimizing ground settlement. This was particularly important in the developed Wan Chai area and below the busy road network. This paper will discuss the underground risks and technical aspects of the mitigation measures that were undertaken prior to commencing the TBM excavation under shallow ground cover in an urban environment at the north Wan Chai area of Hong Kong Island.

Figure 1. EAL Cross-Harbour Extension alignment.

2 ALIGNMENT AND GEOLOGY OF TBM TUNNEL DRIVES

The EAL Cross-Harbour Extension involves construction of two sets of twin 7.45m Ø TBM tunnels to the east and west respectively of the Exhibition Centre Station. The Eastern Bored Tunnels are approximately 680m and Western Bored Tunnels are approximately 470m in length. Figure 2 shows the horizontal alignment of the four TBM tunnels.

The ground topography for the entire TBM tunnel alignment is on flat low-lying ground along the

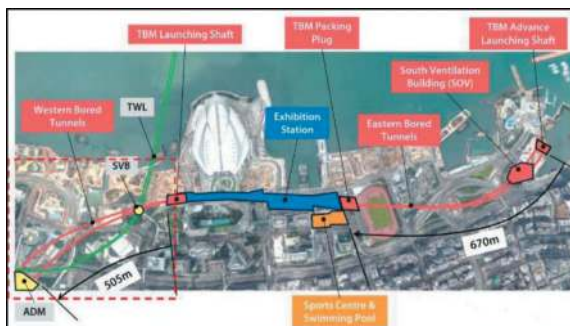

Figure 2. Horizontal alignment of TBM tunnels.

northern coastline of Hong Kong Island, all in reclaimed land. The reclaimed Fill materials below the ground level consist of Marine Deposits, Alluvial Deposits and generally underlain by Completely Decomposed Granite (CDG) soil and Slightly Decomposed Granite bedrock. For the upper Eastern Bored Tunnel, the risks involve excavation under shallow ground cover in soft Marine Deposits, Alluvial Deposits with the tunnel crown just below the bottom of the reclaimed Fill and old seawall revetments. Figure 3 shows the typical geological profile for the tunnel section between Canal Road and Wan Shing Street in the north Wan Chai area.

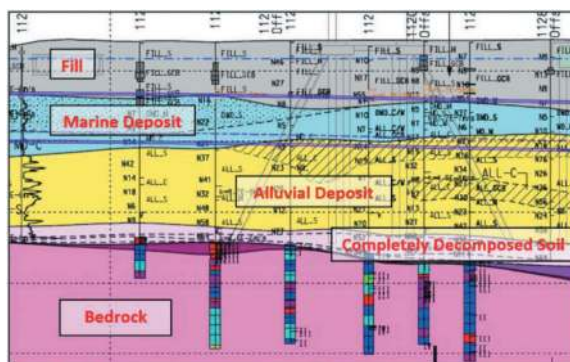

Figure 3. Typical geological profile of Eastern Downtrack Tunnel.

Based on project specific site investigation results, the Eastern upper downtrack alignment was found to have a complex geological profile. The solid geology consists of Granite bedrock at 20 to 30m below surface level. Above the bedrock stratum, Completely Decomposed Granite (CDG) is overlain by a stratum of sandy to clayey alluviums and sedimentary marine deposits of varying thicknesses below the top reclaimed fill layer. The reclaimed fill is identified to contain construction debris e.g. reinforced concrete, bricks, plastics, woods and steel bars as well as rubble mound that had previously formed as parts of temporary or permanent sea walls. At the shallowest location, the tunnel excavation took place with cover of less than one TBM diameter and at some

locations, the TBM passed closed to existing live structures with less than 1m of very soft soil in between. Figure 3 highlights one of the significantly more challenging areas in terms of ground cover and potential obstructions. To minimize the risk of excessive ground settlement and impact to existing underground facilities and to reduce the risk associated with cutterhead and cutting tools (disc, picks and scrappers) maintenance under compressed air intervention (CAI), the vertical alignment of the upper and lower tunnels was revised with small but significant changes.

- Deeper Uptrack Tunnel: raised to a higher level to minimize excavation in the transition zone between the CDG and granite bedrock;
- Upper Downtrack Tunnel: lowered generally by 0.5m, deeper at localized areas, to avoid old seawall and revetments below the TBM, thereby increased the margin of confinement pressure design which is under the influence of daily hydraulic gradient fluctuation near Victoria Harbour.

The revised and lowered alignment of the Upper Downtrack Tunnel minimized the risk of slurry leaks into old seawall rubbles along stretch of the alignment. However, the revised vertical alignment also increased the risk of TBM excavation closer to existing facilities including a trunk sewer which required extensive geotechnical instrumentation and a stringent monitoring programme. Alternative alignment of the upper and lower Eastern Bored Tunnels and the surrounding geology are shown in Figures 4(a, b).

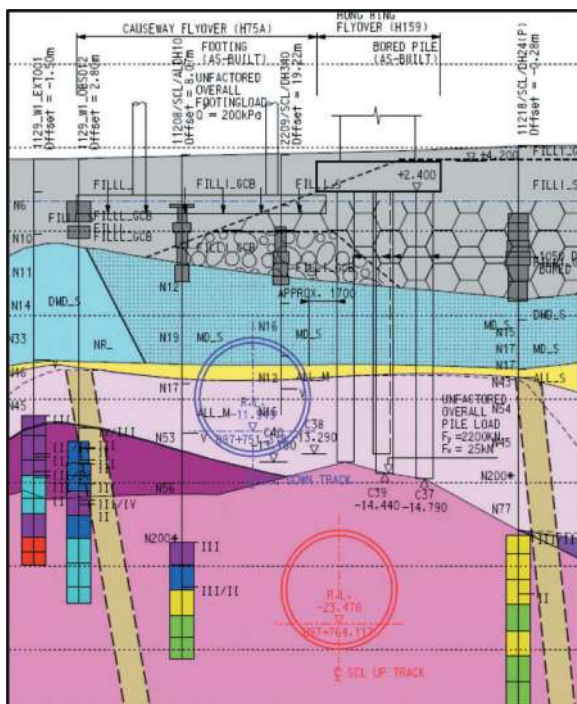

Figure 4a. Tunnel level and typical geological sections.

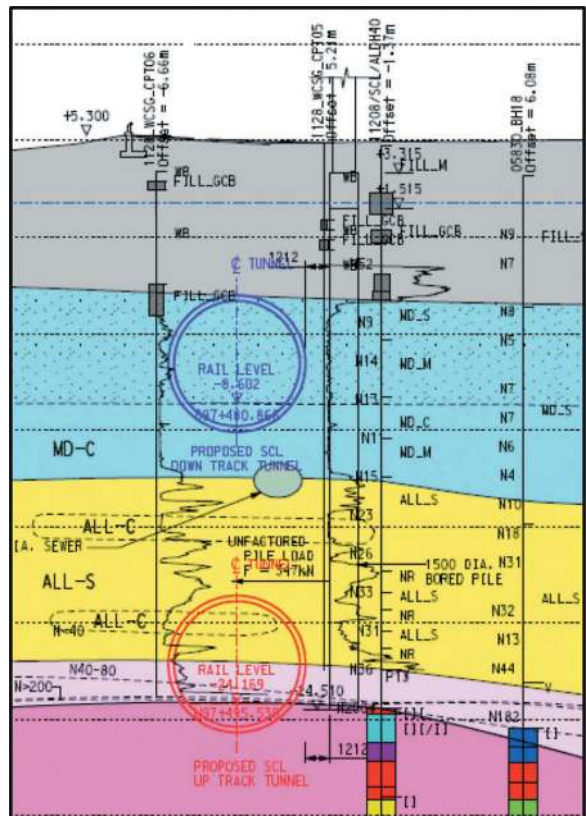

Figure 4b. Tunnel level and typical geological sections.

3 SITE CONSTRAINTS

The Causeway Bay and Wan Chai districts are highly developed with its coastline extended under various phases of reclamation. The Eastern Bored Tunnels traverse below reclamation constructed in the 1960s and 1970s which are now built with multi-lane carriageways, vehicular flyovers and viaducts, commercial buildings and other major underground utilities. In addition, there are pile foundation

Figure 5. Historic reclamation up to 2000s.

supporting box culverts, trunk sewers, footbridges, abandoned ferry piers and left-in temporary works for the development in this area. Figure 5 shows the tunnel alignment in the historic reclamation.

The contract Geotechnical Baseline Report compiled at the design stage of the project involved extensive record search and desktop study followed by advanced ground investigation programme to identify known structures, pile foundations and underground obstructions. At the construction stage with new project interface and further desktop studies, additional major obstructions were identified in the form temporary left-in sheetpiles and old pile foundation coinciding with both the Uptrack and Downtrack tunnel alignment. The risk assessment also included the possibility of encountering old World War II ordnance.

With the existing obstructions identified at various locations along the alignment at the design stage, an advanced works contract was awarded to remove and clear the underground obstructions from the ground surface. The buildings and structures protection works and removing some of the existing obstructions including those identified after contract award were executed by the tunnelling contractor. Figure 6 shows the location of major pile obstructions below the Canal Road Flyover and Wan Shing Street Footbridge.

Figure 6. Major pile obstructions below Canal Road Flyover and Wan Shing Street Footbridge.

4 ADVANCED WORKS

4.1 Pile obstruction removal

Removal of pile obstructions behind the TBM cutterhead in the excavation chamber has been done in previous MTR projects. However, such operation, particularly under compressed air intervention (CAI) at depth or under shallow ground cover, is complex and carries inherent risks to the tunnel workers, tunnelling operation, and other stakeholders.

With several structures supported by piles that conflicted with the TBM alignment, advance works to remove these obstructions were carried out to mitigate tunnel excavation risks. They include piles supporting the Percival Footbridge (9 nos. bored

piles), Canal Road Box Culvert (21 nos. pre-stressed concrete piles) servicing the Wanchai district, Canal Road Flyover (6 nos. pre-stressed concrete piles) which is a main artery connecting the south of Hong Kong Island and the Cross Harbour Tunnel, and the Marsh Road drainage sewer (2 nos. precast concrete pile). As-built records of the latter pile obstructions on Marsh Road were not available. Their presence and locations were instead confirmed by site trial pits and geophysical survey.

The sheetpile obstructions at Wan Shing Street was critically identified prior to the shallow Downtrack tunnel drive. A study of this project interface and old site photos revealed the risk of left-in temporary works from the cable trench which could result in slurry leak, excessive ground settlement and programme impact. Subsequent geophysical survey confirmed this risk and help identified up to 100 nos. sheetpiles that clashed with the tunnel alignment. With the assistance of the utility company and government departments, temporary traffic management scheme was quickly implemented to allow safe removal of the sheet piles without impact to the 11kV and 132kV electrical cables prior to the TBM excavation.

Figure 7. Traffic management and temporary trenching for sheetpile removal at Wan Shing Street.

4.2 Protection of existing facilities and structures

The advanced works associated with pile obstruction removal involved well planned engineering schemes. To remove the piles supporting the Canal Road Box Culvert, full diversion of the culvert and complete reinstatement was done. Adjacent to the box culvert, underpinning of the Canal Road Flyover was undertaken before removing the piles under low headroom condition with specially designed plant.

One of the most critical protection measures was designed and implemented for the Hung Hing Flyover and Causeway Flyover trunk artery. These two individual bridge structures, spanning over the tunnel alignment, are both supported by pile foundation at one end and shallow foundation at the other ends and pile

removal was not necessary. However, the two structures separated by a longitudinal movement joint and its combination of foundation types posed a unique challenge to excavating the shallow Downtrack tunnel in reclaimed fill just underneath the structures.

Furthermore, the Canal Road Flyover, Hung Hing Flyover and Causeway Flyover are “red routes” meaning traffic stoppage at any stage during construction was not allowed. Despite these challenges, ground treatment below one of the shallow foundations was carried out to improve ground stiffness and hydraulic jacks were installed below Hung Hing Flyover to control excessive movement. The protection measures combined with use of the Variable Density TBM resulted in just 5mm movement and well below structural capacity and serviceability of the bridge structures.

Figure 8. Underpinning of Canal Road Flyover to facilitate pile obstruction removal.

Figure 9. Hung Hin Flyover and Causeway Flyover.

5 TBM TUNNELLING STRATEGY

5.1 Choice of TBM

During the project’s tender stage, the three deepest tunnels under the same contract were specified to be excavated by using Mixshield TBMs. However, the shallow cover east Upper Downtrack tunnel was initially specified to be completed by an EPB TBM, avoiding the potential risk of slurry blowouts that could occur using a Mixshield TBM.

One of the tenderers highlighted the key concerns in using an EPB TBM with greater risk of collapse, higher ground settlement due to inefficiencies in managing the confinement support because of the complex geology, limited cover and possibility of encountering unforeseen obstruction in reclaimed ground. Further risks using the EPB TBM included foam blowouts, a more complex process for completing compressed air interventions and given the geology, a concern of the moisture content for spoil disposal (to be below 25%) not easily achieved.

The project team was aware of the experience from the Klang Valley MRT project in Kuala Lumpur, where a Variable Density (VaD) TBM was used for the first time, to overcome the complex Karstic limestone geology where problems (slurry blow-outs) had previously occurred using Mixshield TBM’s (Schaub, 2014; B  ppler, 2016). The machine was developed to give the advantage of both a Mixshield TBM and an EPB TBM in providing an adequate face support medium (B  ppler, 2016). The Variable Density TBM can make use of a thicker, denser slurry inside the excavation chamber instead of a thin slurry or earth paste. By using a higher density at the excavated face than a normal Mixshield TBM, the VaD TBM was more suited to the shallow eastern Downtrack tunnel. The proposal to use a VaD TBM for the first time in Hong Kong was then adopted.

5.2 Special features of Variable Density (VaD) TBM

To mitigate the risk of blow out to the ground surface while controlling stability of the excavation face, a range of slurry density was considered. The project’s VaD TBM operated in two different modes of excavation, a Low-Density mode where slurry is supplied similarly to a slurry TBM (roughly 1.05-1.20T/m³) through the slurry circuit, and a High-Density mode that took the TBM to the lower boundary of an EPB TBM where density in the excavation chamber was limited to 1.50T/m³. This value is the maximum density that can be applied with the variable density process against the geology to avoid a blow out. Above this density, a full switch to EPB mode would have been required including foam conditioning to prevent plugging inside the cutter head and installation of a conveyor belt for spoil mucking out. The concept of the Low and High-Density modes and basic formula to determine the recommended density between the TBM axis and the ground level is shown in Equation (1) and Figure 10.

$$\text{Slurry Density} = \frac{\text{Design confinement pressure at axis (kPa)}}{\text{Depth from surface to TBM axis(m)} \times 9.81} \quad (1)$$

Excavated material is removed from the pressurised excavation chamber through a screw conveyor. For

operation, the screw was not required to reduce the support pressure from the front like a regular EPB TBM as a slurryfier box remained pressurised with the slurry circuit. The primary function of the slurryfier box is to dilute material removed from screw to a suitable density thereby allowing hydraulic transportation to the Slurry Treatment Plant (STP) for separation.

Figure 10. Blow out control using Low or High Density with same confinement pressure (Straesser, 2016).

To enable the higher density slurry mode in the excavation chamber, regulation of slurry injected to the excavated face is necessary. The Bentonite Injection Ratio (BIR) controlled this injection. The BIR is the flow of slurry sent to the excavation chamber divided by the flow of material physically excavated, with the basic formula shown in Equation (2).

$$\text{BIR (\%)} = \frac{\text{Flow of slurry (m}^3/\text{hr)}}{\text{Flow of excavated materials (m}^3/\text{hr)}} \quad (2)$$

The ratio is adjusted by the operator depending on the density of slurry measured in the excavation chamber. When the density is too low in the excavation chamber, the flow of slurry must be reduced and vice versa, if the density it too high, the flow of slurry must be increased.

Part of slurry injected to the front is sent to the working chamber where it is pushed to the excavation chamber through the communication pipe. The remaining slurry is directed through the face injection lines located on the cutter head which work the same as the foam injection lines found on an EPB TBM. A 2m³ tank supplies slurry to the 6 individually controlled pumps with the facility to add a polymer to aid dispersion in the excavation chamber if necessary. In semi-automatic mode, the PLC system regulates the flow through the face injection lines to make up the total slurry reaching the set BIR. In manual mode, the operator has control of the pumps which can be adjusted independently.

6 TBM PERFORMANCE

6.1 Confinement pressure

The complexity of the geology in conjunction with the shallow ground cover for the Downtrack tunnel, circa 6.5m made up of fill material in reclamation as far back as 50 years ago required specialist design and technology. As such the TBM was operated as a standard slurry mix shield or in a high density mode to avoid slurry blow out using specific verifications to limit the slurry and face support pressure.

Face support pressures, annulus grout pressures and compressed air intervention pressures were designed for ultimate limit state and serviceability limit state. Reference was made to GEO Report No. 249, GEO (2009) and GEO Report No. 298, GEO (2014) for the confinement pressures design. This ULS confinement pressure defines the minimum face support pressure. For the Service Limit State (SLS), the ground and building settlements at surface are verified with the 2D finite element models, to define the recommended pressure. Finite element analysis for soil-structure interaction were also carried out for validation and rigorous analysis for sensitive areas. To define the confinement pressures to be applied, a set of 2D (plain strain) Finite Element models were developed along the tunnel alignment. Slurry pressure to support the excavation and grout pressure injected by TBM behind the segmental lining are considered in the models to account for their interaction and the associate effect on the surface settlement. PLAXIS 2D revision 2015 is used to model the excavation.

6.2 VaD TBM excavation performance

Despite the eastern tunnels were relatively short (~680 m each) and learning curves considered, the Eastern Downtrack tunnel excavated with the VaD TBM completed the drive in 81 days with an average excavation of 8.3 m/day including stoppages for assembly, break in and false tunnel dismantling. In comparison, the Eastern Utrack tunnel excavated with a Mixshield TBM completed the drive in 86 days, excavating an average of 7.9 m/day. The difference is largely a result of more rock and transition sections for the Mixshield drive, due to the deeper alignment, requiring more CAI interventions. Table 1 provides a comparison of average excavation rates for the various types of geology encountered by the Mixshield TBM and the VaD TBM.

The VaD TBM was driven through an initial long transition of rock/CDG and mixed face soil with boulders and several CAIs were required to maintain and replace the excavation tools. For the remainder of the drive, due to the shallow ground cover and potential unstable ground conditions, most of the CAIs were pre-planned and carried out as much as possible in defined and ground treated locations. This minimized

risks to the public on the surface, as well as the workers working in compressed air.

In addition, the TBM design included the contractor's in-house system which monitors the instrumented disc cutters during excavation, reduced the risk of failure and improper maintenance of the cutter head. Due to the complexity and challenges within the complex geology of the Eastern Down-track excavation within transitions and reclaimed areas, the cutting tools system provided the TBM operator with accurate data including the ground repartition at the excavation face, unforeseen obstructions, and presence of corestones.

The progress of the VaD TBM was impacted by the processing time to treat the excess slurry in the Marine Deposit area with up to 60% fines content. As a result, the processing time of the filter presses at the STP was restrictive to TBM progress but this was anticipated due to limited works area available has restricted the capacity of the STP.

Upon completion of the TBM drives, the measured volume loss of the two upper Downtrack and the lower Uptrack tunnels are found to be in between 0.1 – 1.0% which is well within the predicted volume loss of 0.5 – 1.5% from the confinement pressure analysis. Reasons for this better than expected performance could be due to conservative soil parameters, effective advanced ground treatment implemented on site and diligent operation of the VaD TBM. The VaD TBM performed within the expected settlement values based on the designed confinement definition.

There was continual monitoring along the alignment with a suite of geotechnical instrumentation including numerous Automatic Deformation Monitoring System (ADMS) and monitoring points on the ground surface, roads, existing structures and services as the TBM progressed (Auvergne, 2017). No TBM stops or impacts to the surface (roads, footbridge) occurred as a result of either effects on the surface settlement or risk to the safety of the public.

7 RISK MANAGEMENT

Generally, TBM projects, particularly in an urban environment, comprise of an initial stage with advanced works to clear the tunnel alignment of obstructions and prepare for construction. This is then followed by execution of the construction contract and tunnelling operation. The tunnelling works for the project adopted the requirements set out in A Code of Practice for Risk Management of Tunnel Works (The International Tunnelling Insurance Group, 2006) to manage the tunnelling risks from feasibility to the design stage and throughout the construction period including the early contractor involvement process in the procurement stage. The risk assessments for various aspects related to the project and 3rd party stakeholders were systematically identified with mitigation measures and action implemented in advance of procuring the works contract. The resulting live “design for safety and constructability” risk register were taken forward to the procurement and construction stage. The MTR project team was well involved in the risk assessment at each stage of the project with designers, tenderers and the winning contractor.

In addition to the hazards and risks identified at the design and procurement stage, lead information received post contract award was act upon promptly to minimize the risk to the TBM excavation. Conducting comprehensive ground investigations and geophysical survey at Marsh Road and Wan Shing Street and the subsequent pile removal works are just two examples of the risk management process. The project also had the benefit of an International Expert Panel consisting of world-renowned tunnelling expert Dr. Alastair Biggart and experts in geotechnical and structural engineering, Professor John Burland of Imperial College London and Mike Glover of ARUP respectively, to provide expert advice on the design and construction. The input from the panel members included technical review of particular design matters and site constraints

Table 1. Comparison of excavation rates for the Mixshield TBM and VaD TBM.

	Up Trak Tunnel (Mixshield TBM)			Down Track Tunnel (VaD TBM)		
	Length	Av Progress Rate		Length	Av Progress Rate

Total Length/Av rate	673m	7.9m/day	10.0m/day	677m	8.3m/day	11.1m/day

against construction methodologies via workshops and site visits with project team members. The input and support from the panel members is one of the key steps in mitigating the project risks.

8 CONCLUSIONS

Undertaking the shallow Eastern Downtrack tunnel alignment has significantly raised the risk profile of the project. The decision to adopt the hybrid EPB/VaD TBM for the ground condition was deemed a success. The ground settlement associated with the tunnel excavation was well below the predicted level, there was no impact to the existing buildings, structures and utilities along the alignment and road traffic in the busy districts was not affected. Although the EPB mode was not necessary for the entire 670m long tunnel drive, the TBM and its multi-density slurry mode operated efficiently with good maintenance and production.

The success of the tunnel drive can also be summarized with a risk management process which includes a relentless approach to record search on construction history and having a good geological model along the tunnel alignment and comprehensive advanced works to remove obstructions.

ACKNOWLEDGEMENT

The authors would like to thank the Railway Development Office of Highways Department of the Government of the Hong Kong Special Administrative Region for its permission to publish this paper and their support particularly during the construction stage of the project. Although this paper bears the names of the authors, the staff from design consultant Ove Arup & Partners, contractor Dragages Bouygues Joint Venture

and their suppliers, and the MTR project team all played a vital role on the success of the project.

Is a large TBM diameter unfavourable under squeezing conditions?

Alexandros N. Nordas*, Thomas Leone & Georgios Anagnostou
ETH Zurich, Zurich, Switzerland

ABSTRACT: A notable hazard in shield tunnelling through squeezing ground is the entrapment of the tunnel boring machine (TBM) due to insufficient thrust force. One often associates larger tunnel diameters with higher risks compared to smaller ones, mainly due to the higher propensity for problems related to an increased tunnel face size. However, depending on the tunnel diameter, different technical limitations exist that are associated with particular TBM parameters and the construction process, the effects of which are complex to assess and often mutually competing with respect to the TBM entrapment risk; all such limitations considered, the question arises: is a larger tunnel diameter always more critical? The present paper addresses this question by numerically investigating the effect of the tunnel diameter on the risk of TBM entrapment during mechanised excavation and after construction standstills, considering relevant technical limitations, a broad range of geotechnical conditions, as well as the effect of time-dependency of squeezing. The investigations yield an interesting finding – larger diameter tunnels are more favourable in poor quality ground, while the opposite holds in higher quality ground, as well as in the case of pronouncedly time-dependent ground behaviour. Besides their theoretical value, the results of the presented investigations also provide practice guidance concerning the use of experiences acquired from existing tunnels about the required thrust force as a reference for different diameter tunnels constructed under the same geotechnical conditions.

1 INTRODUCTION

A situation sometimes encountered in tunnelling practice is that of different diameter tunnels constructed under practically the same geotechnical conditions, *e.g.* a smaller diameter pilot tunnel constructed prior to the main tunnel for exploration, advance drainage or ground improvement; or a road tunnel upgraded by later construction of a safety tunnel of smaller diameter. In such cases, the larger diameter tunnel usually poses a higher risk during construction, as a large cross-section is unconditionally less favourable for certain hazards (*e.g.*, collapse of the tunnel face), and more likely to encounter adverse conditions (*e.g.*, weak zones, water inflow *etc.*; Kovári 1979; Schneider 2002). In the cases of mechanised construction with a shielded tunnel boring machine (TBM), one of the most critical hazards is TBM entrapment due to insufficient thrust force (“shield jamming”; Ramoni and Anagnostou 2010). Although one may tend to think that a larger diameter tunnel is also more critical in relation to this hazard, this is not always straightforward when it comes to assessment for two reasons.

First, depending on the tunnel diameter, there are different technical limitations for certain TBM parameters, including the annular overcut around the

shield, shield length, shield and lining stiffnesses and installable thrust force (Ramoni and Anagnostou 2010). These limitations often have mutually competing influences on the risk of shield jamming, which render their combined effect complex to assess.

Second, the tunnel diameter also poses limitations on certain parameters of the construction process, including the TBM advance rate during excavation and the duration of construction standstills. These are only relevant in the cases of time-dependent ground behaviour, and thus in squeezing ground. The latter may undergo rapid convergences following excavation, but its behaviour is often characterised by continuous deformations over a period of days, weeks, or even months due to creep or consolidation (Kovári and Staus 1996; Barla 2001; Anagnostou and Kovári 2005; Anagnostou 2007).

Considering all aforementioned factors, the question of whether a larger diameter tunnel is more critical than a smaller one in relation to the risk of shield jamming becomes complex and far from straightforward to answer qualitatively. Although the problem of shield jamming in mechanised tunnelling through squeezing ground – additionally considering creep and consolidation effects – has overall attracted significant attention in the literature (for a recent review see Leone *et al.* 2023), the effect of the tunnel diameter on the risk of shield jamming

*Corresponding author: anordas@ethz.ch

(henceforth referred to as “scale effect”) has not been addressed thus far in the literature.

This question will be numerically investigated here, considering all factors mentioned above, a broad range of geotechnical conditions including pronounced creep of the ground, and the main two operational conditions – ongoing excavation and restart after a construction standstill. For details concerning the case of consolidation, the reader is referred to Nordas *et al.* (2023), which focuses principally on time-dependent ground behaviour and examines the differences between creep and consolidation.

The paper starts with the problem definition and the computational assumptions adopted in the numerical investigations (Section 2). Subsequently, it presents some theoretical considerations that improve the understanding of the problem (Section 3), as well as the practical considerations and limitations concerning the TBM and construction process parameters which must be considered in the simulations (Sections 4 and 5). Finally, it presents the results of the numerical investigations into the scale effect; first, for the case of time-independent ground behaviour, where the scale effect is associated solely with the TBM parameters (Section 6), and then for the case of time-dependent behaviour, where the construction process parameters are also relevant and a distinction must be made between the conditions prevailing during excavation (Section 7) and those during restart after a longer standstill (Section 8).

2 COMPUTATIONAL ASSUMPTIONS

Consideration is given to the rotationally symmetric problem of a deep, cylindrical tunnel of radius R , crossing homogeneous and isotropic rock subjected to a hydrostatic *in-situ* stress field (σ_0). A numerical model of the advancing tunnel heading has been developed in Abaqus® (Dassault Systèmes, 2018) to simulate the mechanised excavation and lining installation, as well as the conditions during a subsequent TBM standstill of arbitrary duration (Figure 1). A detailed description of the computational assumptions can be found in Nordas *et al.* (2023), while some key aspects of the model are discussed hereafter.

On account of rotational symmetry, the model assumes uniform overcut ΔR and backfilling around the segmental lining. The excavation process, which in reality consists of intervals of continuous TBM propulsion (with the net advance rate v_N) regularly alternating with standstills for lining erection (zero advance rate), is simulated as continuous with an average advance rate v ; this simplification has been shown to be sufficiently accurate in most cases (Leone *et al.*, 2023). At each numerical excavation step, part of the ground equal to the 0.5 m round length (Figure 1) is removed ahead of the face and an equal part of lining is installed immediately behind the shield

tail (step-by-step simulation method; see, *e.g.*, Franzius and Potts, 2005). The tunnel face is considered unsupported, taking into account the fact that open shield TBMs are employed in most practical cases of mechanised tunnelling through squeezing rocks. The tunnel support is modelled by radial springs that account for the shield and lining stiffnesses (K_s and K_l) as well as for the radial overcut ΔR (for details see Ramoni and Anagnostou, 2010).

In transient analyses considering creep, a linear elastic-viscous perfectly plastic constitutive model is adopted for the rock, with a Mohr-Coulomb yield condition and a non-associated visco-plastic flow rule based on Perzyna’s theory (Perzyna, 1966); this is suitable for modelling rheological processes in squeezing ground, where the dominant portion of time-dependent deformations is plastic. The model has six parameters – Young’s Modulus E , Poisson’s ratio ν , uniaxial compressive strength f_c , angle of internal friction ϕ , angle of dilation ψ , and the viscosity η , which determines the rate of visco-plastic deformations. Details on its formulation and numerical implementation in Abaqus® can be found in Leone *et al.* (2023). In the absence of creep ($\eta = 0$), the constitutive model degenerates into the classic elastoplastic model.

The model provides the longitudinal distribution of the rock pressure $\sigma_R(x)$ on the shield at any time instance. The simulated excavation length is set equal to 60 excavation steps which is sufficiently long for achieving steady state with respect to the advancing heading; the standstill phase of duration t is initiated thereafter.

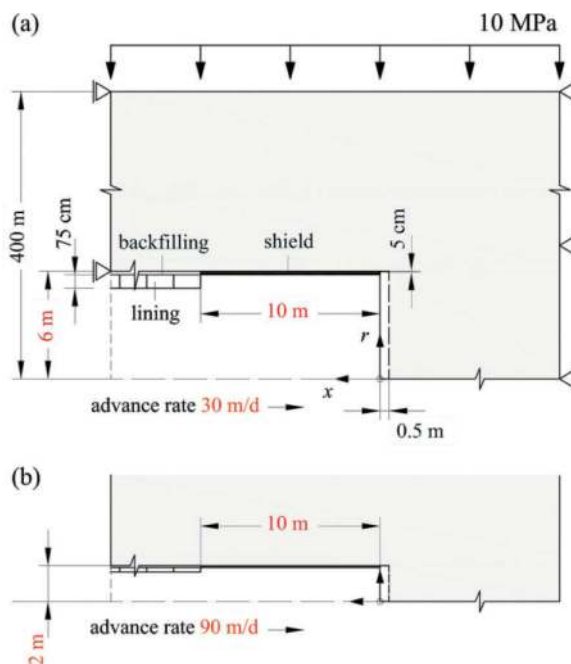

Figure 1. Axisymmetric computational model of the advancing tunnel heading for tunnels with diameter of 12 m (a) and 4 m (b) (Parameters: Table 1).

3 THEORETICAL CONSIDERATIONS

The risk of shield jamming is assessed based on the required thrust force to overcome shield skin friction, which depends on the rock pressure exerted on the shield (Ramoni and Anagnostou, 2010). In the following, the average pressure $\bar{\sigma}_R$ will be considered. It is obtained via integration over the shield length L and depends in general on all problem parameters, including the *in-situ* stress σ_0 , tunnel radius R , ground parameters E , ν , f_c , ϕ , ψ , η , TBM parameters K_s , K_l , L , ΔR , and process parameters, *i.e.* advance rate v , and standstill duration t (Nordas *et al.*, 2023):

$$\frac{\bar{\sigma}_R}{\sigma_0} = f\left(\frac{E \Delta R}{\sigma_0 R}, \nu, \frac{f_c}{\sigma_0}, \phi, \psi, \frac{L}{R}, \frac{K_s R}{E}, \frac{K_l R}{E}, \frac{v \eta}{R E}, t \frac{E}{\eta}\right) \quad (1)$$

In practice, different technical constraints exist for the TBM parameters and the advance rate depending on the size of the tunnel cross-section (here the tunnel radius R), while the rock parameters may also differ at the representative material volume which, however, is not as relevant in weak, squeezing ground (Section 4). Therefore, the dimensionless parameters in Eq. (1) cannot in general take the same values for tunnels of different size, which gives rise to the scale effect.

Evidently, there is not much use in trying to quantify the combined influence of all parameters qualitatively; even by neglecting time-dependency to simplify matters (the last two terms in Eq. 1 become irrelevant), the combined influence of the TBM parameters is cumbersome to assess, due to their mutually competing effects (*e.g.*, L/R and $\Delta R/R$ both decrease with increasing R , but the former is favourable for the rock pressure, while the latter is unfavourable). Therefore, one must resort to numerical simulations. However, before undertaking this it is useful to understand the influence of each parameter, as it offers a better comprehension of the problem. The influence of the TBM parameters is generally known (Ramoni and Anagnostou, 2010), and so in this instance we focus on the last two parameters related to the advance rate v and the standstill duration t , which are only relevant in the cases of time-dependent ground behaviour due to creep. To examine their influence, we consider an idealised situation where all other dimensionless parameters in Eq. (1) related to the ground and TBM are fixed regardless of R .

First, let us examine the isolated influence of the last term related to the standstill duration t . We can do this by considering a case where the excavation occurs rapidly in relation to the rate at which the ground responds to it ($v \eta \rightarrow \infty$), which renders the penultimate parameter infinite regardless of R and the rock pressure only dependent on the last parameter. Since R does not appear in the last parameter of Eq. (1), one can conclude that the rock pressure develops at the same rate regardless of the cross-section size.

Next, let us examine the influence of the penultimate term related to the advance rate v , by considering a case where the excavation is not followed by a standstill and the last term becomes irrelevant. First of all, in order to compare the rock pressure in tunnels with different R , v alone is not the most suitable measure of the rate of advance. When the shield reaches any given tunnel cross-section, it remains exposed to pressure at that section for as long as it is required for its entire length L to pass through it; therefore, the shield pressure that ultimately develops depends on the time required for the TBM to advance by one shield length, *i.e.* L/v ($= (L/R)/(v/R)$), which is only a function of v/R since L/R is considered fixed here regardless of R . A more suitable measure of the rate of advance would thus be v/R – considering the same v/R means that the TBM takes the same time to advance by one shield length irrespective of R . For a given v/R , the normalised advance rate $(v/R)(\eta/E)$ is constant, which means that the pressure develops at the same rate irrespective of R – exactly as in the case of the standstill examined previously.

Combining the above, for both conditions – during advance and for restart after a standstill of the TBM – there would be no scale effect in the case of time-independent ground behaviour, but also in the case of creep, if the same dimensionless parameters related to the ground and the TBM could be specified for different diameter tunnels and these could be excavated with the same rate v/R . In all other cases, there will be a scale effect, which can only be quantified numerically.

4 PRACTICAL CONSIDERATIONS

Notwithstanding the value of the theoretical considerations discussed in Section 3, the scale effect resulting from the combined influence of all parameters is far more complex due to the aforementioned constraints and limitations concerning the advance rate, the TBM parameters and, possibly, also the ground parameters. These are discussed in the following subsections.

4.1 Advance rate

The assumption adopted in Section 3 – that v/R can be the same for the two tunnels, *i.e.* v is proportional to R – is particularly erroneous, as it means that a larger diameter tunnel could be excavated at a higher rate. In practice, it is well-known that the larger the boring diameter, the slower the TBM advances, *i.e.* v decreases with increasing R . In fact, v can be assumed inversely proportional to R , which then makes v/R inversely proportional to R^2 , as discussed hereafter.

Mechanised excavation can be idealised as a “stop-and-go” process, where intervals ΔT_1 of continuous TBM propulsion over the length of one prefabricated segmental lining ring L_T regularly

alternate with standstill intervals ΔT_2 for the corresponding ring installation. The net advance rate of the TBM during continuous excavation can thus be expressed as $v_N = L_T/\Delta T_1$, while the average advance rate during the “stop-and-go” process considered in this work (Section 2) can be expressed as $v = L_T/(\Delta T_1 + \Delta T_2)$ (Leone *et al.*, 2023).

The net advance rate is defined as $v_N = \text{ROP} \cdot \text{RPM}$, where ROP is the rate of penetration and RPM the number of rotations of the TBM cutterhead per minute. For tunnels under identical ground conditions ROP can be assumed to be the same, provided that the installed thrust force is higher in the larger TBM, as is common in practice. RPM can be assumed inversely proportional to R , considering that the linear velocity of the gauge cutters is limited to 150-200 m/min to avoid overheating, irrespective of the TBM diameter (Rispoli *et al.*, 2020; Hamburger and Weber, 1992). Under these assumptions, v_N becomes inversely proportional to R . Assuming that the lining ring length L_T is the same regardless of R , ΔT_1 becomes proportional to R . It is reasonable to assume that ΔT_2 is also proportional to R (see, *e.g.*, Tahernia and Rostami, 2021; Farokh, 2013, 2020), which then makes v inversely proportional to R .

It is indicatively noted here that, by incorporating the above realistic assumption in the theoretical analysis of Section 3, the conclusions concerning the scale effect during advance already change completely – the normalised advance rate $(v/R)(\eta/E)$ becomes inversely proportional to R^2 , which means that the pressure develops faster in a larger tunnel. In practice, this means that if the tunnel diameter was, *e.g.*, four times larger, the pressure would develop 16 times faster (as if the ground viscosity η was lower by a factor of 16). On the other hand, the scale effect during a standstill preceded by a rapid advance ($v \eta \rightarrow \infty$) is not influenced; however, as the tunnel size influences the advance and standstill phases differently, the overall scale effect already becomes very complex to assess – this is even more so the case when the technical constraints for the TBM parameters are additionally considered, as discussed next. This underscores the importance of incorporating these limitations in our numerical investigations.

4.2 TBM parameters

The TBM parameters (overcut ΔR , shield length L and shield and lining stiffnesses K_s and K_l) that can be materialised in practice are limited to a specific range, regardless of the tunnel diameter. Therefore, the nondimensional parameters $E\Delta R/(\sigma_0 R)$, L/R , $K_s R/E$ and $K_l R/E$ cannot in general take the same values for a large and small tunnel. Furthermore, when evaluating potential scale-effects with respect to the risk of shield jamming, it is not sufficient to only consider the shield loading or the required thrust force (which depend on the parameters in Eq. 1), but also the installed or installable thrust force. The latter

increases with the tunnel diameter, which introduces an additional scale effect to be considered. Typical values for these parameters based on technical data gathered from various TBMs can be found in Ramoni and Anagnostou (2010).

4.3 Ground parameters

The strength and stiffness of the ground tentatively decrease with increasing representative volume and, in turn, tunnel diameter, hence scale-effects may exist also in relation to the ground parameters. However, as squeezing ground is often weak at the scale of specimen, the differences between a small and a large diameter tunnel with respect to the ground parameters are not significant and can be neglected.

5 ASSUMPTIONS OF QUANTITATIVE ANALYSIS

Two tunnels with diameters $D = 4$ m and 12 m excavated under identical ground conditions will be analysed numerically using the computational model introduced in Section 2 (Figure 1) and considering practically relevant TBM and process parameters based on the limitations discussed in Section 4, as given in Table 1.

The average advance rates during the stop-and-go operation are selected to be inversely proportional to the diameter (Section 4.1). The common overcut $\Delta R = 50$ mm and shield length $L = 10$ m adopted for both tunnels are realistic, considering that the corresponding normalised values $\Delta R/R = 2.5\%$ and 0.8% , and $L/R = 5$ and 1.7 , are typical for $D = 4$ m and 12 m, respectively (*cf.* Fig. 6 in Ramoni and Anagnostou, 2010). The thicknesses d_s of the shield and d_l of the lining are assumed proportional to the radius R ; this assumption is reasonable and makes the normalised radial stiffnesses $K_s R/E = (E_s/E) d_s/R$ and $K_l R/E = (E_l/E) d_l/R$ identical for the two tunnels, and dependent only on the Young’s moduli E_s , E_c and E of steel, concrete and the ground, respectively.

To assess the risk of shield jamming, the required thrust force F_r must be considered in combination with the installed thrust force F_i . Therefore, the comparison between the two tunnels is based on the ratio F_r/F_i , which expresses the percentage of F_i utilised by F_r and will be hereafter referred to as “thrust utilisation factor” (TUF). The required thrust force F_r is computed as $\mu 2\pi R L \mu \bar{\sigma}_R$, where μ denotes the static friction coefficient. Strictly speaking, this expression holds for the conditions during TBM restart after a standstill and not during advance; however, the former is the most critical operational stage in most cases (see Ramoni and Anagnostou, 2010), hence the expression in general provides a conservative estimate. The installed TBM thrust force is assumed to increase proportionally with the cross-section area, and thus with R^2 , according to the

expression $F_i = 5 R^2 \text{ MN/m}^2$ which provides values in the high end of the range of technical data collected from various TBMs (*cf.* Fig. 7 in Ramoni and Anagnostou 2010).

The scale effect is first analysed by disregarding creep (rapid squeezing development), where it is solely influenced by the TBM parameters (Section 6). Subsequently, the case of time-dependent ground behaviour due to creep is examined, considering the conditions during TBM advance (Section 7) and at restart after a 200-day long TBM standstill (Section 8).

Table 1. Parameters considered in the numerical simulations.

Ground	
Young's Modulus, E [GPa]	1
Poisson's ratio, ν [-]	0.25
Uniaxial compressive strength, f_c [MPa]	var.
Angle of internal friction, ϕ [°]	25
Dilatancy angle, ψ [°]	5
Depth of cover, H [m]	400
<i>In-situ</i> stress at tunnel axis, σ_0 [MPa]	10
Viscosity, η [MPa d]	var.
TBM	
Boring diameter, D [m]	4 or 12
Radial overcut, ΔR [mm]	50
Shield length, L [m]	10
Radial shield stiffness, K_s [MPa/m]	875 ($D = 12\text{m}$) 2625 ($D = 4\text{m}$)
Shield thickness, d_s [m]	0.15 ($D = 12\text{m}$) 0.05 ($D = 4\text{m}$)
Young's modulus of steel, E_s [GPa]	210
Average Advance rate, v [m/d]	30 ($D = 12\text{m}$) 90 ($D = 4\text{m}$)
Shield skin friction coefficient, μ [-]	0.15
Installed thrust force, F_i [MN]	180 ($D = 12\text{m}$) 20 ($D = 4\text{m}$)
Lining	
Young's modulus of concrete, E_c [GPa]	30
Lining thickness, d_l [m]	0.75 ($D = 12\text{m}$) 0.25 ($D = 4\text{m}$)
Radial lining stiffness, K_l [MPa/m]	625 ($D = 12\text{m}$) 1875 ($D = 4\text{m}$)

6 RESULTS DISREGARDING CREEP

Figure 2 shows the thrust utilisation factors of the two tunnels with $D = 4\text{ m}$ (solid lines) and $D = 12\text{ m}$ (dashed lines) as functions of the rock quality, expressed by its uniaxial compressive strength f_c .

The results of Figure 2 contradict the common perception that a smaller diameter tunnel is less vulnerable than a larger one. This may be unconditionally true for other potential hazards (*e.g.*, instability of the tunnel face), but not for shield jamming, where it is only true in higher quality ground ($f_c > 3.2\text{ MPa}$), while the opposite holds in weaker ground. The TUF

Figure 2. Thrust force required to overcome shield skin friction normalised by the installed thrust force (“thrust utilisation factor”, TUF), as a function of the uniaxial compressive strength of the ground f_c (no creep; parameters: Table 1).

Figure 3. Results of a parametric study about the effects of rock strength f_c , rock stiffness E and overcut ΔR on the thrust utilisation factor (TUF) (F_r after the design nomograms of Ramoni and Anagnostou, 2010, for a 400 m deep tunnel with $\sigma_0 = 10\text{ MPa}$, $\nu = 0.25$, $f_c = 0.5 - 4\text{ MPa}$, $\phi = 25^\circ$, $\psi = 5^\circ$, $L = 10\text{ m}$, $K_s R/E = 10$, $K_l R/E = 0.5$, $\mu = 0.15$, $F_i = 20$ and 180 MN for $D = 4$ and 12 m , respectively).

of the TBM in the larger diameter tunnel is generally less sensitive to variations of rock quality than in the smaller diameter tunnel and is consistently lower than 1, which means that the tunnel excavation is feasible for the considered strength range, whereas the small tunnel excavation is only feasible in higher quality ground ($f_c > ca. 2.7$ MPa).

Considering this interesting finding, a more extensive parametric study was conducted to assess its general validity. The computations concern a 400 m deep tunnel ($\sigma_0 = 10$ MPa) and have been performed using the design nomograms of Ramoni and Anagnostou (2010). Concerning ground parameters, consideration is given to variable uniaxial compressive strength $f_c = 0.5 - 4$ MPa, Young's moduli $E = 500 f_c$ and $1500 f_c$, which respectively correspond to the lower and upper limits of possible stiffnesses for a geomaterial with given f_c , and otherwise identical parameters to those given in Table 1, which were also considered by Ramoni and Anagnostou (2010).

Concerning TBM parameters, consideration is given to overcuts $\Delta R = 50, 75$ and 150 mm, which respectively correspond to the relatively small value adopted in the computational example (Table 1), an intermediate value and an unusually large value. The shield length and installed thrust force are as given in Table 1, but different normalised radial stiffnesses of the shield $K_s R/E = 10$ and the lining $K_l R/E = 0.5$ are considered, which correspond to those assumed by Ramoni and Anagnostou (2010) for producing the design nomograms; although the latter assumption leads to more conservative predictions for the required thrust force, it does not affect the conclusions of the study otherwise.

The results of the parametric study (Figure 3) confirm that a larger diameter tunnel is always less vulnerable than a smaller one in weak ground (dashed lines for $D = 12$ m consistently below solid lines for $D = 4$ m in the range of low f_c). Moreover, it is less sensitive to variations of the ground quality and its excavation is practically feasible in all cases considered, in contrast to the smaller diameter tunnel, which exhibits a much higher sensitivity to the ground quality and its excavation is only feasible in higher quality ground.

7 RESULTS FOR CREEP AND TBM ADVANCE

In the example of Figure 2, the TUFs of the two TBMs are equal for $f_c = ca. 3.2$ MPa, which means that the competing effects of the TBM parameters (Section 3) outweigh one another and the scale effect associated with these is eliminated. Therefore, the transient computations have been performed for this strength (and the parameters of Table 1). This enables examining the isolated influence of the advance rate v or, equivalently, the viscosity η in the case of creep (note the dimensionless expressions in Eq. 1).

Figure 4 shows the thrust utilisation factor as a function of η for the two tunnels with $D = 4$ m (solid lines) and $D = 12$ m (dashed lines).

Figure 4. Thrust utilisation factor (TUF) as a function of the viscosity η ($f_c = 3.2$ MPa; other parameters: Table 1).

With the exception of the range of high viscosities, a scale effect clearly exists with respect to the risk of shield jamming: an increase in diameter results in a higher utilisation of the thrust force, as reflected by the vertical distance between the dashed line and the solid line that is consistently below it. This means that in the case of time-dependent ground behaviour, the situation is more favourable for the smaller diameter, which is also consistent with the results discussed in Section 6 and shown in Figure 2: time-dependency delays squeezing, hence the rock responds to tunnel excavation as if it were of a higher quality, and an increase in rock quality renders a smaller diameter more favourable. It is noted here that this result is qualitatively consistent with the theoretical considerations discussed in Section 4.1, according to which the rock pressure on the shield develops faster on the larger TBM for a given advance rate (or, equivalently, viscosity η herein).

The scale effect is negligible in the range of high viscosities because the rock behaviour is practically elastic, hence the convergences around the advancing shield area are small anyway, regardless of the tunnel diameter.

The scale effect can also be demonstrated in an alternative way. Let us consider a case where the 4 m diameter tunnel was constructed first, and the actual applied force was equal to 20% of the installed one (TUF = 0.2). Assuming that the strength and stiffness parameters of the rock are known and correspond to the ones in Figure 4, the rather low required thrust force could be explained on the basis of the convergence delay due to time-dependency (point A in Figure 4). What could one expect for the main, larger diameter tunnel? In order to limit the effect of squeezing and maintain the same, low TUF = 0.2, the viscosity η would have to be higher by a factor of about 50 (point B vs. A); equivalently, for the same η (as in point A), the

advance rate v in the main tunnel would have to be about 50 times higher (note dimensionless expressions in Eq. 1). This is, of course, impossible, but provides another interpretation of the scale effect.

For the parameters adopted in this example, the TUFs of both TBMs are consistently lower than the value of ca. 0.7 which corresponds to time-independent behaviour (very low viscosity; cf. Figure 2), indicating that the excavation of both tunnels is thoroughly feasible. However, the assumed values for the installed thrust force $F_i = 5 R^2 \text{ MN/m}^2$ (20 MN for $D = 4 \text{ m}$, 180 MN for $D = 12 \text{ m}$; Table 1) are very high for rock TBMs; with a moderate assumption, e.g. $F_i = 3 R^2 \text{ MN/m}^2$ (12 MN for $D = 4 \text{ m}$, 108 MN for $D = 12 \text{ m}$), jamming of the larger TBM might occur in the range of $\eta = \text{ca. } 10\text{--}100 \text{ MPa}\cdot\text{d}$, while the smaller TBM would remain entirely in the safe region.

8 RESULTS FOR CREEP AND RESTART AFTER STANDSTILL

Transient computations have been performed considering the same parameters as before (Table 1 and $f_c = 3.2 \text{ MPa}$), as well as a high viscosity $\eta = 10,000 \text{ MPa}\cdot\text{d}$ to ensure that the behaviour during advance is elastic and, therefore, relevant shield loading develops only during the standstill (see $\text{TUF} < 0.1$ for $\eta = 10,000 \text{ MPa}\cdot\text{d}$ in Figure 4). This enables an examination of the isolated influence of the standstill duration t .

Figure 5 shows the thrust utilisation factor as a function of t for the two tunnels with $D = 4 \text{ m}$ (solid lines) and $D = 12 \text{ m}$ (dashed lines).

Figure 5. Thrust utilisation factor (TUF) as a function of the standstill duration t ($f_c = 3.2 \text{ MPa}$; $\eta = 10^4 \text{ MPa}\cdot\text{d}$, other parameters: Table 1).

The same conclusions as for the advance stage examined in Section 7 can basically be drawn also here. There is a clear effect of the tunnel diameter on the thrust force required for restart after a standstill

and the associated shield jamming risk, as expressed by TUF. This scale effect is reflected by the width of the band defined by the dashed and solid lines.

9 CONCLUSIONS

The present paper numerically investigated the effect of the tunnel diameter on the risk of shield jamming during mechanised tunnel construction in squeezing ground, considering the various technical limitations concerning the TBM and construction process parameters depending on the tunnel diameter and the markedly time-dependent response that squeezing ground often exhibits. Exemplary numerical simulations with practically relevant parameters demonstrated that a larger diameter is always more favourable than a smaller one in poor quality ground, while the opposite is true in the case of higher quality ground or ground exhibiting time-dependent behaviour, where the delay in ground deformations is equivalent to an improvement of the ground quality.

The paper only considered time-dependency due to creep, but the conclusions drawn hold also for the case of consolidation – the other common mechanism of time-dependency in squeezing ground. Scale effect in this case is slightly less pronounced. For more details, the reader is referred to Nordas *et al.* (2023).

Provided that data are available concerning the required thrust force in an existing tunnel, the findings of the present paper provide useful indications and guidance concerning the risk of shield jamming during the later construction of an adjacent, different diameter tunnel.

ABSTRACT: Over the last two decades, large diameter Tunnel Boring Machine (TBM) tunnels have been increasingly utilized for underground road and rail transportation projects. Among those, longer and deeper subaqueous tunnels also became feasible and competitive with increased technological developments and applying innovative solutions. Notably in recent years, several subaqueous large diameter tunnels have been designed and safely constructed under high water pressures and in challenging environmental conditions, e.g. seismic regions, with the aid of smart technologies and digital tools.

This paper discusses developments of large diameter subaqueous tunnels; focusing on special considerations in design and construction, risk management and sustainable low carbon solutions using key examples from recent projects.

Keywords: TBM, Large diameter, Subaqueous, Sustainable solutions

1 INTRODUCTION

In recent years, several subaqueous TBM tunnels have been successfully designed and constructed in depths greater than 100m, lengths extending over 4km, and in highly seismically active regions ($\geq 7.0Mw$). In order to overcome environmental challenges, innovative and robust design and construction techniques together with sustainable solutions have had to be considered and effectively applied. Constructing subaqueous tunnels using TBM, by their very nature, face higher risks against blowouts and/or sinkholes. Therefore a more rigorous risk management approach is required to help identify and mitigate, or eliminate if feasible, the associated risks.

2 SUBAQUEOUS TUNNELLING METHODS

For large scale subaqueous tunnelling projects, mainly four types of tunnelling methods are utilized, including:

- TBM Tunnels
- Immersed Tube Tunnels

- Mined Tunnels (Drill & Blast, Sequential Excavation Method)
- Offshore Cut-and-Cover Tunnels

2.1 *Subaqueous TBM tunnels*

In recent years, longer and deeper, large diameter subaqueous TBM tunnels are being constructed. For example the Eurasia subsea tunnel, located in Turkey, is a 106m deep, double-deck road tunnel. This was constructed with a TBM designed to withstand up to 12 bar hydrostatic pressure. In Hong Kong SAR, a number of subaqueous tunnels have been constructed with TBM diameter $\geq 13m$. Table 1 below shows details of some of the larger diameter subaqueous TBM tunnels together with lengths, depths and tunnel lining outer diameters. The projects shown in Table 1 are all road tunnels, including three lane per tube and double-deck tunnels. There are some large diameter TBM tunnels accommodating double-track railways such as Riyadh Metro (completed), three contracts in Singapore (CRL Phase 2) which are under construction and few others. Those tunnels are smaller in diameter compared to the road tunnels listed in Table 1, in the range of 10m ~ 13m OD.

Table 1. Some of the Large Diameter Subaqueous Tunnels.

Project	Length below Sea/ River (m)	Depth below Sea/ River (m)	Outer Diameter (m)
Eurasia Tunnel (Turkey)	3340	106	13.2
Shantou Su Ai Tunnel (China)	3046	65	14.5
Tokyo Bay Aqua Line (Japan)	9400	60	13.9
Tuen Mun – Chek Lap Kok Link (Hong Kong, SAR of China)	5000	55	13.5 & 16.9
Karnaphuli River Crossing (Bangladesh)	2450	50	11.8
Chong Ming South Tunnel (China)	7470	60	15.0
Shenzhen Mawan Subsea Tunnel (China)	2063	40	15.0
Port of Miami Tunnel (USA)	1300	37	12.5

Figure 1. Tuen mun – Chek lap kok link TBM tunnel, Hong Kong, SAR of China.

2.2 Immersed tube tunnels

There are over 180 immersed tube tunnels in the world, including those under construction. In recent years, with the help of advancing technology, deeper and longer immersed tube tunnels could be designed and built. Figure 2 and Figure 3 show the deepest and longest immersed tunnels constructed to-date.

2.3 Subaqueous mined tunnels

Large scale subaqueous mined railway or road tunnels are generally deep, passing through rock strata. The longest mined tunnel to-date is the Seikan railway tunnel located in Japan. This railway tunnel passes beneath the Tsugaru Strait and connects the Aomori Prefecture on Honshu Island and the Hokkaido Island.

Figure 2. Deepest immersed tube tunnels.

Figure 3. Longest immersed tube tunnels.

Figure 4. Tunnel element prefabrication and floating at casting yard (HZMB Link).

Its 23.3km long subsea section, extends approximately 240m below the sea level (approximately 100m below seabed). The deepest mined tunnel for transportation is the Ryfylke tunnel, located in Norway, extending 292m below the sea level at its deepest point.

2.4 Subaqueous cut-and-cover tunnels

Subaqueous Cut-and-Cover tunnels are also called offshore Cut-and-Cover tunnels. The construction method utilized for these types of tunnels usually involves marine cofferdams or sheet/pipe piling, constructing the cut-and-cover tunnel in dry condition, and

backfilling after completion of the tunnel. Subaqueous cut-and-cover tunnels are usually shorter and shallower compared to subaqueous TBM and mined tunnels. A road tunnel example is show below in Figure 5.

Figure 5. Central - Wan Chai Bypass, Hong Kong, SAR of China.

3 SUBAQUEOUS TBM TUNNELS IN SEISMIC REGIONS

Tunnels generally perform better during earthquakes than above-ground structures such as bridges, buildings, towers and similar. Tunnels are constrained by the surrounding ground and, in general, cannot be either excited independent of the ground or be subjected to strong vibratory amplification during earthquakes except when the tunnel passing through or near the active fault zone. In addition, as it gets deeper below the ground, the amplitude of seismic ground motion attenuates, and therefore the magnitude of damage to the tunnel structure is smaller compared to above-ground structures.

A Probabilistic Seismic Hazard Assessment (PSHA) returns the probability of a given ground motion to be exceeded within a year, which is usually called “return period”. Most commonly referred return periods for seismic design of tunnels are as follows:

- 100 years return period (40% probability of exceedance in 50 years)
- 475 years return period (10% probability of exceedance in 50 years)
- 975 years return period (5% probability of exceedance in 50 years)
- 2475 years return period (2% probability of exceedance in 50 years)

As an example, the AREMA (2020) design code in the US gives three levels of seismic design motion i.e., at PGA_{100} , PGA_{475} and PGA_{2475} which are corresponding to return period of 100 (Serviceability), 475 (Ultimate) and 2475 (Survivability).

Circular tunnels undergo three primary modes of deformation during seismic shaking:

- Ovaling
- Axial
- Curvature deformations

Axial and curvature deformations are induced by components of seismic waves that propagate along the longitudinal axis (see Figure 6) (Wang, 1993; Owen and Scholl, 1981).

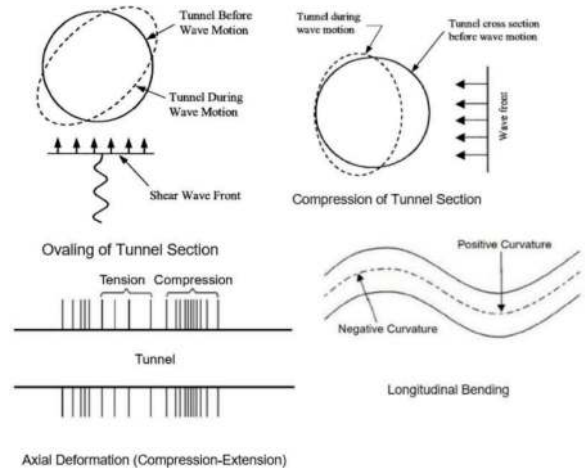

Figure 6. Deformation modes of circular tunnels due to seismic waves.

As mentioned above, the effect due to earthquake on the tunnels is generally less significant than above-ground structures. However, careful assessment is required especially there is risk of liquefaction, or significant change in ground types at high seismic regions (Figure 7). In such cases, special mitigation measures may be required.

Figure 7. TBM tunnel excavating through rock and soft soil.

Seismic waves travel faster through hard rock strata compared to soft soil layers. The deformation or shaking is stronger at soft soil layers which may cause excessive deformation in longitudinal and/or transverse direction of the tunnel at the vicinity of boundary between soft soil layer and the rock. For some projects, seismic joints are installed at the vicinity of soft soil/rock

boundary to minimize the effect of seismic activity at high seismic regions. These seismic joints are full ring like a flexible joint allowing a certain amount of movement in longitudinal and transverse directions. A sample application on a TBM tunnel constructed in a high seismic region is shown in Figure 8.

Figure 8. Seismic joint application on a TBM tunnel.

4 CROSS PASSAGES LINKING SUBAQUEOUS TBM TUNNELS

Cross passages are provided between two TBM tunnels at regular spacing for evacuating passengers to non-incident tunnel in case of emergency (Figure 9).

Figure 9. Cross passage between two TBM tunnels.

In some cases, the cross passages may also be used to house the MEP equipment of other services. Depending on the country and local regulations, whether it is rail or road, the spacing between two cross passages varies. For railway tunnels, one of the most common design codes referred to is NFPA 130

which limits the spacing between two cross passages to maximum 244m (800ft).

Cross passage construction for subaqueous tunnels is higher risk than one constructed on land due to high water pressures, and difficulties in employing ground improvement under marine condition. Ground improvement from above the sea or river surface may not be feasible or quite costly, which may require other methods such as ground freezing (Figure 10) or ground improvement from inside the cross passage.

Figure 10. Ground Freezing at Cross Passage location.

Another innovative construction method, applied for the first time and proved successful at Tuen Mun - Chek Lap Kok Link project (Hong Kong, SAR of China), uses a mini-TBM for most of the cross passages sub-sea section. Local regulations required two large-diameter sub-sea TBM tunnels to be linked at every 100m which resulted a total of 57 cross passages.

A 3.665m diameter slurry mini-TBM was used to construct the sub-sea cross passages. On the launching side of the cross passage, a jacking-pipe system was setup for the mini-TBM break-in. On the retrieval side, a steel pressurized chamber was installed to receive the mini-TBM for break-out. A pipe-jacking system was adopted to excavate the cross passages using a mini-TBM (Figure 11, 12, 13). This innovative method helped safely construct 39 cross passages in about 13.5 months.

Figure 14. Hyperbaric Shuttle, TM-CLKL, Hong Kong, SAR of China.

Figure 13. Steel pressurized chamber for receiving mini-TBM.

5 SATURATION DIVING FOR CUTTERHEAD INTERVENTION (CHI)

Disc replacement or cutterhead maintenance for subaqueous large diameter TBM tunnels is an extremely high-risk activity. Apart from the planned cutterhead interventions, there may be the need of unplanned interventions as well for TBM repair as emergency. In order to minimize unplanned interventions, grouted blocks are created as safe havens, which, enable the intervention at atmospheric conditions.

However, in some cases where the ground condition is unstable under atmospheric condition, hyperbaric interventions may become necessary, especially when the pressures exceed 3.5bar for cutterhead maintenance. A compressed air intervention cannot be carried out at high (>5~8 bar) pressures. In such hyperbaric environments, saturation diving techniques could be employed. This comprises a team of divers living in a man lock under hyperbaric habitat and being transported to the TBM in a pressurized shuttle that docks with an airlock on the pressure bulkhead.

The divers breathe mixed gases throughout their stay in the habitat before decompression. Decompression can take a few days as the pressure is

reduced step by step until atmospheric pressure is achieved.

For TM-CLKL project, a team composed of 4 workers, specialized in hyperbaric works have been deployed. The duration of the work cycles was 28 days. For that purpose, a living habitat was built on the ground (Figure 15).

Figure 15. Living habitat for saturation diving on the ground.

6 CONFINEMENT PRESSURE

A slurry TBM can be used in almost all ground conditions under high water pressures. The principle of the slurry TBM is to apply an adequate pressure on the slurry contained in the excavation chamber. This pressure is thus transferred to the excavation face to obtain a pressure value as close as possible to that calculated in relation to the in-situ stress.

In subaqueous tunnels, high pore pressures can occur at very shallow depths of ground cover, resulting in particularly adverse effects on face stability and deformation. In the event that a tunnel connection opens to the seabed, potential hazards may include high water inflows or even complete flooding of the tunnel. It is imperative to control TBM confinement pressure to prevent face collapse, blowout, excessive ground settlement, and excessive ground heaving.

7 CASE STUDIES – LARGE-DIAMETER SUBAQUEOUS TBM TUNNELS

7.1 Tuen Mun – Chek Lap Kok Link (TM-CLKL), Hong Kong, SAR of China

TM-CLKL is a strategic subsea traffic route serving as a direct connection between the Northwest New Territories and Hong Kong – Zhuhai – Macao Bridge (HZMB), the Airport and North Lantau and also an alternative route to the Airport (Figure 16). This project comprises a dual two lane, trunk road about 10km long, of which about 5km consist of TBM and cut & cover tunnels, connecting a 16.5 hectares of reclaimed land in Tuen Mun (Northwest New Territories) and the reclaimed site of HKBCF. TM-CLKL also comprises a toll plaza together with associated tunnel operation facilities at north. Cross passages are provided at every 100m spacing between the two tunnel tubes for emergency escape purposes.

TM-CLKL is a pioneering subsea TBM project in Hong Kong with the following key features:

- The World's largest TBM tunnel in 17.6m excavation diameter constructed in mixed ground conditions;
- The Longest and deepest TBM subsea tunnel in Hong Kong at 5km long 17.6m/14m excavation diameter bored tunnels; max. water head of above 5 bars respectively;
- Two mini TBMs deployed to construct large amount of cross passages connecting twin tubes of main tunnels (57 cross passages including 48 subsea cross passages);
- New technologies adopted for better and safer tunnel operation, such as changing TBM cutterhead of different diameters; saturation diving approach to smooth and shorten the TBM maintenance procedures; articulated robot arm to access the excavation chamber at hyperbaric conditions

7.2 Chongming south tunnel, Shanghai, P.R.China

The 7.5 km Chongming South Channel Tunnel was the largest diameter TBM tunnel when it was completed in 2009. This tunnel is part of the 25.5 km long Shanghai – Chongming expressway, linking the Changxing and Chongming islands to the city. The expressway consists of the tunnel and a cable bridge from Chang Xing Island to Chongming Island (Figure 18).

The tunnel section comprises two 15.0m OD tunnels and the TBM diameter is 15.43m, connected by eight cross passages. The length of each tunnel is approximately 7.5 km and there is a further 1.5 km approach road. The upper part of the tunnel is a three lane road and the lower part is for the utilities and accommodating a light railway.

Due to high hydrostatic pressures and hyperbaric environment, similar to TM-CLKL, saturation diving technique was adopted for cutterhead interventions.

Figure 16. TM-CLKL Project Location.

Figure 17. TM-CLKL – Twin TBMs (14m dia) break-out.

The tunnels were excavated in soft ground. Ground freezing technique was also used for cross passage construction. Cast iron lining segments were replaced the 650mm thick reinforced concrete segmental linings at the junction between the bored tunnel and cross passage. The gallery at the lower part of the tunnel was constructed as precast boxes (Figure 19).

7.3 Shanghai bund tunnel, Shanghai, P.R.China

This project is located at one of the busiest commercial areas of Shanghai city. The 1km long, 13.95m OD TBM road tunnel has double-deck with three

Figure 18. Chong Ming south project location.

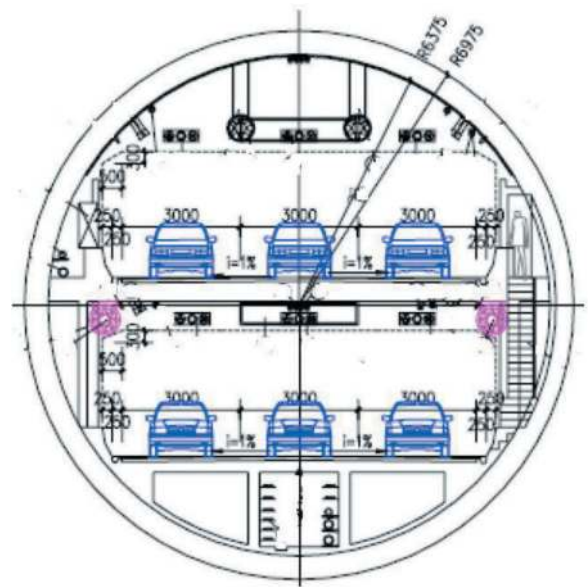

Figure 21. Shanghai bund TBM tunnel cross section.

Figure 19. Chong Ming south tunnel during construction.

lanes in each direction, accommodating total six lanes in a single TBM tunnel (Figures 20, 21).

Figure 20. Shanghai bund project location.

The tunnel had very shallow cover and passed through several sensitive structures including existing metro tunnels (with small separations), existing bridges, subways and is very near to many historical buildings such as the old Hong Kong Shanghai Bank Building located along the river bank

8 CONCLUSIONS

This paper discusses the design and construction development of large scale subaqueous tunnels, focusing on large diameter TBM tunnels. It explains some of the challenges specific to subaqueous TBM tunnels, giving innovative and, practical application examples. With recent technological developments and innovative solutions, larger diameter and longer subaqueous TBM tunnels are expected to be constructed in the future.

ABSTRACT: The Tuen Mun-Chek Lap Kok Link (TM-CLKL) project is one of the most impressive infrastructure developments in Hong Kong. The project comprises a 9km two-lane carriageway connecting Tuen Mun and North Lantau via 5km long sub-sea tunnels, which presented complex hydrogeological conditions and numerous technical and geotechnical difficulties. The project was completed successfully through the application of innovative techniques, including the world's largest Tunnel Boring Machine (TBM), the first use of saturation diving in Hong Kong, TBM tunnelling in newly reclaimed land, and the first deployment of innovative pipe jacking of cross passages.

The construction team deployed a 17.6m diameter slurry-type Mix shield TBM for the northern approach tunnels, followed by two 14.2m diameter slurry-type Mix shield TBM's for sub-sea tunnel construction. The large diameter of the TBMs facilitated efficient and speedy construction while eliminating risk of high-pressure sea water ingress up to 5.8 bars. Additionally, the use of saturation diving technique was applied for TBM cutterhead interventions, with robot cutter-changing to manage complicated ground conditions, providing a safe and stable work environment.

The project also utilized ground-breaking designs such as the peanut shafts in the northern landfall and the world's first 15-cell caterpillar-shaped cofferdam in the southern landfall, reducing costs and improving safety while minimizing environmental impact. The tunnels and buildings' construction involved large volumes of precast concrete elements manufactured off-site, improving quality, efficiency, and working conditions inside the tunnel while reducing the number of workers required onsite.

The TM-CLKL project's commitment to innovation and the application of novel construction techniques overcame numerous challenges, raising the project to global acclaim. Understanding the project's success may contribute to the development of sustainable infrastructure worldwide, where future developments continue pushing the boundaries of construction excellence.

Keywords: Tunnelling, TBM, Performance, Cross passages, Peanut shaft, Saturation diving

1 INTRODUCTION

The TM-CLKL comprises a 9km dual two-lane carriageway between Tuen Mun and North Lantau. It commences at the Lung Mun Road and Lung Fu Road Roundabout in Tuen Mun Area 46, before heading southeast on elevated structure to a landing point on the newly formed reclamation, referred as the northern landfall. The landing of the northern landfall marked the beginning of the sub-sea tunnel as the road alignment turns

south. The sub-sea tunnel stretched for 4.2km, passing beneath the Urmston Road, the busiest navigation channel in Hong Kong cited between Lantau Island and Tuen Mun. The alignment daylight at the eastern edge of the newly reclaimed land of Hong Kong-Zhuhai-Macao Bridge Hong Kong Port, referred as the southern landfall, as illustrated in Figure 1.

The tunnel alignment passes through a number of complex geotechnical interfaces as is shown on figure 2.

Figure 1. Site location plan (Chan et al., 2019a,b).

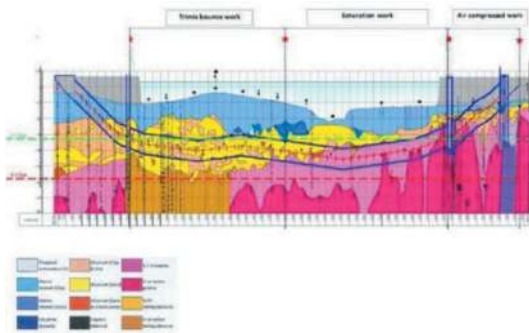

Figure 2. Geological profile of the TM-CLKL sub-sea tunnels (Chan et al., 2019a,b).

The sub-sea tunnels, with the internal diameter of 12.4m, each contained a two-lane carriageway, made up to an external diameter of 14.2m (S882) for tunnel excavation as shown in Figure 3. However, in the tender design, it was proposed to replace an approximately 500m length of cut and cover structure within the northern landfall reclamation area in Tuen Mun with a bored tunnel through an extension of the sub-sea bored tunnels.

The proposed scheme required the northbound exit tunnel to contain a third climbing lane, which was a challenge as it required the internal diameter to be increased to 15.6m with a corresponding increase to

Figure 3. 14.2m diameter TBM (S882) in the Nansha factory.

the external diameter of 17.6m for excavation, making it the largest diameter TBM in the world, as illustrated in Figure 4. Due to the large dimension of the bored tunnels and shallow cover within freshly reclaimed areas, a similarly innovative solution needed to be developed for the associated launching shaft at the northern landfall to house such a large machine.

This Technical Paper will focus on the world first and pioneering aspects of the TM-CLKL project.

Figure 4. 17.6m diameter TBM (S880).

2 DESIGN INNOVATION

2.1 Peanut shafts

With a typical large diameter tunnel boring machine of up to 10m it is possible for a conventional cut and cover structure system to span vertically to provide sufficient working space for the tunnel boring machine launching operations but requires a number of horizontal struts and waling beams to provide lateral support. However, in the northern landfall, due to high lateral loads from the still consolidating newly reclaimed land and the adjacent sea such a design would be expected to be bulky which would limit the use of excavators and vehicles inside making excavation slow. Furthermore, for a machine with an external diameter of 17.6m, a typical TBM launching system becomes practically infeasible due to the need for a minimum clear height of 19m inside the excavation and therefore an alternative approach was required.

In order to cater for the large dimensions of the two tunnel boring machines used for the TM-CLKL project, an innovative strut free multi-cell system, namely the multi-cell “peanut” shaft was adopted as shown in Figure 5. The peanut shaft comprised three interconnected circular diaphragm walls with a varying thickness of 1.2m in Cell 1 and 1.0m in Cells 2 and 3, approximate dimension is 100m by 50m. The cells are designed to work in hoop stress by transferring the radial earth pressure forces acting on the outside of the excavation in compression around the perimeter walls. Only two cross walls and two cross beams between Cells 1 & 2 and Cells 2 & 3 are required as lateral support for the excavation, the cross-wall thickness was 1.2m.

Figure 5. Interconnected cellular cofferdam solution.

This method allows more flexibility in geometry, having the width of the excavation determined by the cell diameter and the length by the number of cells used.

2.2 Caterpillar shafts

To the south of the TM-CLKL, where it approaches the man-made island of the Hong Kong-Zhuhai-Macao Bridge Hong Kong Port, an innovative 15-cell Caterpillar Cofferdam was used to cope with the adverse site geology at the newly reclaimed area as illustrated in Figure 6, with very thick (over 30m) and very deep (up to 50m below ground level) layers of marine deposits and alluvium clays. The cofferdam has a length of 500m and a depth of 43m, circular cells are formed by a perimeter diaphragm wall in an arch shape, ranging from approximately 25 to 37m long and 44 to 57m wide each, hoop forces induced on the walls are transferred at the junction of the cells to the “Y-panels”, which are transversally supported by reinforced concrete struts and cross-wall. Fewer rebars were used, allowing unobstructed construction space and maximising working space for the TBMs and cut and cover tunnel.

Figure 6. Caterpillar-shaped cofferdam for southern cut and cover tunnel (Schwob, a, et. al, 2020).

2.3 Tunnel lining design for largest diameter tbm

The TM-CLKL used the world’s largest slurry-type Mixshield TBM (S880), creating an internal diameter of 15.6 m with an excavated diameter of 17.6m as shown in Figure 7, composing the northern approach tunnel. The TBM tunnel was lined with pre-cast universal concrete segmental lining, and the lining was designed as an undrained lining with a design life of up to 120 years (Chan, et. al, 2019). To enable an adequate tunnel lining, its structural stability and deformation of the lining were checked. Structural stability was checked in compliance with the Code of Practice and the crack width of the lining was controlled to be not more than 0.2mm for durability assessment.

Figure 7. Typical cross section of the 17.6m tbm.

The lining segments are grade 55/20 concrete, with 700mm thick for the tunnel internal. The tunnel itself is made up of twelve precast concrete segments which sequentially assembled to form a ring as illustrated in Figure 8.

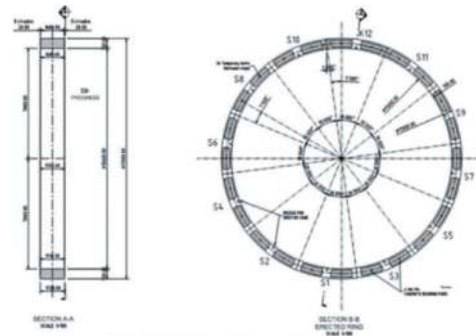

Figure 8. Typical cross section of segmental lining (Chan, et. al, 2019).

2.4 Tunnel settlement control design principles for largest diameter tbm

A large portion of the initial 17.6m TBM drive was in freshly reclaimed land, which was a major challenge as it required some enhancements to the northern reclaimed land. The original land was composed of

layers of marine deposits and clayey alluvium, the layers were disturbed by the backfilling work and consolidated under the new loads from the tunnelling works.

In order to achieve the strength parameter of the compressible soil, it was taken as the surcharge imposed on compressible soils, in which bands of drains of high permeability were installed, after that the reclamation was backfilled, with the surcharge of up to 12.5m and during the process, water was squeezed out of the soil matrix and particles were squeezed more tightly together, leading to an increase in the shear strength of the material. The consolidation period was scheduled to be up to 4 to 6 months, according to Schwob et. al (2020), a final efficiency of 90% consolidation under the weight of the surcharge was reached at the end of the consolidation period.

If the ground condition did not meet the success conditions, local ground improvement by jet grouting would be performed. Reaching the end of the consolidation and surcharge period, the twin tunnels were excavated.

2.5 Tunnel internal structures and integration of design for manufacture and assembly (DfMA) principles

Efficient space proofing of the tunnel was carried out to enhance the functionality of the large diameter of tunnel, the majority of the E&M equipment were placed underneath the carriageway, a dedicated service gallery underneath the road deck was provided for operational and maintenance access without disrupting tunnel traffic, also the provision of undercarriage ventilation duct, for the supply of fresh air to the main tunnel carriageway through openings in the parapet and an E&M ventilation duct, for the supply of fresh air and extract smoke from the service corridor through the damper openings in the event of fire, as required in the tender design.

Large portions of the sub-sea tunnel internal structures were precast elements, which were

fabricated at an off-site precast yard. The service gallery, the overhead ventilation duct (OHVD) and the road barrier were all precast elements, utilising DfMA extensively. The construction programme for the tunnel internal structure was extremely tight, access to TBM needed to be maintained during the internal structure construction, therefore a dedicated service gallery installation gantry were designed and placed behind the TBM, allowing installation of the precast service gallery units whilst maintaining uninterrupted access for the TBM tunnelling logistics.

2.6 Cross passage head wall and reaction block design

Cross passages between the two main tunnels were constructed at every 100m interval, three methods were adopted to excavate a total of 57 cross passages, and a total of 46 cross passages were within the sub-sea tunnel section. Two types of cross passage, namely the Type A and Type B cross passage were introduced in the original scheme, for which Type B was very large. By introducing the under-road gallery, the cross passages were unified to just one single type (Type A), as the E&M installations were removed from Type B.

Due to the high hydrostatic pressure at the sub-sea condition, it has made the cross-passage construction a potentially high-risk activity for a conventional ground freezing or grouted solution. To mitigate these risks, a pipe jacking method using a mini tunnel boring machine (MTBM) was devised for the construction of cross passages in the sub-sea tunnel section.

2.7 Cross passage lining design to suit construction methodology

One of the most critical challenge was within the interface between cross passages and the main tunnels. Construction of the cross passages were carried out after the erection of the main tunnel lining. In order to stabilise the main tunnel segmental lining at cross passage locations, area of special segment with increased quantity of reinforcement was provided. The redistribution of stress induced by cross passage opening was taken up by six special heavily reinforced segments and by cast-in-situ Tympanum structure, which were constructed at both ends of the cross passage. These were used to resist the temporary and permanent loads around the cross passage opening, allowing the MTBM of cross passage to excavate through the reinforced concrete of the main tunnel lining.

During the break-in and excavation stage of the cross passages, temporary and permanent sealing system installed between the circumferential faces of segmental lining was induced to prevent water ingress and leakage under high water pressure. Each segment of the cross passage was fitted with two layers of 65mm thick of ethylene

Figure 9. Typical sub-sea tunnel internal structure (Chan, et. al, 2019).

propylene diene monomer compressible gasket which provided sufficient redundancy in the event that one seal failed.

3 CONSTRUCTION INNOVATIONS

3.1 Saturation diving

The TM-CLKL project faced challenges due to the adverse geology along the alignment, including transition from granite to decomposed granite and alluvium. These conditions required specialized maintenance and interventions for the cutter heads. The soft marine deposits on the seabed further complicated face stability. Two specially designed TBMs were driven in parallel. A slurry pressure system maintained the face, ensuring confinement pressure of up to 5.8 bars at the deepest sections. Efficient maintenance of the cutter tools was crucial to meet demanding production rates. The abrasive granite in the initial part of the alignment caused rapid wear on the disc cutters, necessitating daily hyperbaric interventions.

The saturation technique, implemented for the first time on such a large scale in an underground project, involved lengthening the cycles to 28 days. This technique avoids subjecting workers to daily compression/decompression cycles and allows for longer periods of intervention. A specialized team of four workers trained in hyperbaric works was housed in a pressurized living habitat on the surface. The habitat included hyperbaric chambers, compression/decompression chambers, and medical caissons equipped with necessary equipment for providing care in the event of injury. To maintain the proper functioning of the installation, various parameters such as chamber pressure, temperature, humidity, and gas mixture had to be constantly monitored. Surface teams, operating from a fully equipped control room, were responsible for monitoring and ensuring the installation's proper functioning. Additionally, a doctor certified for hyperbaric works was available full-time to intervene if necessary. In total, the team comprised of six doctors, three nurses (day/night), forty-five professional hyperbaric workers, twelve live support technicians and three hyperbaric operation supervisors.

The worker's team was transported daily through a pressurized shuttle from the living habitat to the TBMs. The shuttle connected directly to the hyperbaric chambers of the TBMs, allowing for the replacement of the disc cutters to commence. This allowed for efficient cutter tool replacement while minimizing risks.

The implementation of the saturation technique improved safety and efficiency. With support from the Client, necessary approvals were obtained for this innovative technique in Hong Kong. The pressurized living habitat and continuous monitoring of parameters ensured worker well-being and safety. The shuttle system facilitated easy access to the hyperbaric chambers for cutter tool replacement, contributing to steady tunnel excavation progress. Total Saturation Dives

since Dec 2015: > 300, Total discs changed in Saturation: 1000, The best dive: 13 discs changed, Maximum Intervention Pressures: 5.8 bars, and no decompression illness or other health problems since the commencement in December 2015.

3.2 Development of robotic cutter change

“Telemach” robotic cutter change system, developed by Bouygues Travaux Publics, has revolutionized the replacement of worn TBM disc cutters. This tele-operated robotic system allows for safer and more efficient cutter replacement without the need for manned interventions. The project made a step further in the automation of maintenance systems with the “Telemach” robot. The “Telemach” is in a dedicated air locked chamber in the TBM shield. It can access the excavation chamber under hyperbaric conditions of up to 7 bars and replace worn or damaged disc cutters with new one. This robot, similar to those used in the car industry but with greater difficulty, is equipped with advanced features such as stereoscopic laser vision, force control with touch sensors, water cleaning jet of 400 bars, and torque control tensioning device. The robot has an industrial robotic arm of 500 kg payload and is stored inside its own pressurisation locker where it can be maintained between intervention. The system can locate the disc cutter and adapt the movements of the robot accordingly in a compressed air environment in the presence of spoil. Telemach successfully performed a fully automated disc cutter replacement cycle in January 2016, proving its effectiveness on the TM-CLKL project, and it has been used on several projects by Bouygues Construction. This innovation was recognised with the ITA Tunnelling Award 2017 for safety initiatives of the year.

Figure 12. Robotic arm in the TBM shield.

Figure 13. New cutter disc fixation (Bouygues's patent).

3.3 Development of TBM monitoring systems

The TBM Monitoring System was implemented in TM-CLKL project to improve intervention efficiency by providing advanced knowledge of the cutter head's condition. Bouygues Travaux Publics developed innovative technologies equipped on the TBMs, such as the Mobydic system. This system offers real-time mapping of the cutterhead (temperature, rotation, wear state, load), identifying each disc cutter and detecting any abnormal behaviour caused by excessive wear. It also assesses the ground type based on disc cutter pressure, providing an accurate view of the TBM's operating environment. The data is collated, analysed, and displayed both numerically and pictographically. The Mobydic system optimizes excavation processes, reduces hyperbaric interventions, and improves accuracy in assessing excavated volumes. Moreover, it produces automated reports and develops geotechnical models of the excavation. This system is especially powerful in heterogeneous condition, by avoiding disc cutter overload and brake away. It identifies geological conditions, obstructions encountered, spoil clogging of the cutter chamber and areas of cutter tool wear/damage which in turn reduces the duration of hyperbaric interventions.

The Snake system is another crucial component of the TBM Monitoring System. This remote-controlled, poly-articulated arm is equipped with a high-quality zoom camera and a high-pressure water jet of 400 bars for cleaning and inspecting the cutterhead. The snake-arm robot has a diameter of 125mm and a 3m horizontal reach, with a pressurization system to operate in hyperbaric conditions. It cleans the TBM heads and eliminate clogging before the Snake's inspection. The Snake

system allows inspections in areas where it is not possible to send workers, enhancing maintenance organization and optimizing TBM usage.

These systems have proven to be essential in TM-CLKL project in ensuring the optimal operation of TBMs while reducing human interventions. As a result, they are now widely implemented in most of the company's TBMs.

3.4 Mini-TBM for cross passage construction

To ensure the safety of road users during emergencies, a total of 57 cross passages were built every 100m of varying length from 8m to 13m to provide a means of egress between the two tunnel tubes. The construction of these cross passages presented a significant challenge, as they had to be built under 6 bars (max.) high pressure conditions due to being located under the sea. Instead of using traditional ground freezing techniques, the project team developed an innovative solution by utilizing MTBM with a diameter of 3.6m. This world's first groundbreaking mechanized approach allowed for better control over the construction schedule and minimized the exposure to geological risks, resulting in a significant reduction in construction time.

Initially, ground freezing was proposed as the stabilization method for the construction of these cross passages. However, detailed technical reviews found that the design parameters were weaker and it required additional drilling and freezing time, leading to delays. As an alternative, the Contractor proposed using a pipe jacking method with a MTBM. This method offered several advantages, including enhanced safety, suitability for high water pressure conditions, the elimination of the need for ground treatment, and reduced impact on the main tunnel's internal structure. Additionally, it provided greater certainty in terms of construction time.

The operation of the MTBM involved tunnelling through hard rock and soft ground. The cross passages were excavated after the main tunnel lining had been erected. The stress redistribution around the cross-passage opening was managed through segment ring and a tympanum - a reinforced concrete structural frame. Each main tunnel intersected the cross passage, with one ring being completely cut while the adjacent rings were partially cut. The MTBM was equipped with a soft eye using fiberglass reinforcement to prevent damage to the cutterhead. The loads from the centre cut ring were effectively transferred to the adjacent rings through shear keys or shear cones. The jacking frame, equipped with hydraulic jacks, was pulled on the tympanum on the launching side of the cross passage. With cutterhead power of 400kW and torque of 800kNm, the MTBMs' excavation was carried out in short advances, with a typical length of each jacking pipe being 1.33m.

The jacking pipe was composed of permanent pre-cast reinforced concrete, with the internal

diameter of 3,000mm. Six types of precast concrete jacking pipes were designed for the cross passages, known as first pipe, last pipe, standard pipe A, standard pipe B, lubrication pipe A and lubrication pipe B, with lubrication pipe A had the longest length of 1,330mm. At each of the pipe connection, a double wear barrier was adopted to ensure long-term water tightness with a design life of 120 years against corrosion.

A jacking pipe was installed at each advance, and on the receiving side, the MTBM would break out to a pressurized steel bell to maintain the pressurized regime and prevent water or soil ingress into the main tunnel. Emergency seals provide additional inundation prevention in case of water ingress.

This project marked the first time that cross passages had been constructed using TBM pipe jacking methodology between two main tunnel tubes. The innovation could achieve construction of 39 cross passages within less than 13.5 months, in average 3 numbers per month. The excavation cycle is approx. 18 days, with the average advance rate of the MTBM was 2.3m/day, and a best record of 13.2m/day. The MTBM and associated equipment were designed and developed by the Contractor and the TBM supplier. Overall, the use of the MTBM and pipe jacking technology proved to be a successful and efficient method for constructing the cross passages.

Figure 14. Cross passages with MTBM.

3.5 World's largest tbm – guinness world record

At early stages of the project, the North Approach Tunnels were initially planned as a cut and cover structure. However, the land above the North Approach tunnels had to be made available for partial handover to third parties and for a timely start of the sub-sea TBM drives. To address the time constraints and minimize earth movements, the Contractor proposed using two TBMs instead. The world's largest TBM, the Mixshield S-880 "Qin Liangyu," (in Chinese "秦良玉") was employed to excavate one of the 630m long tunnel. With its impressive power output of 5,600kW and a torque of

27,722kNm, the TBM has a shield diameter of 17.6m, an overall length of 120m and weighs 4,850 tonnes.

The 17.6m tunnel section was excavated up to a point the TBM's shield was converted into one of 14.2m diameter to complete the rest of the tunnel alongside another TBM. Core components and the back-up plants were taken from the largest machine to continue the excavation. The two 14.2m TBMs broke through at the same time to complete the tunnels on 27 February 2019. This achievement marked the first double breakthrough in Hong Kong and set the Guinness World Record for the World's Largest TBM.

Figure 15. World's largest TBM tunnel.

Figure 16. First double TBM breakthrough in hong kong.

3.6 Development of tailor-made launching gantry – overhead ventilation duct slab installation

To optimize the utilization of DfMA principles, the Contractor and her sister company, VSL, collaborated on the design and manufacturing of an internal slab structure gantry (ISSG). This self-launching gantry was tailored to install over 5,000 precast slabs for the OHVD in the two tunnels.

The OHVD slabs, which are precast and pre-tensioned, span across previously cast corbels and come in different lengths and weights, ranging from 11.5 to 23t. Additionally, there are shorter slabs that combine to form longer slabs, with openings in between and spanning across two long slabs at regular intervals.

The ISSG gantry consists of longitudinal main beams of 800mm in depth supported by front and rear lower crossbeams spanning 20m, with an additional movable crossbeam for launching operations. The rear and movable crossbeams are equipped with mechanical and hydraulic jacks, while the front crossbeam rolls on nylon wheels along the corbels. The outrigger extensions of the three crossbeams are designed to accommodate different corbel spacings, ranging from 9.0 to 12.5m. The main beams support a winch trolley lifting unit with a chain drive system, allowing movement of the slabs along the main beams.

The lifting process involves picking up a slab, clearing the traffic window, moving the main beams to the center for rotation by about 45 degrees and adjustment in crossfall and gradient, and then lifting the slab above the corbels. The slab is then moved backwards to its final position and lowered onto the corbels. Remote control via a touch panel manages slab installation and gantry launching. Various sensors have been installed to enable automation and coordination of different movements, reducing reliance on the gantry operator and minimizing the risk of slab collisions with corbels or tunnel lining. Typically, 16 to 20 slabs can be installed per shift. Overcoming the technical challenge of designing the specialist equipment to fit the available headroom, the ISSG gantry was easily dismantled and re-assembled inside the tunnel to accommodate multiple relocations between tunnels during the construction sequence.

Figure 17. Launching gantry – overhead ventilation duct slab installation.

4 CONCLUSION

The TM-CLKL project has developed a large number of world first achievements, such as the world's

largest TBM, first large-scale deployment of Peanut and Caterpillar shaft design and first large scale deployment of microtunnelling techniques for inter tube cross passages. This deep undersea and geotechnically complex project has seamlessly integrated world class design innovation with state of the art construction methodology and the Project is globally recognized as a true benchmark.

The deep collaboration between the Contractor and the Contractor's designer has been an exemplar model, together with the huge support from the Client in facilitating the solutions to a large number of design and construction challenges has been major contributing factors in the success of this Project.

ACKNOWLEDGMENTS

The Authors would like to record appreciation to Highways Department, Hong Kong SAR (the Client), and Ms Natelie Mak who coordinated the inputs into this paper. The Authors would also like to thank the literally hundreds of people involved in the design and construction of the TM-CLKL project, we salute you all, a truly global team effort.

Khalid Saif Al-Khayareen

Manager of Drainage Networks Projects Department, Public Works Authority

ABSTRACT: Musaimeer outfall tunnel is one of the longest storm water tunnels in the world with a total length of 10.2 km. The tunnel will accommodate surface and storm water received from the drainage networks from 270 km² of urban areas in southern Doha. The tunnel was excavated by Tunnel Boring Machine (TBM) and encountered three distinct rock masses Rus formation, Midra-Shale and Simsima Limestone along with water inflows at high pressure, complex mixed ground, and weaker ground strata prone to cavities with the presence of vertical and lateral fractures connected to the sea bed. The geotechnical parameters in sub-sea tunnelling were assessed through all main project stages; a) Evaluation b) Verification and c) Application. The TBM required periodic atmospheric or hyperbaric interventions at the cutter head for cutter tool maintenance. During this process, the face was mapped and compared to off-shore borehole logs. Geophysical seismic reflection/refraction and resistivity surveys were also carried out. A non-intrusive radar system facility, installed on the TBM cutter-head, able to probe ahead in real time the ground conditions was used continuously. By monitoring TBM excavation parameters such as, thrust force, torque, penetration, cutter head rotation speed correlation with encountered ground conditions were made.

Keywords: TBM, Sub-sea tunnel, hydrostatic pressure, offshore geophysics, non-intrusive radar system, face mapping, TBM parameters

1 INTRODUCTION

The outfall tunnel extends from the pump station, 10.15 km off-shore discharging drainage flows in to the Gulf. The discharging will be performed through a vertical riser shaft and a marine outfall diffuser field. Figure 1 shows the project location.

2 TENDER GEOTECHNICAL INVESTIGATION

The Client Public Works Authority (Ashghal) undertook a significant geotechnical investigation program for this particular project which consisted of 22 off-shore boreholes at 500 m centers, which provided the following geotechnical data.

1. Cores for inspection
2. In-situ packer tests.
3. Pressure meter tests at each location.
4. Geophysical surveys including Sonar Bathymetry, Magnetometer, Seismic Reflection and Seismic Refraction.

Figure 1. Project Location.

5. laboratory mechanical and chemical tests on soil, rock and water samples.

This investigation data was combined on a long geotechnical profile and become the basis for

selection of the selection of TBM and tunnel segmental lining type. Figure 2 shows the long geological profile, with the tunnel alignment superimposed.

Figure 2. Outfall tunnel geotechnical section.

The detailed evaluation of this geotechnical data was a challenge, although there was significant experience of TBM tunnelling in the Doha area, there was no previous experience on subsea tunnelling in the area. The above data indicated the rock quality to be fairly competent along the tunnel alignment, however, there were two major tunnelling risks which required mitigation by the Designer and Contractor.

2.1 Karstic features

The first risk was the possibility of the TBM encountering karstic features along the tunnel alignment. Although the tender geotechnical investigation has shown no evidence of karstification within the calcareous formations of Rus, Midra and Simsima limestone. However, the risk was still valid. The size of a potential karstic feature was also very important resulting in limited mitigation measures, considering that the accessing and intervention from offshore would be very expensive and time prohibited. To mitigate this risk the TBM was installed with grouting ports and associated drilling and grouting equipment.

2.2 Hydraulic connection to seabed

The second risk was associated with the hydraulic connection between the seabed and the TBM tunnel. In this case the full hydraulic water pressure, would be directed to the advancing TBM cutterhead, requiring an increase in the face pressure and thrust accordingly to balance and advance the tunnel. However, there were significant factual evidence that along approximately 55% of tunnel alignment, competent and low permeability rock would be encountered by the TBM, providing protection against water infiltration from above. This assessment was based on Rock Quality Designation records and the Lugeon field tests performed in the offshore boreholes. Evaluation indicated that 25 % of the tunnel alignment, was rock of poorer quality with increased permeability based on lugeon tests. To mitigate this risk, the TBM was designed to withstand the full hydraulic pressure of 4.5 bar.

3 TENDER GEOTECHNICAL INVESTIGATION

The TBM selected to excavate the outfall tunnel was an EPB (Earth Pressure Balance) designed to support a maximum face working pressure of 4.5 bar. EPB configuration has a cutterhead, excavation chamber, main bearing or drive, screw conveyor, front, middle and tail shields, man locks, thrust system, articulation, erector and brushes as part of the tail shield seal system. In addition, there are 18 gantries, 180 m long accommodating all electromechanical parts, additive tanks and rescue chambers.

To minimize or eliminate the risk uncontrolled water inflow into the tunnel during construction, the TBM had double “guillotine gates” located at the end of the screw conveyor. These are used during normal operation and closed automatically in case of power failure. To accommodate 4,5 bar of water pressure the TBM screw was a total length 13.5 m. A fourth row of wire brush seals was also installed in the tailskin.

4 POST TENDER INVESTIGATIONS

The Contract requirements specified the possible implementation of an additional 24 offshore boreholes if required. It was considered that in terms karst identification and possible hydraulic connection to the sea, the drilling of further boreholes would provide minimal benefit to the TBM operation, and would provide additional isolated data on the alignment, and limited understanding to the overall hydrogeological and structural conditions along tunnel alignment.

The Contractor decided to implement a detail geophysical investigation survey as a more beneficial approach to mitigate the major geotechnical risks and provided more complete geotechnical information regarding variations in geology, areas of seawater saturation, areas of cavities, weak disturbed zones or other discontinuities under the seabed between the existing 22 boreholes. This alternative was accepted by the Client.

Two different types of offshore geophysical surveys were conducted along the outfall tunnel alignment. The Electrical Resistivity Tomography (ERT) and the Seismic Reflection Geophysical Tomography.

4.1 Electrical resistivity tomography survey

The objective of Electrical Resistivity Tomography (ERT) is to determine the subsurface distribution in two or three dimensions (2D and 3D) of resistivity, using geological parameters such as soil/rock type and mineral content, as well as the porosity and degree of water saturation in the rock. The ERT survey was performed satisfactorily in good weather conditions and the data was processed, analysed and interpreted. The survey covered 10 km of triple, parallel ERT marine profiles, aligned along the tunnelling corridor (West to East), at 3 m spacing, then integrated into sixteen transversal ERT marine profiles distributed in a North to South direction along the tunnel alignment.

After conducting the offshore survey, the most accurate electro stratigraphic model was developed and refined. Correlation between resistivity value variations and the main three different geologic units was then identified. A number of “conductive anomalies” and “resistive anomalies” were detected along ERT profiles and documented accordingly. Figure 3 is an extracted section from the ERT survey. The chainages start from zero at the TBM launch chamber and increase with tunnel alignment.

Figure 3. ERT for alignment Ch.1+500 to 5+500.

4.2 Seismic reflection geophysical survey

The Seismic Reflection Geophysical (SRG) process consists of recording the acoustic waves generated at the surface which have been reflected back by sub-surface structures or interfaces. A reflection will occur when the density and/or the velocity changes occur at the boundary between two different materials. The acoustic waves are recorded from numerous hydrophones, installed at fixed distance along a seismic cable (streamer).

The SRG survey was used to correlate the existing borehole defined stratigraphy, confirm the extend of topsoil formations and identified possible vertical weak zones, that may result in excessive water ingress along the TBM tunnel alignment. Figure 4 shows a typical section of this survey.

Figure 4. SRG for alignment Ch.1+500 to 5+500.

Based on the interpretative of Seismic Reflection Long and Cross sections certain structural vertical zones/faults were identified indicating possibilities of increased water ingress, these are features are marked F5 to F10 in Figure 4, and are points on the survey were abrupt changes in the seismic wave received profiles. This assessment identified 20 locations coded these F1 to F20.

5 PREDICTED GEOTECHNICAL CONDITIONS ALONG THE TUNNEL ALIGNMENT

With the use of the pre and post tender geotechnical and geophysical data, it was possible to

build up an overall picture, of the underground conditions, indicating critical tunnelling areas, schedule possible and preferred locations for the TBM interventions and reduce the tunnelling risk level. In order to ensure the TBM advances smoothly the cutterhead requires regular inspection, maintenance and repair. The most efficient way to carry this out is in ground conditions which are safe under atmospheric conditions. This operation becomes more complex and time consuming in poorer ground conditions which require hyperbaric support. To mitigate the impact of various ground conditions an assessment is made by linear meter of the likely hood of favourable sections where only atmospheric interventions is anticipated, on moderate sections where atmospheric interventions is anticipated but hyperbaric may also be required and on unfavourable sections where TBM interventions should be avoided, unless absolutely required. Figure 5 illustrates a typical section of the predicted geotechnical profile, the favourable (green), moderate (blue) and unfavourable (red) zones are colour coded accordingly.

Figure 5. Predicted geotechnical conditions profile.

6 REAL TIME NONDESTRUCTIVE RADAR SYSTEM

The TBM is provided with a non-intrusive electrical induced polarization prediction system able to provide predictions of the ground conditions and interpretations up to three tunnel diameters ahead and two thirds of the tunnel diameter in real time. The Bore-tunnelling Electrical Ahead Monitoring (BEAM) System is based on a geotechnical principle that rock mass has different resistivities at varying frequencies, expressed with the Percentage Frequency Effect (PFE). The information is displayed in a matrix which combines both resistivity and PFE. The interpretation of the matrix, which is shown in Figure 6, is based on the columns and rows; factors on the columns refer to the karst interpretation (P1:P4) while factor on the rows (R3: R1) refer to the possibility of water inflow. There was a computer located in the TBM operators cabin where the information and interpretation are showed on real time as the TBM advances, the TBM operator can monitor and correlate with other parameters, if required.

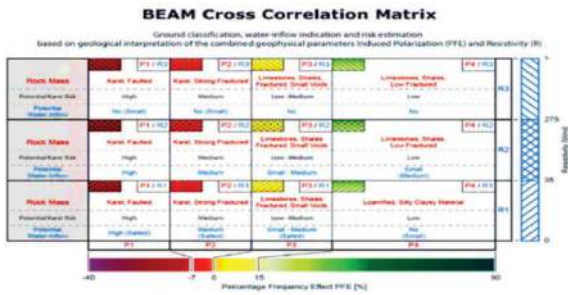

Figure 6. Beam correlation matrix.

Figure 7 Shows the real time Beam display the TBM passing through an limestone strata with low fracture and small voids, potential karst risk is low-medium and potential aquifer risk is small-medium.

Figure 7. Beam display.

However, in Figure 8 the TBM is shown tunnelling in a rock mass with higher potential risk of karsts and aquifers, this particular location refers to a previously identified fault F8. The interpretation from the matrix is compared with specific parameters on the TBM, like torque, thrust force, penetration rates, advance speed and cutterhead rotation speed.

Figure 8. Beam display for F8.

Refer to the predicted geotechnical conditions profile the TBM expected to encounter F1 to F20. The BEAM system gave indication 10-15 m before entering those zones. Table 1 contains all the predicted data from the predicted geotechnical

conditions profile shown in Figure 5 along with an estimation relative to the tunnel chainage, The next column then records the actual chainage any anomaly was encountered. The next column records if the BEAM detected the feature and the final column indicates the face pressure required to successfully advance through the particular section. It can be observed that 11 of the 20 F zones were correctly identified and a good correlation with predicted condition. It can also be noted that the correlation greatly increased over the tunnel alignment Chainage from 2,600 to 10,200 m when 10 out of 14 F features were identified and allowing appropriate TBM operations to be executed to maximize advance rates.

However, there are limitation in that the actual ground water pressure can not be predicted. The system can provide an estimation of the possibility that water inflow or aquifers might be encountered. The system is not able to identify whether the TBM is advancing through Rus formation, Midra Shale or Simsim limestone, it can only identify intrinsic properties of rock mass.

7 TBM ENCOUNTERED ROCK MASS

TBM tunnelling operations commenced on 03 February 2019 and tunnel completion had encountered 741 m of Rus formation (full face), 205 m of Rus formation affiliated with Midra Shale formation, then 660 m of Midra shale formation (full face), then 298 m of Midra Shale affiliated with Simsim limestone formation, then 406 m of Simsim limestone formation (full face), then 328 m of Simsim limestone affiliated with Midra Shale formation, then finally from chainage 2,638 m geological formation was Simsim limestone (full face) which continued until the tunnel completion at the riser shaft, at chainage 10,156 m on 03 February 2021.

Those geotechnical factors found along of Midra shale constrained the performance of the TBM in terms of advance rates. The torque of the TBM increased up to 75 % of its nominal capacity, the penetration rates were very low. The injection of water and other conditioning agents in the excavation chamber reached 25m³ per ring which in effect doubled the excavated volume per ring. However, this increase in conditioning made it possible to reduce scenarios of clogging of the cutterhead and severe damages to the cutting tools which still required a high number of cutterhead interventions in atmospheric conditions. Logistics in the tunnel were significantly affected and required a re-configuration of the trains regarding to the number of skips required to dispose the excavated material due the doubling of the volume per ring.

In the Simsim limestone formation divided into 2 conditions, i.e. Simsim limestone with high pressure of groundwater (3.8- 4.0 bar) and Simsim limestone with low pressure of groundwater (below 2.0 bar). The Simsim limestone with highest pressure of

groundwater at chainage 2638 m – 2756 m (118 m), and chainage 3678 m – 5247 m (1569 m).

In both cases geotechnical engineers and TBM team were monitoring and correlating the geotechnical profile and BEAM system profiles to adjust and optimized the performance of the TBM.

7.1 TBM production in different geological formation

Referring to boreholes information, additional geophysical investigation and actual geological conditions recorded the TBM advance through six different formations with associated high or low ground water pressure, with some formation occurring more than once. The six formations are:

- Rus Formation (RF) – full face
- Rus Formation with Midra Shale (RF+MS)
- Midra Shale (MS) – full face
- Midra Shale with Simsim Limestone (MS+SL)
- Simsim Limestone (SL) – full face
- Simsim Limestone with Midra Shale (SL+MS)
- High water pressure (HP) and Low water pressure (LP)

Figure 9 shows the graph of averages TBM production in different geological formation, from start to completion of the tunnel. The average advance rates are shown as Tunnel rings per day. Each tunnel ring is 1.30 m long. The baseline programme (BLP) was based on 14 rings per day and the overall average for the project was 13.2 rings per day.

Figure 9. Averages progress in geological formations

7.2 TBM progress and BLP

The BLP for the tunnel construction is divided into an initial learning curve of 300 m in length, followed by 27 No. drives of varying length and duration and was based on 24 hours per day and 6 days per week. Actual TBM production rate compared to the BLP is shown in Figure 10.

Figure 10. Variance with BLP from 03 February 2019 to 03 February 2021.

The actual variance with the BLP is shown in Figure 10 as green (ahead of BLP) and red (behind BLP) and the various geological formations as explained in section 7.1 are also shown. TBM excavation commenced 90 days ahead of BLP and over the course of the construction period deteriorated to 14 days behind programme before recovering and eventually completing the tunnel 57.9 days ahead of BLP.

7.3 TBM production in different geological formation

The TBM progress can be split down into five sections:

Firstly, when the TBM excavated through the Midra shale starting from ring no. 571 to ring no. 1465 (Ch. 743m – 1905m), from 21 April 2019 to 20 August 2019, the TBM lost 43.36 days from the BLP, variance started at +89.5 and become +46.14. In this geological formation, TBM advance speed was slow due to the need to inject water and soil conditioner, averaging more than 25m³ per ring, this bulked up the excavated material to more than 8 skips (4 Skips normal) this resulted in boring times of 90 minutes per ring. In this period there were eight cutterhead intervention changing 20 cutters.

The second section was when the TBM excavated through mixed Simsima limestone/ Midra shale from ring no. 1,778 to ring no. 2029 (Ch. 2312m – 2638m), from 15 September 2019 to 7 October 2019, TBM losing 3.02 days from the BLP, variance started at +48.67 and become +45.66. Midra shale excavation reduced TBM progress slower due to need to inject soil conditioner.

The third section was when TBM excavated through the Simsima limestone with high groundwater pressure up to 3.5 bar, resulting in slower TBM progress due to a significant increase in all the boring parameters. From ring no. 2,020 to ring no. 2,120 (Ch. 2,626m – 2,756m), from 8 October 2019 to 21 October, TBM losing 5.28 days from the BLP, variance started at +45.66 become +40.37.

The fourth period was when the TBM excavated Simsima limestone with high groundwater pressure for a second time. This was expected from geological information in boreholes BH-A7 to BH-A10. Starting from ring no. 2830 (Ch. 3679m) on 11 December 2019 to 29 May 2020, with EPB pressure more than 3.4 bar, reducing the TBM advance rate. Additionally in this section two series of cutterhead intervention had to be carried out in compressive air conditions that are significantly more difficult for smaller TBM. Special divers working in hyperbaric condition with pressure 3.5 bar to 4.0 bar really consumed the time because one intervention period was only 120 minutes. In this period the TBM lost 64.54 days from the BLP, variance deteriorated from +50.36 to -14.18.

The fifth period was from 30 May 2020 until tunnel completion on 03 February 2021. Simsima Limestone formation with UCS max. 23-24 MPa is favorable for the TBM operation, only problem is when it is encountered with high groundwater pressure. In Figures 9 and 10 can see that progress in Simsima limestone with low pressure was always higher than other formations. From 30 May 2020 to 03 February 2021, TBM gained 72 days from the BLP, variance started at -14.18 and ended at +57.90. In this geology formation, all TBM boring parameters are low and muck material only 4 to 5 skips per ring, allowing the TBM to advance at higher speeds.

8 CONCLUSIONS

Tunnelling works is considered a highly challenging part of this project, due to the fact that is constructed on subsea conditions, has a small inner diameter (3700 mm), long length with no intermediate access points. The need for comprehensive, accurate and in-depth geotechnical information was critical to a successful tunnel completion. There is no single advance ground investigation method that can completely predict the ground conditions in front of a TBM. There are however a number of systems that can give an insight into a particular aspect of the geological conditions that lie in front of the TBM. When the results of these methods are integrated, the prediction can be comprehensive.

On this project, the key issue was the cross correlation with other methods and observed geology in a standard format which allows the identification of patterns and trends. This may well be unique to this project.

The BEAM had good correlation with the identified F features in the tunnel alignment 2,600 to 10,200 m.

Simsima limestone is favourable for TBM mining, except when associated with high groundwater pressure.

Green TBM: Design targets, features and power efficiency

Andrea Petriccioli*, Laura Tafuri & Remo Grandori
Webuild S.p.A., Milano, Italy

ABSTRACT: The awareness of the importance and the need to reduce the energy consumption in any human activity, including in the execution of large infrastructures, has led the major construction companies to set very ambitious targets for reducing their energy consumption. The type, design and specifications of the TBMs to date have been developed with the main targets of increasing their productivity and their capability to deal with the most different geological formations and ground behaviors without much consideration of the energy aspects as the installed power and consumptions. Moreover, for several decades until today, technicians, consultants and manufacturers, specified more and more power to be installed on the TBMs, increasing the energy absorption during the tunneling process. The TBMs and the auxiliary systems are highly energy-intensive and are responsible for a large part of the power consumptions of an infrastructure project. Considering that more than 40 TBMs will be used simultaneously in the coming years in Italy for an important expansion of the Italian railway network, Webuild has developed the concept design of the Green TBM. The Green TBM encompasses various equipment, systems and control logics in an overall vision with the target of reducing the energy impact of tunnel excavation by about 20%, with comparable or lower boring times. The article describes how, from the initial concept, the first Green TBMs have been designed and manufactured in cooperation with the manufacturers. The different systems are analyzed, describing their contribution for the reduction on energy consumption and improved power quality.

Keywords: TBM, green, efficiency, energy, Webuild

1 INTRODUCTION

The Tunnel Boring Machine (TBM) is a complex system which requires the integration of capital aspect of civil, mechanical, electrical and control engineering. The evolution of the TBM to increase the productivity in a wide range of geological formations has led to an increase of the installed power on the machine, and the TBM represents the highest energy user for a construction site.

The EU Recovery Fund is increasing the investments in infrastructure projects. The Italian high-speed/high-capacity rail network will be expanded, especially in inland region of southern Italy, where the geographical aspects require to excavate hundreds of kilometers of tunnels in various lots. More than 40 TBMs will be used in the years 2024-2027.

Webuild is the biggest Italian infrastructure construction company, and is leader in many joint-ventures selected to build the new railway lines. Targets to increase the efficiency of the projects, reducing energy costs and CO₂ emissions led to

development of a new concept design for a more efficient TBM, called the “Green TBM”.

The target of the Green TBM is to reduce the energy incidence during the tunnel construction, defined as (1), by a factor of 20%.

$$I = \frac{E}{V} \quad (1)$$

Where I is the intensity (kWh/m³), E is the total energy absorbed by the TBM to bore the tunnel (kWh) and V is the total excavated material (m³).

The first project where the Green TBM is applied is the Messina – Catania Lot. 1&2 in Sicily, with four TBMs, 2 EPB and 2 dual-mode EPB-open, 9.3 meter diameter. The first one (in Figure 1) will start to bore by the end of 2023.

The paper will begin to introduce the main components of the electric systems onboard the machine.

Then it will describe how the concept of the Green TBM has been applied to the various parts of the machine, furthermore deepening all the different points of the concept design in two sections,

*Corresponding author: a.petriccioli@webuildgroup.com

Figure 1. FAT of the first green TBM for ME-CT lot. 2.

dedicated to the systems and to the equipment. In the end, the paper will present the testing activities that will be carried out to validate the expected target, and the conclusion with a recap of the main aspects.

2 ELECTRIC SYSTEM OF A TBM

The following section will describe the electric system applied to shielded TBM in the 8÷12 m diameter range, which is of interest for the railway projects in Italy, but could be generalized for different type of machines.

The power required to a TBM construction site is in the range of 7÷9 MW. The highest part is dedicated to the machine, that generally has more than 6 MW of installed power. The TBM is fed by a high voltage line, in Italy at 15 or 20 kV 50 Hz, via a cable reel.

These data give the idea of how important is to increase the electric efficiency of the TBM to reduce the energy used by the project.

2.1 Main drive

The main drive motors accounts for around 60÷70% of the installed power. The motor speed is regulated by variable frequency drive (VFD). Given the high power demand, the VFDs are fed by dedicated transformers at 690 V. For ME-CT project, the main drive has a 11×350 kW or 10×400 kW configuration.

2.2 Backup

One or two transformers power the backup low voltage network at 400V. The loads are mainly motors and, in residual portion – less than 50 kW – lights, sockets and controllers. The motors that require speed regulation are fed by VFD (e.g., foam, bentonite and dewatering pumps), otherwise directly by the grid (e.g., hydraulic power pack, compressors).

3 CONCEPT DESIGN OF THE GREEN TBM

The Green TBM concept was conceived in 2020. Preliminary specifications were issued the following year,

and in 2022 the detailed design was developed for Italian railway projects. In 2023 the first Green TBMs have been manufactured, and excavation work will soon begin.

The target of a 20% reduction in the energy incidence is ambitious, and can be reach only gathering different solutions. Some of the solutions that will be exhibited have already been engineered and are in use. The special feature of the Green TBM was to bring together elements that were originally separate, or not applied to the tunnelling industry, adding to this automation logic aimed at minimizing energy consumption.

The following discussion will be divided into “systems” and “equipment”. “Systems” refers to those control logics that act simultaneously on multiple TBM items. By “equipment”, on the other hand, we mean the individual items with specific functions that make up the various systems of the machine. This subdivision is not only conceptual but also practical.

3.1 Systems

Indeed, the development of “systems” logic is tied to finding a solution through a problem-solving process. These solutions must first be conceived, and then integrated within the complex automation system of the TBM so that they do not create interference with other control logics nor between each other. The effectiveness of the solution must then be evaluated in the field in order to proceed, if necessary, with calibration or modification of the logic.

The systems that have been implemented are:

- Automatic utilities management
- Eco cruise mode
- Continuous mining

3.2 Equipment

Instead, the work on “equipment” has been of a different kind. First, the main components that could be worked on in terms of energy efficiency were identified. Then, for each item, the technical solutions currently in use, those available on the market and those already applied to the tunnelling sector were studied. In choosing the systems to be adopted, consideration was given to higher technical standards, the EU Ecodesign directive and the EU Commission Regulation 2019/1781.

The improvements on the equipment that have been implemented regard:

- Cutterhead design
- Transformers
- Electric motors
- Power quality
- Diesel generator

The two following chapters will describe the solutions implemented in the Green TBM, entering in detail in systems and equipment.

4 TBM SYSTEMS

The following TBM system have been integrated in the TBM main PLC.

4.1 Automatic utilities management

The “Automatic utilities management” is a control system that act on electric motors of the machine, with two separate logics.

4.1.1 Automatic stop-start of motors

The hydraulic power pack absorb much of the energy of the TBM backup. Thrust and screw conveyor hydraulic circuits are generally managed by more than one electric pump: trust pumps can be two to four (or more) and screw conveyors pumps are generally two.

The “automatic stop-start” function detects when the load demand is low and switch off the pumps in excess, in order to keep running the minimum requested electric motors. When the load demand increases, the motors are automatically reactivated.

The TBM operator does not need to select which motor need to be started, because the TBM PLC manages all the operations automatically. To avoid overuse of one motor and underuse of the others, the system cycles the “default” motors among the available ones.

4.1.2 Automatic belt speed

TBM conveyor belt is usually kept at a fixed speed when in operation, even if the TBM advance speed is low and the excavated material is less than the nominal one. The “automatic belt speed function” regulates the VFD of the belt according to the actual advance speed, estimating the amount of muck discharged by the screw conveyor.

The scale system along the TBM belt provide the feedback to the control loop, so that the system can better adapt to the actual discharged muck.

4.2 Eco cruise mode

The “Eco cruise mode” (ECM) refers to an automatic management of thrust and cutterhead rotation speed during the advance. The link between advance speed, penetration and cutterhead rotation speed is described in (2).

$$A = P \cdot \Omega_c \quad (2)$$

Where A is the advance speed [mm/min]; P is the penetration [mm/rev] and Ω_c is the cutterhead rotation speed [rev/min].

The starting point that led to the conception of the ECM is that the energy incidence described in (1) is higher when the Ω_c provided by the main drive motor is minimized and the thrust – thus, the penetration – is maximized. Due to mechanical and geotechnical constraints, P and Ω_c cannot exceed predefined values. Moreover, these two limits are different when it comes to EPB and open excavation mode, and this is taken into account in the logic.

Figure 2 describes the functional logic of ECM in EPB mode, while Figure 3 is related to the Open mode. It has to be noted that the first two TBMs for ME-CT Lot. 2 are dual mode Open-EPB, so the ECM is present in both variants.

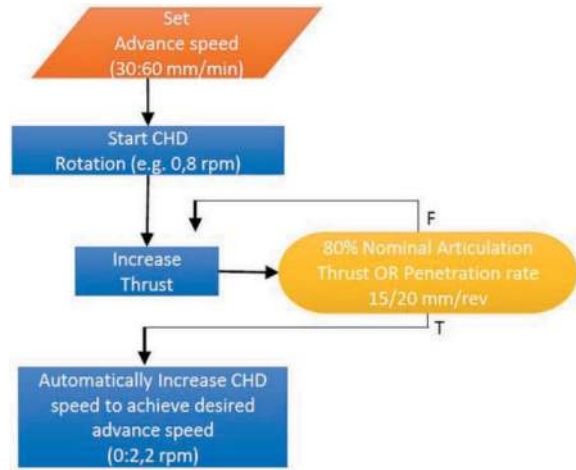

Figure 2. Eco cruise logic in EPB mode.

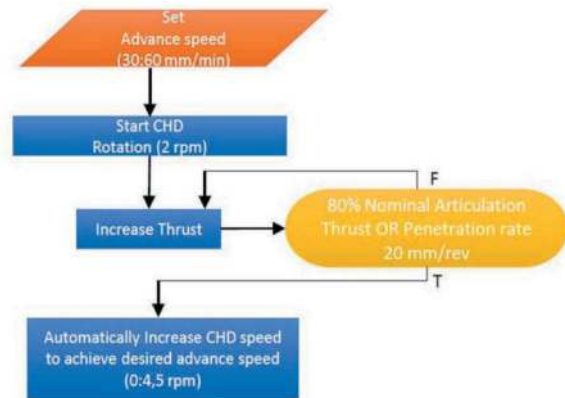

Figure 3. Eco cruise logic in open mode.

Once advance speed is set by the operator in the HMI, the ECM automatically adjusts rotation speed and thrust to reach the target speed with the minimum energy incidence.

4.3 Continuous mining

Continuous mining is a well know excavation method that allows shield TBM to excavate while mounting the ring. This is possible because the pressure of the thrust cylinder groups that need to be retracted to install the segment is redistributed on the adjacent groups, to keep the same center of thrust. Figure 4 shows in blue the redistribution of the pressures (y-axis, in bar) when the cylinder group 4, 5, 6 (x-axis) are retracted to install the segment, compared to the normal advance pressures in green. The new pressures are computed automatically by the TBM PLC, also considering the constraint of the pressure limit of the cylinders.

Figure 4. Pressure distribution during Continuous Mining.

The first target of the continuous mining is to increase the productivity of the TBM, decreasing the excavation time of the tunnel. There are also two side effect that are very important when it comes to energy efficiency, and this is the reason why it is included in the Green TBM framework.

4.3.1 Baseload energy

The first one is that the continuous mining energy absorbed is less than the sum of the energy requested by the excavation sequence and the ring mounting sequence. The reason of this is that the baseload power of the machine – usually 100 to 300 kW – would be requested for the time of both sequences, while during the continuous mining the sequences take place at the same time, the advancing time per ring is reduced and so it is for the baseload energy.

4.3.2 Auxiliary tunnel systems

Tunnel excavation requests a various amount of auxiliary system, which are necessary for the TBM operation. Some of these system (e.g., the conveyor belt), run only when the machine is advancing, while some others are requested to run uninterruptedly for safety reason. Among these, the most energy demanding ones are lighting and ventilation. The power requested by these systems can be more than 500 kW for long tunnel: reducing the time they have to be active will lead to a relevant energy saving.

5 TBM EQUIPMENT

The improvements related to TBM equipment are in mechanical, electromechanical and electric fields. The equipment may vary according to the different TBM manufacturers, but generally speaking the framework concepts are the same.

5.1 Cutterhead design

The design of the cutterhead is optimized to improve the outflow of excavated material, reducing the advance resistance. This target is achieved using three solutions:

- Connection to main bearing via rounded connection arms (Figure 5)

- Increased central opening
- Increased number of loading buckets

Figure 5. Rounded connection arms.

5.2 Transformers

Commission Regulation (EU) 2019/1783 defines new efficiency requirements for power transformers, implementing the new technical standard EN 50078 as additional requirement to the IEC EN 60076 standard. From July 2021 the highest standard for transformer efficiency have shifted from Tier 1 to Tier 2, with new requirements in terms of maximum full-load and no-load losses and to the peak efficiency index (PEI), defined in (3) for ONAN transformers.

$$PEI = 1 - \frac{2P_0}{S_r \sqrt{P_0/P_k}} \quad (3)$$

Where P_0 is the no-load losses [W], S_r is the rated power [VA] and P_k is the full-load losses [W]. These new requirements are different according to insulation and power, Table 1 compares Tier 1 and Tier 2 class for a 2500 kVA ONAN transformer, commonly used on TBM.

Table 1. Comparison between Tier 1 and Tier 2 transformer.

2500 kVA ONAN	Tier 1	Tier 2
Max. load losses [W]	22000	18500
Max. no-load losses [W]	1750	1575
Min. PEI [%]	99.737	99.797

Although Tier 2 standard is not mandatory in underground mining applications, Webuild's choice is to adopt it to reduce energy losses of the transformers.

5.3 Electric motors

The vast majority of the power absorbed in the TBM is used by electric motors: the increase in efficiency in these components is essential to the Green TBM concept. The standard IEC EN 60034-30-1:2014 state minimum requirements to meet different levels of efficiency, varying according to power and number of

poles, from IE1 (worst) to IE4 (best). Figure 6 shows the IE classes for 4-pole 50 Hz motors.

Figure 6. IE classes for 4-pole 50 Hz motors. [From ABB, 2018].

Since July 2023, the EU Regulation on electric motors and variable speed drives 2019/1781 requires three-phase motors to be IE3, between 75 kW and 200 kW to be IE4.

5.3.1 Backup motors

In order to achieve a better result than the minimum EU regulation, Webuild requires to install IE4 motors in the backup regardless of the power, except for those applications where suitable motors are not yet available. The shift from IE3 to IE4 for motor under 75 kW and over 200 kW impacts around 70 motors per TBM, accounting for 70% of the installed power in the backup. The expected energy saving is 2÷3%, and include energy intensive users as hydraulic, bentonite and grout pumps.

5.3.2 Main drive motors

Main Drive is the most energy intensive user of the TBM: improving its efficiency is a key point to reduce energy consumption. Some peculiar aspects must be considered: Main Drive motors are the most powerful in the machine (350÷400 kW each), they operate in a wide range of different speeds and load levels, they need to provide high torque at low rotation speed.

Generally, the type of motor used in the Main Drive is the cage asynchronous motor (AM). In this motor, the rotating magnetic field is produced by the stator windings through a magnetization current. On some TBMs, Webuild chose and will evaluate a more innovative technology: the permanent magnet synchronous motor (PMSM). In the PMSM the magnetic field is produced by permanent magnets on the rotor, increasing efficiency especially at partial load. This is clearly visible comparing the 3D plots of Figure 7 and Figure 8 (courtesy of CRCHI).

The rotation speed of the motor is indicated in RPM, power in kW, the efficiency is on the vertical axis.

These plots highlight the higher efficiency of the PMSM with respects to the AM in the whole

Figure 7. Efficiency of asynchronous motor.

Figure 8. Efficiency of permanent magnet synchronous motor.

operative range, and the great improvement at partial speed and load, where the difference broads. Analysis and comparison of data during mining, considering the type of excavated material, will allow to evaluate the motors in real operating conditions.

5.4 Power quality

Power quality is a topic of close concern for TBMs, as electrical disturbances produced by large motors and VFDs can greatly affect the electric grid. In particular, asynchronous motors fed directly from the grid absorb a large amount of reactive energy to produce the rotating magnetic field, increasing the phase shift between voltage and current sinewave, while VFDs produce harmonic sinewaves, which induce losses and disturbances on the grid.

5.4.1 Displacement power factor

Displacement power factor (DPF) is defined as per (4).

$$DPF = \frac{P_1}{A_1} = \frac{A_1 \cos \varphi}{A_1} = \cos \varphi \quad (4)$$

P_1 is the real power of the fundamental sinewave (at 50 Hz), A_1 is the total apparent power of the fundamental sinewave, $\cos \varphi$ is the phase shifting between voltage and fundamental current. Lower DPF means that for the same amount of real power, the apparent power required is higher, thus the

circulating current and the Joule losses on the distribution network are higher. Induction motors have low power factor (0.75 to 0.88), requiring correction capacitors. Italian distribution system operators require an average minimum of 0.95. Webuild enhance this requirement, adopting automatic displacement power factor corrector to reach 0.97.

5.4.2 Harmonic currents

Harmonic currents are waveform multiple of the fundamental current (50 Hz in Europe) produced by the rectifying bridges of the VFDs. The distortion power factor is defined in (5), assuming $\cos\varphi=1$.

$$PF_{THDi} = \frac{P_1}{A} = \frac{\sqrt{3}VI_1}{\sqrt{3}VI_{rms}} = \frac{I_1}{I_{rms}} = \frac{1}{\sqrt{1+THDi^2}} \quad (5)$$

THD_i is the total harmonic distortion, defined in (6).

$$THD_i = \frac{\sqrt{\sum_{h=2}^{\infty} I_h^2}}{I_1} \quad (6)$$

I₁ is the fundamental current, I_h are the harmonics multiple of the fundamental.

Harmonics cause energy losses, overheating, vibrations, disturbances on electronic devices. Webuild decided to adopt the IEEE 519:2022 standard “Harmonic Control in Electric Power Systems”, requiring the TBM manufacturers to comply to the limits of section 5.2, and containing the THD_i under 10%.

5.4.3 Improvement in total power factor

The total power factor (PF) is defined in (7) from (4) and (5).

$$PF = DPF \cdot PF_{THDi} = \cos\varphi \frac{1}{\sqrt{1+THDi^2}} \quad (7)$$

The apparent power *A* absorbed the grid is shown in (8).

$$A = \frac{P}{PF} = P \frac{\sqrt{1+THDi^2}}{\cos\varphi} \quad (8)$$

The current is determined by *A*. To reduce the circulating current (and thus the losses) using the same power the electric equipment must have high $\cos\varphi$ and low harmonics. The impact of $\cos\varphi$ and THD_i on the total power factor PF is shown in Table 2, the value obtained by Webuild is in bottom right.

Table 2. Resulting power factor.

	THD _i 50%	THD _i 25%	THD _i 10%
cosφ 0.75	0.67	0.73	0.74
cosφ 0.90	0.80	0.87	0.89
cosφ 0.97	0.87	0.94	0.96

The result achieved can be considered the best in class regarding power quality, ensuring the minimum energy losses and the minimum disturbance on the electric grid of the construction site and the distribution network.

5.5 Diesel generator

During high-voltage cable extension or in case of power outage, the essential supply loads are powered by an emergency diesel generator. The generator has no requirement in terms of efficiency or emission control. However, the choice of Webuild is to adopt a Stage V engine, defined in EU Regulation 2016/1628, which is the most advanced in the world. Stage V generators are designed to optimize diesel consumption and to reduce the pollutant emission (PM, CO, NO_x), implementing the selective catalytic reduction (SCR).

Table 3 offers a comparison between a non-regulated and a Stage V engine, all values are in g/kWh.

Table 3. Engine stage comparison.

	non-regulated	Stage V
Fuel cons.	213	191
CO	>5.0	3.5
NO _x	>9.2	0.4

This equipment has not a direct effect on reducing the energy incidence defined in (1), but it has been included in the Green TBM framework due to its effect on reducing CO₂ and pollutant emissions.

6 TESTING ACTIVITIES

The effectiveness of the innovations implemented for the Green TBM will be evaluated with extended testing activities along the duration of the projects. TBMs for Messina – Catania project will start to bore at the beginning of 2023. The data analysis during the first months will allow to collect a preliminary dataset and to tune the systems.

Three categories of tests will be adopted:

- ON/OFF test: a section of the tunnel will be excavated with the system off, then the system will be turned on and a section of equal length will be excavated;
- Comparison: electricity consumption will be compared between a TBM equipped and one not equipped with the innovation;
- Calculations: if the previous two methods are not applicable, calculations based on the equipment utilization parameters will be used.

Table 4 present which type of test will be used according to the different improvements introduced by the Green TBM.

Table 4. Testing activities.

Improvement	Test	Note
Automatic utilities management	ON/OFF	
Eco cruise mode	ON/OFF	According to geology
Continuous mining	ON/OFF	According to geology
Cutterhead design	Calculation	
Transformers	Calculation	
Electric motors	Calculation/ comparison*	*Comparison only regarding PMSM and AM of Main Drive
Power quality	Calculation	
Diesel generator	Comparison	With diesel generators of other TBMs

The results will be presented in a future paper, following the data analysis of the first tunnels.

7 CONCLUSIONS

Green TBM represents a new approach to reduce CO₂ emission and energy cost in infrastructure projects with a mix of new and existing state-of-the-art technologies. TBM systems and equipment have been integrated to increase energy efficiency an operational performance. The high number of TBMs

for Italian projects will allow to significantly reduce the energy consumption of the construction sites. An extensive evaluation of the effectiveness of the innovations implemented will be performed in 2024.

ACKNOWLEDGMENTS

The authors would like to thank the engineers of TBM manufacturers CREG, CRCHI, Herrenknecht, and Webuild Plant and Equipment department for their efforts in the development of the Green TBM concept design.

On the interplay between face extrusion and shield loading in squeezing conditions

Th. Pferdekämper* & G. Anagnostou
ETH, Zürich, Switzerland

ABSTRACT: This paper investigates the risk of shield jamming in mechanized tunnelling through heavily squeezing rocks that already experience large deformations at the tunnel face (extrusion), close the gap around the shield at a small distance behind the face and practically start exerting pressure upon the shield immediately after excavation. This may lead to the entrapment of the tunnel boring machine (TBM), if the installed thrust force is not sufficient to overcome shield skin friction. In addition, the excavation of the extruding ground, which happens continuously as part of the advance process, leads to additional extrusion and deformations ahead of the tunnel face and, due to longitudinal arching, to a potentially considerable additional shield loading. This paper investigates this aspect, comparing the results of a novel computational method that accounts for the continuous excavation of the extruding face with those of conventional tunnel advance simulations, which do not account for the cutterhead-ground interaction. According to our simulation results, the conventional simulations are adequate for moderate squeezing, but underestimate the pressure developing under heavily squeezing conditions.

Keywords: TBM, Shield jamming, Face extrusion, Thrust force requirements

1 INTRODUCTION

Squeezing occurs when tunnelling through weak and highly deformable rocks at high depth of cover. Large convergences of the cavity wall and extrusions of the tunnel face have been observed in several conventionally excavated tunnel stretches through weak rocks. In mechanized tunnelling, however, cavity deformations can be assessed only indirectly during advance, by measuring the weight of the spoil material at tunnel face and recording the necessary torque and thrust force.

The risk of TBM entrapment in squeezing ground conditions can be counteracted by installing a sufficiently high thrust force and, to a certain extent, excavating a larger tunnel diameter (“overcut”) to accommodate the ground convergences (thus preventing the ground from establishing contact with the shield). However, the radial overcut is limited to 15-25 cm at the tunnel face, as a larger overcut would make the steering of the TBM difficult. If the squeezing intensity is high, the radial gap around the shield may close already during the tunnel advance, leading to the development of a ground pressure upon the shield extrados (σ_R in Figure 1).

Figure 1. Radial pressure σ_R acting upon the shield during TBM advance, tunnel face extrusion δ_F and core deformation δ_C .

In addition, the TBM dimensions limit the number and diameter of the installable thrust cylinders too. In this case, if the installed thrust force is not sufficient to overcome the friction caused by the ground pressure, the TBM gets trapped. This results in

*Corresponding author: thomas.pferdekaemper@igt.baug.ethz.ch

expensive, time-consuming repair works, and, if it occurs frequently, may endanger the economic viability of a TBM drive.

For this reason, assessing the risk of shield jamming and estimating the required thrust force is probably the most important preliminary design step in the case of potentially squeezing ground.

To assess the interaction between ground, shield and lining, various methods have been proposed in the literature over the last decades (see Leone *et al.*, 2023, for a recent review). Anagnostou *et al.* (2018) and Pferdekämper *et al.* (2023) showed that, due to the extrusion of the face, the excavation volume during TBM advance under severe squeezing conditions can significantly exceed the theoretical tunnel volume. This is because the TBM continuously excavates material that was originally outside the theoretical tunnel cross-section but enters it during the tunnel advance (δ_C in Figure 1). This raises the question of whether the extrusion induced over-excitation might lead to an increase in the ground pressure acting upon the shield extrados (via arching in longitudinal direction). The potentially unfavourable interaction between the shield and the behaviour of the tunnel face has not yet been investigated.

This paper quantifies the aforementioned interaction taking explicitly into account the extrusion-induced over-excitation in the numerical analyses, which provide the rock pressure developing on the shield σ_R during advance in heavily squeezing rock.

2 NUMERICAL TBM ADVANCE ANALYSES

To quantitatively investigate the influence of face extrusion on shield loading, we compare results of TBM advance analyses that do not consider this interaction with results of finite element (FEM) computations with a novel computational model that accounts for the excavation of the extruding face.

2.1 Without considering continuous face excavation

Figure 2 shows, exemplarily, the result of a TBM advance analysis performed with the numerical FEM code HYDMEC (see Anagnostou 2007). The tunnel radius R is equal to 5 m and the shield length L to 10 m (typical values for a traffic tunnel). Table 1 summarises the parameters used for this computation.

The black and the red bold lines in Figure 2 represent the theoretical and actual (deformed) tunnel boundaries, respectively.

The limitation of conventional TBM advance computations becomes evident in severe squeezing ground conditions, as the volume of ground that entered the tunnel face during advance might be considerable (red dotted area in Figure 2). Numerically, the extruded volume supports the surrounding tunnel core limiting its deformation and, presumably, the ground pressure acting upon the shield σ_R . In reality,

Figure 2. Deformed tunnel boundaries with large tunnel face extrusion δ_F (steady-state method after Anagnostou 2007).

Table 1. Parameter set.

Tunnel radius R	5 m
Shield length L	10 m
TBM overcut ΔR	0.15 m
Shield stiffness K_S	2000 MPa/m
Lining stiffness K_l	100 MPa/m
<i>In-situ</i> stress σ_0	10 MPa
Uniaxial compressive strength f_c	0.5 MPa
Friction angle φ	15°
Dilation angle ψ	1°
Young's modulus E	1000 MPa
Poisson's ratio ν	0.25

however, such a convex face cannot occur during TBM advance, because the rotating cutterhead continuously removes the ground extruding at the tunnel face. This process results in a vertical tunnel face but a larger-than-expected excavation volume (“over-excitation”).

2.2 Considering excavation of extruding ground

A novel computational model was developed within the framework of the feasibility study for a demanding tunnel project (Anagnostou *et al.* 2018). The model, that includes a re-profiling and stress re-mapping algorithm, was implemented in a Python script and executed with the commercial FE software Abaqus® (see Pferdekämper *et al.* 2023). The first results, considering a rigid shield and zero overcut for the purposes of simplicity, have been published by Pferdekämper *et al.* (2023).

As schematically indicated by Figure 3, the novelty of the developed algorithm lies in the repeated excavation of the extruding ground at the face (“re-profiling”). The continuous TBM advance is approximated by discrete excavation steps of finite length Δx . The simulation of every excavation step begins with the deactivation of the core region of length Δx (volume V_0) in front of the tunnel face (Figure 3a). This causes additional radial

Figure 3. Schematic representation of the numerical re-profiling algorithm within a step-by-step advance computation.

displacements of the ground around the shield, which eventually lead to the gap closure and to an increase in shield loading. Additionally, in highly deformable grounds, the deactivation of volume V_0 may also lead to considerable extrusion of the tunnel face and radial displacement of the excavation boundary (V_1 in Figure 3b). In contrast to any previous investigation, the numerical algorithm makes sure that before simulating the next excavation step, the TBM excavates the volume V_1 too, which leads to an additional increase of the ground pressure acting upon the shield and to further displacements of the core boundaries (Figure 3c). The latter becomes increasingly smaller with each re-profiling round, hence core boundary displacements converge towards zero after a sufficient number of iterations (Figure 3d). As soon as the displacement at the face reaches a sufficiently small length (less than 1% of the step length Δx), the numerical re-profiling is considered complete and the algorithm continues with the next excavation step.

The algorithm tracks the shield-ground interaction storing the actual radial gap and contact pressure between shield and ground in an array after each computation and writing the values into the input file of the subsequent re-profiling round or excavation step.

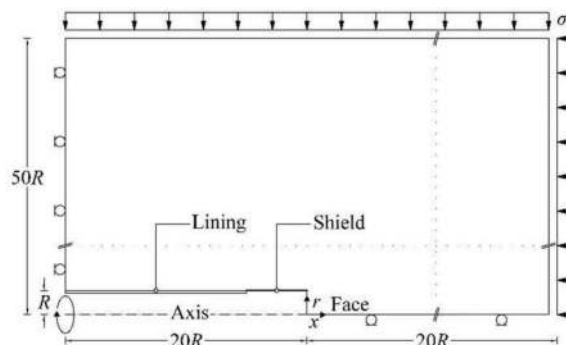

Figure 4. Numerical model setup.

Figure 4 schematically shows the numerical model setup used to investigate the TBM advance problem. For a deep tunnel in a hydrostatic *in-situ* stress field (σ_0), an axisymmetric model can be considered, which in the present case extends radially for $50R$, where R is the tunnel radius. The TBM advance is simulated from the left boundary up to the middle of the model for a length of $20R$, to avoid boundary effects. Three different step lengths with increasing degrees of precision (and computational effort) are considered for the step-by-step procedure ($\Delta x = R/5$, $R/10$ and $R/20$). The ground is taken to be linearly elastic (with Young's modulus E and Poisson's ratio ν), perfectly plastic obeying the Mohr-Coulomb yield criterion (with friction angle φ and cohesion c). The flow rule is non-associated (dilation angle ψ). Shield and lining are modelled by radial springs that account for their stiffnesses (K_s and K_l) as well as for the radial overcut ΔR (Ramoni and Anagnostou, 2010).

3 RESULTS

To quantify the difference in the required thrust force F_f between conventional and novel TBM advance computations, we consider the results presented by Ramoni and Anagnostou (2010) for a single-shield TBM with typical dimensions (see Figure 5). In general, the required thrust force to overcome skin friction F_f is a function of all the parameters given in Table 1, but, for dimensional reasons, the significant parameters of the problem are only the following (Ramoni and Anagnostou, 2010):

$$\frac{F_f}{\mu 2\pi R L \sigma_0} = f\left(\frac{L}{R}, \frac{\Delta R E}{R \sigma_0}, \frac{f_c}{\sigma_0}, \frac{K_s R}{E}, \frac{K_l R}{E}, \nu, \varphi, \psi\right) \quad (1)$$

Considering the favourable effect of the friction angle on face extrusion, we compare the worst case investigated by Ramoni and Anagnostou (2010), that is $\varphi = 15^\circ$ (with $\psi = 1^\circ$ and $\nu = 0.25$) and moderate to heavy squeezing ground conditions ($f_c/\sigma_0 = 0.05 \div 0.2$, where f_c is the uniaxial compressive strength). Moreover, for comparison purposes, we assume the same shield and lining stiffnesses. The complete set of dimensionless parameters is given in Table 2.

Figure 5. TBM dimensions and shield and lining stiffnesses considered in the comparative axisymmetric analyses (single shield TBM).

Figure 6 graphically represents Equation 1; it shows (in dimensionless form) the determined required thrust force F_f as a function of the overrun ΔR and of the normalized strength f_c/σ_0 . The lines represent the results after Ramoni and Anagnostou (2010) and the diamonds are the numerical results obtained with the novel numerical algorithm and hold for an excavation step length $\Delta x = 0$ (obtained by linear extrapolation).

The required thrust force F_f can be obtained by multiplying the results of Figure 6 with the shield surface ($2\pi RL$), the primary *in-situ-stress* σ_0 and the skin friction coefficient μ .

Table 2. Dimensionless parameters of this study.

Shield length L/R	2
TBM overrun $\Delta RE/R/\sigma_0$	1; 3; 5
Shield stiffness $K_s R/E$	10
Lining stiffness $K_l R/E$	0.5
Uniaxial compressive strength f_c/σ_0	0.5; 1; 1.5; 2
Friction angle φ	15°
Dilation angle ψ	1°
Poisson's ratio ν	0.25

Figure 6. Dimensionless required thrust force as a function of the TBM overrun and the ground strength ($\nu = 0.25$, $\varphi = 15^\circ$, $\psi = 1^\circ$).

According to Figure 6, conventional TBM advance computations generally underestimate the required thrust force. In terms of absolute values, the underestimation is rather slight. The relative error, too, is small in the potentially critical case of very weak and soft ground (low f_c , low E).

3.1 Influence of TBM overrun

The influence of TBM overrun on required thrust force and maximum ground pressure is discussed based on the results for cases A, B and C in Figure 6. The parameters of the black point B are the same as the ones given in Table 1.

Figures 7 and 8 show the distribution of the radial stress acting upon a 10 m-long shield, considering a short excavation step length ($\Delta x = 0.25$ m) and a uniaxial compressive strength f_c of 0.5 MPa or 2.0 MPa, characterising severe and rather moderate squeezing conditions, respectively.

In the case of severe squeezing and small overrun (A in Figure 7), the radial gap around the shield practically closes at the tunnel face ($x = -0.25$ m). The maximum pressure in the region of shield-tail ($x = -9.75$ m) is about 85% of the primary *in-situ* stress, and is caused by the stiffness change between shield K_s and segmental lining K_l . This maximum pressure might be relevant for the structural design of the steel shield.

Integrating the radial pressure over the shield length and considering a lubrication of the shield with friction coefficient $\mu = 0.2$ (a conservative assumption for a lubricated shield, see e.g., Gehring 1996), we obtain a required thrust force of 258 MN, which is high. From a design perspective, it is possible to reduce the shield-ground friction by increasing the

overcut ΔR . However, in severe squeezing conditions, the increase of the overcut from 5 cm to 25 cm leads to a reduction in the required thrust force of only 19% (see A and C in Figure 7).

On the contrary, in the case of moderate squeezing, the increase of the overcut from 5 cm to 25 cm leads to a considerable 85% reduction of required thrust force and, in addition, to a significantly lower maximum ground pressure (4 MPa instead of 8.5 MPa in Figure 8). Therefore, the overcut is very beneficial for the design of the TBM in moderate squeezing conditions, but not in severe squeezing conditions.

3.2 Influence of re-profiling

The influence of the re-profiling algorithm on the load acting upon the TBM is discussed considering the results for cases D (with re-profiling) and D' (without re-profiling) of Figure 6.

Figure 7. Radial stress distribution along a 10 m-long shield for severe squeezing ($f_c = 0.5$ MPa, $\sigma_0 = 10$ MPa).

Figure 8. Radial stress distribution along a 10 m-long shield for moderate squeezing ($f_c = 2$ MPa, $\sigma_0 = 10$ MPa).

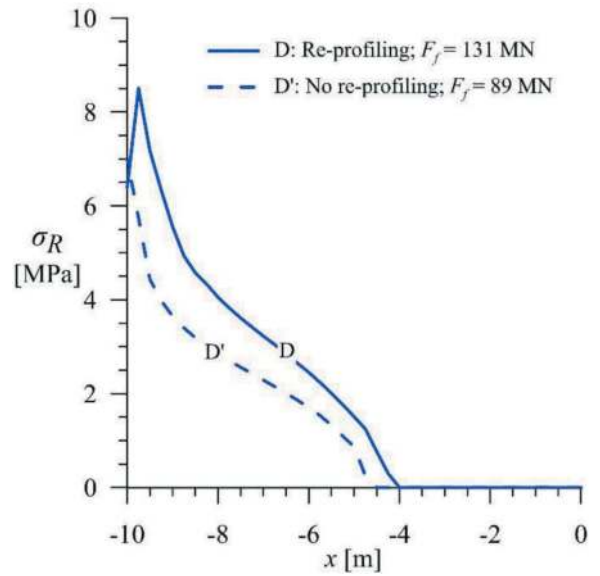

Figure 9. Radial stress distribution along a 10 m-long shield, with and without the re-profiling algorithm ($f_c = 1$ MPa, $\sigma_0 = 10$ MPa, $\Delta R = 0.25$ m).

According to the stress distributions (Figure 9), a consideration of the continuous excavation of the extruding material at the face results in an earlier closure of the gap between shield and ground (4.00 m vs. 4.75 m behind the face) and in a higher maximum radial pressure in the shield tail area (8.5 MPa vs. 7.0 MPa) and in a higher thrust force (131 MN vs. 89 MN).

4 CONCLUSIONS

This paper focused on severe squeezing conditions, characterised by a large extrusion of the ground at the face, and investigated whether the continuous excavation of the extruding ground might affect shield loading to a considerable degree. This was done by comparing the shield loading obtained from conventional TBM advance simulations with the loading obtained by means of a novel numerical algorithm that takes into account the interaction between cutterhead and ground at the face by means of successive re-profiling rounds. The excavation of the extruding ground results in an increase in the excavated tunnel volume. The latter considerably exceeds the theoretical tunnel volume in the case of severe squeezing (see Pferdekämper *et al.* 2023). Besides the practical implications for the spoil removal, mucking-out logistics and disposal site size, the aforementioned over-excavation results – via longitudinal arching – in a higher shield loading and a higher risk of shield jamming. This was confirmed by the performed comparative analyses. Conventional numerical simulations of the TBM advance, which do not take into account the excavation of the extruding ground during the boring

process, underestimate the ground pressure that develops upon the shield, but the effect is rather small (less than 20%) in the potentially critical situation of highly deformable ground.

Research on curved tunneling and bending angle calculation of articulated shield tunneling machine*

Wei Qiao, Xiangyu Zhou & Xingsheng Liang

China Railway Construction Heavy Industry Corporation Limited, Changsha Hunan, China

ABSTRACT: In order to accurately control the curve of articulated shield tunnelling machine and provide a theoretical basis for the size design of shield tunnelling machine and the selection of hinged form, the working principle of active hinged shield tunnelling machine, passive hinged shield tunnelling machine and double hinged shield tunnelling machine was firstly analyzed in detail, and its performance characteristics and application scenarios were compared. Then, according to the tunnelling attitude of the shield body in the tunnel curve section, the calculation method of bending angle between shield bodies was analyzed by analytic geometry, and the corresponding range of active and passive hinged bending angles of the double articulation system was calculated under the set turning radius of the tunnel trajectory curve. Finally, the telescopic stroke of the articulated cylinder was calculated to control the hinged bending angle, and the double-articulated shield tunnelling machine was used for example analysis, and the angle was checked in the range of no interference between the cylinder and the tunnel. This method accurately simulates the curve driving attitude of the shield tunnelling machine, thus providing a theoretical reference for the design of shield body size and cutter head overcutting tool when considering the minimum turning radius.

Keywords: shield tunnelling machine, articulation system, analytic geometry, the curve of driving

1 INTRODUCTION

TBM is a large-scale underground equipment used for tunnel excavation. At present, shield tunneling is the most promising and competitive tunnel construction method. Compared with other excavation methods, it has the advantages of safety and reliability, highly automated, fast excavation speed, etc. Therefore, the TBM is widely used in underground tunnel, pumped storage project and metro project [1]. The full-face TBM is mainly composed of three core systems: cutterhead drive system, hydraulic propulsion system and articulated system (attitude positioning system) [2], which play different important roles, as shown in Figure 1. The cutterhead drive system makes the TBM cutterhead rotate at a certain speed to cut and excavate the soil body; the hydraulic propulsion system makes the TBM cutterhead advance along the tunnel axis at a certain speed; the articulated system makes the TBM cutterhead follow the excavation direction of the tunnel.

The deviation between the actual axis of tunnel and the design axis is directly related to the construction quality of shield tunnel. During tunnel excavation, it is necessary to adjust the attitude of TBM in real time to change its movement direction, so as to

control its movement trajectory. The moment and

Figure 1. Schematic diagram of TBM structure.

thrust of attitude adjustment are provided by articulation cylinder. Therefore, to reasonably control the thrust and stroke of articulation cylinder is the key to reduce tunnel excavation error and improve tunnel construction quality. The articulated system is an important part of TBM, which consists of dozens of hydraulic cylinders used to adjust the tunneling attitude of TBM and control the bending angle of TBM during curved tunneling. However, the existing articulated turning technology has not yet formed a systematic technical theory.

*Corresponding author: 1434493225@qq.com

At present, the articulated TBM is mainly divided into three forms: passive articulation, active articulation and double articulation. Many scholars at home and abroad have analyzed and studied it. It mainly includes innovative design and research on the structure and composition of articulated system, articulated sealing system, etc., comparative analysis of the advantages, disadvantages and application scenarios of active articulation and passive articulation, and analysis and research in combination with the layout method of propulsion system considering the influence of articulated system [3-5]. Han Xue, et al. studied the characteristics and working principle of the articulated system of TBM, established a simulation model of the articulated hydraulic system, and analyzed the working characteristics of the hydraulic valve group [6]. Dong Weidong, et al. used the prism method of ENZAN to precisely calculate the attitude of active articulation TBM during tunneling [7].

2 WORKING PRINCIPLE OF ARTICULATED SYSTEM

Working principle of active articulation: As shown in Figure 2, the articulation cylinder is connected between the front shield and the middle shield, the middle shield and the shield tail are connected into a whole by bolting or welding, and the thrust cylinder is fixed on the supporting ring plate of the middle shield of TBM, that is, the articulation cylinder is at the front end of the fixed point of thrust cylinder; the whole middle shield and shield tail are pushed by the reaction force of the thrust cylinder supported on the segment, while the articulation cylinder connects the middle shield with the front shield. The acting force of the articulation cylinder is transmitted to the front shield and cutterhead, and then the telescopic stroke of the articulation cylinder is adjusted in zones to control the turning angle, thus realizing curved tunneling of the TBM. Since the middle shield and shield tail are coaxial with the segment, the reverse thrust F formed by the thrust cylinder and the segment is consistent with the radial direction of the segment, so that no lateral force will be generated.

Working principle of passive articulation: As shown in Figure 3, the articulation cylinder is connected

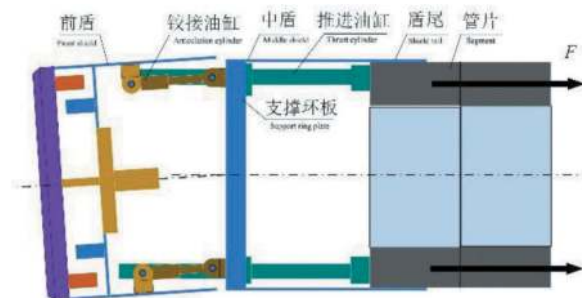

Figure 2. Active articulation.

between the middle shield and the shield tail, the front shield and the middle shield are connected into a whole by bolting or welding, and the thrust cylinder is fixed on the supporting ring plate of the middle shield of TBM, that is, the articulation cylinder is at the rear end of the fixed point of thrust cylinder; the front and middle shields are moved forward by the reaction force of the thrust cylinder supported on the segment, and the articulation cylinder drags the shield tail to move forward, that is, the shield tail moves forward in a serpentine shape with the front and middle shields. The articulation cylinder adjusts the telescopic length of the cylinder in zones and then generates a bending angle between the shields to realize turning. It can be observed in Figure 3 that since the middle shield is not coaxial with the shield tail and the segment, the reverse thrust F formed by the thrust cylinder and the segment has a certain angle with the radial direction of the segment, which will generate lateral force.

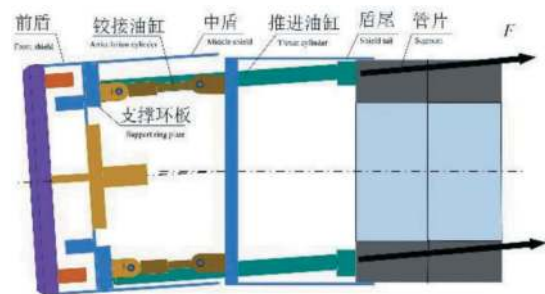

Figure 3. Passive articulation.

There is an active articulation system between the front shield and the middle shield, and a passive articulation system between the middle shield and the shield tail, so that the TBM forms two sets of articulation systems, which are called double-articulated TBMs. **Working Principle of Double Articulation:** As shown in Figure 4, the front shield and middle shield are connected by an active articulation cylinder, the middle shield and shield tail are connected by a passive articulation cylinder, and the thrust cylinder is fixed on the supporting ring plate of the middle shield of TBM; the middle shield is moved forward by the reaction force of the thrust cylinder supported on the segment, and the passive articulation cylinder drags the shield tail forward, while the front shield and cutterhead are pushed by the action force of the active articulation cylinder, so as to adjust the telescopic stroke of the active articulation cylinder in zones to control the bending angle of the front shield and the middle shield, and adjust the telescopic stroke of the passive articulation cylinder to control the bending angle of the middle shield and the shield tail, thus realizing curved tunneling of the TBM. Similar to the passive articulation system, since the middle shield is not coaxial with the shield tail and the segment, the reverse thrust F formed by the thrust cylinder and the segment has a certain

angle with the radial direction of the segment, which will generate lateral force.

Figure 4. Double articulation.

Table 1. Comparison of characteristics and applicable working conditions of various articulation forms.

Articulation type	Performance characteristics	Applicable working conditions
Active articulation	Good deviation correction operability, large thrust of articulation cylinder, no lateral force for propulsion, uniform stress on segment, small requirements for internal space of shield, Large minimum turning radius, small drag force of articulation cylinder	accurate stroke control, adaptable to tunnels with small turning radius
Passive articulation	Large lateral force of thrust cylinder on segment, easy to cause fragmentation of segments,	adaptable to tunnels with certain turning radius
Double articulation	Two articulation systems, more adaptable to curved tunneling of the tunnel, small lateral force of thrust cylinder, small requirements for internal space of shield,	adaptable to tunnels with larger long diameter and smaller turning radius in shield design.

3 CALCULATION OF BENDING ANGLE BETWEEN SHIELDS

3.1 Calculation of front shield rotation range and cutterhead over-excitation length

During tunneling along a curved trajectory, the central perpendicular line passing through the cutterhead plane needs to be tangent to the axis of excavation trajectory, as shown in Figure 5(a). The cross section of turning plane of the curved tunnel is taken for analysis, and the contour line of the front end face of

cutterhead needs to point to the center of the tunnel curve [8-9]. Through analysis on the shield body of TBM, its front shield and cutterhead are fixed as a whole, while the outer diameter of cylinder of front shield is designed to be slightly smaller than that of cutterhead. During curved tunneling, the over-excitation cutter shall be extended as required to meet the distance requirement between shield body and curved tunnel, without mutual interference affecting shield attitude [10]. Therefore, the over-excitation radius is calculated to ensure that the rear end face of the front shield does not interfere with the contour trajectory of the tunneling section, and the curve radius is also changed when the front shield and cutterhead carry out curved tunneling. Then, when the over-excitation is t , the rotation angle range of the front shield and cutterhead is calculated to meet the movement of the front shield in the tunnel.

(a) Schematic Diagram of Front Shield and Cutterhead Positions on Cross Section of the Curved Tunnel

(b) Schematic Diagram of Bending Angle of Front Shield

(c) Intersection point between the upper turning point on the rear end face of front shield and the outer contour of tunnel

Figure 5. Attitude of front shield during curved tunnelling.

When the TBM is tunnelling with a certain radius of circular curve, the cross section passing through the center of the curve is analyzed. The plane coordinate axis is established with the center of the tunnel contour curve as the origin and the front end face of the cutterhead is used as the y axis, so that the trajectory function of the outer contour of tunneling section can be derived:

$$x^2 + y^2 = (R + r + t)^2 \quad (1)$$

As shown in Figure 5(a), R is the radius of tunnel circular curve, r is the radius of outer cylinder of front shield, and t is the over-excavation length of cutterhead. Inner contour trajectory function of tunneling section:

$$x^2 + y^2 = (R - r - t)^2 \quad (2)$$

When the curve radius is changed for tunneling, the front shield and cutterhead rotate with the center of the front end face of cutterhead as the circle center. The trajectory function of upper turning point on the rear end face of the front shield of TBM is:

$$x^2 + (y - R)^2 = \left(\frac{a}{2}\right)^2 + (r)^2 \quad (3)$$

其中: a为刀盘加前盾长度。

Where: a is the length of cutterhead plus front shield.

As shown in Figures 5(b) and (c), the calculation equations of intersection point can be derived from the coordinates (x_1, y_1) of the intersection point between the trajectory of upper turning point on the rear end face of front shield and the outer contour trajectory of tunneling section:

$$\begin{cases} x^2 + (y - R)^2 = \left(\frac{a}{2}\right)^2 + (r)^2 \\ x^2 + y^2 = (R + r + t)^2 \end{cases} \quad (4)$$

The calculation equations of intersection point can be derived from the coordinates (x_2, y_2) of the intersection point between the trajectory of lower turning point on the rear end face of front shield and the inner contour trajectory of tunneling section:

$$\begin{cases} x^2 + (y - R)^2 = \left(\frac{a}{2}\right)^2 + (r)^2 \\ x^2 + y^2 = (R - r - t)^2 \end{cases} \quad (5)$$

When the TBM rotates through the circle center position of the front end face of the cutterhead until the trajectory of upper turning point on the rear end

face of front shield intersects with the outer contour trajectory of tunneling section, the rotation angle is as follows:

$$\alpha = \alpha_2 - \alpha_1 \quad (6)$$

Where

$$\alpha_1 = \arctan\left(\frac{a}{2r}\right) \quad (7)$$

$$\alpha_2 = \arctan\left(\frac{x_1}{y_1 - R}\right) \quad (8)$$

When the TBM rotates through the circle center position of the front end face of the cutterhead until the trajectory of lower turning point on the rear end face of front shield intersects with the inner contour trajectory of tunneling section, the rotation angle is as follows:

$$\beta = \alpha_1 - \beta_1 \quad (9)$$

Where

$$\beta_1 = \arctan\left(\frac{x_2}{-y_2 + R}\right) \quad (10)$$

Through calculation, when the front shield and cutterhead conduct curved tunneling and the curve radius is changed, the rotation angle range of the front shield and cutterhead is (α, β) .

The range of over-excavation t is calculated to meet the requirement that the upper and lower turning points on the rear end face of the front shield of TBM are within the contour of tunneling section, and it can be derived that:

$$t > \sqrt{a^2 + (R + r)^2} - R - r \quad (11)$$

3.2 Calculation of bending angle of middle shield

During tunneling with curved trajectory, a certain angle will be formed between the middle shield and the front shield to ensure that the outer cylinder of the middle shield does not interfere with the tunnel, while thrust and steering are conducted between the front shield and the middle shield through active articulation. As shown in Figure 6, for the convenience of calculation and understanding, it can be simplified as that the middle shield rotates around O_1 . Therefore, the outer diameter of cylinder of the middle shield can be calculated to meet the distance requirement between the shield body and the curved tunnel so that they do not interfere with each other. It is easy to see from this that the middle shield can rotate at a certain angle without interfering with the

inner wall of the tunnel. Therefore, the rotation angle range of the middle shield can be calculated to meet the movement of the middle shield in the tunnel.

Figure 6. Attitude of middle shield during curved tunneling.

Where, h is the radius difference between the middle shield and the front shield, and b is the length of the middle shield. The calculation equations of intersection point can be derived from the coordinates (x_3, y_3) of the intersection point between the trajectory of upper turning point on the rear end face of front shield and the outer contour trajectory of tunneling section:

$$\begin{cases} (x-a)^2 + (y-R-r+h)^2 = b^2 + (2r-2h)^2 \\ x^2 + y^2 = (R+r+t)^2 \end{cases} \quad (12)$$

When the middle shield of TBM rotates through the circle center O_1 until the upper turning point on the rear end face of middle shield intersects with the inner contour trajectory of tunneling section, the rotation angle is as follows:

$$\lambda = \lambda_2 - \lambda_1 \quad (13)$$

Where

$$\lambda_1 = \arctan\left(\frac{b}{2r-2h}\right) \quad (14)$$

$$\lambda_2 = \arctan\left(\frac{x_3-a}{y_3-R+r-h}\right) \quad (15)$$

The calculation equations of intersection point can be derived from the coordinates of the intersection point between the trajectory of lower turning point on the rear end face of front shield and the inner contour trajectory of tunneling section: (x_4, y_4)

$$\begin{cases} (y-R+r-h)^2 + (x-a)^2 = b^2 \\ x^2 + y^2 = (R-r-t)^2 \end{cases} \quad (16)$$

When the middle shield of TBM rotates through the circle center O_1 until the lower turning point on the rear end face of middle shield intersects with the inner contour trajectory of tunneling section, the rotation angle is as follows:

$$\tau = \arctan\left(\frac{R-r+h-y_4}{x_4-a}\right) \quad (17)$$

The bending angle range of the middle shield is calculated when the curve radius of the tunnel is R to ensure that the outer cylinder of the middle shield does not interfere with the tunnel, and the rotation angle range of the middle shield is (λ, τ) . Similarly, the bending angle range corresponding to the shield tail of the passive articulation system in a tunnel with a certain turning radius can be derived.

3.3 Calculation of bending angle of double articulation system

Since the middle shield and the shield tail form an articulation angle with the front shield and middle shield respectively under the action of the active articulation cylinder and passive articulation cylinder, the value of articulation angle is taken within a range, and its range depends on the condition that the cylinders of middle shield and shield tail do not interfere with each other in the tunnel. Here, an angle suitable for tunneling can be taken. As shown in Figure 7, the center of the tunnel curve where the rear end face of the middle shield passes through and the center of the curve where the rear end face of the shield tail passes through can be taken to make the thrust cylinder parallel to the segment, reduce the generation of lateral force, calculate its articulation angle, and check whether the angle is within the range where the cylinder doesn't interfere with the tunnel.

Figure 7. Attitude of shield body during curved tunneling.

In order to simplify the calculation, the cylinder length can be regarded as the chord length and the articulation angle can be calculated. The articulation angle is:

$$\theta = \theta_1 + \theta_2, \quad \theta_1 = \frac{a+b}{R} \cdot \frac{180}{\pi}, \quad \theta_2 = \frac{c}{R} \cdot \frac{180}{\pi} \quad (18)$$

4 CYLINDER STROKE DERIVATION AND CALCULATION EXAMPLE ANALYSIS

4.1 Cylinder stroke derivation

Active articulation or passive articulation makes an angle between the front shield and the middle shield of the TBM, or between the middle shield and the shield tail, which is controlled by the telescopic stroke of the articulation cylinder. The telescopic stroke of the articulation cylinder at each location when the angle δ is generated is calculated here. In Figure 8(a), the normal direction of TBM turning direction is X axis, and the shaft center of TBM is Z axis to obtain the distribution diagram of its articulation cylinders. From the projection of ZOZ plane, Figure 8(b) is obtained, where δ is the articulation bending angle; from the projection of XOY axis plane, Figure 8(c) is obtained. By taking the position (x_i, y_i) of any articulation cylinder, its stroke is calculated.

Assuming that the radius of the trajectory circle at the articulation point of the oil cylinder is r_1 , and the uniform extension distance of the oil cylinder is l , then the extension distance L_i of the oil cylinder at the location (x_i, y_i) vis:

$$L_i = l + (r_1 - x_i) \cdot \tan \delta \quad (19)$$

4.2 Calculation example analysis

The bending angle and over-excavation size of each shield body under the minimum design curve radius of 150,000 mm are calculated by taking a certain type of soil pressure balance TBM with double articulation system as the analysis object. Its main dimensional parameters are shown in Table 2.

During normal tunneling, the over-excavating cutter is not extended. That is to say, during over-excavation $t = 0$, it is only necessary to calculate the rotation angle range of the front shield and cutterhead when the front shield and cutterhead carry out curved tunneling and change the curve radius, so as to meet the movement of the front shield in the tunnel. The rotation range of front shield is calculated, which is derived from Section 2.1 and solved by Equations (4), (5), (7), (8) and (10):

$$(x_1, y_1) = (1665, 153991), (x_2, y_2) = (1621, 145991), \\ \alpha_1 = 23.077^\circ, \alpha_2 = 22.645^\circ, \beta_1 = 22.015^\circ$$

$$(x_1, y_1) = (1665, 153991), (x_2, y_2) = (1621, 145991), \\ \alpha_1 = 23.077^\circ, \alpha_2 = 22.645^\circ, \beta_1 = 22.015^\circ$$

When the TBM rotates through the circle center position of the front end face of the cutterhead until

(a) Distribution Diagram of Articulation Cylinder

(b) Projection of XOZ plane

(c) Projection of XOY plane

Figure 8. Geometric simplification diagram of articulation cylinder.

Table 2. Main dimension parameters of TBM.

Item	Size/mm
Length of front shield plus cutterhead	3400
Length of middle shield	3170
Length of shield tail	3245
Stroke of active articulation cylinder	310
Stroke of passive articulation cylinder	200
Diameter of outer cylinder of front shield	3990
Cutterhead diameter	4000

the upper and lower turning points on the rear end face of front shield are within the contour of tunneling section, the rotation angle range is as follows:

$$(\alpha, \beta) = (0.432^\circ, 1.062^\circ)$$

The range of over-excavation t is calculated to meet the requirement that the upper and lower turning points on the rear end face of the front shield of TBM are within the tunnel, where

$$x_1 = a, y_1 = R + r, x^2 + y^2 = (R + r + t)^2$$

So:

$$t > 37.5\text{mm}$$

The rotation angle range of middle shield is calculated under the over-excavation distance of 37.5 mm. When the middle shield of TBM rotates through the circle center O_1 until the upper and lower turning points on the rear end face of middle shield intersect with the inner and outer contour trajectories of tunneling section, the rotation angle range is as follows: The following can be obtained through the Equations (12), (14), (15) and (16):

$$(x_3, y_3) = (6833, 153875), \lambda_1 = 21.390^\circ, \\ \lambda_2 = 23.594^\circ, \lambda = 2.204^\circ$$

$$(x_4, y_4) = (6564, 145827), \tau = 3.400^\circ$$

Rotation angle range:

$$(\lambda, \tau) = (2.204, 3.400)$$

Here, an angle suitable for tunneling can be taken. The center of the tunnel curve where the rear end face of the middle shield passes through and the center of the curve where the rear end face of the shield tail passes through can be taken to calculate the bending angle and check whether the angle is within the range where the cylinder doesn't interfere with the tunnel. The solution obtained is as follows:

$$\theta_1 = 2.510^\circ, \theta_2 = 1.239^\circ, \theta = 3.749^\circ$$

The bending angle of middle shield is $2.510 \in (2.204, 3.400)$, meeting its non-interference condition. The bending angle of shield tail is $\theta_2 = 1.239^\circ$. As the shield tail is less than the length of front shield plus cutterhead, the shield tail also meets the condition of no interference with the tunnel contour under the over-excavation distance of 37.5 mm when there is no bending angle. The soil pressure balance TBM with double articulation system has a bending angle of 3.749° under the minimum design curve radius of 150,000 mm.

The telescopic stroke of articulation cylinder is calculated when it rotates at a certain angle. As

shown in Figure 9, if the radius of trajectory circle at the articulation point of oil cylinder is 3,700 mm, the uniform extension length l is 50 mm for the oil cylinder at the location (2110,3039). If it turns left and the articulation bending angle is 1.24° , the 270° direction is the forward direction of the X axis, and the calculated extension distance of cylinder 1 is 175.8 mm.

Figure 9. Layout diagram of oil cylinders.

5 CONCLUSIONS

In order to accurately control the curved tunneling of articulated TBM and provide theoretical reference for the design of shield size, cutterhead over-excavation cutter size and selection of articulation form, three articulation forms (active articulation, passive articulation and double articulation) are studied for TBM.

- (1) Analyze the working principles and characteristics of three articulation forms of TBM, show the shield attitude during curved tunneling and the stress of thrust cylinder on segment, and compare the tunneling conditions applicable to the three articulation forms.
- (2) By analyzing the articulated TBM, study the bending attitude of shield body during curved tunneling, and put forward an analytical geometry method to calculate the boundary conditions for the movement of shield body in the tunnel, so as to calculate the rotation angle range of each shield. Here, calculate the rotation angle range of front shield and cutterhead when the front shield and cutterhead carry out curved tunneling and change the curve radius; calculate the over-excavation range of cutterhead over-excavation cutter to meet the requirement that the upper and lower turning points on the rear end face of front shield are within the contour of tunneling section; and calculate the range of bending angle of middle shield under a certain

radius of tunnel curve to ensure that the outer cylinder of middle shield doesn't interfere with the tunnel.

- (3) Analyze the rotation angle corresponding to the stroke of each cylinder to obtain the corresponding relation between the telescopic stroke and the bending angle of the cylinder. Calculate the rotation angle of each shield during curved tunneling of double articulation system through an example, and check whether its angle is within the range where the cylinder of shield body doesn't interfere with the tunnel.

ABSTRACT: To study the motion law and characteristics of large-sized particles in the slurry discharge pipeline of slurry TBM, the two-way coupling method based on FVM-DEM is used to simulate the solid-liquid two-phase flow in long pipelines. In order to verify the feasibility of the numerical method, the solid-liquid two-phase flow in vertical pipelines is simulated. The calculated results are in good agreement with the experiments with the error of pressure drop being less than 5.0%. Then this method is used to simulate the motion characteristics of large-sized particles with irregular shapes in long-distance continuous pipelines. It is found that the increase of mud viscosity has little effect on particle velocity compared with the results of clear water. Local convergence phenomenon of large-sized irregular particles appears, which is easy to cause pipeline blockage. Therefore, the second blockage of large particle size slag is needed in advance in circulation system to prevent blockage of the pipeline.

Keywords: Slurry TBM, CFD-DEM, Two-way coupling, Long pipelines, Slurry circulation system

1 INTRODUCTION

In the planning and construction of urban subway tunnel, The slurry balance shield has become a priority construction machinery for the construction of cross-river tunnels, because there are some advantages such as less construction impact, strong adaptability to geological conditions, safety and speed. The slurry circulation system is an important part of the slurry TBM. However, there are few studies on the circulation system of slurry TBM and its slag carrying capacity, especially on the transportation characteristics of large-size slag.

At present, researchers have carried out a lot of research on the transportation of solid particles in pipelines. Zhou et al, (2011) analyzed the relationship between particle composition characteristics and conveying speed and obtained the particle volume fraction. F. Ravelet et al, (2013) studied the influence of particle size and density on the formation of fixed bed or dispersed flow of particles through

experiments and revised the empirical formula. Wang et al. (2015), adopted the experiments to study the influence of different hydraulic parameters on the pressure loss of the pipeline and determined the functional relationship between different hydraulic parameters and pressure loss. Edelin et al, (2015) analyzed the optimal concentration of particles transported in clear water from the perspective of energy. In the experiments of Cao et al, (2016), the hydraulic characteristics of coarse particles under different hydraulic parameters was analyzed by high-speed camera. Wu (2019) designed a slurry circulation system. With water as the carrier fluid, the critical velocity law of large-sized pebbles in different pipeline positions in the circulation system, as well as the typical movement pattern and velocity of different pipeline forms under different flow velocities are obtained.

With the rapid development of computer technology, the numerical simulation method is increasing widely applied to the study of pipeline transportation. Compared with the experimental method, the numerical

*Corresponding author: renzhen90@163.com

method has the advantages such as short research cycle and low investment cost. Jiang et al. (2012) used eulerian multiphase flow model to study the influence of flow velocity and average solid volume fraction on the flow characteristics of nitrogen slurry. Gopaliya et al. (2016) constructed a solid flow model by using two-phase flow theory, and analyzed the flow state of iron ore filling slurry and sand slurry in horizontal pipe. Xia et al. (2017, 2018) studied the influence of shape coefficient, constant volume particle size and quantity of rock slag on the starting speed of rock slag and the influence of shield machine operation parameters on the pressure loss of circulation system and the conveying speed of rock slag. Yang et al. (2018) studied the transport characteristics of slag in the horizontal straight pipe of the slurry TBM circulation system. Yang et al. (2018) used CFD and DEM to establish the corresponding model, and pointed out that the stones were mainly distributed at the bottom of the horizontal straight pipe. Dai et al (2021) simulated the pipeline internal flow by coupling software Fluent and EDEM. From the perspective of computational fluid mechanics, the movement performances of particles such as concentration distribution and velocity distribution in the vertical pipeline are obtained. In addition, the wall shear stress under different working conditions is also analyzed. Song et al. (2021) simulated the characteristics of solid-liquid two-phase flow under different working conditions in vertical pipelines and analyzed the influence of large particle solid-liquid two-phase flow with different properties on deep-sea mining transportation system. Chen, et al (2022) studied the internal mechanism of pipeline wear through the results of motion trajectory, flow state and solid volume distribution during the transportation of particles with three different length-to-diameter ratios by coupling CFD and DEM.

Scholars have done a lot of research on the transportation of slag in the pipeline, but there are relatively few studies on the movement of large and medium-sized slag in long distance. This paper makes a preliminary study on the transportation of large irregular slag in horizontal long pipelines. This paper includes the following parts, the first part is introduction, the second part is the numerical method, and the third part is the numerical method verification and simulation results analysis. Finally is the conclusion.

2 NUMERICAL METHOD

2.1 CFD-DEM model

CFD method is one of the important means to solve complex flow problems and plays an important role in the numerical simulation of solid-liquid two-phase flow. The discrete element model (DEM) in the commercial CFD software STARCCM+ has three advantages in the numerical simulation of the solid-liquid two-phase flow of large-size particles in the pipeline.

Firstly, the particles are solved in the Lagrangian coordinate system, so that the position of each particle can be tracked. The second is to consider the interphase force between particles and liquid at the same time to realize the two-way coupling of flow field and particles. At last, the interaction force between particles is considered to explain the interaction between particles.

The motion of the particles is solved in the Lagrangian coordinate system and the position of each particle in the flow field is located. The flow of liquid is solved in the framework of Euler coordinate system. The interaction between liquid and solid particles is considered by introducing the volume fraction of the solid-liquid two-phase.

The continuity equation of liquid phase is:

$$\frac{\partial(\varepsilon_1\rho_1)}{\partial t} + \nabla \cdot (\varepsilon_1\rho_1u) = 0 \quad (1)$$

The momentum equation of the liquid phase is:

$$\frac{\partial(\varepsilon_1\rho_1u)}{\partial t} + \nabla \cdot (\varepsilon_1\rho_1uu) = -\varepsilon_1\nabla p + \nabla \cdot (\varepsilon_1\mu\nabla u) + \varepsilon_1\rho_1g + F_{pl} \quad (2)$$

where

$$F_{pl} = -\frac{\sum F_{pl,i}}{\Delta V_{cell}}$$

where ρ_1 is the density of the liquid; t is time; ε_1 is the volume fraction of the liquid phase; u is the velocity of liquid; p is the static pressure of liquid; μ is liquid dynamic viscosity; F_{pl} is the sum of the forces of the discrete phase (solid phase) to continuous phase (liquid phase) in the grid cell; ΔV_{cell} is the grid element volume.

The particle motion including the variation of particle velocity and position with time is calculated by DEM model based on Newton's law of motion. The equations of translational motion and rotational motion of a single particle are respectively shown as:

$$m_i \frac{dv_i}{dt} = \sum_j F_{c,ij} + \sum_k F_{nc,ik} + F_{lp,i} + F_{g,i} \quad (3)$$

$$I_i \frac{d\omega_i}{dt} = \sum_j (M_{t,ij} + M_{r,ij}) \quad (4)$$

where m_i is the mass of a single solid particle i ; v_i is the moving speed of particle i ; $F_{c,ij}$ is the contact force between particle i and particle j ; $F_{nc,ik}$ is the non-contact force between particle i and particle j ; $F_{lp,i}$ is the acting force of fluid on the particle i ; $F_{g,i}$ is the

body force on particle i ; I_i is the moment of inertia of particle i ; ω_i is the rotation speed of particle i ; $M_{t,ij}$ is the tangential friction torque between particle i and particle j ; $M_{r,ij}$ is the normal friction torque between particle i and particle j .

2.2 Geometry model and boundary condition

The pipe material is carbon steel, length $L=10\text{m}$, pipe diameter $D=100\text{mm}$, roughness $100\mu\text{m}$. The mixing transport speed V_{mix} is 3.0m/s and solid particle volume transport concentration C_V is 5% . The RNG $k-\varepsilon$ turbulence model was used for liquid phase simulation. The velocity inlet and pressure outlet are used to set the boundary conditions. The fluid calculation domain is shown in Figure 1. The thickness of the first layer boundary layer is set to 10.0 mm and the boundary layer is set to 4 layers with an elongation of 1.4. The model is divided by trimmer mesh with a total of 536,512 mesh elements and 557,865 mesh nodes.

The Lagrangian phase model selects composite particles, two-way coupling, turbulent dissipation, pressure gradient force, drag force and DEM particle model.

Figure 1. Pipeline and grid distribution.

2.3 Two-way coupling procedure

In STAR-CCM+, the interactions between the dispersed phase and the continuous phase are simulated as one-way coupling or two-way coupling (CD-adapco (2022)).

With one-way coupling, only the continuous phase influences the dispersed phase, but not in the reverse direction. With two-way coupling, the effects of the dispersed phase on the continuous phase such as displacement, interphase momentum, mass, and heat transfer are taken into account.

The displacement of the continuous phase by the dispersed phase is accounted for through the volume fraction. The volume fraction of a Lagrangian phase is the fraction of the local cell volume which that phase occupies. It is calculated for both discrete material particles and DEM particles.

Figure 2 depicts the two-way coupling procedure. The volume fraction, force distribution and flow field information of the fluid phase and the solid phase are calculated in CFD. At the end of a time step

calculation, the force acting on the particles is transferred to the DEM model. The position and velocity of particles are updated in DEM. After the DEM calculation is completed, the position and velocity of the particles are transferred to the flow field of the FVM.

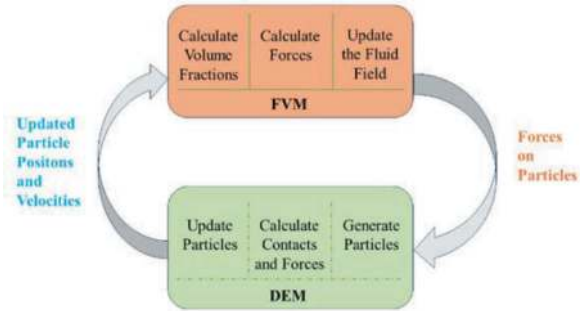

Figure 2. Two-way coupling procedure.

2.4 Source smoothing method

To make the CFD-DEM method can be used for the calculation of large particles and ensure its calculation accuracy, the source smoothing method is introduced in StarCCM+ (CD-adapco (2022), Liu (2019)). The main idea is that when the grid resolution is less than the particle, the multiple grids containing the particles are combined to form a large virtual grid cluster which is used to calculate the volume fraction of the particles, the movement of the particles, the force and other parameters. At the same time, the effect of particles on the fluid will also be assigned to each grid in the virtual grid cluster. Figure 3 describes the treatment of large-sized particles.

Figure 3. Source smoothing method.

3 ANALYSIS OF SIMULATIONS

3.1 Experiment verification

In order to verify the reliability of the numerical simulation method, simulation results and experimental data of solid-liquid two-phase flow in vertical pipe are compared as shown in Figure 4. The experimental results are obtained from the tests of Xia (2004). The

solid phase transport concentration is 5.0%, the diameter of solid particle is 15.0mm. As shown in Figure 4, the numerical simulation results are in good agreement with the experiments. The maximum error between the two is less than 5%. This shows that the current numerical simulation method is credible.

Figure 4. Comparison between CFD and EFD.

3.2 Effect of viscosity on slag transportation

In order to simulate irregular particles, the composite particle model is selected. The composite particles model uses multiple shapes (spheres) to represent non-spherical particles. The shapes are fixed together and do not separate during the simulation.

The slag stone transported by the circulation system is mostly pebbles. In order to simulate the shape of pebbles, 15 spherical particles were used to form irregular pebble particles, as shown in Figure 5.

Figure 5. Irregular particle.

In the numerical simulations, the influence of viscosity on particle transport is studied. Water and slurry with viscosity being from 0.02 to 0.05 mpa-s were selected for comparative analysis. In the simulations, taking the slurry TBM with diameter being 15.0m as an example, the amount of slag stone can be calculated according to the tunnelling speed of 15.0mm/min. When the particles are generated, the maximum particle size is set to 50.0mm and the average particle size is 30.0mm.

In order to monitor the distribution and motion state of particles in the local area, two cylindrical sections with a length of 1.0m in the middle and outlet of the pipeline are selected, as shown in Figure 6.

Figure 6. Local monitoring area layout.

Figure 7 describes the variation of solid particle concentration under different working conditions. It is shown that the solid particle concentration under clean water condition is higher than that under other conditions. However, the concentration of solid particles does not change much under different viscosity conditions. It indicates that the slurry with slightly larger viscosity is beneficial to the transportation of slag, but the change of viscosity has little effect on the transportation of slag.

Figure 7. Time history of concentration at different viscosities.

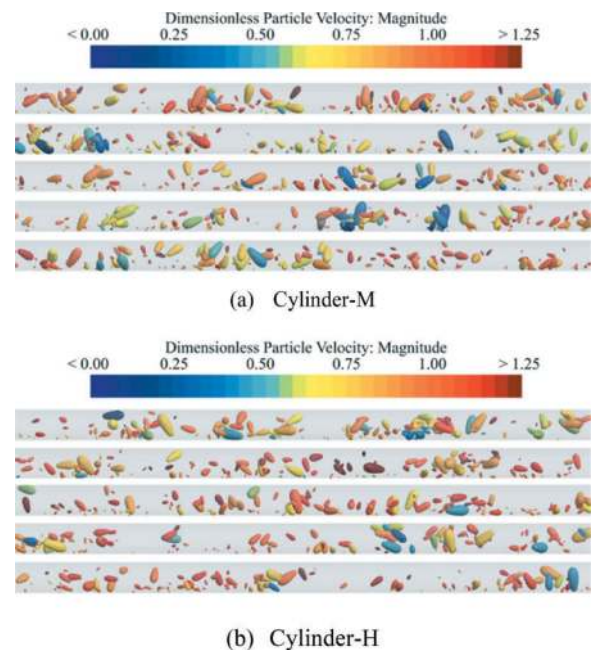

Figure 8. Dimensionless particles velocity in local pipe.

Figure 8 shows the dimensionless particle velocity in the local regions. The variation of dimensionless particle velocity is little under different viscosity conditions. However, under different working conditions, there is a same phenomenon, that the large size particles will gather in different positions. The main reason for this phenomenon is that the large

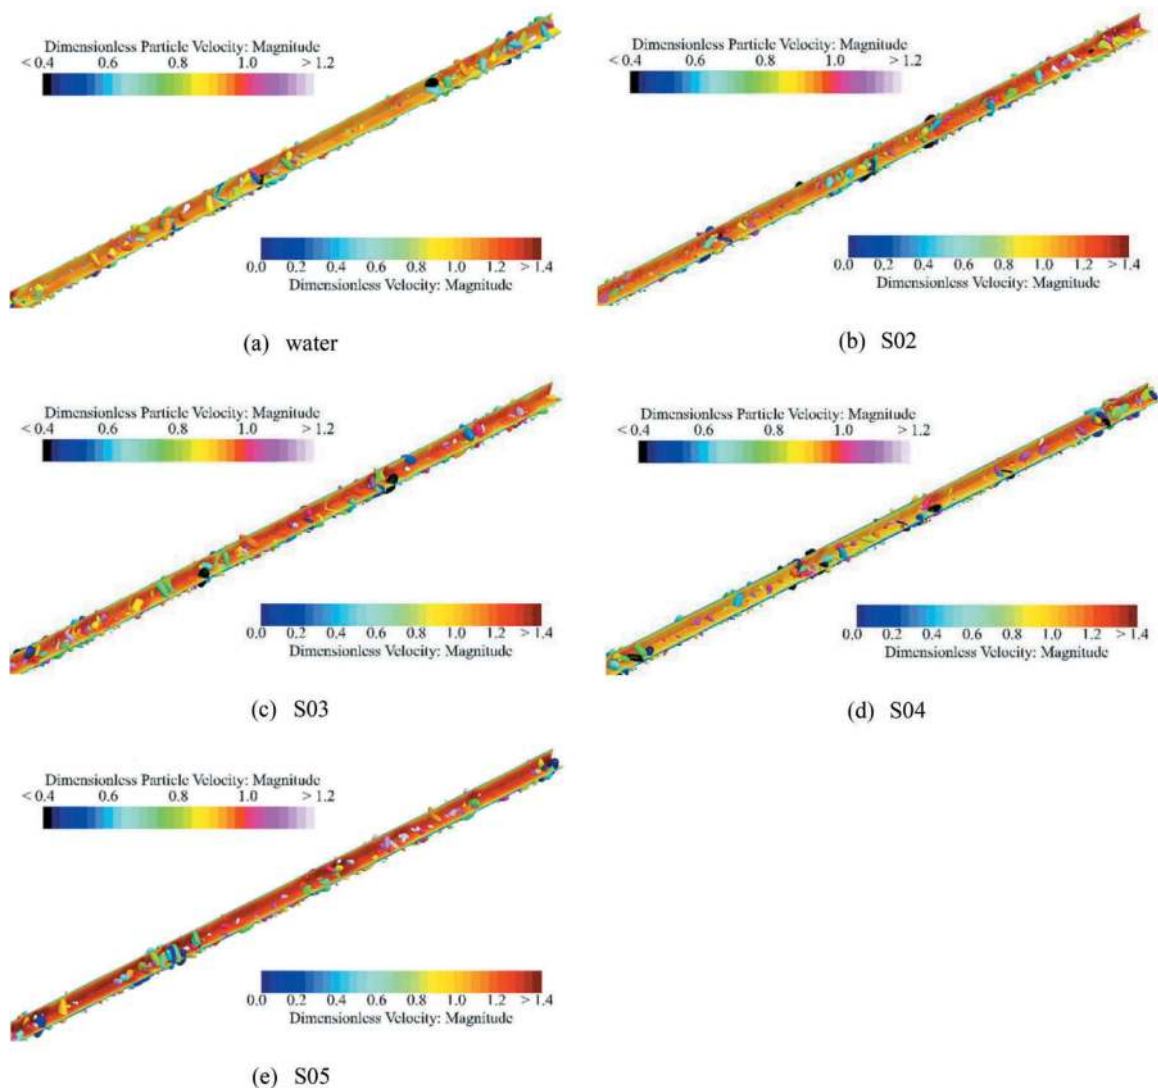

Figure 9. Dimensionless particle velocity and dimensionless fluid velocity.

mass of the particles leads to a relatively low speed so that they are not easy to transport.

Figure 9 describes the dimensionless velocity of particles and the dimensionless velocity of flow field under different viscosity conditions. It can be more obvious that large particle size particles will occasionally aggregate. This leads to the pipeline is easy to block in the process of conveying slag. Moreover, the velocity of the flow field will increase at the location of large particle size slag aggregation. This is because the accumulation of large-size slag blocks the pipeline, resulting in a decrease in the flow area and an increase in the flow rate.

4 CONCLUSIONS

In this paper, STARCCM+ software is used to simulate the transport characteristics of large-size irregular particles in long-distance pipelines. The combination of FVM and DEM are used to simulate the two-way coupling of particle motion. In order to

simulate the large particle size irregular slag stone, the source term smoothing method is adopted in the current numerical simulation. The current numerical results are good agreement with experiments with the error of pressure drop being less than 5%.

By comparing the motion characteristics of particles under different viscosities, it can be found that the viscosity has little effect on the transport characteristics of slag. However, due to the large mass, large-size slag stones are prone to local convergence, resulting in pipeline blockage. Therefore, for the slurry TBM circulation system, it is not recommended to transport slag stones with a particle size exceeding more than half of the pipe diameter.

Shaoping Wang

School of Automation Science and Electrical Engineering, Beijing University of Aeronautics and Astronautics, Beijing, China

ABSTRACT: The matching degree of slurry characteristics and formation parameters has great significance for maintaining the stability of the working face and safe and efficient construction in slurry TBM. Based on CFD-DEM fluid discrete element numerical coupling method, the slurry penetration process was modelled and simulated for summarizing the microscopic mechanism of slurry film formation and the effect of slurry characteristic parameters on slurry film. The self-designed slurry penetration test apparatus was used to compare and verify the simulation conclusions. The neural network genetic algorithm was used to fit the test data, and the slurry penetration prediction function for specific formation was obtained. The results show that the formation-slurry particle size ratio has an important effect on the morphology of filter cake, with the increase of slurry density as well as viscosity, slurry invasion depth decreases, and filter cake thickens. The fitting function is verified by the slurry penetration test of the drilled core formation in engineering field, and good feedback is obtained.

Keywords: Slurry TBM, Slurry characteristics, Slurry penetration process, Neural network

1 INTRODUCTION

With the advancement of urbanization in China, slurry shield tunnelling method has been widely applied. Especially for the underground space construction in high-density areas, landmark buildings, cross-river and cross-sea tunnels, the excellent control effect of slurry shield tunnelling on the stability of excavation surface and its ability against ground settlement are particularly outstanding. The key of slurry shield tunnelling technology lies in the slurry film formed by the slurry at the excavation surface, which converts the slurry pressure into effective stress that can balance the earth pressure to maintain the stability of the excavation surface. As the “blood” of slurry shield tunnelling, the characteristics of slurry play a vital role in the quality of the slurry film. In this regard, domestic and overseas scholars have conducted some research on the formation of the slurry film, and have reached some conclusions from both theoretical and application perspectives, with slurry penetration test being the main research method.

Fritz (2007) conducted slurry penetration film-forming experiments to address the issue that slurry could not provide support to the excavation surface in

formations with permeability coefficients much greater than 10^{-3} m/s. It was found that adding appropriate coarse particles and high polymer additives to the slurry helps to form a slurry membrane in high permeability formations. Han et al. (2008) conducted penetration experiments with different slurry viscosities under the same slurry ratio and density, and concluded that the higher the slurry viscosity, the thinner, denser and more physically stable the formed slurry film. Min et al. (2013) carried out penetration tests in 5 types of formations with different permeability coefficients by using different slurry ratios, and divided slurry penetration film formation into 3 types: “filter cake”, “filter cake + infiltration zone” and “infiltration zone” type. Lin et al. (2020) carried out penetration experiments in sandy soil layers with different permeability coefficients. They concluded that using the D_{15}/d_{85} value can roughly divide the slurry film types, and the relationship between formation permeability coefficient and filter cake thickness can obtain the k-line theory of filter cake. Xia W. (2023) carried out research on the reasonable slurry ratio based on the Zirui Tunnel project of Chengpu Railway. The study found that: the slurry ratio has a significant impact on the efficiency of slurry TBM excavation. Slurries with low density and

*Corresponding author: renzhen90@163.com

viscosity can lead to excessive slurry loss and inability to timely build slurry pressure; while slurries with high density and viscosity can lead to filter cake buildup on the cutterhead, reducing excavation efficiency. Min et al. (2014) verified the relationship between formation permeability coefficient and film formation type through penetration experiments, and pointed out that the amount of filtrate mass can be used as a criterion for judging the formation of filter cake, and can also be used as an evaluation criterion for slurry film quality. Lian (2017) analyzed the effects of slurry properties and formation permeability coefficient on slurry film formation through slurry penetration experiments, and proposed the relationship between slurry effective stress conversion rate and film formation type. Jiang et al. (2016) analyzed the effects of slurry density, ratio, pressure and other factors on the gas tightness of the slurry membrane through self-made slurry penetration experiments. Min et al. (2015) carried out closed air experiments on slurry membranes formed under different slurry penetration modes in the sandy cobble formation crossed by the Nanjing Weisan Road Cross-River Tunnel using a self-developed slurry membrane air tightness apparatus. The test concluded that: first use low-density and low-viscosity dilute slurry to penetrate the formation to form a stable penetration zone, then replace the dilute slurry with high-density and high-viscosity slurry to form a slurry cake type membrane on the excavation surface, thus forming a composite membrane with better air tightness. Ni et al. (2013) used discrete element numerical simulation to simulate the slurry penetration process and summarized the influence of different formation-slurry particle size ratios on film formation. Liu (2019) realized the simulation of the slurry penetration process by using Fluent and EDEM coupling, analyzed the factors affecting film formation and the relationship between particle size ratio and film formation type. It was proposed that under the same conditions, the slurry density has a greater influence on the invasion depth, while the slurry pressure has less influence.

To address the issue of difficult slurry film formation in high permeability formations, fluid discrete element simulation technology has been used to simulate the slurry film formation process and summarize the effects of formation-slurry particle size ratio, slurry density, viscosity on slurry film formation. This paper focuses on verifying the simulation conclusions through self-made slurry penetration test equipment; and fitting a Slurry permeability prediction function based on test data using neural network. This function can predict the slurry film type according to the slurry properties and formation attributes, and provide reference for adjusting parameters to ensure safe excavation.

2 SIMULATION CONCLUSIONS OF SLURRY PENETRATION PROCESS

The Fluid-discrete element numerical coupling technology was used to simulate the slurry infiltration

process, and the influence of the particle size ratio D/d , slurry density, and viscosity on the slurry film was analyzed. The following conclusions were drawn: When $D/d < 3$, slurry infiltration forms a “filter cake”; when $3 < D/d < 7.5$, it forms a “filter cake + infiltration zone”; when $D/d > 7.5$, it forms an “infiltration zone”, as shown in Figure 1.

Figure 1. Influence of particle size ratio on film.

As the slurry density increases, the number of particles that can block the formation pores per unit volume increases, and the blocking ability becomes stronger. The depth of particle infiltration decreases, and the filter cake formed becomes thicker, as shown in Figure 2.

Figure 2. Influence of density on film.

The greater the slurry viscosity, the better the cohesion between particles, and the stronger the “bridging effect”. The depth of slurry infiltration decreases, and the filter cake formed becomes thicker, as shown in Figure 3.

Figure 3. Influence of viscosity on film.

3 SLURRY PENETRATION TEST

A self-made slurry penetration test apparatus (Figure 4) was used to verify the simulation

conclusions. The test apparatus mainly consists of three parts: a pressure loading device, a penetration column body, and a data acquisition device.

Figure 4. Experimental apparatus.

3.1 Formation-slurry particle size ratio

A fixed slurry formulation was used. The slurry properties were determined using a slurry balance, soviet funnel and medium pressure water loss tester. The particle size d_{85} at 85% on the slurry particle distribution curve was taken as the representative particle size. Different experimental formations were prepared. The particle size D15 at 15% on the formation particle distribution curve was taken as the representative particle size, to study the effects of different formation-slurry particle size ratios (D15/ d_{85}) on slurry permeability. Tables 1 and 2 show the slurry formulations and properties, respectively.

Table 1. Slurry composition.

Material	water	Bentonite	CMC
Quantity	1000 mL	70 g	1.5 g

Table 2. Slurry performance parameters.

Performance	proportion	Viscosity	API filter loss	d_{85}
Parameter	1.06	25.03 s	18 mL/30 min	0.074 mm

Natural river sand was sieved into different size fractions using a standard sieve shaker. Experimental formations with different particle size distributions were prepared by mixing the fractions in certain proportions (Figure 65). A total of 4 different formations were prepared in this test (Table 3).

In this test, the same slurry formulation was used to perform pressurized penetration tests in the differently prepared formations. Pore pressure in the formations

Table 3. Strata information.

Num.	ST1	ST2	ST3	ST4
D15	0.225 mm	0.4 mm	0.5 mm	0.7 mm
F-S particle ratio	3.04	5.40	6.80	9.46

Figure 5. Grading curve.

and filtrate volume were recorded to observe and analyze the effects of different formation-slurry particle size ratios on slurry permeability. The test involved 5 pressure steps, each being 50 kPa, up to a maximum pressure of 250 kPa. At each pressure step, the pressure was held constant for 3 minutes. Figure 6 shows the test results for the four formations.

Figure 6. The particle ratio test results.

As shown in Figure 6a, due to the high content of fine particles in the formation, as pressure increased, it was difficult for the slurry particles to penetrate into the formation. There was almost no slurry invasion, and the filtrate was clear. Eventually, a filter cake of about 5 mm formed on the surface, showing a “filter cake” type membrane. As shown in Figure 6b, the slurry invaded the formation incompletely with relatively clear filtrate, forming a “filter cake + infiltration zone” type membrane. A filter cake of about 4 mm formed on the surface. In the ST3 formation, the slurry was not completely lost, but the filtrate was slightly turbid. A filter cake of about 2 mm formed on the surface, but with lots of pores on the surface, resulting in poor sealing capacity. The final membrane was a “filter cake + infiltration zone” type (Figure 6c). In the ST4 formation, the slurry was completely lost, without filter cake building up on the surface. The turbid filtrate indicated an “infiltration zone” only (Figure 6d).

Figure 7. The fluid loss curves.

As shown in Figure 7, as the formation-slurry particle size ratio increased, the filtrate mass also increased. In the ST1 and ST2 formations, the filtrate mass versus pressure curves showed a “step-ladder” shape, and the filtrate mass changed stably at each pressure step. This indicates that the slurry film reached a steady state, and the pressure change had little influence on the slurry film structure. In the ST3 formation, there was a sudden increase in filtrate mass at the third pressure step, indicating slurry film instability. The slurry film structure gradually stabilized after holding the pressure constant for 3 minutes. In the ST4 formation, the slurry started slowly invading the formation even without applied pressure. With the first pressure step, the slurry quickly penetrated into the formation, and was completely lost when pressure reached 100 kPa. However, the filtrate curve showed a stabilizing trend, indicating the slurry particles still played a role in plugging the formation pores.

3.2 Slurry proportion

Using the fixed ST2 formation, two groups of slurries with the same viscosity ($\pm 2s$ error) but different proportions were prepared by adjusting the slurry formulations. Penetration tests were conducted to study the effect of slurry proportions on permeability. The slurry formulations and properties are shown in Table 4.

Table 4. Slurry performance parameters of different density.

Num.	Mark	Material			Performance		
		water	S/B	CMC	Prop.	water	S/B
1	S1	1000 mL	80 g	0.5 g	1.07	26.2 s	15.5 mL/30min
	S2	1000 mL	120 g	0	1.10	25.0 s	17.5 mL/30min
2	S3	1000 mL	80 g	1.1 g	1.07	38.3 s	12.5 mL/30min
	S4	1000 mL	150 g	0	1.13	39.4 s	14.5 mL/30min

Figure 8. The proportions test results.

Figure 9. The invasion depth results.

At the end of the test, as shown in Figure 8, the S1, S2, S3 and S4 slurries formed “filter cake + infiltration zone” type membranes in the formation, with filter cake thicknesses of 2mm, 5mm, 4mm and 8mm, respectively. The comparison between S1 and S2, and between S3 and S4 shows that under the same viscosity, higher slurry proportion leads to thicker and denser filter cake.

Figure 10. The Fluid Loss Curves.

3.3 Slurry viscosity

Using the fixed ST2 formation again, four slurry samples with the same density but different viscosities were prepared by adjusting the CMC content while keeping the degree of hydration constant. Penetration tests were conducted to study the effect of slurry viscosity on slurry film. The slurry formulations and properties are shown in Table 5.

As shown in Figure 11, the S5 was completely lost in the formation without forming a filter cake on the surface. The S6, S7 and S8 slurries formed “filter cake + infiltration zone” type membranes, with filter cake thicknesses of 2mm, 4mm and 7mm, respectively. It shows that under the same density, higher viscosity leads to thicker filter cake and shorter maximum invasion depth (Figure 12).

Table 5. Slurry performance parameters of different viscosity.

Num.	Mark	Material			Performance			
		water	S/B	CMC	Prop.	Vis.	API	
1	S5	1000 mL	80 g	0	1.07	18.4 s	22.5 mL/30min	
2	S6	1000 mL	80 g	0.5 g	1.07	26.2 s	15.5 mL/30min	
3	S7	100 mL	80 g	1.1 g	1.07	38.3s	12.5 mL/30min	
4	S8	1000 mL	80 g	1.5 g	1.07	48.6 s	10.5 mL/30min	

Figure 11. The viscosity test results.

Figure 12. The invasion depth results.

The comparison shows that different viscosities can lead to different membrane morphologies in the same formation (size ratio 5.4). This indicates that the formation-slurry particle size ratio is not the only factor in determining the membrane type. Minimum requirements for slurry density and viscosity must also be met in order to form corresponding membranes within the respective size ratio range.

Figure 13. The fluid loss curves.

Figure 13 shows that when slurry density is the same, higher slurry viscosity leads to lower filtrate mass, and the membrane transitions from an unstable state to a stable state. When CMC dissolves in water, it forms a viscous gel-like substance. This gel has swelling capacity to fill and plug pores and fractures in the formation. The gel barrier prevents loss of slurry solids and water into the formation. Meanwhile, CMC can adsorb onto the formation surface, increasing adhesion between the slurry and formation. This effectively prevents slurry invasion into the formation.

3.4 Comparison of simulation and experimental results

Slurry penetration tests were conducted to verify the effects of formation-slurry particle size ratio, slurry proportion, and viscosity on the slurry film. The results show that when the size ratio falls around the three ranges for slurry film classification, the test results matched well with the simulation predictions. Higher slurry density and viscosity led to shorter invasion depth and thicker filter cake, consistent with the simulations. The test results agree well with the simulation conclusions.

4 SLURRY PERMEABILITY PREDICTION FUNCTION

During shield tunnelling, as the formation is not fixed and parameters like permeability and representative particle size change constantly, the required slurry properties need to be adjusted accordingly to maintain a stable working face. Therefore, a slurry permeability prediction function is developed, which can predict the slurry film type formed by the current slurry properties based on real-time formation conditions, providing references for selecting tunneling parameters and ensuring safe, intelligent tunneling.

The input of the prediction function considers four factors: formation permeability (A), formation represent particle size D15 (B), slurry density (C), and slurry viscosity (D). The output is the permeability prediction coefficient (O), also called slurry loss coefficient. When $O \leq 0.15$, it is belong to “filter cake” type; when $0.15 < O < 0.85$, it is belong to “filter cake + infiltration zone”; when $O \geq 0.85$, it is belong to “infiltration zone”. Higher O means more slurry loss and deeper invasion.

The BP neural network can approximate arbitrary nonlinear functions with strong fitting capabilities. It can adapt to complex data patterns and relationships by learning and adjusting the network weights and biases. Using the experimental results as the dataset for function fitting and testing, the weights of various factors are adjusted through forward and back propagation until the error between predicted and actual values reaches a given criterion, ending the network training.

Table 6 and Figure 14 show examples of the training dataset and BP neural network structure, respectively.

Table 6. Train data set examples.

S/N	Factor A (cm/s)	Factor B(mm)	Factor C	Factor D(s)	Factor E

5 CONCLUSIONS

Regarding the problem of slurry film formation in high permeability formations, simulation analysis and experimental verification were used to study the slurry penetration process and types, as well as the effects of different slurry properties on the slurry film. The conclusions are:

- (1) The formation-slurry particle size ratio has a significant impact on the film structure. The “filter cake + infiltration zone” type is optimal, providing effective wellbore strengthening while the impermeable filter cake helps maintain stable formation pressure.

- (2) Under the same viscosity, higher slurry density means more particles per unit volume to plug the formation, resulting in shorter invasion and thicker filter cake.
- (3) Under the same density, higher viscosity means more viscous particles per unit volume, increasing friction between particles and formation pores, resulting in shorter invasion and thicker filter cake.
- (4) The size ratio alone does not determine film type. Minimum requirements for density and viscosity must also be met to achieve the expected film type.
- (5) Based on experimental data, a neural network prediction function was developed and verified to effectively predict slurry permeability using formation and slurry parameters.

The simulation conclusions are verified by the slurry penetration tests, with excellent agreement. Simulations can provide quick solutions for complex conditions and greatly shorten research cycles. Machine learning algorithms can also be integrated to predict slurry film conditions based on available data, providing reliable support for intelligent tunnelling.

Passage of TBM EPB under buildings with deep foundations, with physical interference

Hugo Rocha*, Fernando Hirata, Guilherme Robbe, Waldir Giannotti & Thiago Pires
São Paulo Metro Company, São Paulo, Brazil

ABSTRACT: The excavation of tunnels in urban areas often encounters existing building foundations within the excavation sections. Passage through, and potential cutting of, these foundations generally require sophisticated engineering techniques. However, the difficulties are much greater when it comes to mechanized excavation compared to conventional excavations.

For the excavation of 10,764 meters of track tunnels on Line 5 of the São Paulo Metro, three tunnel boring machines were used. Two machines with a diameter of Ø 6.9m excavated 5,021 meters, while one machine with a diameter of Ø 10.5m excavated 5,743 meters, crossing deep foundations of buildings. One with a Ø 6.9m diameter traversed an area where precast piles were expected, near the outlet shaft. The second, with a Ø 10.5m diameter, cut through the foundation piles of two housing condominiums in the region of Chacara Klabin station, also near the outlet region. For all passages, several geotechnical studies, risk analyses, and monitoring using accelerometers in the properties were conducted, which were vacated for this purpose.

The article provides a descriptive summary of the passages beneath the buildings, the conducted geotechnical studies, monitoring, measures adopted, and the obtained results. In all cases, the measures proved to be effective and led to success.

1 INTRODUCTION

The São Paulo Metro in Brazil commenced its implementation in the 1970s, making it more than 50 years old. Compared to other major Western cities like New York, London, and Paris, whose main lines were established in the early 20th century, São Paulo's metro system is relatively recent. Due to this delayed implementation, there were challenges in acquiring free surface areas and limited urbanized spaces for installation, as well as fewer existing obstacles that interfered less with urban life. São Paulo, during the initial implementation phase, was not fully developed, yet it faced high traffic levels and significant surface occupation.

However, during the implementation of the first Line 1, a substantial part of the line was executed through a long Cut and Cover (C&C) method, covering approximately 10.5 km from the city center to the south (Figure 1). This occurred during a historical period with limited interference from civil society and fewer environmental constraints compared to today, resulting in extensive expropriation requirements. Presently, such an approach is unfeasible due to

increased civil society influence, stricter legislation, environmental limitations, and the soaring cost of expropriations. In fact, Cut and Cover construction is now more expensive than their tunnel counterparts. As a result, in the ongoing construction of new lines, the use of C&C is limited to shallow stations, ventilation shafts, and a few work access points.

Tunnel layouts offer more flexibility in development as they are not bound by street layouts and can be constructed deeper. However, they often encounter various surface obstacles and subsurface structures, posing challenges to their construction and development.

The most recent completed and operational line of the São Paulo Metro is Line 5, situated in the southern part of the city. The backbone of this line comprises track tunnels excavated using EPB TBMs, including one section with a TBM of Ø 10.6 m and another section with two TBMs of Ø 6.9 m. Throughout the line's trajectory, several notable interferences with surface and subsurface structures were encountered, necessitating detailed studies to navigate these obstacles effectively without causing significant damage to the structures. Notable interferences include:

- c) Platinum Tower Building - encountered interference with the TBM of Ø 10.6 m.

2 CASE STUDIES

2.1 Residence at Rita Joana de Souza 297

The house located at Rua Rita Joana de Souza 297 falls directly on the alignment of the tunnel, set to be constructed by a TBM EPB Ø 6.9 m. The tunnel's shallow coverage was necessary due to the proximity of the breakthrough (refer to Figure 3). This three-floor house, approximately 25 years old, includes a lowered garage and is in an average state of conservation, requiring repairs that, however, do not entail any structural risks (see Figure 4). The house is built on a soft surface layer of soil (peat), necessitating deep foundations supported by a series of piles driven to depths of 13-15 meters. These piles

consist of alternating layers of sand and clay without encountering a more resistant layer (see Figure 5). The depth of these piles resulted in interference by 2 to 3 meters with the excavation section of the tunnel boring machine tasked with excavating route 1.

Figure 3. Location plan of the building in relation to the tunnels.

The most viable solution to avoid property demolition involved the partial demolition of the piles to the extent of interference using the discs on the head of the tunnel boring machine. This approach aimed to preserve the property while addressing the interference. Given the existing chronic foundation problems and numerous structural cracks, special care was essential during the TBM installation.

Figure 4. Photo of the house façade.

Figure 5. Geological/geotechnical section of the site.

After conducting down-hole seismic geophysical tests and evaluating the potential loads on the foundations, it was determined that the foundations were oversized. It was concluded that localized cutting of part of the pile tips would be viable without causing significant damage. During the passage of the TBM, the structure would be monitored using precision leveling and accelerometers.

Extreme executive care was recommended during the process regarding:

Installation of cutting tools on the perimeter and the 4 arms of the cutting head. Ensuring that the foundation of House 297 would be cut regardless of its position in relation to the excavation section.

Reduction of TBM speed to 15 mm/min at each encounter with House 297's piles. This speed allowed the process to be controlled so that if any problem occurred, it would be detected in time to act on and resolve it.

Implementation of outlined mitigation measures to ensure that the work was prepared for the eventual implementation of contingency measures. This allowed for greater ease and safety in tunnel excavation beneath House 297.

Through this, the speed was obtained by integrating the acceleration graphs and, as mentioned above, the established limit was 40 mm/s. According to DIN 4150-3 standard 'Structural Vibration – Effects of Vibration on Structures,' vibrations exceeding this value would pose risks of damage to the property's structure. During the monitoring conducted, the highest speed value recorded was 0.1 mm/s (Figure 6).

Figure 6. Acceleration (mm/s^2) versus Time (s).

No significant vibrations were observed during the passage of the TBM, nor were there any changes in the TBM control parameters indicating pile cutting. The passage under the building was successfully completed without incident.

2.2 Residential Klabin/Residential Souza Ramos

The excavation of the section between Santa Cruz and Chácara Klabin stations, in its final portion, was carried out beneath two single-family house complexes: Residential Souza Ramos and Residential

Klabin. Both were built on soft soil areas, and their foundations were supported by precast piles that would be intersected by the TBM.

Figure 7. Overall view of the section with influence curves and risks.

Each set of houses did not have a sufficient amount of available information; however, to make the project feasible, the following activities had to be developed:

- Residential Condominium Souza Ramos.
 - a) Determination of loads on each pile
- Residential Condominium Klabin.
 - a) Determination of pile depth: Down-hole tests (Figure 8)

Figure 8. Downhole geophysical profile indicating pile depth at 7 meters.

- b) Determination of the load-bearing capacity of each pile: based on local soil (Figure 9)
- c) Determination of the quantity of piles.
- d) Determination of loads on each pile.

The following potential damage types were identified in the buildings:

- Surface damages (ground floor, connections, boundary walls) due to settlements originating from the tunnel.

Figure 9. Indication of pile positions.

- Structural damages to the houses, due to settlements originating from the tunnel and due to the loss of pile capacity.

To evaluate the settlements originating from the tunnels, two scenarios were considered with different levels of soil loss, depending on the local massif and coverage (Figure 10).

Based on the zoning of potential effects from the TBM's passage under the properties, a risk map was developed, and a preventive evacuation of selected properties was carried out due to vibration effects and structural risks (Figures 11 and 12).

Figure 10. Profile indicating the separation into regions with different levels of risks.

Figure 11. Profile indicating the separation into regions with different levels of risks.

2.3 Platinum tower case

Near to the breakthrough of the TBM at Moema station, there was an expectation of proximity to a diaphragm wall and tie rods installed for the

Figure 12. Resulting from structural damages (Scenario 1).

Figure 13. 3D model of the TBM passing beneath the houses and intersecting their foundations.

basements of the 13-story Platinum Tower building, adjacent to the route (Figure 14). This building was constructed after the design of Line 5 but before the passage of the TBM. At that time, an agreement was made with the building's construction company to install the tie rods in a way that ensured no physical interference with the future tunnel. However, the construction company did not guarantee the exact location of the tie rods, which could physically interfere with the TBM, potentially causing serious operational

Figure 14. General view of the location with the building and TBM.

problems, especially at the cutting head and screw conveyor (Figure 15).

Figure 15. Schematic section of the location.

The passage of the TBM alongside the building would pose a high risk under these conditions. To mitigate this risk, in addition to all the instrumentation of the building and diaphragm walls, the tie rods were extracted by over-drilling and removal of the tie rods' strands (Figure 16) from the building's garage, thus minimizing the risk. The passage of the tunnel boring machine occurred with very low impact on the building and no interception of tie rods by the TBM (Figure 17).

Figure 16. Removal of tie rods' strands.

Figure 17. Deformations observed in the building structure.

3 CONCLUSIONS

The passage of tunnel boring machines in densely urbanized areas, although theoretically causing fewer surface deformations than conventional methods, requires careful consideration of existing interferences. The possibility of intervention in the excavation face is much more restricted, and the contact of the equipment with these buried structures can cause serious damage to both the structures and the machine. The prior determination of these interferences and their treatment with adequate risk management greatly minimizes their effects on both the surroundings and the equipment.

TBM performance in rock conditions of water diversion tunnel constructions (Mae Ngad-Mae Kuang tunnel) in Chiang Mai Province, Thailand

Kaisorn Sarapagdee*, Anchalee Laddakul & Thanaphon Saelao

Geotech Pillar Co., Ltd., Bangkok, Thailand

Panya Consultants Co., Ltd., Bangkok, Thailand

ABSTRACT: The knowledge of rock type and technology using for tunnel opening is essential for any mechanical excavation. The double shield TBM (DS TBM) was selected to excavate the complex geological structures for the water diversion tunnel construction projects (Mae Ngad-Mae Kuang Tunnel) in Chiangmai Province, Northern Thailand. The TBM tunneling contains several factors to control in the TBM excavation and the tunnel construction, the overall machine performance and factors controlling the TBM performance are important to summarize in detail. Furthermore, the impact of unfavourable ground conditions affected the tunnel construction times such as the bad rock conditions, the fault zones, the high pressure of groundwater ingress, and unplanned downtimes. Machine utilization and boring cycle are the most important factor illustrating the overall TBM performance related to construction times. The major incidents during TBM excavation need to be comprehended as the key parameter indicating the machine performance in the problematic zones. In addition, this study summarized the tunneling time consumption and evaluated the machine utilization and boring cycle time of the DS TBM. The consistency of TBM boring was an important key to increasing productivity, while the standstills must be reduced as much as possible. The DS TBM have proved that the field penetration index (FPI) can be indicated the problematic zone and the difficult ground conditions. In conclusion, the FPI could be used to warn the problem zones in adverse ground conditions and the complex ground conditions zones. Additionally, the overall machine performance of the TBM, the machine utilization, and the TBM boring cycle are the essential factors considering an impact on the construction times.

1 INTRODUCTION

The Mae Ngad-Mae Kuang (MNMK) tunnel project was designed by jointly attended members of Royal Irrigation Department (RID), Panya Consultants Co., Ltd. (PY), and 3G Gruppe Geotechnik Graz ZT GmbH, according to the solely selected option for the construction of each tunnel project, there is the double shield TBM (DS TBM) accounted for the geological, geotechnical, and hydrological uncertainties and associated costs as well as a risk analysis. Hence, the identification of the actual rock mass type (actual RMT) and the actual behaviour (actual BT) can be determined or reviewed during the construction to detect these variable ground conditions as much as possible. Consequently, the information in the detail design stage can be clarified and reappraised the adverse geological situations during

the implementation, as well as the relevance between the ground conditions and the TBM performance can also be explained.

Overall, TBM performance needs to be predicted during the design stages to appropriately determine the right machine operation and a plan for tunnel construction. Obviously, the actual TBM performance is significantly different from the predicted TBM performance because some unknown factors cannot be evaluated in the predictive models, which some TBM performance parameters are exaggerated because of a wrong prediction of geological conditions. Hence, major factors affecting the TBM performance need to be summarized and concluded. Likewise, a deep understanding of the background in the TBM tunneling must be clear to recap the TBM performance, including the ground conditions, the TBM selection, the TBM tunnel designs, the cutter

*Corresponding author: Kaisorn_s@panyaconsult.co.th

head designs, the TBM performance parameters, construction operations of the DS TBM, major incidences in the projects, and so on. Following a summary of overall TBM performance, the TBM database need also be improved, and solid comprehension of the factors affecting the overall TBM operation must be clarified.

Due to the lack of subsurface information of the geological and geotechnical investigations in the detail design stage, the hard rock DS TBM boring processes during the operation can be predicated the actual ground condition. As uncertainties of the complex geology affected mainly the time of tunnel construction, the key issues during TBM excavation should be realized factors affecting the productivity of TBM tunneling.

2 BACKGROUND

2.1 Geological and geotechnical models

2.1.1 Geological history

The geological models of the MNMK tunnel were delineated in the design stage. The geological uncertainties are inevitable to eliminate as the costs of geological investigation are limited to provide clearly descriptive information of the rock formations. However, the geological interpretation of geologists is helpful to indicate the ground conditions in the study area to provide general information for the engineering design. The complexity of the geology along the tunnel alignments is a tough task to accurately interpret the geological models because the rocks/soils are not uniform. Which, the tunneling projects are located on the complex rock formations in the Inthanon zone where the Palaeozoic and Mesozoic rocks were detached overlying the crystalline complex rocks. Moreover, the orogenic of the Triassic – Jurassic Granitoids is also observed in the study area.

2.1.2 Geological models

The geological conditions were proposed by Schubert et al. (2005a) in the design phases of the MNMK tunnel project based on the publication in the Geology of Thailand (Ridd et al., 2011). The Thung Song Group is the oldest rock group in late Ordovician – Silurian in the study area, which the formation consists mainly of Limestone and Shale. The upper parts of rock formations are covered by the Lower – Upper Paleozoic, Tertiary, and Quaternary sedimentary rocks. The Permo – Triassic Volcanic rocks and Triassic Granitoid intrusion are related to the main granite belts.

The geological mapping of the MNMK tunnel project can be shown in Figure 1 as the previous studies for the review of geological models of the MNMK by Sutiwanich et al. (2006) can also be shown in Figure 2.

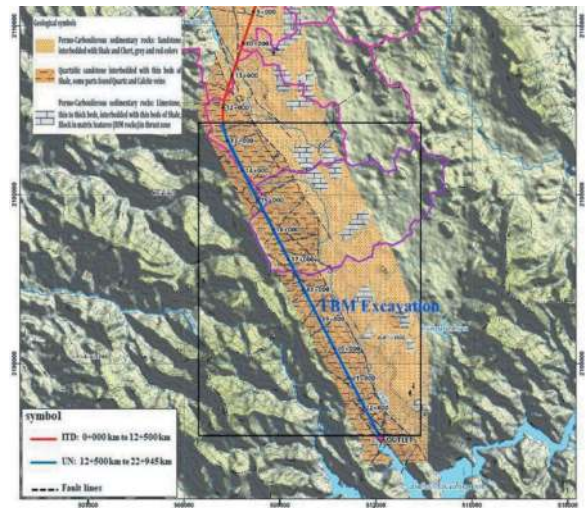

Figure 1. The geological mapping along the MNMK tunnel alignment in scale 1:10,000.

2.1.3 Rock mass type (ground type)

The guideline for the determination of ground type was proposed by the Austrian Guideline for Geomechanical Design of Underground Structures (Austrian Society for Geomechanics, 2010) used in the tunnel projects. The outline information was gained by the geological investigation (e.g., the field investigation, core drilling, and laboratory testing) which the key parameters will be used to define the rock mass type based on similar geotechnical properties. Therefore, the geotechnically relevant parameters (Table 1) are used to determine the ground types. The geotechnical parameters are basically included lithology, the thickness of rock formations, joint/fracture conditions, rock mass/intact rock strength, degree of weathering, and so forth.

The selection of parameters depends on the project phase and a certain extent on the possible construction methods. For this project, 18 rock mass types (Table 2) have been determined using the criteria listed as the classes used in each criterion are shown in brackets.

- Rock types such as Marble, Limestone, Quartzite, Sandstone, Siltstone, Plutonic rock, Volcanic rocks, and fault rocks distinguished according to the source material, and alluvial deposits
- Bedding thickness (>60 cm, 60 – 20 cm, and 2 – 20 cm)
- Joint persistence (low and high)
- Fracturing (low and high)
- Joint roughness (rough and smooth)
- Karstification (none, small cavities, and large cavities)
- Intact rock strength (< 10 MPa, 10 – 50 MPa, 50 – 150 MPa, and 150 – 250 MPa)

2.1.4 Rock mass behavior (ground behavior)

The ground behaviors are predicted by the influencing factors for each section of the tunnel. The

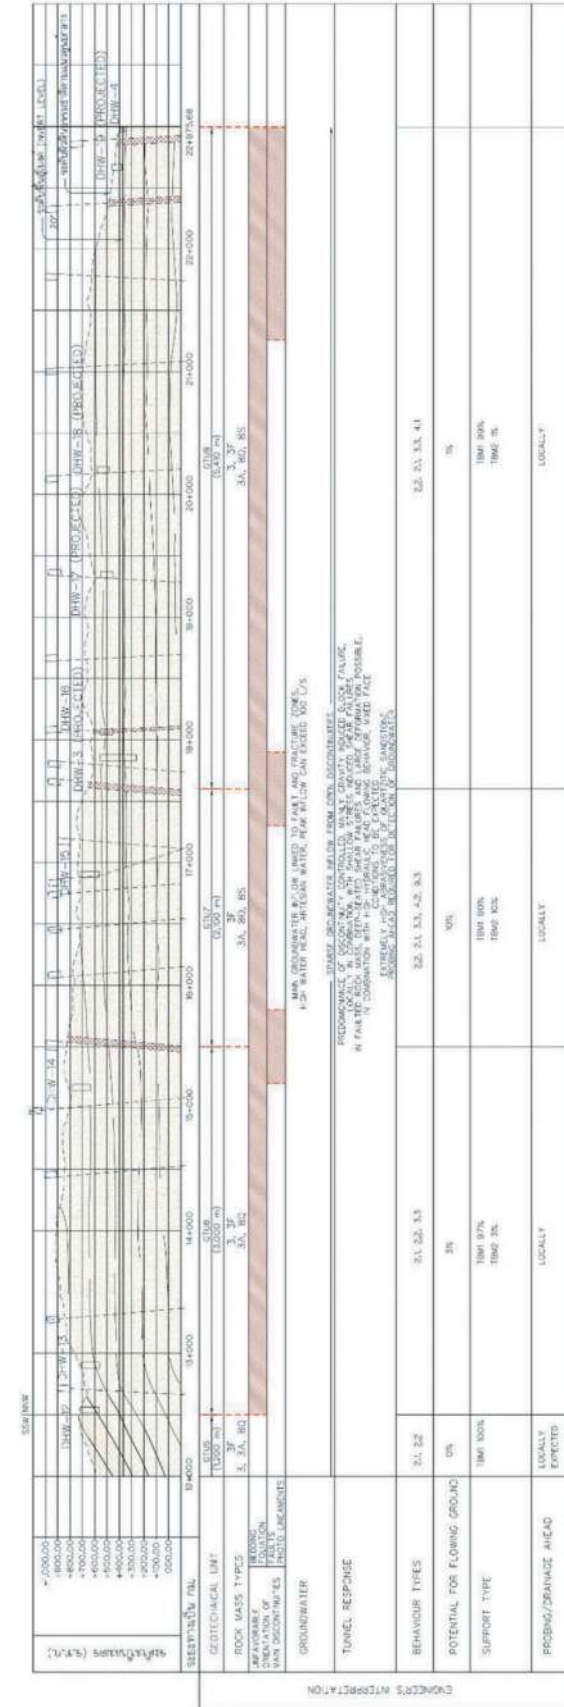

Figure 2. The geological model of the MNMK tunnel (Sutiwanich et al., 2006).

Table 1. Example of selected key parameters for different general rock types (Austrian society for geomechanics, 2010).

ROCK TYPES	KEY PARAMETERS																		
	INTACT ROCK PROPERTIES					DISCONTINUITIES													
Plutonic Rocks	Mineral Composition	Clay Mineral Composition (qualitative)	Clay Mineral Composition (quantitative)	Concentration	Grain Size	Texture	Ratio Matrix/Fragments	Porosity	Abrasion/Wear/Forms	Solution Phenomena	Swelling Properties	Strength Properties	Anisotropy	Block Shape	Block Size	Persistence	Aperture	Shear Strength/Roughness	bedding

factors influencing the rock mass behaviors are essentially tunnel size, primary stresses around the opening, water conditions, and the relative orientation of discontinuities in the rock mass to the tunnel axis. The ground behaviors are estimated as the ground reaction to the excavation under unsupported conditions (i.e., without consideration of supports) or other construction measures.

After estimation of the rock mass behaviors for each tunnel section, the behavior type (BT) can be grouped the single rock mass behavior into the basic categories as shown in Table 3. Methods for determining rock mass behaviors can be empirical or analytical, using closed-form solutions block analyses or numerical simulations as appropriate. The excavation method and the support systems are then designed based on the behavior types as a ground response in a way to meet the requirements, like constructability, stability, serviceability, and economic aspects.

Table 3. General categories of behavior types (Schubert et al., 2005a).

Behavior Type (BT)	Description of potential failure modes/mechanisms during excavation of the unsupported rock mass
1 Stable	Stable rock mass with the potential of small local gravity induced falling or sliding of blocks
2 Stable with the potential of discontinuity controlled block fall	Deep reaching, discontinuity controlled, gravity induced falling and sliding of blocks, occasional local shear failure
3 Shallow shear failure	Shallow stress induced shear failures in combination with discontinuity and gravity controlled failure of the rock mass.
4 Deep seated shear failure	Deep seated stress induced shear failures and large deformation
5 Rock burst	Sudden and violent failure of the rock mass, caused by highly stressed brittle rocks and the rapid release of accumulated strain energy
6 Buckling failure	Buckling of rocks with a narrowly spaced discontinuity set, frequently associated with shear failure
7 Shear failure under low confining pressure	Potential for excessive overbreak and progressive shear failure with the development chimney type failure, caused mainly by a deficiency of side pressure
8 Ravelling ground	Flow of cohesion-less dry or moist, intensely fractured rocks or soil
9 Flowing ground	Flow of intensely fractured rocks or soil with high water content
10 Swelling	Time dependent volume increase of the rock mass caused by physical-chemical reaction of rock and water in combination with stress relief, leading to inward movement of the tunnel perimeter
11 Heterogeneous rock mass with frequently changing deformation characteristics	Rapid variations of stresses and deformations, caused by block-in-matrix rock situation of a tectonic melange (brittle fault zone)

2.2 Double shield TBM (DS TBM)

The MNMK tunnel project was initially studied by 3G Gruppe Geotechnik Graz ZT GmbH in the detail design stage in 2005 in which the first hard rock TBM excavation was recommended for excavation around 10+476 km from the outlet at the Mae Kuang reservoir to 12+500 km along the tunnel alignment (Figure 1). The DS TBM were chosen as the best choice to excavate through some parts of the long water diversion tunnel projects in the complexity of a geological setting in Northern Thailand. According to the geological, geotechnical, hydrological

uncertainties, and associated costs, a risk analysis was performed to evaluate the options for the tunnel constructions in the tender design stage (Schubert et al., 2005b). However, the DS TBM must properly be designed the special measures when the TBMs are going to encounter such as the squeezing ground phenomena, the rock bursting, the swelling or slacking ground, the blocky ground or jointed rock, the clay clogging, the effects of high strength rocks and high abrasion, and significant water inflows, etc.

2.3 TBM Performance prediction models

The MNMK tunnel project is used the NTNU model, which has been developed by the Norwegian University of Science and Technology since 1976 using the statistics based on field studies of 35 tunnel jobs with more than 250 km in the database of tunnels documented in detail (Bruland, 2000c). The philosophy of the NTNU model is to predict the reliable TBM performance combining relevant rock properties and machine parameters (Mascias, 2016). Furthermore, the factors influencing the TBM performance as shown in Table 4 can also be evaluated by the RMi parameters to characterize rock masses for TBMs in which the rock material, the jointing, and TBMs are considered as the main factors affecting the TBM performance, as shown in Figure 3 (Palmström, 1995).

Table 4. Hard rock mass and machine factors influencing TBM performance (Palmström, 1995).

Rock mass factors	Machine factors
- Rock mass jointing (k_j) <ul style="list-style-type: none"> ◦ type and continuity ◦ frequency ◦ orientation 	- Thrust per cutter (M)
- Rock porosity	- Cutter edge bluntness (b_c)
- Rock drillability (DRI)	- Cutter spacing (A)
- Rock hardness/abrasiveness	- Cutter diameter (d)
- Stress in rock	- Torque capacity and RPM
	- The machine's capacity for handling large chips or blocks
	- General solidity against blows and vibrations
	- Cutterhead curvature and diameter (D)
	- Backup equipment

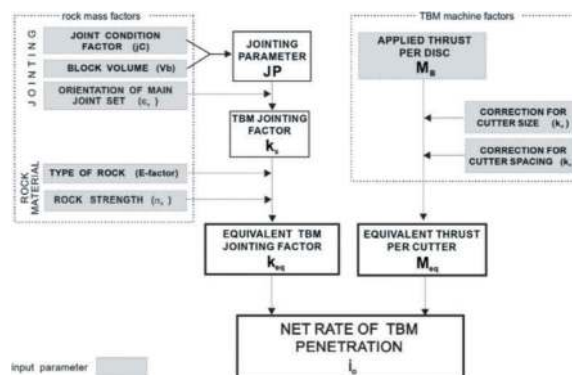

Figure 3. Layout of a method to predict TBM penetration using RMi parameters based on the NTH mode (Palmström, 1995).

2.4 TBM performance analysis

The TBM performance and an impact on the time of the tunnel construction, there are various details of actual TBM operating in the tunnel projects. The time of construction is controlled by the overall machine performance, which this term can be illustrated through machine hours spent to excavate the length of the tunnel, basic machine operation parameters (e.g., applied thrust, torque, and cutterhead RPM, etc.). The overall performance is also expressed as the gross advance rate of the machine and illustrated in terms of tunneling time consumption (Figure 4).

Figure 4. Summary of machine performance (Bilgin et al., 2005).

However, machine utilization is very difficult to predict in actual TBM tunneling. There are some of the most important concepts needed to review for the evaluation with the TBM utilization including the rock mass boreability, the boring cycle time of the TBM tunneling, and cutter consumption. Basically, the machine utilization can be calculated as the (1) (Moosazadeh et al., 2018).

$$U(\%) = \frac{\text{Boring Time}}{\text{Total Time}} = \frac{T_b}{\sum T_i} \quad (1)$$

Where the boring time (T_b) is the net boring time, and the total time ($\sum T_i$) is the summation of the duration of the main activities and TBM downtimes.

The utilization factors (i.e., classification of the main activities and the downtimes) can be varied depending on the prediction models to estimate the machine utilization in percentages of total tunneling time. The utilization factors in the real construction of TBM tunneling are collected in performance records based on the objectivity of the shift log data.

3 DATA COLLECTION

3.1 Rock mass parameters

In the geotechnical design, the ground conditions were interpreted in the design stages to distribute the expected rock mass types (RMT), rock mass

behaviors type (BT), and groundwater ingress to consider the support types and the additional measures along the tunnels. Hence, the TBM excavation relies on the interaction between the machines and the rock mass behaviors elaborated in the geotechnical sections along the tunnels. Due to closed face tunneling machines for handling wide ranges of ground conditions, the DS TBM are quite difficult to collect the data for rock mass characteristics in front of the cutterhead or behind the shields. Generally, the TBM tunneling in the MNMK tunnel used muck logging to assess the RMT and the BT during the TBM excavation. The parameters in muck logging forms include as follows.

- Rock mass types (RMT) depend on the geological information in the tender documents of tunnel.

- Weathering conditions are used to describe the weathering degree of rock chips.

- Roughness conditions are used to illustrate the characteristics of surfaces of fractures/joints.

- Rock Strength is one of the most useful parameters used to clarify the stability of the tunnel and indicate weakness zones. The strength tests in the field can be observed by using empirical methods such as geological hammers smashing, point load testing, and Schmidt hammer testing.

- Chip sizes are probably ambiguous to interpret the rock mass characteristics. The percentages of each size for muck logging are implied to the frequency/spacing of joint sets. The appropriate chip sizes should be in medium size, whereas the large size and the small size are related to the blocky ground and the faulted rocks, respectively.

- The shape of muck chips is generally used to empirically distinguish whether existing fractures or mechanical fractures.

- Joint spacing is difficult to interpret in the field because the DS TBM. Normally, the geologist can roughly estimate the spacing by their experiences in which the open slots behind the tail shield for invert segments may be used to calibrate or clarify the joint spacing in the back-mapping.

- Water Inflows are also one of the most important factors affecting the TBM performance in every tunnel project.

- The coarseness index (CI) was defined as the sum of the cumulative weight percentages retained on each sieve used, which compares a measure of the size and distribution of the produced debris, as shown in Figure 5.

3.2 Machine performance and records

TBM operational parameters are recorded by the onboard acquisition system gathering signals in the machine control panel. The machine operational parameters are varied by the TBM operation in the TBM excavation encountering different ground conditions. To compute the TBM performance parameters, the operational parameters, and some

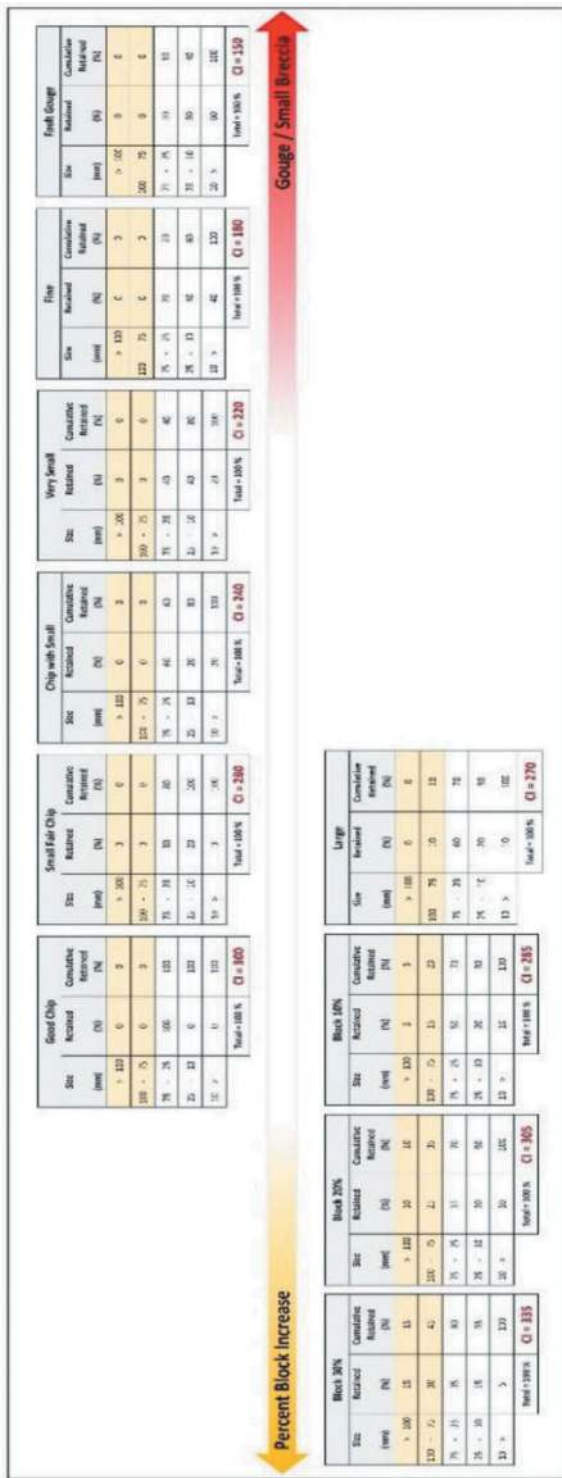

Figure 5. The coarseness index (CI) classification chart.

parameters of the TBM configurations were used to calculate in the analysis. These data sets can be used to estimate other important factors considered while describing basic TBM performance parameters.

The main activities and sub-activities of the tunneling performance were collected and recorded in the shift logs. The records can be used for back-analyses of machine performance.

3.3 Time Consumption and majors issues

In TBM tunneling, the additional time consumption is difficult to estimate as used to speculate the machine utilization in tunnel projects. The overall machine performance was reduced the efficiency since the major issues during the DS TBM operation resulted from several factors as follows.

- Downtime TBM: The downtime for TBM systems and system elements can be categorized as (1) Machine Breakdown (2) Lining systems (3) Muck Removal Systems (4) Utilities (5) Surveys (6) Personnel and (7) Miscellaneous.

- Unexpected Rock Mass Conditions: Due to the complexity of rock masses, unpredictable geological conditions may affect TBM performance, which are an impact on the time of the construction.

- TBM Stopped for Stabilizing Zones of Difficult Ground Conditions: About difficult ground conditions, the DS TBM need to be stopped to treat the problematic zones of adverse ground conditions such as squeezing ground, extremely high groundwater ingress, karst filling with sand/water, and so on.

3.4 TBM performance parameters

Basic machine performance parameters were used to summarize the field performance study approaches compared with the engineering back-mapping as follows.

- Penetration rate (PR) is defined as the advance or the excavated distance divided by the operating time during a continuous excavation phase (i.e., the penetration rate is not considered the time required for installing rock supports, maintenance, etc.).

- Machine Utilization (U) is defined as the ratio/percentage between net boring time and total shift time (i.e., the TBM utilization expresses the amount of time in which the machine has been effectively used for boring). The utilization factors (UF) can be assessed and evaluated by using the main activities of the TBM operation based on data from the shift logs/performance records. The UF can be subdivided into more specific activities and evaluated for given time periods (e.g., shift, day, week, or month) or for given tunnel sections (e.g., tunnel length or geological conditions).

- Advance rate (AR) is defined as the TBM advance speed for a period computed by considering the TBM delays due to rock support, maintenance, and so on.

- Field penetration index (FPI) is calculated as the ratio between average cutter load and attained penetration per cutterhead revolution. The FPI can also be defined as FPI_{blocky} as the TBM field performance to the rock mass conditions in the blocky ground. To compare possibly, the FPI is calculated in (2).

$$FPI = \frac{D}{c} \frac{F_n}{p} \quad (2)$$

Where D is the diameter of the cutterhead and the total number of cutter discs on the cutterhead.

4 RESULTS

4.1 Summary of the MNMK TBM

The first hard rock TBM tunneling in Thailand was successfully constructed in early 2021 with the total length 10.45 km. The DS TBM was selected to operate in the Carboniferous sedimentary rocks where there are several interruptions to deal with the difficult ground conditions such as high-water ingress, blocky ground, severe inrush materials, and squeezing ground during TBM excavation.

The TBM is also located in the thrust fault zone, where the minor systematic faults crossing the alignment were interpreted 20 lines in the geological models. During the TBM excavation, the major issues from high groundwater ingress, geological hazards, and mechanical breakdowns that reduce the productivity of the TBM excavation.

The overall machine performance of the TBM was mainly influenced by excessive groundwater ingress and the major incidences caused by geological conditions.

The total number of days for 10.45 km was 1,350 days, where the total production was 54%, and the total no production was 46%. The maximum average machine utilization was 66.7% in the period of the best performance, whereas the mean was just 21.2% compared to the whole period of TBM excavation. The top gross advance rate was 203.4 m/week, while the mean was 48.6 m/week of the total tunnel length. The Figure 6 shows the tunneling time consumption that the most time-consuming is standstill TBM around 24.9%, which the DS TBM had waited for excavation. The time needed to overcome the major incidences of the TBM was 17.1%, of which the times of segments fallen were spent more time to recover the machine performance and a large amount of groundwater ingress. On the other hand, the TBM downtimes are defined as the time during the machine is unavailable for use, which the major

Figure 6. The tunneling time consumption of the MNMK TBM.

Figure 7. The TBM downtimes of the MNMK TBM.

influences of TBM downtimes consisted of segment erector issues 17.6%, electrical issues 15.5%, hydraulic/mechanic/electric system issues 13.5%, rail issues 11.6%, and so on, as shown in Figure 7.

During TBM excavation in the fault materials such as RMT 8Q and RMT 8S, the discharged fractured rocks or completely weathered rocks were flowed into the TBM with the high-water ingress.

4.2 Overall machine performance

The TBM was launched from the outlet of the Mae Kuang reservoir to the upper section. In the first period, the TBM learning curve had taken for almost 29 weeks, where the tunnel chainages were 22 +947 km to 21+593 km or around 1.35 km, as the average advance rate was 46.97 m/week. The top performance during this period was reached 134.38 m/week, in which the achieved machine utilization was gone to the maximum of 79.17% for the available shift time, and the mean was 34.67% for the learning curve. The Figure 8 and Figure 9 are shown the distribution of the gross advance rate and the net advance rate of the machine utilization was explicitly illustrated the variation of TBM productivities.

4.3 Summary of the geological conditions

The actual rock mass types were different from the expected rock mass types, as summarized in Figure 10. The Quartzitic-Sandstone fractured (RMT 3F) was mainly found in the Carboniferous sedimentary rock formation as 43.57% along the tunnel. The Sandstone/Siltstone – Shale intercalation fractured (RMT 4F) was 32.29%, while the Siltstone – Shale fractured (RMT 5F) was 0.44% of the total actual rock mass types. However, the faulted rock masses including RMT 8Q and RMT 8S were found almost 24%, which was completely different from the expected ground types.

The groundwater conditions were slightly increased to more than 50 L/sec. The cumulative amount of water in the TBM exceeded the limit to

more than 320 L/sec, as shown in Figure 11. According to the design, the extremely high-water ingress was excessive 100 L/sec, where the TBM should be stopped boring to treat the ground or block the water ingress.

4.4 Collapsed segments

4.4.1 At chainage 16+563 km

One of the major incidences is that the precast lining concretes, including No. 4559 to 4561 were collapsed in chainage 16+563 to 16+561 in the 6th period (Figure 12). At chainage 16+582 km the rock chips were found as the faulted rock mass (RMT 8S) and the 5 L/sec of the groundwater ingress. The faulted meta-sandstone formation was grey color, moderately weathered, highly fractured, and iron oxides covering a fracture surface. The chip sizes were average cutting size around 1 to 3 cm and a large cutting size around 3 to 9 cm with blocky angular and poorly sorted chip sizes. Then, the groundwater ingress had increased to approximately 10 L/sec at the cutterhead while the cumulative water in the tunnel had been almost 230 L/sec. In the night shift, the segment C of ring No. 4556 at chainage 16+563 km to 16+561 km was fallen over the conveyor in the Deck-1 and bridge areas (Figure 13), where there was an abundant inflow of rock material and water through the opening at the collapsed segment in the top section. The inrush material resulted in the major obstruction in correspondence of the backup bridge, and the access to the TBM area has been inhibited.

Figure 12. The major stoppage (i.e., the 1st incidence of the collapsed segment) (a) collapse occurred (b) water inflows into the tunnel (c) inrush materials with water inflows (d) the collapsed segments (e) cleaning the inrush materials (f) support tunnel with H-beam steel arch.

Figure 13. The constructed model after the TBM tunnel inspection for the collapsed segments in chainage 16+582 to 16+554.

The summarized in the field performance studies, the cutterhead coefficient (i.e., a ratio between the cutter torque and the thrust force) was a primary indicator to review the machine behaviors, as shown in Figure 14. During the TBM had excavated via the RMT 8S in chainage 16+583 km to 16+553 km in which the cutterhead coefficient had slightly dropped into 0.10 to 0.05 indicating the squeezing ground. The FPI will be higher values when the blocks of rocks are ruptured from the tunnel face, and face collapse occurs. The cutterhead coefficient was decreasing while the FPI was increasing from approximately 20 kN/mm/rev to almost 80 kN/mm/rev. The loosen segment was also induced to fall by the water ingress because the stability of the rock mass was degraded by groundwater. The cutter torque and the cutter rotation increased in the highly fractured rock mass when the cutting wheel friction decreased. Furthermore, the auxiliary thrust during re-gripping had increased before the TBM stuck as the TBM struggled to push forward, leading to excessive pressures on the segmental lining.

Figure 14. The key indicators reviewing the machine behaviors in the major stoppage.

4.4.2 At chainage 14+475 km

The major incidence of the TBM was the segments collapsed in the thrust zone (Figure 15). The field performance data (Figure 16) could be well indicated the problematic zones in this incidence. The cutterhead coefficient slightly dropped from 0.18 to 0.10 in around chainage 14+574 to 14+576 km, while the FPI was starting to increase from approximately 20 kN/mm/rev to 60 kN/mm/rev at chainage 14+575 km. These factors are a good indicator used to caution against the adverse behavior of the ground interacting with the machine. The cutter torque and the RPM had raised in accordance with the cutterhead coefficient and the FPI.

4.5 Extremely high-water ingress

After the first incidence through the number nine fault zone, the advance rate slightly increased around 69.07 m/week. The maximum advance rate was 123.40 m/week in the extremely high-water ingress conditions. The achieved machine utilization was an average of 36.7%, where the TBM still dealt with the high groundwater inflow. The water inflows had

Figure 15. The major stoppage (a) segmental lining cracking (b) cluster cracks of the collapsed segments (c) damage of the segmental lining (d) the collapsed segments (e) H-beam steel rib used for supporting the problematic zone (f) inspection and working for support the ground.

Figure 16. The key indicators reviewing the machine behaviors in the major stoppage.

increased up to 170 L/sec, where the TBM needed to stop to implement the special measures. The boring cycle time had increased by 11.9%.

4.6 TBM excavation in the thrust zones.

The TBM had been operated in the difficult ground conditions as the utilization was reduced by the inrush materials and high-water inflows around 120 L/sec to 140 L/sec. The advance rate during the TBM excavation through the thrust zone was an average of 73.24 m/week. The maximum of advance rates was 146.24 m/week. The achieved machine utilization was on average 42%, and the maximum of achieved machine utilization was 82%. The boring was 40% of the total available shift time, and inspection and maintenance of the cutterhead and backup systems were 29%. Figure 17 is showed the boring cycle time almost 12% of the total shift time for the special measures in the thrust zone. Figure 18 is showed the major TBM downtimes, which were ventilation issues 50.86%, rail issues 18.48%, hydraulic/mechanic/electric issues 9.23%, erector issues 5.73%, and so on.

Figure 17. The boring cycle time during the TBM excavation in the thrust zone.

5 CONCLUSIONS

The MNMK water diversion tunnel construction projects in Northern Thailand was selected the double shield TBM to excavate the ground based on the geological conditions related to risks and uncertainties. The TBM-data analysis was performed using the collected data from the TBM to summary of the overall TBM performance and the recommendation for future TBM tunnel projects in hard rocks can be established as follows.

- 1) The TBM had finished the TBM excavation in the Carboniferous clastic sedimentary rock formation with a tunnel length of 10.45 km, The operation days was 1,350 days, the total production was 54% and the total no production was 46%. The best gross advance rate was 203.42 m/week, as well as the best net advance rate was 40.59 m/day. The average rate of advance could be summarized as 48.6 m/week.
- 2) The maximum average machine utilization was 66.7%, and the mean was 21.2% of the whole period of the TBM operation. On the other hand, the tunneling time consumption shows the stand-still TBM was 24.9%, the incidences of the collapsed segments were 17.1%, the net boring was

12.4%, special measures were 11.5%, TBM downtimes were 8.6%, other main activities were 7.5%, and the TBM maintenance/inspection/cleaning/utilities were around 18.0%.

- 3) The explicit difference between the actual RMTs and the expected RMTs was almost 24% in the faulted rock mass types where the RMT 8Q and the RMT 8S were mostly found in the thrust zone as more than the prediction.

ACKNOWLEDGMENTS

I would first like to give special thanks to Dr. Thanu Harnpattanapanich who provided the best suggestion and the comprehension in the TBM tunneling, and their profound knowledge in the TBM tunnel design. I appreciatively acknowledge the Consults Team of Construction Supervisions for support big data. My thanks are also provided by the GEO team of GTP and PYG, who always helpful to support data.

A new AFTES guideline: Suitability and selection process of pressurized TBMs in urban contexts

Magali Schivre*

Incas Partners, Paris, France

François Renault

Vinci Construction Grands Projets, Nanterre, France

ABSTRACT: The aim of this new AFTES (French Tunneling & Underground Space Association) recommendation is to provide a guide for assessing the suitability of pressurized TBMs for use in urban contexts, together with an approach for documenting the choices made. While soil-related constraints are a prime factor in this choice, there are sometimes several types of machines that may be suitable, and it is other constraints, such as environmental or economic ones, that will guide the final choice. The purpose is not to guide towards a single choice of machine, but to make each of the parties involved aware of the importance of the constraints that can influence this choice, and therefore the program and economics of a project.

The recommendation defined by the AFTES working group is structured around achieving three major objectives for the successful implementation of a project using a pressurized tunnel boring machine in an urban context: safety, transparency, and performance.

Furthermore, as the range of applications for these machines continues to expand, with multi-purpose machines with additional equipment, the guideline recommends determining the most suitable types of confinement (e.g. paste, liquid, or gaseous) before selecting the machine's typology and its equipment.

Similarly, taking into account specific configurations and risks are reviewed (e.g. presence of boulders) to define the design of the tunnel boring machine and its complementary equipment (e.g. crusher), and countermeasures are proposed if available and necessary.

Additionally, the working group suggests that the adopted approach for selecting the confinement type and tunnel boring machine, be outlined and synthesized in an "environment and excavation conditions" model.

Keywords: TBM, urban, pressurized, suitability, model approach, confinement mode

1 DIFFERENT OBJECTIVES OF AN URBAN PROJECT INFLUENCING TBM'S SELECTION

The comparison between urban tunnels and other underground structures reveals two major sets of challenges. First, insertion constraints include restricted alignment, limited construction space, engagement with multiple stakeholders, presence of neighbouring structures, and the potential discovery of forgotten anthropic objects in the subsoil. Second, technical complexity arises from poor ground quality, the water table's presence, difficulties in obtaining permits for preliminary investigations, and the relatively shallow ground cover. These constraints represent substantial risks to nearby residents and third parties, necessitating careful project design to ensure success.

The aim of the new AFTES (French Tunneling & Underground Space Association) recommendation

"*Suitability and selection process of pressurized TBMs in urban contexts*", is to provide a guide for assessing the suitability of pressurized TBMs for use in urban contexts, together with an approach for documenting the choices made.

The selection of tunnel boring machines (TBM) and their equipment is a critical step in any project, and it must ensure the fulfilment of three major project objectives:

Safety: Safety is the fundamental requirement for any excavation project, emphasizing the protection of both third parties and personnel involved. This involves maintaining the stability of the excavation face, minimizing the impact of TBM operations on the surrounding environment, and ensuring the safety of all personnel throughout the project.

Transparency: Beyond safety, gaining acceptance from local residents in urban projects requires a design that optimally utilizes available space and

*Corresponding author: mschivre@incas-partners.com

minimizes the project’s impact on the broader environment. This includes considerations like road congestion, noise and dust emissions, vibrations, and respects of working hours. Proper disposal of excavated materials and the overall logistics of the construction site significantly affect nearby residents. As a result, the entire project should aim to be as “transparent” as possible to address these concerns.

Performance: The project needs to be optimized in terms of costs and scheduling, making it essential to consider efficiency and timely completion.

The new AFTES Guideline suggests that it is essential to consider these major objectives related to urban projects, rather than just geological and geotechnical aspects, when selecting the TBM. The process of selecting the TBM begins with the exclusion of confinement methods that do not meet the fundamental safety requirements mentioned earlier. Subsequently, an analysis of various criteria is conducted to compare the remaining confinement methods, ultimately choosing the one that best aligns with the project’s overall objectives.

2 STUDYING THE FEASIBLE FACE CONFINEMENT TYPES, RATHER THAN MACHINE TYPES

Applying pressure to the excavation boundaries serves to ensure the stability of the cutting face, limit water ingress, and minimize ground displacement. Tunnel boring machines (TBMs) with face confinement mechanisms achieve these objectives.

There are three main types of face confinement, determined by the consistency of the material used to fill the excavation chamber:

- Paste Confinement: Involves filling the chamber with excavated materials, possibly with additives, to create a viscous mixture.
- Liquid Confinement: Uses a viscous fluid to fill the chamber.
- Gaseous Confinement: Fills the chamber with compressed air.

The choice of face confinement depends on the geotechnical context in which it will be deployed. Some pressurized TBMs can operate with different types of face confinement, and certain TBMs are “multimodal,” meaning they can switch between different confinement modes.

The capacity of various pressurized TBMs to implement the different confinement modes mentioned above is summarized in Figure 1 below. Obviously, even without considering multimodal tunnel boring machines, some machines can operate with multiple types of face confinement.

Therefore, the approach suggested by the new AFTES recommendation is to first focus on identifying the possible face confinement options before selecting a machine technology.

The evolution of the last 15 years demonstrates that there is more overlap between pressurized

AFTES		TYPE OF PRESSURIZED TBM			
		EPB	SLURRY SHIELD	COMPRESSED AIR	MULTIMODE
FAMILIES OF CONFINEMENT	PASTE	XX			(3)
	LIQUID		XX		(3)
	GASEOUS	X (1)	X (2)	XX	(3)

XX	Standard front confinement	(1) EPB : partial filling of the excavation chamber
X	Possible confinement subject to evaluation of the advantages/disadvantages/risks	(2) SLURRY : air bubble communicating with the excavation chamber
		(3) Depend on the MULTIMODE type

Figure 1. Type of pressurized shield versus confinement.

shielded TBM thanks in particular to continuous improvements and technological developments that make it possible to extend the application scope of the various types of TBM, with also addition of specific equipment to compensate for deficiencies:

- Increasing confinement pressures, particularly for slurry TBMs.
- Enhancing the precision with which face support is managed by injecting pressurized bentonite to limit variations in chamber pressure, for the various types of TBM.
- Adaptability, enabling use in ground with different particle size distributions and permeability, with for slurry TBM: anti-clogging measures and improved behaviour in cohesive soils; managing cutting face stability by generating cake. And for EPB TBM: modifying the mechanical properties of excavated earth by injecting additives directly into the cutting chamber.

3 ANSWERING TO “SAFETY” OBJECTIVE

Ensuring Front Stability and Minimizing the TBM’s Impact on the Surrounding Area.

3.1 Identification of current conditions and suitable confinement

As the range of applications for these pressurized machines continues to expand, with multi-purpose machines with additional equipment, The AFTES guidelines discuss in a very precise way the optimal conditions for implementing various face confinement types (e.g. paste, liquid, or gaseous) and the potential corrective measures to expand standard application fields.

The optimal conditions are primarily characterized by:

- The grain size and/or permeability of the soils being traversed.
- Their Atterberg limits and moisture content.
- Hydrogeological conditions.

- Mechanical strength parameters affecting the minimum and maximum confinement pressure to be maintained.
- The deformability of the overlying soils.

Ground investigation campaigns should, therefore, focus on providing these pieces of information. In a very concise manner, the optimal conditions for applying paste, liquid, and gas face confinement modes are illustrated in Figure 2.

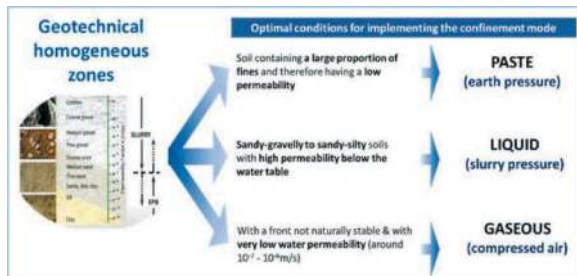

Figure 2. Optimal condition for the different type of confinement.

The grain size and Atterberg limits help evaluate the feasibility of implementing the face confinement type. The strength and deformability parameters of the overlying soils determine the required confinement pressure values to maintain front stability and keep settlements within acceptable limits. It is important to compare the maximum confinement pressure with the acceptable range for each confinement mode.

3.2 Addressing specific configurations and risks to determine the TBM design and supplementary equipment

The specific configurations and risks which have influence on the pressurized TBMs are reviewed. For each of them, the guideline introduces a common technical language, gives an indication on the predictability (spatial and temporal) of the following phenomenon:

- Sticky/clogging soils
- Erratic blocks & boulders or anthropic obstacle (cf. Figure 3)
- Voids of natural or anthropic origin
- Mixed fronts
- Polluted soils

For each specific configuration, the AFTES guidelines provides recommendations in identifying the consequences on the TBM type based on the type of confinement and evaluating the level of impact (cf. Figure 4).

The AFTES guidelines also provides recommendations in anticipating appropriate mitigation measures that can be implemented regarding the type of TBM.

- assessing the difficulty of implementing these countermeasures.

Erratic blocks & boulders or anthropic obstacle

Definition
Erratic Block(s) of significant-sized ranging from a few decimeters to metric-sized blocks within a soft matrix that does not exhibit any coherent trend and has a random distribution.
Encounter with an Anthropogenic Obstacle: When the tunneling machine encounters a man-made obstruction. This obstacle could be a foundation, anchor, sheet pile, or drilling casing. The obstacle might be in use or abandoned.

Risk event
These blocks or elements may require fragmentation for excavation. They can potentially cause damage to the cutterhead and its tools in case of dislodgment. They might get stuck in the cutterhead openings and disrupt its operation.
After passing through the chamber, they could also damage the mucking system (e.g., blockages, breakage, malfunctions).
This situation may lead to stability issues at the tunnel face.

PREVISIBILITY	ERRATIC BLOCKS		
	Existence	Localization	Characteristics
	✓	⚠	⚠
	ANTHROPIC OBSTACLE		
	⚠	⚠	⚠

Geological and hydrogeological conditions

For erratic blocks:

- Quaternary fluvial alluvium
- Moraines and fluvio-glacial alluvium
- Weathered granite massif

Figure 3. AFTES definition of “Erratic blocks & boulders or anthropic obstacle”.

- anticipating the impacts on the TBM design and its equipment (e.g., crushers).

Mitigation measures are classified as “easy to implement on-site” provided that their implementation has been considered during the TBM’s design, including the TBM equipment, as illustrated on Figure 5.

4 ANSWERING TO “TRANSPARENCY” OBJECTIVE

The succeed of a project will pass through limiting the impact on the environment and aligning with available worksite areas.

4.1 Environmental impact of construction works

4.1.1 Excavated materials

Regarding **excavated material management**, more than the type of confinement, it’s primarily the **mucking system** that should be considered. For instance, it’s possible to install a dilution system at the rear of an Earth Pressure Balance (EPB) TBM and evacuate the muck through a hydraulic system (as seen in the example of the Botlek tunnel in the Netherlands). Similarly, a multimodal TBM capable of EPB and slurry confinement can be associated with a hydraulic mucking disposal system with a surface separation plant.

The Figure 6 illustrate a separation plant, placed on a temporary deck over the bench and the Seine River to minimize impact on the city life.

TBM CONSEQUENCES - Erratic blocks / anthropic obstacle								
CONSEQUENCES	Initial IMPACT level			Localization				Comments / Examples
	PASTE	LIQUID	GASEOUS	Excavation Chamber	Cutterhead	Casing	Back up / Hydraulic chain	
Block/element larger than the wheel sizing or causing obstruction to the aspiration, requiring a TBM stop to remove it.	3	3	3	X	X			The machine should be stopped as soon as possible to minimize the consequences
Breaking or damaging cutting tools or bits upon impact, necessitating a near-term TBM stop for replacement	1	1	1		X			Depending on the geology or nature of the obstacle, the breakage of cutting tools/bits may require a specific TBM stop
Damage to the screw conveyor	2	2	2	X				In extreme and rare cases, this could result in the breakage of the screw conveyor or casing tear
Disruption of the hydraulic mucking operation when encountering anthropogenic elements (bars, piles, etc.).	NC	1	NC				X	Be cautious of the risk of water hammer (a sudden surge of pressure).
Damage in the mucking conveyor system.	2	NC	2				X	If there is no crusher or grizzly behind the screw, there is a risk of blocks falling from the conveyor (human risk) Belt tear, which can be more serious when encountering metallic elements.
Challenges in TBM guidance and maintaining confinement.	2	2	3	X	X	X		The risk is heightened in unstable terrains.
Note: In cases of repeated encounters with pebbles/blocks, this can lead to wear and damage to the marine pipes. It may also be necessary to consider protections for the cutting wheel face against wear, including potential reinforcements.								
CONSEQUENCES and INITIAL IMPACT LEVEL								
The possible consequences of the main geotechnical risks or specific configurations are evaluated for the different types of confinement concerning their impact on the operation of the tunnel boring machine and worker's safety								
0	Negligible Without impact or Not concerned (NC)	No further consideration of the hazard is needed						
1	Significant, but presumably acceptable	Construction can begin, but risk factors must be closely monitored through appropriate procedures, and the project must be supplemented with a series of predefined measures that can be adapted during the execution phase						
2	Important	Construction cannot commence until the risk is reduced or eliminated. Risk mitigation measures should be identified and implemented as long as their cost is not disproportionate to the risk reduction achieved.						
3	Unacceptable	Risk-taking is unacceptable regardless of the potential benefit. It should be avoided at any cost or impact on the schedule. The impact should be rééduque to at least "important."						

Figure 4. Impact and consequences on TBMs regarding confinement “Erratic blocks & boulders or anthropic obstacle”.

The choice of mucking disposal system will impact both the nature and quantities to be evacuated and their potential reuse in case of revaluation. It’s important to remember that the in-situ soil is different from the excavated muck, which accumulates in the muck pile. This difference can be attributed to the confinement method (e.g., addition of additives or bentonite) and the mucking disposal method.

The AFTES guideline discusses and compares the mucking disposal methods using conveyors belt (suited for paste and/or gaseous confinement) and the hydraulic mucking disposal method (suitable for all types of confinement):

- Nature of excavated material depending on their conditioning in the case of conveyor belt mucking

MITIGATION MEASURES - Erratic blocks / anthropic obstacle					
MITIGATION MEASURES	Preventive (P) Corrective (C)	Level of difficulty to implement it			Comments / Examples
		PASTE	LIQUID	GASEOUS	
Equip the TBM with a crusher to reduce the size of blocks	P	▲	●	▲	Determine type of crusher regarding the expected block nature (e.g., jaw or roller crusher). For paste confinement, the crusher (or a "gritzy") is located behind the screw conveyor, while in the case of liquid confinement, it is located at the bottom of the excavation chamber.
Determine the sizing of the cutterhead openings based on the desired calibration	P	▲	●	●	The cutterhead must gradually gnaw away at the block(s). The cutterheads with liquid confinement may have larger openings, limited by the block size.
Appropriately size the screw conveyor (pitch, strength, diameter) and casing	P	▲	▲	▲	Limited by the block size and the cutterhead openings.
Outfit the cutterhead with specialized tools for encountering metallic obstacles	P	●	●	●	
Include inspection hatches for clearing metallic elements or facilitating repairs	P	●	●	●	Stone traps ahead the pumps or inspection hatches on a screw conveyor.
Use pipes with sizes compatible with the block size coming out of the crusher, with suitable mesh screens	P	NC	●	NC	
Instrumentation of the cutterdiscs	P/C	●	●	●	Instrumentation allows for the detection of block/obstacle encounters and the reduction of penetration pitch, reducing the risk of cutter breakage
Install a metal detector and/or electromagnet to detect potential tool breakage or the presence of metallic obstacles	P/C	●	▲	●	In the case of liquid confinement, detection can only be carried out from the surface.
Equip the TBM with non-destructive surveying equipment (seismic, radar, etc., currently in development)	P/C	●	●	●	Various advanced inspection techniques exist, but their effectiveness varies depending on the context, with few conclusively successful experiences. These are promising technologies whose use should be encouraged, as they contribute to overall risk management
Perform preventive maintenance on the cutterdiscs and tools	C	▲	●	▲	Increase the frequency of cutterdiscs and tool inspection and maintenance. These zones should be pre-identified in the PAT
Advance at reduced speed when the occurrence is predicted	C	●	●	●	Advancing at very slow speeds (e.g., microspeed, penetration speed, rotation speed) should be considered in the design to make it feasible. These zones should be pre-identified in the PAT
Remove the obstacle or block with hyperbaric intervention .	C	▲	●	▲	
DIFFICULTY LEVEL TO IMPLEMENT MITIGATION MEASURE ON SITE					
NC	Not concerned				
●	Easy to implement on site, to be previously considered in the design				
▲	medium difficulty of implementation				
◆	very difficult to implement, (could have an impact on the requirements)				

Figure 5. Countermeasures regarding confinement on TBMs regarding confinement “Erratic blocks & boulders or anthropic obstacle”.

- Nature of excavated material in the case of hydraulic transport
- Difference in quantities of excavated material based on the mucking method
- Possibility of reuse or future valorization

4.1.2 Vibrations, noise and pollution

As of today, there is no evidence to suggest that one type of confinement TBM generates more vibrations than another type. This is a non-discriminatory factor for choosing the confinement method. However, it remains true that this issue should be addressed during the early phases of a project. The building survey should identify structures sensitive

Figure 6. EOLE separation plant, Slurry TBM D11,4m – 6km.

to vibrations (laboratories, recording studios, hospitals, etc.) and prioritize alignment options that keep a distance from these buildings.

Most of the surface equipment generating noise is the same regardless of the type of machine. Typically, the loudest sources are the mortar preparation plant, ventilation, and transport vehicles. However, there are differences related to the slurry disposal method: the separation plant in the case of liquid confinement and material chutes in the case of conveyor belt mucking.

The ground that the TBM will encounter can contain various types of pollutants. Depending on the type of machine chosen, these pollutants can have an impact on the safety of workers and the deposition of excavated materials. Without specific processes, paste and gas confinement methods expose workers more to existing pollutants such as hydrocarbons, H₂S, and asbestos fibers compared to liquid confinement.

4.2 Urban site constraints for construction

The worksite is the visible part of the construction site. It serves as the Owner's showcase and acts as the primary point of contact with local residents. It must prioritize discretion to ensure effective acceptance. Proper dimensioning of the worksite is crucial for achieving and controlling the project's planning objectives.

4.2.1 Areas for worksite installations and access

Substantial differences exist in terms of required surface of worksite installation regarding the different confinement mode.

For each type of tunnel boring machine technology, there is a minimum size of worksite installation below which it is no longer feasible and an optimal size from which no loss of productivity is expected.

The AFTES guideline suggests that the optimal area depends on several key parameters:

- The TBM excavation diameter.
- Work organization (which can be carried out 5 days a week, 6 days a week, or 7 days a week, for example), authorized hours for slurry disposal or material supply, which will dictate the number of buffer stock days required.
- The maximum excavation speed. Note that to guarantee the project's average excavation speed, a common approach is to consider a ratio of 2 between the maximum speed and the average speed.
- The TBM confinement technology (paste, liquid, gas, or multimodal).
- The management mode and characterization of excavated materials (bins for chemical identification or space required for revaluation).
- Activities that are conducted concurrently or sequentially with the excavation on the same site (e.g., starting shaft or metro station for a metro project).

The chart provided by the AFTES Guideline in Figure 7, illustrates based on past projects that the space needed increases with the diameter, and that separation plants need large spaces potentially restricting the space available for other site facilities, especially in urban locations.

4.2.2 Starting shaft size

The challenge of acquiring a substantial land area in urban areas leads to a desire to reduce the dimensions of the starting shaft. The choice of the starting shaft size can determine the type of tunnel boring machine that can be used and also have significant implications for the project schedule.

There is a minimum starting shaft size below which it is no longer possible to assemble and launch a TBM. This size corresponds to the length of the TBM pushed against the face, plus sufficient space for supplying the first segments. Furthermore, TBMs equipped with a screw conveyor (compressed air pressure, earth pressure, or variable density) require a sufficient assembly area length to insert the screw conveyor into its casing.

Using a slurry TBM can, therefore, be advantageous when the starting shaft size is severely constrained.

The assembly and startup phases are often accident-prone due to the use of excavation equipment in degraded mode. From a safety perspective, it is essential to prefer a starting shaft size that limits the number of temporary phases.

5 ANSWERING TO “PERFORMANCE” OBJECTIVES

After considering aspects related to face stability and the project's impact on the environment, economic and scheduling factors should also be considered when choosing the type of tunnel boring machine.

Figure 7. Illustration of lessons learned: Matching available size according to excavation diameter and mucking type – GT4 database.

Some elements of the cost of tunnel construction depend on the type of TBM used, primarily including equipment investment costs, operating costs, and excavation material disposal costs.

The “bare” machine costs refer to the machine itself without the specific equipment indicated below. The chart provided by the AFTES Guideline in Figure 8 shows that within the same diameter range, EPB and SLURRY TBMs are in a similar price range, while Multimode TBMs have slightly higher investment costs.

In the assessment of the investment gap between machines, specific equipment associated with each TBM technology should be taken into account. The main elements include:

- Cost of a hydraulic slurry circuit per kilometer for liquid confinement.
- Cost of a conveyor per kilometer for paste or gas confinement.
- Cost of a separation plant per excavated diameter.

Figure 8. Cost of a “bare” new TBM based on its type and diameter – GT4 database.

Similarly, since tunnel excavation activities are often on the critical path for projects, it’s important to assess the time differences in project completion based on the chosen TBM technology. For example, the project duration depends on:

- Assembly/startup
- Excavation rates vs. geology: they are highly dependent on the presence of clay, influenced by the strength and abrasiveness of the ground. They also depends on the size of the worksite and the size of the separation plant
- Stop-time and maintenance time

However, there can be significant differences in the duration of stop-time. The Figure 9 highlights different types of downtime based on the technology used, leading to significantly different expected durations.

TBM stop-time can be categorized into four main families:

- Planned stops, primarily due to inevitable tasks such as extending easements.
- Waiting times, which encompass machine downtime due to external breakdowns unrelated to the TBM.
- Scheduled maintenance.
- Miscellaneous breakdowns.

MUCKING or CONFINEMENT	PRESSURIZED TBM DOWNTIME			
	Unavoiding Tasks => Planned Stops	Waiting Times	Maintenance	Breakdowns
LIQUID confinement + Hydraulic mucking	Extension of Slurry Lines Relay Pump Installations	Waiting at the Slurry Treatment Station (e.g., drumming blockage)		Slurry pumps
LIQUID confinement + Conveyors mucking	Extension of Conveyor Belts Installation of boosters	Conveyor Belt Blockages		Belt tear
All types	Extension of Utilities (air/water) Extension of Electrical Power Cable Extension of Ventilation Cleaning of Mortar Injection Lines	Downtime Waiting for the TSV or other Segment Supply; Waiting for the Mortar Plant (excavation interruption if no mortar to inject)	Daily maintenance Hyperbaric interventions	TBM TSV Mortar Plant

Figure 9. Stop-time tasks regarding confinement/mucking.

ENVIRONMENTAL & TBM MODEL

Imaginary Project - DETAILED DESIGN

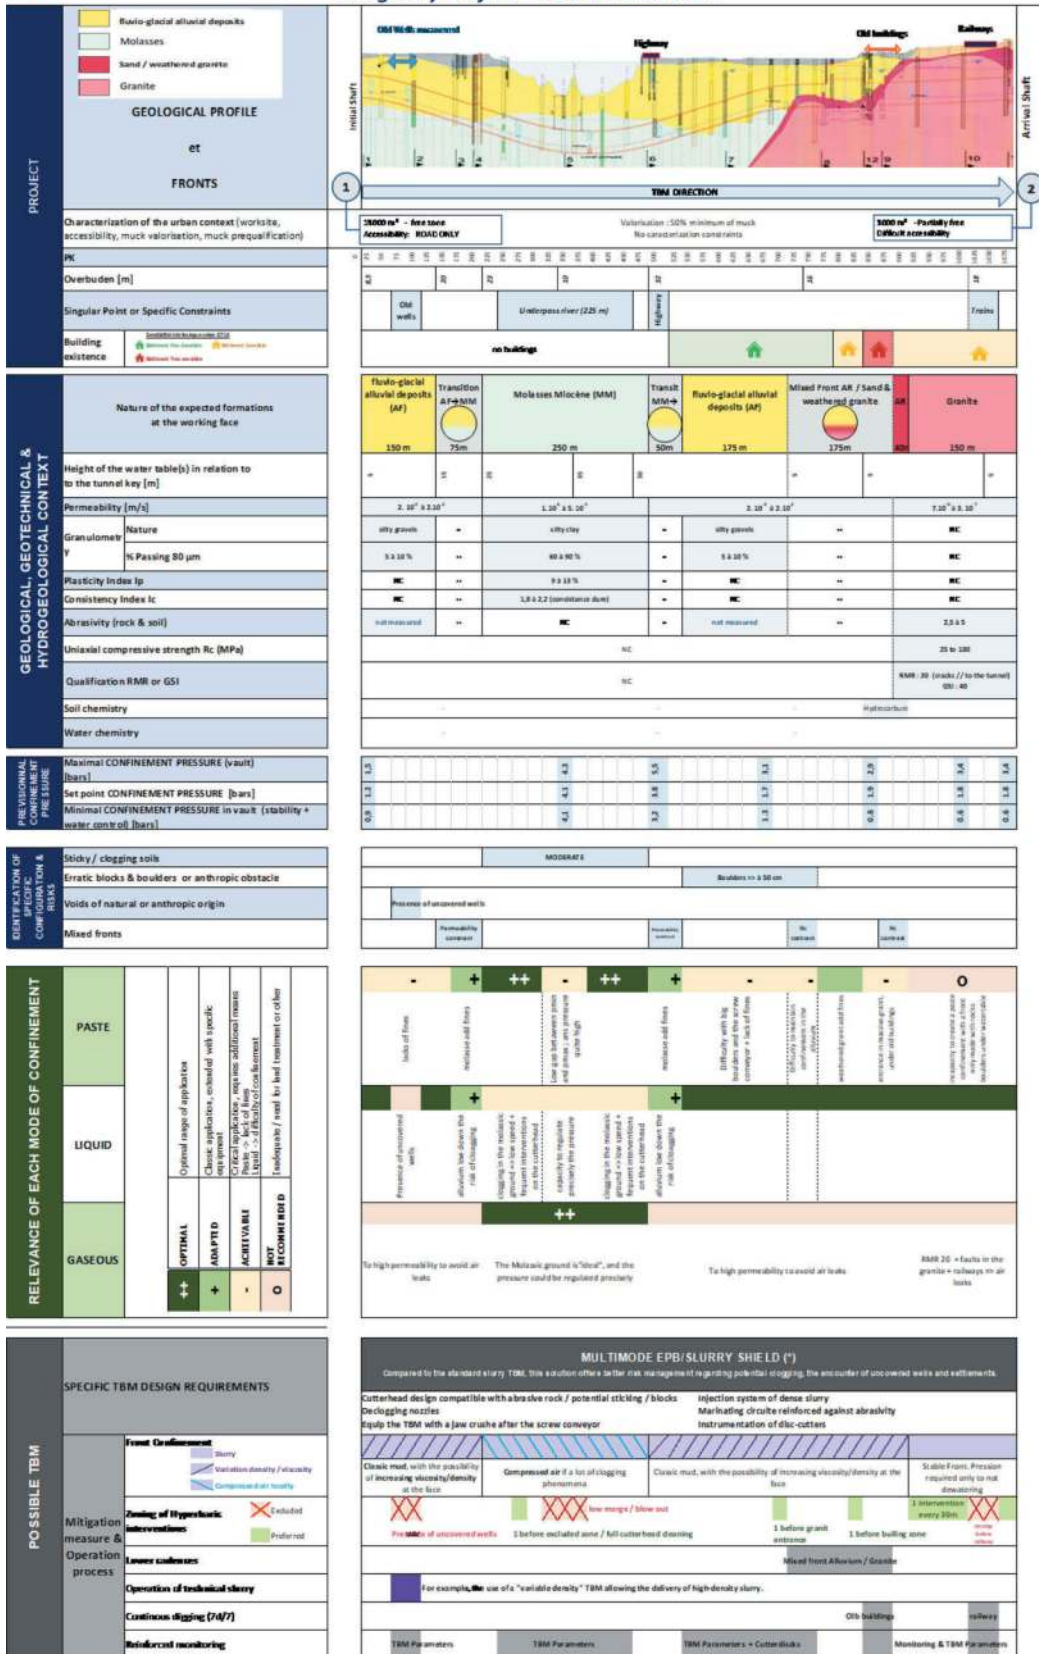

Figure 10. AFTES environmental & Excavation conditions model.

6 SUGGESTING A STEP-BY-STEP APPROACH FOR CHOOSING FACE CONFINEMENT AND TBM

The aim of the AFTES approach is not to propose a logic for defining the “ideal” TBM for a given project because, as mentioned earlier, there are numerous parameters, some of which are difficult to quantify, that can influence this assessment.

Among these parameters, one should not overlook the unique experience of each company, which enables them to master the technology they intend to implement. Instead, the objective is to present an approach that addresses all the criteria discussed earlier, ensures traceability, and provides a concise overview.

During the design phase, it is necessary to gradually reduce uncertainties until a project is developed that meets the required program while maintaining acceptable costs and residual risks. This is an iterative process, and assessing the suitability of a TBM type is a part of it.

This methodology can be applied during the design phases and when selecting the TBM by the company. Its secondary goal is to guide the necessary geological studies and assessments for managing construction risks effectively. Furthermore, it allows for maintaining a concise record of the considerations made during the project’s development.

The AFTES guidelines suggests that the adopted approach for selecting the confinement type and TBM machine, should be outlined and synthesized in an “Environmental and Excavation Conditions Model”, in a concise document.

Its primary objectives are to:

- Ensure traceability.
- Locate the elements of the project context, including obstacles and structures traversed by the project, all along the layout.
- Include geotechnical and hydrogeological characteristics of the ground that impact the choice of excavation methods.
- Present confinement pressure values, all along the layout.
- Identify specific configuration & risks.
- Asses the relevance of each mode of confinement (paste/liquid/gaseous), with a classification from “not recommended” to “optimal” as illustrated in Figure 11.

++	OPTIMAL	Optimal range of application
+	ADAPTED	Classic application, extended with specific equipment
-	ACHIEVABLE	Critical application, requires additional means Paste -> lack of fines Liquid -> difficulty of confinement
O	NOT RECOMMENDED	Inadequate / need for land treatment or other

Figure 11. Relevance of confinement mode.

- Select the design & the equipment of the machine:

The identification of preliminary measures for the TBM’s design, including the implementation of specific equipment based on the TBM’s type. This involves referring to the countermeasures detailed previously (as in Figure 5) and considering technological advancements that enable the use of a tunnel boring machine outside its typical domain.

- Anticipate the operation phase of the TBM, with the location of the mitigation measures with:

The listed measures include the zoning of confinement mode based on the recommended TBM type. For example, for slurry TBM, it involves identifying areas where the machine can operate under air pressure mode in regions affected by clogging soils in the presence of an impermeable environment. For EPB, it entails locating areas that require working in full-face mode with slurry confinement and proper conditioning.

The topics also cover hyperbaric interventions zoning, including the identification of areas where interventions should be excluded or prioritized, work with specific technical mud, slow-rate excavation, continuous 7/7 excavation, enhanced monitoring of TBM parameters, and implementing suitable control thresholds, vigilance zones for mud loss, and preventive maintenance integrated into the TBM’s advance plan, which may necessitate interventions at the face.

Using this model, which provides an overall and cross-sectional view of the project’s challenges, the designer and after the contractor can determine which types of confinement are compatible with the project and whether additional ground treatments or other accompanying measures are necessary.

An example of a concise Environmental and Excavation Conditions Model, suggested by the guideline, is illustrated on Figure 10. It is entirely based on a theoretical imaginary project.

7 CONCLUSIONS

The aim of the new AFTES guidelines “Suitability and selection process of pressurized TBMs in urban contexts” is to provide a guide for assessing the suitability of pressurized TBMs for use in urban contexts, together with an approach for documenting the choices made.

While soil-related constraints are a prime factor in this choice, there are sometimes several types of machines that may be suitable, and it is other constraints, such as environmental or economic ones, that will guide the final choice. It is essential to address Specific Configurations and Risks to Determine the TBM Design and Supplementary Equipment (e.g., crushers).

The purpose is not to guide towards a single choice of machine, but to make each of the parties involved aware of the importance of the constraints that can influence this choice, and therefore the program and economics of a project.

The AFTES guidelines also suggest to study the Feasible Face Confinement Types, rather than Machine Types, and after suggest a Step-by-Step Approach for Choosing Face Confinement and TBM, summarized in an Environmental and Excavation Conditions Model.

ACKNOWLEDGMENTS

We would like to express our deep gratitude to the dedicated team of the AFTES Working Group

“Mechanization”. Their unwavering commitment and voluntary contributions of their valuable time were instrumental in the development and sharing of this methodology. Without their efforts, this work would not have been possible.

ABSTRACT: The Los Angeles, California JWPCP effluent outfall tunnel will transport secondary-treated effluent from the Joint Water Pollution Control Plant in Carson to the White Point Manifold. Upon completion, through ground conditions ranging from soils to hard rock, the tunnel will be approx. 11km long with a finished internal diameter of 5.5m. This paper will present the Tunneling Conditions Assessment Report (TCAR) and Tunnel Operation Plan (TOP) developed prior to construction, as well as the actual TBM performances achieved along the northern portion of the alignment in soft ground, shallow cover, and beneath a densely urbanized area.

Keywords: Tunnelling, Slurry TBM, Performance prediction, Soft Ground

1 INTRODUCTION

The aim of the new Los Angeles, California JWPCP effluent outfall tunnel is to provide relief and redundancy to the existing tunnels (shown in red in Figure 1) as well as providing additional overall conveyance capacity. Upon completion, the tunnel – approximately 11 km long with a finished internal diameter of 5.5 m – will transport secondary treated effluent from the Joint Water Pollution Control Plant (JWPCP) in Carson to the White Point Manifold on the coast.

The tunnel is currently under construction using a Mixshield TBM with precast segmental concrete lining designed to cope with the baseline maximum water pressure of 9.1 bar (according to the Geotechnical Baseline Report – GBR 2018). This paper focuses on the northern portion of the alignment (i.e., approximately 5.5 km), completed in November 2023 (shown in blue in Figure 1).

2 EXPECTED TUNNELLING CONDITIONS

The geological conditions and the tunnelling conditions expected along the northern portion of the alignment determined in the pre-excavation phase

Figure 1. Project area, with existing and new tunnel alignments.

(Schuerch et al., RETC 2023) are summarized in the following section. For the southern portion of the alignment, refer to Schuerch et al., WTC 2023).

*Corresponding author: martino.scialpi@pini.group

2.1 Geology and hydrogeology

Along the northern portion of the alignment, the TBM was expected to encounter heterogeneous soils of the Lakewood Formation and San Pedro Sand. Locally, the Timms Point Silts and the Alluvium were expected to reach the tunnel elevations. Table 1 shows the expected geology along the different tunnel reaches of the northern portions:

- Lakewood Formation, San Pedro Sand: Predominantly sand, sand with varying amount of silt and clay, lenses of gravels and shells.
- Alluvium: Clays, silts and sands with organic debris, gravels, cobbles and boulders.
- Timms Point Silt: Predominantly silt, siltstone, claystone and mudstone with seams of sand, organic fragments, shells and gravel.

The overburden, consisting of the abovementioned heterogeneous deposits, varies approximately from 14m to 35m. The hydraulic head varies along this portion between 3 and 18 m. The hydraulic conductivity of the soils is highly variable ranging from very low to very high (10-9 to 1 cm/s).

Table 1. Tunnel reaches and expected geology.

Reach	Length [m]	Geology
1	3900	Lakewood, San Pedro Sand
2	180	San Pedro Sand, Timms Point Silt, Alluvium
3	1700	San Pedro Sand, Alluvium, Timms Point Silt

2.2 TBM technical specifications

The 6585 mm dia. Mixshield TBM shown in Figure 2 was designed and manufactured for the specific project conditions. The key technical specifications are summarized in Table 2.

Table 2. TBM specifications.

Type	Mixshield TBM
Bore Ø	6585 mm
TBM Length	13 m
Operating Pressure	Max: 10 bar
Cutterhead Speed	0-3.8 rpm
Torque	Nominal: 4.5 MNm; Breakout: 5.6 MNm
Cutter Type	17" – 18"
No. Cutters	40
Thrust per Cutter	267 kN
Thrust Force	Nominal: 79 MN; Max: 158 MN
Total Length	242 m
Min Curve Radius	240 m

Figure 2. Mixshield TBM “Rachel” being assembled at the Carson launch shaft.

2.3 Main geotechnical hazards

Based on the anticipated tunnelling conditions, the potential geotechnical hazards identified in the pre-excavation phase in this portion of the alignment are summarized in Figure 3:

- Face instability, blow-up, and large settlements: Main hazard scenarios to be expected when tunneling through low cohesion soil with low overburden in urban environment. To mitigate these risks, the TBM is to be operated in pressurized mode within the operational ranges of support pressure determined in the design phase, based on the quantitative assessment of these risks.
- Clogging: The excavated material, at its natural moisture content, may stick to the steel of the cutterhead and cutting tools obstruct muck flow and machine advance. This phenomenon, commonly referred to as “clogging”, leads to the wear of the cutterhead and muck handling system, causing downtimes and economic loss. The clogging potential of a material increases with increasing clay content. The risk of clogging can be mitigated by frequent cutterhead cleaning and by introducing ground conditioners.
- Mixed face: During excavation in mixed face conditions, low advance rates can be experienced. Excessive or uneven wear of the cutting tools and, in the worst case, damages to the cutterhead may be caused by strength contrast between softer and harder layers, with impact loading of tools and eccentric/asymmetrical loading of the head.
- Boulders and cobbles: Boulders may jam against the cutterhead openings first and against the rock crusher second, making the muck handling process, out of the excavation chamber more difficult. Boulders and cobbles may lead to severe wear of the cutterhead, tools and tool mountings, as well as generate local instability in case of over-excavation, frequent stops for maintenance works, downtimes and economic loss.

- Inflow of hydrocarbons, gasses or abandoned oil wells: The tunnel alignment develops across known active and dormant oil fields (Torrance Field and Wilmington Oil Field). Oil well removal as well as gassy conditions management may be very time consuming and expensive. Based on this, the tunnel was classified as “gassy”, with direct impact on TBM and ancillary equipment specifications.

These risks are discussed in more detail in Schuerch et al., RETC 2023 along with possible impacts on TBM performances and mitigation measures. As a result, the Tunneling Operational Plan (TOP) was developed to provide recommendations on the TBM operation alongside with a flowchart to assist the Contractor in the decision-making process (i.e., Decision Making Tree). This tool allows a timely reaction to any deviation of the encountered conditions from the ones assumed in the design, through the early assessment of the geological conditions during advance (Tamburri et al., RETC 2019, Schuerch et al., RETC 2023).

3 CONSTRUCTION OF THE EFFLUENT OUTFALL TUNNEL

3.1 Overview of the construction progress

The construction progress through the northern portion of the alignment is shown in Figure 4. The TBM excavation started with umbilical’s (Karlin, RETC 2023) on September 27, 2021 and reached Sta 195+50 on November 8, 2023. On November 10, 2021, after installation of 75 rings, the advance was paused to add back-up gantries no.2 to no.9, perform all electric and hydraulic connections, and test/commission the whole system. On January 10, 2022 the advance was intermittently resumed to allow progressive installation of back-up gantries no.10 to no.18 and perform final field testing and commissioning. TBM launching and commissioning was officially completed in correspondence of ring no. 161 (Sta 8+25), on February 17, 2022.

Total tunnel excavation duration was 110 weeks (773 days). Figure 4 shows monthly, weekly and daily production. The overall average advance rate was 7.5 m/day.

24 x 1.5m advances were completed on the best day, 101 in the best week, and 302 in the best month.

A total of 12 interventions (9 hyperbaric and 3 under atmospheric conditions in improved ground areas – “safe havens”) were performed along this portion of the alignment.

3.2 Encountered geological conditions

The encountered geological conditions were mainly assessed based upon the observations of the muck (Figure 5) at the Slurry Separation and Treatment

Plant (STP) and excavation face inspections. In general, sand with clay and silt in variable amount were observed all along the alignment. Locally, presence of crushed rock (sandstone, mudstone) and Alluvium was encountered.

3.3 TBM operations

With respect to the potential geotechnical hazards identified in the design phase, Figure 3 shows the main challenges encountered during advance:

- Clogging between Sta. 10+50 and 27+00: The clayey component of the ground progressively clogged the cutterhead causing the blockage of numerous disc cutter bearings and obstruction of the cutterhead openings. This generated rapid and excessive wear of all components exposed to the ground and frequent stoppages for maintenance. The adopted countermeasures included: addition of anti-clogging polymers; frequent stoppages to clean the cutterhead from the accumulated muck; reduction of the thrust force and advance speed to lower the flow rate of excavated material.
- Jamming of the articulated tail shield: High thrust force levels were observed between Sta. 40+50 and 69+70. Within this area, recurrent issues with the tail shield advancement were experienced, with frictional forces exceeding the capacity of the passive articulation cylinders. The adopted countermeasures included: bentonite injection through radial ports; tail shield vibration; increase of face pressure; installation and utilization of 4 auxiliary hydraulic cylinders to advance the tail shield.
- High wear: no significant/excessive cutter wear was observed, generally being higher in Reach 3 than in Reach 1.
- Inflow of hydrocarbons and/or toxic/explosive gas: low level readings of hydrocarbon in slurry and benzene in muck pile at STA 124+45. In general, either no gas was encountered, or the slurry system managed to keep it within the pipelines (with no dispersion in the tunnel environment).
- Boulders and cobbles, other obstructions: no unknown objects were encountered during the drive, and generally no significant cobbles or boulders.

The more relevant TBM performance parameters are discussed in the following paragraphs based on the analysis of the TBM data and geotechnical monitoring data presented in Figure 6.

3.3.1 Advance rate

Figure 6a shows the net advance rate (in mm/min) along the northern portion of the alignment. For most of the drive (approximately 54% between Sta. 25+00 and 130+00), it was in the high range of 40-80 mm/min. The maximum advance rate was governed by the maximum

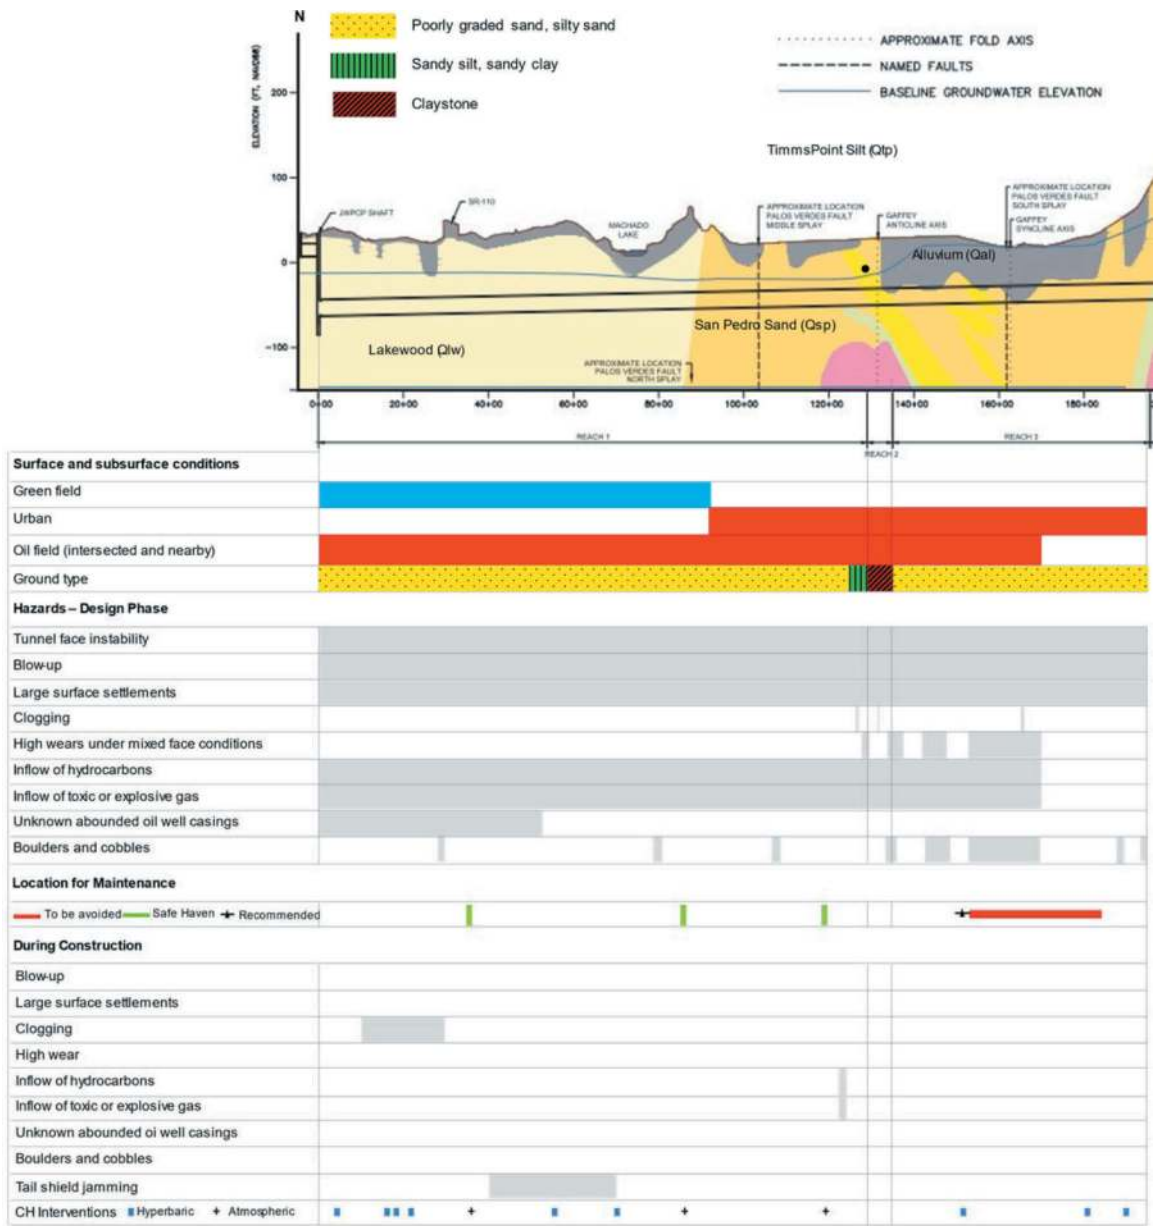

Figure 3. Expected hazards without considering support pressure for the northern section identified in the design (Schuerch et al., RETC 2023) Vs. Actual challenges encountered during excavation (Sta. 0+00 to 195+50).

muck-out capacity of the slurry circuit and the STP. The advance rate was in general lower, in the 20-60 mm/min range, over approximately 41% of the alignment, at the beginning of the excavation up to Sta. 25+00 and again along the last 1675 metres between Sta. 140+00 and 195+00. The lowest advance rate values, down to 8 mm/min, were recorded between Sta. 130+00 and 140+00 where mixed face conditions (soils and crushed rock) were encountered.

3.3.2 Face pressure

Figure 6b shows the face pressure applied during advance along the northern portion of the alignment. The operational range defined in the design phase is also indicated in the chart. The recommended

pressures (green line) were defined as target values to compensate groundwater pressure and to avoid face instability and large surface settlements. During operation, the applied face pressure was consistently kept in line or above target but always below the defined maximum limit (red dashed line) determined in the design phase to avoid blow-up. In particular, between Sta. 160+00 and 180+00 where the allowed operational range was extremely narrow (i.e., min 0.1 bar), the TBM operators carefully managed to always keep the face pressure within the recommended upper/lower limits. As shown in Figure 6.e, the ability to accurately control the face pressure kept surface settlements even below the predicted values (i.e., settlements of 4 to 10 mm).

Figure 4. JWPCP Effluent Outfall Tunnel Northern Drive – Daily, Weekly, and Monthly Production charts.

Figure 5. Pictures of the muck (sand; shell fragments).

3.3.3 Thrust force

Figure 6c shows the total thrust measured during advance along the northern portion of the alignment along with the required thrust estimated in the design phase (15-18 MN). In line with design estimations, the total thrust was measured below 20 MN along most of the alignment except:

- between Sta. 2+00 and 18+00, in part due to cutterhead clogging issues;
- between Sta 40+00 and 70+00, mostly due to higher frictional resistance along the shields, up to jamming of the tail shield;
- between Sta. 180+00 and 185+00 possibly due to mixed face with Alluvium.

Nevertheless, the total thrust was always well below the TBM installed nominal capacity of 79 MN.

3.3.4 Cutterhead torque

Figure 6d shows the cutterhead torque measured during advance along the northern portion of the alignment. With the rotation speed being set at 3 rpm almost over the entire stretch, the measured torque was mainly below the maximum nominal torque of 3.5 MNm. The highest torque was measured

between Sta. 170+00 and 190+00, where Alluvium was encountered at the tunnel elevation, and between Sta. 10+50 and 27+00 where challenges related to cutterhead clogging were experienced.

When filled with sticky ground the head tends to become heavier to turn for the main drive. Moreover, an uneven distribution of this additional weight (by buckets, pockets, or entire quadrants more clogged than others) would shift the cutterhead centre of gravity and generate eccentric loading. In this scenario, the head requires more effort for rotation and generates unsteady load patterns on main drive motors and frequency converters.

3.3.5 Surface settlements

Figure 6e shows the surface settlements estimated in the design phase for the northern portion of the alignment and the actual vertical displacements measured with the multipoint borehole extensometers installed along the alignment. A1, A2 and A3 indicate the three rods of the instrument installed at different depths.

In the design phase, the assessment of the expected settlements was performed by means of analytical calculations taking into account two different values of volume loss: 0.3% as expected conditions (black line) and 0.5% as conservative assumption (red line). The abovementioned values of volume loss were set according to literature and verified by means of numerical analysis for the most critical sections identified along this portion of the alignment.

The actual ground movements were mainly below the expected values and always below the conservative assumption. The back-analysis of the measured settlements indicates a maximum volume loss of 0.35% and a minimum volume loss of 0.01% with an average of 0.1% that is significantly lower than the one assumed for the design.

Figure 6. Main TBM operation parameters and geotechnical monitoring data (Sta. 0+00 to 195+50).

The data monitored during advance show in general small ground deformations over the entire tunnel stretch:

- ≤ 3.3 mm for A1,
- ≤ 4.3 mm for A2,
- ≤ 6.35 mm for A3.

These values are mainly below the “Warning Level I” for extensometers and always below the “Maximum Level”, defined as follows:

- Warning Level I: Relative vertical movement of 2mm for anchors A1; Relative vertical movement of 6mm for anchors A2; relative vertical movement of 23 mm for anchors A3.
- Warning Level II: Relative vertical movement of 3 mm for anchors A1; Relative vertical movement of 9 mm for anchors A2; relative vertical movement of 25 mm for anchors A3.
- Maximum Level: Relative vertical movement of 4mm for anchors A1; Relative vertical movement of 12mm for anchors A2; relative vertical movement of 36mm for anchors A3.

3.3.6 Annular grout

Mainly three (two upper ports and one below springline) out of five ports were consistently used to uniformly inject bicomponent (A+B) grout in the annular gap. Figure 7 shows the total grout volume injected at every ring from all the active ports along with target values. The green line indicates the target volume of 7.3 m^3 or 7,300 liters, as defined in the pre-excavation phase according to the expected conditions. From Sta. 46+90 to 125+00 a revised target volume was defined, reduced to account for a narrower annular gap around the segmental lining and to mitigate the risk of cementation of the tail shield. The red line shows the lower bound that corresponds to the volume in case of full closure of the tail shield gap. The injected grout volumes were consistently on or close to the theoretical target, and well above the minimum recommended value. Proper control of the injected grout volume concurred to the low settlements observed on surface and subsurface.

3.3.7 Quality of the slurry

The functions of the slurry in TBM tunneling are to support the tunnel face and wall, to control groundwater, to lubricate the cutterhead and the muck-out system, to carry the muck in suspension, to facilitate the separation of the muck. The bentonite is used to ensure the micro-stability of the soil grains and to seal the tunnel face in order to transfer the support pressure onto the soil skeleton. To seal the tunnel face, the bentonite slurry has to infiltrate the soil and form a filter-cake.

The quality of the slurry is constantly verified by monitoring specific properties (e.g., density, yield

Figure 7. Total grout volume during TBM advance.

point, sand content) and performances. The used bentonite is adjusted by discharging part of it and by adding fresh bentonite or water in order to fulfil the target values of the bentonite slurry parameters.

Figure 8 shows the density of the slurry (feed and return lines) along the northern portion of the alignment and compares it with the target values defined in the design phase (min-max thresholds in red, target range within the green lines). It can be observed that the density in the return line was consistently above the maximum target value of 1.15 t/m^3 . The local drops below the red-line were usually measured immediately after cutterhead interventions. After treatment at the STP, the density in the feed line was more often lower than 1.15 t/m^3 . Nonetheless, the density of the slurry resulted being clearly higher than target range defined in the design phase, possibly due to the higher-than-expected amount of fines in the soil matrix.

Figure 8. Density of the slurry during TBM advance.

4 CONCLUSIONS

The northern portion of the new JWPCP Effluent Outfall Tunnel, for a length of 5,960 m, was excavated through soft ground in a highly urbanized area

at low overburden (14 to 35m). Despite the challenges identified in the design phase, the Mix-shield TBM tunneling was successful, also due to the Contractor's ability to operate the TBM within the face pressure ranges and backfill grout volume ranges recommended during the design stage. This resulted in no impacts on existing surface and subsurface structures and utilities, also at very shallow covers (as low as two tunnel diameters at some location). Ground movements were below 5mm for most of the drive and well within the tolerances allowed by contract. However, the heterogeneous nature of the ground, at times, enhanced some of the predicted hazards (i.e., clogging and jamming) to a magnitude or severity that required proactive TBM data analysis, parameters adjustments and specific countermeasures promptly implemented in the field to mitigate impacts on estimated advance rates and project schedule.

A review of deterministic approaches in the performance evaluation of Raise Boring Machines (RBMs)

Aydin Shaterpour-Mamaghani*

Geological Engineering Department, Istanbul Technical University, Istanbul, Turkey

Hanifi Copur, Cemal Balci & Deniz Tumac

Mining Engineering Department, Istanbul Technical University, Istanbul, Turkey

ABSTRACT: The raise boring technology was initially developed to meet the requirements of the underground mining sector. However, it was also found extensive application in infrastructure projects, including tunnelling for ventilation and the excavation of deep shafts. The selection and precise performance prediction of Raise Boring Machines (RBMs) during the feasibility (planning) stage of a shaft excavation project are crucial for project budgeting and scheduling. The ability to accurately predict and optimize RBM performance leads to more realistic planning that reduces overall shaft excavation costs. Deterministic approaches are one of the most widely used methods to predict the performance of mechanical miners such as RBMs. Deterministic models offer a more detailed and precise approach to performance prediction by considering various parameters. However, they rely heavily on accurate and adequate input data and initial conditions to produce reliable outputs. This paper aims to review the deterministic models used for predicting the operational and performance parameters of RBMs. The applicability of the available models is discussed and examples are presented for field validation.

Keywords: Shafts, Raise boring machines, Performance prediction, Deterministic model

1 INTRODUCTION

The excavation of tunnel and shaft with mechanical miners has been increasing around the world. These equipments provide two significant advantages over the conventional methods as cutting down the time of tunnel/shaft construction and creating safe working conditions. Raise Boring Machine (RBM) is one of the mechanical miners that is commonly used in mining and construction projects for excavation of shafts. These machines offer an economic, safe, and rapid excavation operation compared to other excavation methods. However, capital cost of these machines is high; assembly and disassembly time could be long in some cases (Shaterpour-Mamaghani et al., 2023).

Ability of the operator and prediction of RBM performance are two crucial aspects significantly affecting shaft construction uncertainty. Performance and success of an RBM is influenced by various variables. One of these variables is the geological and geotechnical characteristics of drilled or excavated rocks. Other variables include RBM related mechanical features and operational parameters (available thrust and torque, reamerhead rotational speed, etc.)

and technical-environmental parameters (Shaterpour-Mamaghani and Copur, 2017).

Early studies on RBM performance attempted to predict performance based on physical-mechanical properties of the drilled or excavated core samples, as well as the results of indentation tests conducted on the samples (Morris, 1969; Bilgin, 1989; Breeds and Conway, 1992; Dollinger et al., 1998; Shaterpour-Mamaghani et al., 2016, 2018, 2023; Shaterpour-Mamaghani and Copur, 2021). However, the research on performance prediction of RBMs based on rock cutting tests, which provide essential data for deterministic prediction of excavation performance, is limited. Deterministic performance prediction based on full-scale linear rock cutting tests is the most commonly used and more reliable method among the many other prediction methods such as empirical, theoretical, computer simulation, testing a prototype machine in laboratory, and in situ testing of a real machine (Copur et al., 2014; Bilgin et al., 2014). Takaoka et al. (1973) investigated cutting performance of spherical and gear type cutters (with a constant load type rotary cutting test device) on a granite and two andesite rocks at different vertical forces and

*Corresponding author: mamaghani@itu.edu.tr

indicated that for both cutters, the depth and width of the grooves increased as the vertical force increased. Lindqvist (1982) investigated the cutting characteristics of two different single disc cutters (9 mm of blunting radius for regular edge single disc cutter and 9 mm of concave blunting radius of disc cutter) and a three-row button cutter (having hemispherical inserts with 18 mm of diameter and 60 mm of kerf spacing) during cutting tests (in single-spiral pattern on conditioned rock surface) on the fine to medium grained granite with 188 MPa of uniaxial compressive strength. He mentioned that optimum depth of cut in combination with smooth side chipping would increase the utilization of available thrust and torque, but also would decrease vibrations and pulse on inserts, cutters, cutterhead, and boring unit. Savidis (1982) performed cutting tests at static and dynamic rates of loading, using spheres and model cutters equipped with buttons on the sandstone, marble, and granite samples. He stated that in the marble and granite samples, optimum spacing to penetration ratio was almost constant for all levels of pitch; therefore, wider button spacing required deeper penetration to achieve a similar level of efficiency. Shaterpour-Mamaghani et al. (2022) discussed the full-scale linear cutting characteristics of the single slice (row) of a real-life multi-row button cutter used with RBMs in double-spiral cutting pattern on five different rock samples and suggested two deterministic approaches (direct and indirect) to predict operational and performance parameters of RBMs; they also proved that a real-life multi-row (multi-kerf) button cutter could be simulated by using only one row of a multi-row button cutter so that the force limitation of the cutting test equipment was overcome.

The main purpose of the current study is to summarize the basic concepts of deterministic models used for estimating performance of RBMs. Some performance estimation examples are also presented by using these methods.

2 BASIC CONCEPTS OF DETERMINISTIC MODELING

Deterministic modeling is a mathematical approach used to describe and analyse systems or processes where outcomes are entirely predictable and certain, given specific inputs and conditions. In deterministic modeling, there is no randomness or uncertainty involved, and the results are based on precise mathematical or physical relationships.

One of the earlier deterministic models was introduced for hard rock Tunnel Boring Machines (TBMs), (Rostami and Ozdemir, 1993). Copur et al. (2014) used a stochastic model implemented into a deterministic model to predict performance of earth pressure balance TBMs using full-scale linear cutting test to predict instantaneous penetration and cutting rates of the constant cross section and/or V-type disc cutters. In addition, Shaterpour-

Mamaghani et al. (2022) used the deterministic methodology given in Rostami and Ozdemir (1993) and Copur et al. (2014) to predict performance of RBMs. This direct deterministic concept is based on directly the full-scale linear cutting tests (limiting or restrictive normal and rolling forces). The details of this deterministic concept are summarized below.

Total thrust ($FT_{cutting}$) (in kN) required for penetrating a cutter into a rock body can be estimated by Equation (1):

$$FT_{cutting} = FN \times N_{cutter} \times f \quad (1)$$

where, FN is average normal force obtained from the full-scale linear cutting tests at optimum cutting conditions (kN), N_{cutter} is the total number of cutters on the reamerhead (it can be taken as total number of rows in this case) and f is a constant related to friction between cutting tool-reamerhead and the excavated rock, and it can be taken as 1.0 for RBMs, since all the cuttings (debris, excavated material) fall down by gravity without causing any important friction on the reamerhead.

The reamerhead net torque requirement ($Tq_{cutting-net}$) (in kNm) can be estimated by Equation (2):

$$Tq_{cutting-net} = FR \times N_{cutter} \times f \times \left(\frac{D_{RBM}}{4} \right) \quad (2)$$

where, FR is average rolling force obtained from the full-scale linear cutting tests at optimum cutting conditions (kN), D_{RBM} is reamerhead diameter (m), and the other parameters are as defined above.

The total net power requirement ($P_{total-net}$) of the RBM reamerhead at optimum cutting conditions (in kW) can be estimated by Equation (3):

$$P_{total-net} = 2\pi \times Tq_{cutting-net} \times \left(\frac{RPM}{60} \right) \quad (3)$$

where, RPM is reamerhead rotational speed (in rpm) and the other parameters are as defined above. RPM can be estimated by Equation (4):

$$RPM = \frac{V_{max}}{\pi \times D_{RBM}} \quad (4)$$

where, V_{max} is maximum allowable cutter speed (for gauge/corner cutter) (m/min).

Different RBM manufacturers may suggest different rotational speeds for reamerheads. Sandvik company recommends maximum RPM based on reamerhead diameter and rock characteristics. For example, it was recommended to use 10 rpm (which gives 75 m/min linear rotational speed) for reamerhead with 2.44 m diameter (Sandvik catalogue). Atlas Copco recommends that the maximum rotational speed should be peripheral speed of the head under 107 m/min (350 ft/min) (Brooke, 2008). Liu

and Meng (2015) stated that speed of side (corner) cutters in reamerhead had to be controlled at 0.7-1.0 m/s. In this study, 10 rpm of the rotational speed is assumed and used for the example calculations given in the next section.

Total consumed (gross) power requirement of the reamerhead ($P_{consumed}$) (in kW) is estimated by Equation (5):

$$P_{consumed} = \frac{P_{total-net}}{\eta} \quad (5)$$

where, η is system efficiency factor of reamerhead rotation motor and is assumed and used 0.85 in this study.

The instantaneous penetration rate (IPR) of RBMs (in m/h) can be estimated by Equation (6):

$$IPR = d_R \times RPM \times \frac{60}{1000} \quad (6)$$

where, d_R is depth of cut per revolution (mm/rev) giving the optimum specific energy for a certain (constant) line spacing, and RPM is rotational speed of reamerhead (rpm).

Indirect deterministic concept is another method that can be used to predict performance of RBMs. It is not always possible to perform full-scale linear cutting tests due to some difficulties such as obtaining large blocks of rock samples from the site, extensive time consumption for experiments and costly experiments, as well as requirement of skilled-trained personnel to run the tests. To overcome these problems, the relationships between rock properties and cutting parameters obtained from the full-scale linear cutting tests can be indirectly used as input in the direct deterministic model, which is called indirect deterministic approach in this study. Shaterpour-Mamaghani et al. (2022) suggested some empirical models (Equations 7-11) based on the relationships between physical-mechanical properties of the rocks and normal force (FN), rolling force (FR), FR/FN, specific energy (SE), and ratio of line spacing to depth of cut per revolution (s_L/d_R) found at optimum cutting conditions. In these equations the FN and FR values are normalized by d_R values obtained at the optimum cutting conditions.

$$\left(\frac{FN}{d_R}\right)_{opt} = 0.00003 \times UCS^{2.858} R^2 = 99\% \quad (7)$$

$$\left(\frac{FR}{d_R}\right)_{opt} = 0.014 \times (UCS \times BTS)^{0.759} R^2 = 98\% \quad (8)$$

$$\left(\frac{FR}{FN}\right)_{opt} = (-0.001 \times UCS) + 0.284 R^2 = 91\% \quad (9)$$

$$SE_{opt} = 0.35 \times (UCS \times BTS)^{0.83} R^2 = 98\% \quad (10)$$

$$\left(\frac{s_L}{d_R}\right)_{opt} = 0.00001 \times UCS^{2.711} R^2 = 98\% \quad (11)$$

3 CASE STUDIES

The results of physical-mechanical property tests, full-scale linear rock cutting tests, and field measurements from some shaft excavations by RBMs given by Shaterpour-Mamaghani et al. (2022) are used to evaluate the deterministic performance prediction models. In Shaterpour-Mamaghani et al. (2022), five rock samples with different geological origins were used in the investigation. The uniaxial compressive strength of the tested samples varied between 77.90 and 130.67 MPa. Moreover, the Brazilian (indirect) tensile strength of the tested samples ranged from 4.90 to 11.09 MPa.

Shaterpour-Mamaghani et al. (2022) mentioned that Sandvik Rhino 1088DC RBM was used in the investigated raise boring projects. Rhino 1088DC RBM is a hydraulically driven rig with maximum 4,000 kN operating thrust. The machine is capable of operating at a torque of 300 kNm in pilot hole drilling and 160 kNm in reaming operation. The reamerhead diameter of this RBM was 2.44 m and equipped with 14 multi-row button cutters. Seven cutters consist of five rows of tungsten carbide inserts and another seven cutters consist of four rows of tungsten carbide inserts (Figure 1). Multi-row button (carbide-insert) cutters (with steel kerfs) with row spacing of around 30-60 mm (with arithmetic average of 45 mm) was used in the RBM. CMR41 (four-row) and CMR52 (five-row) cutters were used as a pair with 180° circumferential (angular) spacing on the reamerhead. The row spacing value sets the cut spacing, while its half is the line spacing. Thus, cutting pattern of the cutters on Rhino 1088DC was double spiral, as its details are described in Copur et al. (2017). Spacings (pitch) between the inserts on a row vary from the inner rows to the outer rows to prevent tracking. Total number of the inserts having a diameter of 22.2 mm in a cutter are 104/four-row-cutter + 128/five-row-cutter (as a pair).

Figure 1. Reamerhead, four and five rows cutters of Sandvik Rhino 1088DC RBM.

The thrust capacity/limit of the cutters used with the RBM (which is a durability limit for the cutters as being important for cutter life) and torque capacity/limit of the RBM reamerhead are considered in the performance prediction. The achievable maximum

depth of cut per revolution is calculated for a certain rock by using these limit values and the force-depth of cut relationships obtained from the full-scale linear cutting tests stated in Shaterpour-Mamaghani et al. (2022). Sandvik company recommended 265 kN/cutter (27 tonnes/cutter) as maximum operating cutter load (Sandvik catalogue). By considering this recommendation, the limiting FN value for average thrust per row is obtained to be 53.0 kN/row (265 kN/cutter/5 rows/cutter). By using torque capacity of the machine (160 kNm) and Equation (2), the limiting FR value is obtained to be 18.74 kN/cutter, and 3.75 kN/row (considering 5 rows). The 5 rows in a cutter is taken into consideration instead of 4 rows, since the maximum force is critical for durability of the 5-row cutters.

By using the limiting FN and FR values as well as force-depth of cut equations (FN- d_R and FR- d_R) mentioned in Shaterpour-Mamaghani et al. (2022) and given in Table 1, it is possible to calculate the achievable maximum depth of cut for each rock. The results of these calculations are summarized in Table 2. It should be noted that the d_R values estimated in Table 2 are not the values obtained at optimum cutting conditions; they are lower than that of the ones obtained at optimum cutting conditions. Then, the smaller depth of cut value limiting either normal force capacity or rolling force capacity is selected for calculation of the instantaneous penetration rate by using Equation (6) for all of the rocks and assuming a rotational speed of 10 rpm as recommended by Sandvik company.

Table 1. Force-depth of cut equations of the investigated rocks (Shaterpour-Mamaghani et al., 2022).

Rocks	FN (kN/row)	FR (kN/row)
Granodiorite	$FN = 48.10 \times d_R^{0.53}$	$FR = 2.05 \times d_R^{1.25}$
Diabase	$FN = 58.55 \times d_R^{0.47}$	$FR = 2.74 \times d_R^{1.13}$
Skarn	$FN = 27.83 \times d_R^{0.51}$	$FR = 2.14 \times d_R^{0.88}$
Limestone-1	$FN = 26.22 \times d_R^{0.55}$	$FR = 2.07 \times d_R^{0.87}$
Limestone-2	$FN = 16.43 \times d_R^{0.67}$	$FR = 0.67 \times d_R^{1.28}$

FN normal force per row, FR rolling force per row.

Table 2. Calculated achievable maximum depth of cut values and deterministically predicted instantaneous penetration rates based on the limiting force values.

Rocks	d_R (mm/rev) *		IPR (m/h)
	Based on FN	Based on FR	
Granodiorite	1.20	1.62	0.72
Diabase	0.81	1.32	0.49
Skarn	3.54	1.89	1.13
Limestone-1	3.60	1.98	1.19
Limestone-2	5.74	3.84	2.30

* Bold values of d_R are used for calculation of IPR. d_R depth of cut per revolution, IPR instantaneous penetration rate.

By considering the limiting depth of cut values obtained based on the force-depth of cut equations (bold values in Table 2) and using Equations 1, 2, 3 and 5, the total thrust, torque, net and consumed power requirements of the reamerhead can be calculated. For example, as seen in Table 2, the maximum achievable depth of cut is obtained as 0.81 mm/rev in the diabase sample by use of FN- d_R equation, which is smaller than the depth of cut value of 1.32 mm/rev obtained based on FR- d_R equation. In this case, for obtaining total thrust ($FT_{cutting}$), FN (kN/row) is first calculated by using FN- d_R equation given in Table 1 for 0.81 mm/rev depth of cut value; then, $FT_{cutting}$ is estimated by using Equation (1) as shown below for diabase sample:

$$FT_{cutting} = FN \times N_{cutter} \times f = 53 \times ((5 \times 7) + (4 \times 7)) \times 1 = 3,339kN$$

where, 5×7 part of the equation indicates 7 cutters with 5 rows and 4×7 indicates 7 cutters with 4 rows, giving totally 63 rows for 14 multi-row cutters in the reamerhead. In addition, for estimating reamerhead torque ($Tq_{cutting-net}$), FR (kN/row) is calculated as being 2.16 kN/row for 0.81 mm/rev based on FR- d_R equation for the diabase sample given in Table 1. Then, $Tq_{cutting-net}$ is estimated by using Equation (2) as shown below for diabase sample:

$$Tq_{cutting-net} = FR \times N_{cutter} \times f \times \left(\frac{D_{RBM}}{4} \right) = 2.16 \times (5 \times 7 + 4 \times 7) \times 1 \times \frac{2.44}{4} = 83.0 kNm$$

Equation (3) is used to estimate the total net power ($P_{total-net}$). When estimating the gross (consumed) power requirement of the reamerhead ($P_{consumed}$) as in Equation (5), $P_{total-net}$ value is divided by the efficiency factor η that is assumed to be 0.85 in this study. The results of these estimations are summarized in Table 3 for all of the rocks. As seen, the thrust (4,000 kN) and torque (160 kNm) capacities of the RBM are not exceeded.

Table 3. Estimated operational parameters of RBM by using direct deterministic method.

Rocks	$FT_{cutting}$ (kN)	$Tq_{cutting-net}$ (kNm)	$P_{total-net}$ (kW)	$P_{consumed}$ (kW)
Granodiorite	3,339	99	104	122
Diabase	3,339	83	87	102
Skarn	2,426	144	151	177
Limestone-1	2,404	144	151	177
Limestone-2	2,549	144	151	177

$FT_{cutting}$ reamerhead total thrust, $Tq_{cutting-net}$ reamerhead net torque requirement, $P_{total-net}$ reamerhead total net power requirement, $P_{consumed}$ reamerhead consumed (gross) power requirement

Another example here is given based on the indirect deterministic performance estimation concept. If diabase sample having a uniaxial compressive strength of 130.67 MPa and a tensile strength of 7.81 MPa is considered, the normal and rolling forces normalized by the depth of cut per revolution are obtained as 33.51 kN/row/mm/rev and 2.69 kN/row/mm/rev by using Equations (7-8), respectively. Then, by using limiting cutter normal and rolling forces ($F_N = 53.0$ kN/row and $F_R = 3.75$ kN/row, respectively), the maximum depth of cut values are calculated as shown below:

$$d_R = (53\text{kN/row})/(33.51\text{kN/row/mm/rev}) \\ = 1.58\text{mm/rev}$$

$$d_R = (3.75\text{kN/row})/(2.69\text{kN/row/mm/rev}) \\ = 1.39\text{mm/rev}$$

As seen, the achievable maximum depth of cut per revolution for diabase is obtained as 1.39 mm/rev, which is the limiting value for the torque and smaller than the d_R value (1.58 mm/rev) limiting the cutter thrust. Then, the instantaneous penetration rate is obtained by using Equation (6) as 0.84 m/h for 10 rpm rotational speed. In addition, by considering 1.39 mm/rev of depth of cut per revolution and using Equations (7-8), the normal and rolling forces are obtained as 46.58 kN/row and 3.74 kN/row, respectively, as shown below:

$$\left(\frac{F_N}{1.39}\right) = 33.51 \text{ kN/row/mm/rev} \rightarrow F_N = 46.58 \text{ kN/row}$$

$$\left(\frac{F_R}{1.39}\right) = 2.69 \text{ kN/row/mm/rev} \rightarrow F_R = 3.74 \text{ kN/row}$$

Finally, by using Equations (1, 2, 3, 5), operational parameters of the RBM are calculated. The results of indirect deterministic estimations by implementing the relationships between the rock properties and linear cutting performance parameters are summarized in Table 4.

Table 4. Estimated operational-performance parameters of RBM by using indirect deterministic method.

Rocks	IPR (m/h)	$F_{T_{cutting}}$ (kN)	$T_{q_{cutting-net}}$ (kNm)	$P_{total-net}$ (kW)	$P_{consumed}$ (kW)
Granodiorite	0.76	1,415	144	151	178
Diabase	0.84	2,934	144	150	177
Skarn	1.39	1,596	144	151	177
Limestone-1	1.63	1,505	144	151	178
Limestone-2	1.76	1,410	144	151	178

IPR instantaneous penetration rate, $F_{T_{cutting}}$ reamerhead total thrust,

$T_{q_{cutting-net}}$ reamerhead net torque requirement,

$P_{total-net}$ reamerhead total net power requirement, $P_{consumed}$ reamerhead consumed (gross) power requirement

When the results of the direct and indirect deterministic performance estimation concepts are compared with the field results mentioned in Shaterpour-Mamaghani et al. (2022), a certain difference is seen between the field performance (unit penetration, instantaneous penetration rate) and operational parameters (thrust, torque, power). As stated by Shaterpour-Mamaghani et al. (2022), these differences are due to the different physical-mechanical (intact) properties of the rocks and the rock mass characteristics (especially existence of joints and fractures) between the samples tested by the full-scale linear cutting and the rock mass excavated in the field at the shaft locations. Massive (joint-free, competent with RQD of 100%) rock blocks were used in the full-scale linear cutting tests, while the rock masses excavated in the shafts have usually some joints and fractures that would also generate a difference and a discrepancy on the predictions.

Another reason for deviations between the predicted and realized (field) performance is the applied levels of the operator dependent parameters in the field, especially reamerhead rotational speed. The operators applied around 3.5-4.0 rpm in the field, while it is assumed in this study that the reamerhead rotational speed is 10 rpm as suggested by the RBM manufacturer. Therefore, these issues generating deviations on the predictions should be properly managed to obtain more precise and reliable predictions. The effects of strength values on the predictions are taken into consideration if the deterministic method by implementing the relationships between rock properties and cutting parameters obtained from full-scale linear cutting tests are used. However, the effect of rock mass characteristics and rotational speed of reamerhead should also be taken into consideration.

Among the tested samples in Shaterpour-Mamaghani et al. (2022), the limestone-2 sample looks like massive or without too much fractures (with high RQD value). The only difference between the core samples and block samples are the uniaxial compressive strength and Brazilian tensile strength (Table 5).

Table 5. Geotechnical properties of the limestone-2 core and block samples.

Samples	RQD (%)	Uniaxial Compressive Strength (MPa)	Brazilian Tensile Strength (MPa)
Core Sample	89 (field)	115.8	5.41
Block Sample	100 (block)	77.90	4.90

It is seen that the unit penetration is well predicted for the limestone-2 sample by the indirect deterministic model. In Equation (6), if an RPM value of 3.8 rpm as in the field application is used instead of 10 rpm along with a predicted d_R value of 2.93 mm/rev, an IPR value of 0.67 m/h is obtained. This indicates that the model suggested in this study works very well for predicting unit penetration and instantaneous penetration rate of

massive rock masses. However, the predicted values of the operational parameters (FT_{cutting} , $Tq_{\text{cutting-net}}$, and P_{consumed}) deviate from the realized field parameters, which requires further investigations in future. The influence of joints within the rock mass on predictions should also be further investigated.

4 CONCLUSIONS

There are quite limited studies on performance prediction of RBMs based on the deterministic model. In this study, some of the recent literature on deterministic performance estimation are summarized. In addition, the direct and indirect deterministic concepts of Shaterpour-Mamaghani et al. (2022) are discussed with examples.

The direct deterministic method (based on limiting normal (thrust) and rolling (torque) forces) uses directly results of the full-scale linear cutting tests if a large block rock sample (~50x60x80 cm) is obtained at the same location of the excavated shaft. The indirect deterministic method uses the statistical relationships between the physical-mechanical properties of rocks and the tool forces obtained from the full-scale linear cutting tests if any large block of rock sample is not obtained (only core samples are available).

It is seen that the direct and indirect methods of deterministic performance estimations for RBMs are reliable methods for especially unit penetration and instantaneous penetration rates within the limits of the available data. However, an improvement is needed for predicting thrust force and torque as well as consumed power parameters of RBMs.

ACKNOWLEDGMENTS

This study summarizes some of the results of PhD study carried out by Aydin Shaterpour-Mamaghani. The authors are grateful to the Scientific and Technological Research Council of Turkey (TUBITAK) for their financial support in Project MAG-217M729. The contributions of Esan Eczacıbaşı (Balya lead-zinc mine), DSI (State Hydraulic Works), Joint-venture Limak-Cengiz-Kolin and Sargin Construction and Machinery Industry Trade Inc are acknowledged, without whom this study could not be accomplished.

Distinctive considerations in the design and construction of large diameter TBM-built tunnels in urban environment – a UK perspective (ID: 379)

Si Shen*

TYPSA UK & Ireland, London, UK

ABSTRACT: Large diameter TBM-built tunnels, particularly in soft ground conditions, is of significant technical challenges in an urban environment. The challenges can be divided into technical and construction related categories. From a design perspective, the volume loss from a large diameter tunnel will result in a significant amount of surface settlement. The utilisation of tunnel space, spatial requirement at launch, lining deformation control and ground settlement control are all technical challenges that the designer should bear in mind. From a construction perspective, substantial power requirement, logistics for transporting the heavy tunnel segments and spoil removal required for the large diameter tunnel is of particular importance in the project delivery. TBM selection for large diameter tunnels in the context of the local ground condition is also different from that for the normal sized tunnel. This paper will provide a general overview of the design and construction of large diameter TBM-built tunnels, with particular reference to case studies from the United Kingdom.
