Study of microgravity survey to predict the Bukit Timah rock head for tunnelling in Singapore

Tan Egk Sze Ernest*, C. Veeresh, J. Kumarasamy & K.H. Goh
Land Transport Authority, Singapore

ABSTRACT: Singapore is a land scarce country with complex infrastructure and a sophisticated underground transportation network which is generally to construct using bored tunnels in difficult geological conditions. Many areas of the island's subsurface consist of Bukit Timah Granite (BTG) Formation, ranging from intact rock to completely weathered residual soils. The Bukit Timah Granite Formation is one of the oldest geological formations which is an intrusive type of igneous rock formed more than 230 million years ago. Top portions of Bukit Timah Granite are generally weathered and decomposed into residual soils. As the water seeps through fractures of granite mass below the weathered soil, chemical process takes places and as a result, the subsurface of the rock is eroded leaving numerous boulders in place. Deep tropical weathering and variability in bedrock level of the Bukit Timah Granite Formation is well established and the inherent complexities pose challenges to the tunnelling works. Tunnelling through rock induces rapid cutterhead wear and incurs high costs. Thus, mapping of the subsurface stratigraphy along the tunnel alignment is an important aspect for safe and economical tunnelling. In recent years, gravity surveys have been successfully employed as a non-intrusive means to predict the underground stratigraphy. Several gravity surveys have been conducted in Singapore to determine the rock-head elevation for tunnelling projects and have achieved varying degrees of success. This paper presents a study on the methodologies adopted in the implementation and interpretation of these surveys and identifies factors that may have contributed to the accuracy of predicted results. Findings from this study are useful for future projects to identify the suitability of gravity surveys for tunnelling projects in Bukit Timah formation.

Keywords: Geophysical, Rockhead, Microgravity Survey, Tunnelling, Bukit Timah Granite

1 INTRODUCTION

In a land scarce country like Singapore, efficient utilisation of space above and underground is critical. Singapore boasts a sophisticated underground transportation network that is constantly being expanded to service ever-growing needs. Many areas of the island's subsurface consist of Bukit Timah Granite (BTG) Formation, ranging from intact rock to completely weathered residual soils. The Bukit Timah Granite Formation is one of the oldest geological formations which is an intrusive type of igneous rock formed more than 230 million years ago. Top portions of Bukit Timah Granite are generally weathered and decomposed into residual soils. As the water seeps through fractures of granite mass below the weathered soil, chemical process takes places and as a result, the subsurface of the rock is eroded leaving numerous boulders in place. Deep tropical weathering and variability in bedrock level of the Bukit Timah Granite Formation is well established (Shirlaw et al.,

2000) and the inherent complexities pose challenges to the tunnelling works. Tunnelling through rock induces rapid cutterhead wear and incurs high costs. Thus, mapping of the subsurface stratigraphy along the tunnel alignment is an important aspect for safe and economical tunnelling. Site investigation to determine the underground geology using bore hole drilling is challenging and inaccessible in several areas due to site constraints and use of reliable non-intrusive methods is an attractive alternative in such conditions. In recent years, microgravity surveys have been successfully employed as a non-intrusive means to predict the underground stratigraphy.

The microgravity survey is a geophysical technique that detects minute fluctuations in the Earth's gravitational field due to variations in the density of subsurface material. Utilisation of the gravity technique for subsurface exploration began in the early twentieth century (Nabighian et al., 2005). Improvements in the precision of gravity data acquisition over the past few decades have increased the popularity of gravity

*Corresponding author: ernest_tan@lta.gov.sg

surveys. Through the reduction and interpretation of gravity data, it is possible to predict the presence of subsurface geological structures such as faults, rock intrusions, dykes, and sills (Saibi, 2017).

Several projects have used gravity surveys in Singapore to determine the soil and rock interface. However, the results of these surveys achieved varying degrees of success in terms of accurately predicting the rock level when comparing with reference boreholes. This study is aimed to achieve a better understanding of the factors which influence the test results and interpretations from various microgravity surveys carried out. The methodology of data collection, processing and interpretation is presented, followed by the project-specific details of each gravity survey in the following sections. Various aspects that affect the microgravity survey results are discussed and findings from this study are useful for future tunnelling projects to accurately determine the rock profile for safe and economical tunnelling.

2 MICROGRAVITY SURVEY

Fundamentally, the underlying concept behind gravity surveys is to measure the deviation of locally observed gravitational acceleration from its theoretically computed value. In gravity surveys, the common unit of measurement is the ‘gal’, which is equivalent to gravitational acceleration of 0.01 m/s². In gravity survey measurements, fluctuations in gravitational acceleration can range from several hundred milligals (mgal) to several microgals (μgal). The term ‘microgravity’ may be used when the accuracy of measurements is better than 0.05mgal, and if the spacing between survey stations is less than 100m (Omnes, 1976). Gravity measurements are performed using a gravimeter, which consists of a mass suspended from a highly sensitive spring. Fluctuations in gravity alter the position of this mass because of the extension or contraction of the spring, and a restoring force is then automatically applied to the mass to bring it back to its original position. The magnitude of this restoring force is proportional to the gravitational force exerted on the mass, and the observed gravity at that location can be obtained after correction for natural instrument drift and removing the effects of the earth’s tides.

The field procedure for data acquisition generally requires establishing a base station. The base station should preferably be at an open location with level ground and with no obstructions and easily accessible. The gravity readings from this base station are then recorded and compared with an absolute gravity station linked to the International Gravity Standardisation Network 1971 (IGSN71). Thereafter, gravity readings are taken in a loop, starting from the base station, and successively moving to the next survey station. The loop ends at the original base station where a second reading is taken; this allows for correction of the gravimeter’s instrumental drift.

The collected gravity data will be subjected to additional corrections (i) Free air correction: to account for the gravity difference due to elevation at which the reading was taken (ii) Bouguer correction: the gravity due to the subsurface material between sea level and the measurement point and (iii) Terrain correction: the effects of localized changes in topography. The final gravity anomaly value after accounting for the above effects was termed as ‘Terrain Corrected Bouguer Anomaly (TCBA)’.

In gravity data interpretation, the TCBA is split into two components: regional and residual components of the gravity anomaly. The regional component is attributed to widespread and deep-seated mass distributions (Mickus et al., 1991), while shallower subsurface mass distributions constitute the residual component. Typically, the regional anomaly is not expected to vary significantly across a small survey site. The residual anomaly data is then subjected to inverse modelling which predicts the subsurface geological structure as a function of sedimentary thickness variation (Wahyudi and Kadir, 2018), based on an assumed density contrast.

3 MICROGRAVITY SURVEY TEST RESULTS

In this section, the microgravity surveys from four different sites are presented: (1) Bishan Park, (2) Central Catchment Nature Reserve, (3) Blackmore Drive and (4) Changi Airport. These surveys were performed by the same geophysical specialist company between 2015 and 2022, using the Scintrex CG5 or CG6 Autograv Gravity Meter.

3.1 Gravity survey at Bishan Park

The site location is shown in Figure 1 and is situated at a public park. A total of 225 survey points were demarcated for this site, with an average square

Figure 1. Survey boundaries and borehole layout at Bishan Park.

spacing of 10 m. The topography was slightly undulating, with ground levels varying between 3.1 to 9.9 meters above the Singapore Height Datum (SHD). Terrain correction was applied during the gravity data reduction process.

Four boreholes were used for control to calibrate the regional component of the gravity anomaly by assuming that the variation follows a smooth first order polynomial as a function of the site coordinates. A final mean density contrast of -650kg/m^3 was adopted in the 3D depth model, based on the estimated difference between the mean density of rock and the less dense overlying weathered soils. The final depth model was then verified against the reference boreholes, shown in Table 1.

3.2 Gravity survey at Central Catchment Nature Reserve (CCNR)

Table 1. Gravity predicted versus actual rockhead at bishan.

Borehole	Ground Level Elevation/ mSHD	Actual Rockhead Elevation/ mSHD	Predicted Rockhead Elevation from Gravity Data/ mSHD	Difference between Predicted and Actual Rock Level/ m
BH-1a	7.9	-17.1	-17.8	0.7
BH-2a	7.4	-8.6	-7.4	1.2
BH-3a	5.7	-14.8	-13.8	1.0
BH-4a	8.2	-12.3	-11.8	0.5

The location of the gravity survey is shown in Figure 2. The survey site was located at a nature preservation site and mostly consists of moderately dense foliage. A total of 254 survey stations were set out, with an average square spacing of 15 meters. The terrain was moderately hilly, with ground elevations varying from 14.4 m to 39.3 m above the SHD.

A total of 20 reference boreholes along the proposed tunnel alignment were adopted for calibration and control of the regional anomaly distribution across the site. To derive the mean density contrast of the residual component, soil densities obtained from lab testing of 12 boreholes located at the southern half of the survey location were initially utilized to determine the average difference in bulk densities between Timah Granite rock and overlying soil layers. This resulted in a sample density contrast of -747kg/m^3 . However, in the 3D depth model, a final adopted mean density contrast of -950kg/m^3 was adopted in order to optimize the correlation with the actual borehole rockhead elevations, which is presented in Table 2.

Horizontal Directional Coring (HDC) was also carried out at CCNR to verify the subsurface stratigraphy along the tunnel alignment. Since the HDC was

performed within the survey area, results could be used to compare against the gravity rockhead predictions.

3.3 Gravity survey at Blackmore Drive

The surveyed location can be seen in Figure 3 and is located within a moderately built-up residential district. A total of 565 survey stations were demarcated

for the gravity survey at an average spacing of 8 m. The elevation of the site varies from 11.7 m to 28.5 m above the topographic datum. Terrain corrections were applied to correct for the undulations in terrain. Situated close to the survey areas are the following structures: (1) An underground rapid transit station at the north boundary of the survey area, and (2) A ten-storey condominium complex located along the north-eastern boundary of the site.

Figure 3. Survey boundaries and borehole layout at Blackmore.

There were 27 boreholes located within proximity of the survey area, 12 of which were terminated in rock, while the remaining 15 either terminated at a shallow depth or did not encounter rock. All available borehole laboratory data from these boreholes were used to determine the average densities of the following soil layers:

- (a) Rock strata,
- (b) soil between Rock and the topographic datum,
- (c) soil between the existing ground level and the topographic datum.

Bouguer corrections were performed based on the density data above the topographic datum to allow for a more accurate correction. Additional corrections for the surrounding structures were also performed to refine the gravity data. For the rapid transit station, the negative gravity contribution due to underground voids was defined based on an as-built 3D model, while the condominium complex was simulated by considering the full three-dimensional outline of the structure, with an assumed bulk density of 300kg/m^3 . This value was adopted based on the specialist's previous project experience and was deemed to be representative of concrete shell structures.

The final density contrast adopted for the 3D depth model was -608kg/m^3 , which was based on the difference between the rock density and residual soils below the topographic datum. Comparison

between predicted and actual rock rockhead elevations are presented in Table 3.

Table 3. Gravity predicted versus actual rockhead at Blackmore Drive.

Borehole	Ground Level Elevation/ mSHD	Actual Rockhead Elevation/ mSHD	Predicted Rockhead from Gravity Data/ mSHD	Difference between Predicted and Actual Rock Level/m

3.4 Gravity survey at Changi Airport

The gravity survey boundaries are shown in Figure 4. A combined total of 1038 stations were marked out at an average station spacing of 10m. The terrain was relatively flat, with ground levels only varying between 2.5 m to 4.9 m above the topographic datum.

A total of 15 boreholes were located within the survey area. An additional five boreholes outside of the data coverage was also used to calibrate the mean density contrast between residual soils and rock. A mean density contrast of -730kg/m^3 was derived from the sample test results, and this value was adopted as the final mean density contrast input into the depth model as it proved to have a good correlation with the actual borehole rock levels, shown in Table 4.

Horizontal Directional Coring performed at the site was within the bounds of the gravity survey and the HDC results were compared against the gravity predicted rockhead depth.

4 DISCUSSION

The interpreted rockhead profiles for Bishan and Changi achieved close matches to the reference boreholes. Furthermore, horizontal directional coring performed at Changi Airport first encountered the rock at approximately -19.3mSHD , which was comparable to the rock level predicted from the gravity survey results (-18.0mSHD). Figure 5(a) shows the location of the HDC trajectory and location of the first encounter with rock, while Figure 5(b) overlays the location with the rockhead model interpreted from gravity results.

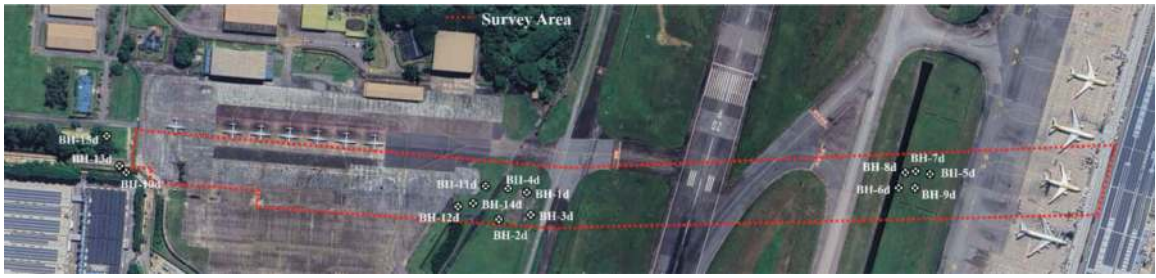

Figure 4. Survey boundaries and borehole layout at Changi Airport.

Table 4. Comparison between gravity predicted and actual rockhead elevation at Changi Airport.

Borehole	Ground Level Elevation/ mSHD	Actual Rockhead Elevation/ mSHD	Predicted Rockhead Elevation from Gravity Data/ mSHD	Difference between Predicted and Actual Rock Level/m
BH-1d	2.9	-27.6	-27.4	0.2
BH-2d	3.1	-16.9	-19.4	2.5

BH-15d	4.7	-30.1	-30.0	0.1

On the other hand, surveys at CCNR and Blackmore encountered situations where the predicted gravity rock profile deviated significantly from the actual borehole rock level. A summary of the predictive errors across the four survey sites are presented in Table 5.

HDC runs were also carried out in CCNR along the trajectories shown on Figure 6(a). The horizontal drilling encountered rock at -5.5mSHD, while the gravity model predicted the actual rock elevation to be at 0mSHD at the same location, incurring an absolute error of 5.5m and a percentage error of 18% (Figure 6(b)).

4.1 Factors affecting gravity predictions of rockhead

4.1.1 Depth to rockhead

The comparison between actual and predicted rockhead level across the four gravity surveys is shown in Figure 7(a). A line of unity was also plotted for

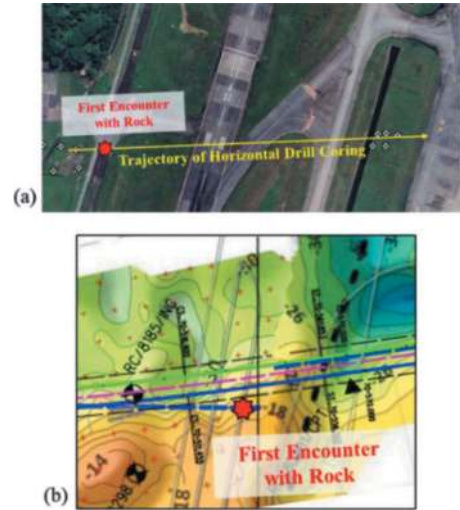

Figure 5(a). HDC Alignment within Changi, Figure 5(b): HDC first encounter with rock superimposed on gravity model.

Table 5. Summary of gravity prediction errors compared to actual rockhead level across survey sites.

Survey Area	No. of BH	Difference between gravity prediction and actual rockhead depth (% of verification BH)			
		<3m	3m to 5m	5m to 10m	>10m
Bishan	4	100	0	0	0
CCNR	20	25	20	30	25
Blackmore	12	16.7	8.3	25	50
Changi	15	73.3	26.7	0	0

reference to indicate a case where the interpreted gravity data matches the actual rock level. The same data above was expressed in terms of the absolute difference between the actual and predicted rockhead elevations in Figure 7(b) to illustrate the relationship more clearly between rockhead depth and prediction error. This reduction in absolute accuracy with depth is expected due to an increased possibility of encountering both lateral and longitudinal density variations that deviate from the input mean density contrast.

The difference between predicted and actual rockhead elevations were also plotted as a percentage of the total depth to the rock. For easy reference, the

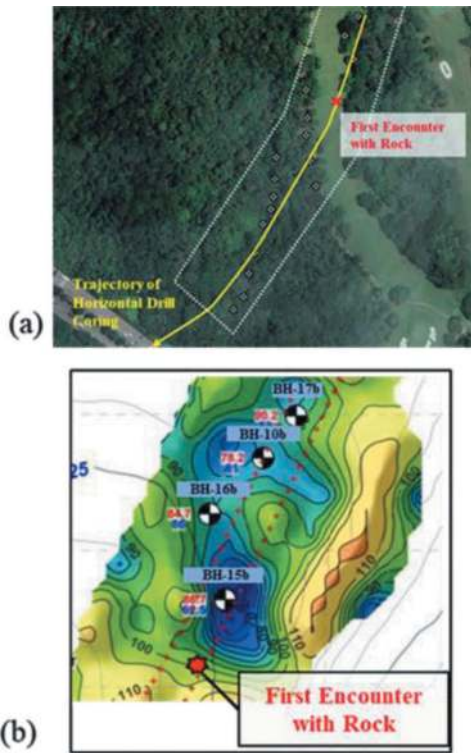

Figure 6(a). HDC Alignment within CCNR, Figure 6(b): HDC first encounter with rock superimposed on gravity model.

results for each individual site were plotted separately in Figures 8(a) to 8(d). Across each of the four sites, most prediction errors were clustered between 0 to 20%. However, there were outlier predictions from the surveys at Blackmore and CCNR which deviated between 30% to 60% from the actual rockhead depth. These outliers could be largely attributed to the steep and undulating rock at several locations which had significant influence on the gravity predictions; this will be discussed in Section 4.1.2. Figure 9 shows the combined results from all sites. A consistent trend line of approximately 15% error across all four sites is observed, and a majority of the data had predictive uncertainties of below 20%. This is to be expected, as the rockhead model is developed based on the residual gravity anomaly distribution which is an expression of the thickness of soil layers above the rock. A greater thickness of overlying soils would logically result in a proportionately increased absolute uncertainty in the depth to rockhead. The average prediction error is generally in agreement with a study performed by Nyquist (2001) to determine the depth to Precambrian bedrock in Montana, USA, where an average prediction error of 3% to 17% was observed for bedrock depths between 20 to 70 meters below ground level.

On the other hand, Abbott and Louie (2000) also reported a potential 50% depth estimation error in their gravimetric study on the depth to bedrock in Nevada, USA, due to a lack of rock and soil density contrast data, thus highlighting the importance of

Figure 7(a). Borehole rockhead with model rockhead elevations, Figure 7(b) Correlation between absolute error from gravity model and actual depth to rock.

gravity data correction and reduction with sufficient background understanding of actual density contrasts between rock and soil.

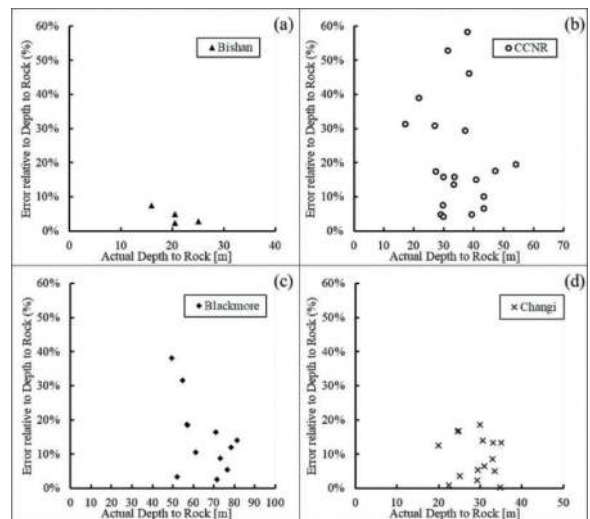

Figure 8. Correlation between percentage error from gravity model and actual depth to rock for individual sites: (a) Bishan, (b) CCNR, (c) Blackmore and (d) Changi.

4.1.2 Undulations in rockhead

For each of these microgravity surveys, the survey points were spaced between 8 to 15 meters in both directions. The observed gravity data was based on discrete points and relies on interpolation methods to derive the continuous gravity anomaly distribution across the survey area. As such, the gravity fluctuations caused by steep and sudden changes in the rock level in between gravity stations may not be precisely reflected in the survey data.

For example, the gravity rockhead predictions for CCNR indicated that the rockhead varied up to 55 meters across the survey area. Results from the 3D depth model (Figure 10) demonstrated that there could be steep undulations in the rock exceeding 20 meters in elevation within a lateral span of 10 meters at the location of BH-15b. The survey stations which were spaced 15 meters apart would not be able to precisely capture the effects of the gravity anomaly due to the lateral and longitudinal influence of the steeply sloping rockhead compared to a borehole, which is effectively a point prediction. Consequently, a significant

Figure 9. Correlation between percentage error from gravity prediction and actual depth to rock.

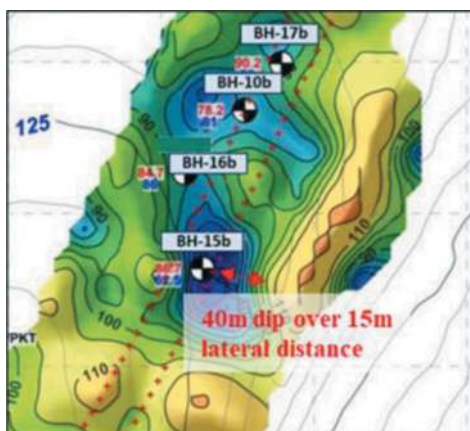

Figure 10. Depth inversion gravity model of CCNR.

difference of 21.7m was observed between the actual and predicted rock depth.

It was also noted that in cases where the difference between predicted and actual rockhead varied significantly, these data points often manifested as outliers from the 20% error margin discussed in the previous section. These data points are identified in Figure 9 (circled in red).

Noting that steep inclinations in rockhead could result in incorrect gravity predictions, a two-stage approach could potentially be adopted when planning gravity surveys:

- i) An initial gravity survey can be conducted based on a larger station spacing between (e.g., 15 meters). Gravity data correction and reduction is to be carried out to establish the residual anomaly distribution across the site. Ideally, several reference boreholes should be drilled within the site to allow for site-specific calibration of the regional anomaly.
- ii) Identify areas within the site encountering significant fluctuations in the residual anomaly over a short distance, as this indicates potential locations with steep rockhead inclinations that may not result in accurate predictions.
- iii) Perform a second gravity survey at these locations with a reduced spacing between stations. The residual anomaly distribution may then be refined based on a higher number of data points within the identified zone, allowing for greater resolution of the rockhead 3D depth model.

4.1.3 Underground structures

Density contrast between rock and soil is a key parameter affecting the data interpretation. The presence of subsurface voids (e.g., underground basements) should be carefully accounted as the contribution to the gravity anomaly could be significant. For the case of Blackmore Drive, the void from the underground rapid transit station void was reported to have an influence of up to 0.328mGal. For reference, the Bouguer Anomaly was observed to have a maximum variation of 0.8mGal across the site, between 33.11 to 33.91mGal. A 0.328mGal contribution from an underground void could result in fluctuations of up to 40% of the range of rockhead elevations. It was also noted that the predicted rock elevation at the location of the closest reference borehole to the station structure, BH-8c, experienced a significant difference of 11.69m between predicted and actual depth to rock. Figure 11 indicates the location of the underground station with respect to BH-8c.

4.1.4 Density variations in soil and rock

In the depth inversion model, a single value of density contrast is input to correlate the rockhead model with the residual anomaly map. To provide a reasonable estimate across the survey area, average density values were computed from lab results from soil sampling of boreholes throughout each site.

Figure 11. Proximity of MRT station to BH-8c.

However, this merely provides a best estimate average density contrast between rock and the overlying soils. Natural variations in soil and rock densities across the site would thus have an impact on the final predicted rockhead level. This could be another underlying reason for locations where the bedrock was predicted to be relatively uniform, but still resulted in significant percentage deviation from the true rockhead level.

5 CONCLUSIONS

Microgravity surveys were carried out at four different sites in Singapore with the objective of profiling the depth to rock, achieving varying degrees of success. The following inferences and conclusions can be made from the case studies of these surveys:

- When considering the prediction error as a percentage of the actual depth to rockhead, it was noted that the average error was relatively consistent at approximately 15% and was not significantly impacted by the rockhead depth. Additionally, majority of gravity predictions were observed to produce prediction errors of less than 20% of the total depth to rock.
- Steep undulations in the rockhead level will influence the accuracy of gravity predictions. This was observed at multiple borehole locations in CCNR and Blackmore Drive. Due to the spacing of the survey points which varied between 8 meters to 15 meters, the resolution of gravity data may be affected, especially if a steep change in rockhead elevation occurs over a relatively short

distance between survey points. Gravity fluctuations due to these geological structures may not be effectively captured as the assumed gravity anomaly distribution between points is generated using interpolation techniques.

- Underground voids (e.g., Basements, storage tanks) have a significant impact on the observed gravity anomaly located nearby to the void, and proper corrections should be applied based on an accurate three-dimensional representation of the void geometry.
- As there will be natural variations in the soil and rock densities across the site, this could give rise to uncertainties in the gravity prediction as a single best estimate value of the density contrast between rock and soil is assumed in the inverse modelling process.

Rock drilling aerosol deslagging technology and CFD-DEM two-way coupling numerical simulation of weak surrounding rock geology

Shuaitao Guo*

China Railway Construction Heavy Industry Corporation Limited, Changsha Hunan, China,

ABSTRACT: To solve the problem caused by weak surrounding rock that is easy to soften or argillize when exposed to water, the technology of drilling aerosol and slag discharge is put forward here, i.e. discharging cuttings formed during the process of drilling through high-speed aerosol forming in the combination of HP air and LP water, so as to realize heat dissipation and dust reduction. To improve the efficiency of aerosol deslagging and avoid blockage and jamming, CFD-DEM two-way coupling simulation method is adopted here to analyze the interaction between the flow field inside the drill bit and cuttings during the process of aerosol deslagging for rock drilling bit, and the contribution of different parts to pressure loss. The distribution and movement trajectory of cuttings under different air flows and pressures are studied to determine the critical pressure required for deslagging, which is then compared with experimental test results. As shown by the result, the critical pressure required for deslagging is 7.5 bar, which basically matches the experimental results, providing a research method and theoretical basis for the design of rock drilling aerosol deslagging bit.

Keywords: Weak Surrounding Rock, Drill Bit, Deslagging and Two-way Coupling

1 INTRODUCTION

Depending on the prosperity of China's transportation industry, railway tunnel construction is becoming increasingly widespread. In the process of tunnel drilling construction, unreasonable construction technology may affect the stability and safety of the tunnel structure provided that weak surrounding rock is encountered in such a low-strength geological environment^[1]. Hence, studying the drilling and deslagging technology in weak surrounding rock geological environment has great significance for tunnel construction. The weak surrounding rock is characterized by broken and loose state, prone to poor stability and easy softening or argillization when exposed to water, bringing great challenges to tunnel drilling construction^[2]. In the geological environment of complexity such as the weak surrounding rock, conventional mechanical spiral deslagging and hydraulic deslagging may easily trigger outburst and pipe jamming^[3]. Therefore, wind deslagging is generally adopted for drilling and deslagging of the weak surrounding rock.

Multiple studies have been carried out on wind deslagging from boreholes at home and abroad. Huber N^[4] et al. simulated the particle transport process in a horizontal pipe by means of simulation and then obtained the movement trajectory of particles in the

horizontal pipe. Muschelkantz^[5] and Matsumoto^[6] respectively put forward empirical and semi-empirical formulae for the prediction of critical wind velocity of pneumatic transport through simulation of such pneumatic transport. Wang Yilong analyzed the influencing factors of gas lift deslagging from gas drainage boreholes by combining simulation and test, and concluded the influence law of coal dust particle size, air volume and quantities of cuttings on deslagging^[7]. Zhang Yu designed a drill pipe structure to prevent jamming for drilling in soft coal seams, by adopting a special spiral blade structure to obtain a better deslagging capacity and jamming prevention performance^[8]. For challenges encountered in mining of soft outburst coal seams, Li Jia optimized the parameters of rib drill pipe through gas-solid two-phase coupling method to obtain the optimal combination of parameters by using range analysis method. The deslagging efficiency of the optimized rib drill pipe structure can reach 15.77%^[9]. Zhang Wei simulated the borehole deslagging process by means of numerical simulation. The critical wind velocity increases logarithmically and the pressure loss also increases with the increase of solid-gas ratio.^[10] Wang Yonglong analyzed the critical conveying wind velocity of coal debris particles group and the solution to pressure loss of drilling system through the theoretical research on the borehole deslagging mechanism

*Corresponding author: 893318677@qq.com

and the time effect of blockage. As shown by the results, the soft outburst coal seam is challenged with large fracture zone area distribution and large expansion deformation of hole wall during drilling, resulting in increased friction coefficient of hole wall, decreased deslagging space, higher transportation resistance of coal debris and increased pressure loss^[11].

Most of the researches about borehole deslagging for weak surrounding rock adopt wind deslagging home and abroad. Excessive dusts however will be generated during the drilling process, which contaminates the construction environment and affects the health and safety of workers. To come up with a resolution, an appropriate amount of water is added into the HP air to form a high-speed aerosol. The deslagging using aerosol can not only avoid softening of weak surrounding rock exposed to water, but also effectively reduce dust spread. However, due to the limited research on aerosol deslagging at home and abroad, there is no simulation and experimental analysis methods for actual working conditions. Hence, this paper mainly analyzes the theory and simulation of aerosol deslagging technology in rock drilling holes, and compares the result with test data, aiming to provide an effective method for the study of aerosol deslagging technology in rock drilling holes in weak surrounding rock geology.

2 BASIC THEORIES

2.1 Pneumatic transport process

Aerosol deslagging is essentially a pneumatic transport process. Pneumatic transport uses the energy of airflow to transport granular materials along the direction of airflow. Pneumatic conveying can be divided into suction type and pressure-feeding type according to the working principle. Suction type refers to conveying by negative pressure below atmospheric pressure, while pressure-feeding type refers to conveying materials through the HP air that is above atmospheric pressure. The pressure-feeding type is usually preferred to in the borehole wind deslagging. In pneumatic transport analysis, for spherical solid particles with a diameter d , the expression of particle suspension velocity can be derived according to the mechanical relationship between gravity and buoyancy balance in the suspended state^[12]:

$$v_n = \sqrt{\frac{4gd(\rho_s - \rho_a)}{3C\rho_a}}$$

Where, v_n represents the suspension velocity of spherical particles, m/s; g represents the acceleration of gravity, m/s^2 ; d represents the diameter of particles, m; ρ_s represents the density of particles, kg/m^3 ; ρ_a represents the density of air, kg/m^3 ; C represents the resistance coefficient of particles, generally taken as 0.44. In fact, the motion of drilling cuttings in the process of

discharging with airflow is extremely complicated. In the vertical direction, there are not only gravity and buoyancy, but also components of mutual collision force between particles in the vertical direction, upward component of turbulence acting on particles, acting force generated by velocity difference between upper and lower surfaces of particles, and components of thrust generated by irregular shape of particles in the vertical direction.

2.2 Basic assumptions

In the process of borehole deslagging, air is taken as gas phase and drilling cuttings particles are taken as solid phase. Generally, the volume fraction of drilling cuttings particles is relatively large, so the interaction between particles cannot be neglected. To accurately simulate the deslagging process, it is necessary to simulate through fluid-discrete element coupling. The discrete element method is an engineering numerical method that can be used to simulate the motion of dense particle flow. Using the discrete element method necessitates the following assumptions:

- (1) Solid particles are spherical, without considering the irregular shape of the particles;
- (2) The solid particles are rigid in properties, without considering the deformation of particles;
- (3) The contact between particles is point contact;
- (4) Crushing and bonding of particles are not considered.

2.3 Aerosol deslagging process

Borehole aerosol deslagging is a complex physical process. As shown in Figure 1, air and water are atomized in the aerosol mixing block, and then enter the drill pipe and inner hole of the bit for deslagging after passing through the pipeline system. Atomization is a physical process in which liquid droplets turn into water mist under the action of gas impact, providing aerosol preparation for deslagging process. High-speed aerosol serves to discharge rock debris formed during drilling in the deslagging process. This paper mainly studies these two processes. The whole physical process from atomization to deslagging is of complexity since the slenderness ratio of the system is too large, and the direct simulation calculation is costly. To improve the simulation efficiency and catch up with the project schedule, the two processes are independently studied, and the aerosol distribution obtained through atomization simulation functions as the input for the deslagging process.

Figure 1. Schematic diagram of aerosol deslagging device.

3 ATOMIZATION SIMULATION

To simulate the atomization process of liquid droplets, a VOF multiphase flow model describes the mixing of air and water, and a VOF-Lagrange transformation model captures the breakage of liquid film and peels off small droplet particles from the free surface to obtain the size distribution of water mist.

3.1 Calculation model and boundary conditions

The 3D model of the water-gas mixing device comprises of a gas mist mixing block and a built-in nozzle as shown in Figure 2, which are geometrically cleaned and simplified. The fluid area inside the water-gas device and the inner wall surface of the pipeline contacting the fluid are reserved. Other non-contact surfaces are deleted, and the CFD geometrical model of the water-gas mixing device is obtained by pumping out the cavity, as shown in Figure 3.

The geometric model is meshed, with a total of 885,422 elements, as shown in Figure 4.

The air inlet boundary is the flow inlet, which is set according to the volume flow of 3,000L/min under standard atmospheric conditions. The liquid water inlet boundary is also the flow inlet, which is set corresponding to a volumetric flow of 1 L/min and an outlet pressure of 12.5 bar. To precisely capture the droplet fragmentation, adaptive grids and adaptive time steps are used for the purpose of simulation.

Figure 2. Solid model of water-gas mixing device.

Figure 3. CFD Geometric model of water-gas mixing device.

Figure 4. CFD grid model of water-gas mixing device.

3.2 Numerical simulation results and analysis

The liquid enters the aerosol mixing block from the built-in nozzle to form a liquid column, which is mixed with high-speed air. The internal velocity nephogram of the aerosol mixing block is shown in Figure 5. The air flow rate near the liquid column is about 20m/s. The pressure nephogram is shown in Figure 6. The pressure distribution in the whole aerosol mixing block is relatively uniform, around 12.5bar, indicating that the liquid column has little influence on the surrounding pressure field. Under the action of airflow impact, the liquid column changes from jet shape to liquid film and large-diameter liquid droplets. It is a primary atomization process, as shown by the frame line in Figure 7a. The diameter distribution range of droplet particles is 0.042mm-0.109mm. Due to the large velocity difference between liquid droplets and surrounding air, the air force acting on the liquid film and large-diameter liquid droplets in the spray exceed their own surface tension in the airflow. The liquid droplets are quickly broken again to generate smaller diameter liquid droplets. The size of the atomized particles after droplet fragmentation is shown by the outline in Figure 7b, with a droplet particle diameter ranging from 0.004 mm to 0.109 mm and an average particle diameter of 0.06 mm.

Figure 5. Velocity nephogram in aerosol mixing block.

Figure 6. Pressure nephogram in aerosol mixing block.

4 SIMULATION OF AEROSOL DESLAGGING

The schematic diagram of the deslagging process of the drill pipe in working state is shown in Figure 8, in which, high-speed aerosol enters the borehole bottom 6 through the inner cavity 1 of the drill pipe and the inner cavity 5 of the bit, driving rock debris to be discharged out of the borehole through the annular channel 4 formed

by the outer wall 3 of the drill pipe and the inner wall 2 of the borehole. The gas-liquid-solid three-phase coupling is involved in aerosol deslagging, indicating that the ideal gas model can serve to deal with the flow of gas phase, the discrete multiphase model can deal with the mixing of water and mist and the discrete element model can deal with the motion of drilling cuttings particles. The gas and liquid phases are described by Eulerian method, and the granular phase is described by Lagrangian method.

Figure 8. Schematic diagram of deslagging process of drill pipe.

4.1 Geometric model and grid division

The calculation model of drill pipe and the local scale-up grid model are shown in Figure 9. The length L_1 of drill pipe is 4.5m, the diameter d_1 of inner hole of drill pipe is 8mm, the outer diameter d_2 of drill bit is 45mm, the inner diameter d_3 of borehole is 49mm, and the drilling depth L_2 is taken as 0.2m.

Figure 9. Calculation model of drill pipe.

4.2 Boundary conditions

The inlet boundary serves as the drill pipe inlet, which is a aerosol two-phase flow. With reference to the atomization simulation results, the average diameter of water mist particles is taken as 0.06 mm, with an deviation of ± 0.05 mm, indicating that the diameter ranges from 0.01 mm to 0.1 mm, the volume fraction of water mist is 0.4%, and the corresponding volume flow rate is 1 L/min. The annular channel outlet adopts the pressure outlet boundary condition so that its pressure is atmospheric pressure. A particle injector is provided on the wall surface at the bottom of the borehole. Since the drilling speed is 3m/min, the rock debris generation rate is calculated as 0.2357kg/s, and the particle diameter is taken as 1mm. The material parameter settings are listed in Table 1.

4.3 Analysis of coupling numerical simulation results

4.3.1 Analysis on sectional pressure loss of deslagging system

The pressure loss of deslagging system can be divided into the pressure losses of drill pipe inner hole, drill bit inner hole, borehole bottom area and borehole annular channel by components, as shown in Figure 10, corresponding to the pressure losses of section AC, section CD, section DE and section EB respectively. The pressure loss in the bottom area of the borehole includes the pressure loss caused by the diffusion of airflow from the outlet of the drill bit hole at the bottom of the borehole, the pressure loss caused by the reverse direction of airflow when encountering the bottom of the borehole and the pressure loss resulting in the drilling cuttings acceleration.

Table 2 shows the pressure loss and proportion of each component of deslagging system under different drill pipe inlet pressures. It can be seen that in the aerosol deslagging system, the pressure loss of the inner hole of drill pipe accounts for the largest proportion, accounting for about 47%, due to the long length of drill pipe and the small diameter of inner hole. The proportion of pressure loss in the bit borehole and the

Figure 10. Pressure nephogram of deslagging system.

bottom area of the drill hole is equivalent, approx. 25%. The borehole annular channel has the smallest proportion of pressure loss, which is less than 3%.

Besides, as the inlet pressure of drill pipe decreases, the proportion of pressure loss in the inner hole of drill pipe and bit increases, while that in the bottom area of borehole and annular channel of borehole decreases.

4.3.2 Analysis of critical deslagging pressure

The velocity nephogram of debris particles under different deslagging pressures is shown in Figure 11. It can be seen that the velocity of debris particles in the annular channel decreases with the decrease of deslagging pressure. When the deslagging pressure is 10bar, 9bar and 7.5bar respectively, the debris particles are evenly distributed in the annular channel without occurrence of any particle deposition. Provided that the deslagging pressure drops to 5bar, all debris particles cannot be suspended in the airflow, but caused to deposit in the gravity direction, resulting in blockage of the annular channel, as shown by the box line in the figure. The average velocity curve

of debris particles is shown in Figure 12. Provided that the deslagging pressure is 5bar, the average velocity of debris particles is only 0.2m/s, approaching stagnation, which will lead to particles accumulation in the annular channel. Where the deslagging pressure increases to 7.5bar or above, the average velocity of debris particles reaches more than 5m/s, ensuring that the particles can be discharged smoothly. Therefore, the critical pressure of aerosol deslagging is 7.5bar, and the corresponding volume flow rate in standard atmospheric state is 1,884L/min under the working condition of drilling speed at 3m/min.

The flow field velocity nephogram of the annular channel in the deslagging system is shown in Figure 13. It indicates that the maximum hole velocity in the drill bit is caused by the sudden change of hole area in the drill bit. By comparing the velocity nephograms under different deslagging pressures, it can be seen that with the decrease of deslagging pressure, the internal velocity and gas flow rate of the deslagging system also decrease accordingly. Since the drilling speed remains constant, the deslagging flow rate remains unchanged. According to the empirical formula $m=0.2396e^{0.235V_a}$ for solid-gas ratio m and critical deslagging wind velocity V_a , where solid-gas ratio m represents the ratio of mass flow rate of cuttings against air mass flow rate, and V_a represents the critical deslagging wind velocity, so that the critical deslagging wind velocity under different deslagging pressures can be obtained^[13]. The wind velocity V of the annular channel calculated by simulation is extracted for comparison, as shown in Table 3, indicating that when the deslagging pressure is 5bar, the critical deslagging wind velocity calculated by the formula is 18.9m/s and the wind velocity in the annular channel is 15.3m/s, which are less than the critical deslagging wind velocity, resulting in

Table 2. Pressure loss and proportion of components of deslagging system under different working conditions.

P _A (bar)	Q (L/min)	Inner hole of drill pipe		Inner hole of drill bit		Bottom area of borehole		Annular channel of borehole	
		Pressure loss (bar)	Proportion (%)	Pressure loss (bar)	Proportion (%)	Pressure loss (bar)	Proportion (%)	Pressure loss (bar)	Proportion (%)

blockage in the annular channel. When the deslagging pressure is 7.5bar, 9bar and 10bar respectively, the wind velocity in the annular channel is greater than the critical deslagging velocity, indicating that the smooth discharge is expected, and the result obtained is consistent with the above results analyzed based on the debris particle velocity nephogram.

4.3.3 Influence of water mist flow on deslagging performance

The content of water mist in aerosol deslagging will produce certain influence on the deslagging performance. The gas velocity in the annular channel is obtained by simulation calculation under different

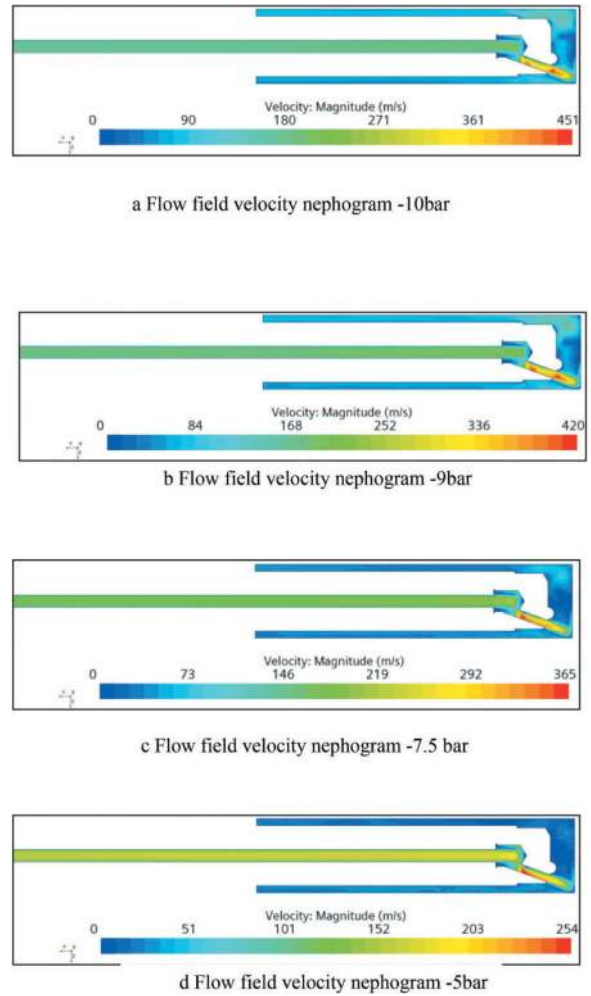

Figure 13. Flow field velocity nephogram under different deslagging pressures.

Table 3. Critical deslagging velocity at different solid-gas ratio.

P/bar	Mass-solid(kg/s)	Mass-air(kg/s)	m	Va	V
5	0.2357	0.01253	18.9	18.9	15.3
7.5		0.02217	10.6	16.1	33.0
9		0.03633	6.5	14.0	54.1
10		0.04141	5.7	13.5	61.4

water mist flow rates at deslagging pressures of 10 bar and 7.5 bar, respectively, as shown in Figure 14. As shown by the figure, under the condition of constant deslagging pressure, the deslagging gas velocity in the annular channel decreases with the increase of water content. According to the above analysis that deslagging wind velocity is critical to the deslagging performance, the smaller the deslagging wind velocity, the more difficult it is to discharge slag, indicating that the increase of water mist flow is adverse to the deslagging effect.

Figure 14. Velocity curve of deslagging gas under different water mist flow rates.

4.4 Test validation

The aerosol deslagging device is carried out on ZYS1133 wall drill jumbo for testing. The drilling object is precast cement pier, and the drilling distance of a single drill pipe is 4 m, which takes 3 min for drilling. The borehole deslagging test process is shown in Figure 15, and the drilling distances are 0.1m, 1m, 2m and 3m respectively. During the drilling process, the aerosol carrying the drilling cuttings is exhausted, so that the dust is kept under well control.

a Borehole test process-drilling for 0.1m

b. Borehole test process-drilling for 1m

c Borehole test process-drilling for 2m

d Drilling test process-drilling for 3m

Figure 15. Field borehole deslagging test.

The test principle of aerosol deslagging is shown in Figure 16. First, the external atmosphere and external water enter the aerosol mixing block through the flowmeter and flow regulating valve respectively to crush and atomize the liquid droplets, thus generating HP airflow containing water mist that enters the bottom of the borehole through the inner hole of the drill pipe for deslagging. The test system has tested three effective parameters, including the flow rate of external water Q_{water} , the flow rate of external air before compression Q_{air} and the pressure P at the inlet of drill pipe.

Figure 16. Test principle.

4.4.1 Test for critical deslagging pressure

The test data under different deslagging pressures are shown in Table 4. It can be seen that when the external water flow is 1L/min, the flow rate of external air is 2,570L/min and 1,810L/min respectively, without borehole blockage provided that the deslagging pressure is respectively 10bar and 7.5bar. The blockage in the borehole under the condition that the deslagging pressure is 5bar and the flow rate of external air is 1,350L/min indicates that the critical deslagging pressure is 7.5bar under such working condition, agreeing with the simulation results.

Table 4. Test data of critical deslagging pressure test.

P(bar)	Q_{water} (L/min)	Q_{air} (L/min)	Drilling jamming
10	1	2570	No
7.5	1	1810	No
5	1	1350	Yes

4.4.2 Comparative analysis of test results and simulation under different water mist flow rates

The influence of water mist flow rate on air flow rate under deslagging pressures of 10bar and 7.5bar is tested respectively for comparing with the simulation results. The deslagging gas flow rate decreases with the increase of moisture content in aerosol, and the simulated air flow rate is slightly greater than the measured value, as shown in Figure 17. The comparison of test and simulation values is shown in Table 5. Compared

with the measured data, the simulated value is greater, with an error within 5%, falling in the allowable engineering error range.

Figure 17. Comparison curve of deslagging gas flow between test and simulation.

Table 5. Comparison of deslagging gas volume under different water mist contents.

P(bar)	Q _{water} (L/min)	Q _{air} (L/min)		
		Measured Value	Simulation Value	Errors
7.5	0.2	2063	2157	4.56%
	0.4	1940	2033	4.64%
	0.7	1830	1926	4.70%
	1	1810	1884	4.09%
	1.2	1761	1825	3.63%
10	1	2613	2706	3.56%
	1.2	2540	2631	3.58%
	2	2420	2496	3.14%
	2.5	2340	2390	2.14%
	2.8	2242	2307	2.90%

5 CONCLUSION

This paper has studied the aerosol deslagging process by combining numerical simulation and experiment:

- 1) In the aerosol deslagging system, the pressure loss in the inner hole of drill pipe accounts for the largest proportion (approx. 47%), the pressure loss in the inner hole of drill bit and the bottom area of borehole is equivalent, accounting for about 25%, and the pressure loss in the annular channel of borehole accounts for the smallest proportion (less than 3%).
- 2) When the moisture content of aerosol is 1L/min and the drilling speed is 3m/min, the critical drill pipe inlet pressure required for deslagging is 7.5bar, and the corresponding air flow rate for deslagging is 1,810L/min.
- 3) The air velocity for deslagging will decrease with the increase of water mist content. The

increased content of water mist is adverse to the deslagging effect.

- 4) Through simulation of the working conditions under diverse water mist flows, the air flow at the inlet is extracted for comparison with the test results, with the obtained simulation error falling within 5%, which in turn validates the accuracy of the simulation.

Uninterrupted continuous forecasting in mechanized tunnelling in rock

Jozsef Hecht-Méndez*, Thomas Dickmann & Dirk Krueger
Amberg Technologies AG, Regensdorf, Switzerland

ABSTRACT: The history of seismic exploration in tunnelling began in the early 1990s and continues until today. Especially in mechanised tunnelling, technologies are advancing. Digital construction requires a digital ground model that must be adapted during the construction to reassess newly gained knowledge about the ground risk. In fast tunnelling with average daily rates of 20-30 metres, geological surprises must no longer play a significant role. The innovative TSP 603-Impact system ensures seismic exploration wirelessly in the TBM area. With TSP-Impact, a mechanical source rapidly transmits high-energy seismic waves from the TBM's shield into the rock mass, enabling a prediction range of 100 metres or more. Wireless transceivers convert the signals into digital data and send them to a tablet. This procedure is carried out at the end of each stroke of the TBM. Thus, reflection-seismic data from different spatial positions on a possible fault can be collected and analysed. Flexible and subsequent installation of the system in the TBM makes it independent and yet easy to operate. Once the data from 20 strokes has been collected, it can be uploaded to the cloud with a unique encrypted identifier for data protection. If no trained site personnel are available to process the data, the data can very quickly reach an authorised expert who will process it and return with a geological forecast after 2 to 3 hours. The 3-D velocity distributions of P- and S-waves can be surface rendered to focus particularly on anomalies characterised by low-velocity zones. A geological model of the predicted area completes the picture. This allows the size and extent of the anomaly to be determined, preventing the risk of failure and collapse in the tunnel with an accuracy of 85-90%. With such a TSP operation once a week, continuous geological prediction can ensure smooth tunnelling.

Keywords: TSP, In-tunnel seismics, geological characterization, risk mitigation

1 INTRODUCTION

During the last three decades, the use of seismic techniques for geological characterization in tunnelling has established as a suitable and reliable methodology. By integrating data obtained from in-tunnel seismic surveys with targeted probe drillings, the existing digital geological model can be improved by reassessing information about the rock mass condition as the excavation moves forward (Dickman et al., 2018). In-tunnel seismics can be applied in all types of tunnelling methods. However, in case of mechanized tunnelling in rock, some special requirements should be fulfilled to apply these techniques with minimum to no impact in the production cycle.

Modern mechanized tunnelling using Tunnel Boring Machines (TBMs) may achieve advance rates of up to 20-30 meters per day, or even more. These high advance rates pose challenges for geological investigations. Firstly, the excavation may reach hazardous zones without sufficient early warning. Secondly, the limited available time for geological investigations adds to the complexity.

Current TBMs are equipped with rigs for probe drilling the rock mass ahead while the TBM is in

standstill. This process is commonly integrated in the project execution. In many cases, probe drilling is carried out on a regular basis, even if the geological baseline report does not indicate a hazard zone nor the rock composition does change. These boreholes are time-consuming and give a rather limited view of the dimension of the geological conditions ahead of the cutter wheel. In order to profit from in-tunnel seismics in the TBM environment, an execution with an uninterrupted production cycle becomes necessary. Moreover, due to the high advance rates, the prediction of the rock condition should cope with the speed of excavation. This challenge can only be met, and the process can only be appropriate to the TBM environment if rapid seismic data acquisition procedures and continuous interpretation and prediction for the job site are put in place.

2 TUNNEL SEISMIC PREDICTION (TSP)

The TSP method is based on the principle of reflection seismics. It is used to image the structural features of the surrounding rock from inside the tunnel by excitation, reception and evaluation of elastic

*Corresponding author: jhecht@amberg.ch

body waves. The method requires a controlled seismic source, which usually consists of small explosive charges in conventional tunnelling. They are blasted in 1.5 m deep boreholes drilled into a tunnel wall. As a rule, 24 boreholes are used (Figure 1).

Figure 1. Schematic visualisation of a standard TSP layout in conventional tunnelling.

The wavefronts initiated by the blasts are travelling through the ground as compressional or P-waves and as shear or S-waves. They are partially reflected at and partially transmitted through interfaces of different physical properties. The wave and its type are measured with 3-component sensors (accelerometers) installed on both tunnel walls, commonly 4 receivers. By capturing the reflected elastic waves and their corresponding travel time, information about the rock mechanical parameters of the ground can be derived and important technical parameters such as the dynamic Young's modulus (E_{dyn}), Poisson's ratio, shear modulus and bulk modulus can be determined.

2.1 TSP 603-Impact system

The TSP 603-Impact system comprises two main elements. One is the TSP 603 wireless system that acquires and processes seismic data in the tunnel. The other is the TSP-Impact as a seismic wave source. The TSP 603 wireless system includes special transceivers which convert the analogue signal picked up by the sensors installed in the rock mass into digital data achieving microsecond accuracy of sync among the transceivers. The data is then transferred to a field tablet where it can be immediately visualised for quality control. The use of wireless transceivers enables easier and safer operation of the TSP system in the TBM environment. At the same time, the use of more receivers/transceivers ensures higher data density. The receivers are additionally equipped with an electronic compass sensor (MEMS) to detect and measure the precise spatial position of the 3-component accelerometers once installed (Figure 2).

The TSP-Impact is a pneumatically driven impact hammer, which has been specially designed for the

high-energy excitation of seismic waves in the underground. It replaces the use of explosives as a seismic wave generator and saves the drill holes where the small explosive charges were otherwise detonated. This means an enormous advantage for TBM tunnelling. For its operation, the controlled impact hammer source simply needs a mains power supply of 230V and compressed air supply of 7 bar. The impact hammer can be easily installed into a TBM's framework.

Figure 2. Two TSP 603 wireless transceivers attached to TSP receivers deployed 1.5 m deep in boreholes through the grout hole of precast segments.

Figure 3. Controlled impact hammer of TSP-Impact. The impact cylinder, in which the impact mass is accelerated, is coupled to the lateral rock wall through an opening in the TBM's shield shell by the feed cylinder below.

The hammer can be mounted directly on the framework of the TBM or on a bracket. In any case, a minimum clearance for proper operation of the hammer is necessary. It must be ensured that the hammer's impact cylinder can couple to the bare rock wall through an opening in the TBM's shield

(Figure 3). Once the hammer is mounted, it remains there for the duration of the complete excavation or exploration section.

The hammer works according to the Stretch-Shot-Relax pattern once the TBM has completed its stroke and come to a stop. From its rest position it stretches into the striking position up to the lateral rock wall, where its impact head is prestressed to the rock mass (Stretch). In the striking position, the impact mass is accelerated inside the cylinder and hammers against the prestressed impact head (Shot). 3 to 8 shots are taken in the same place, each recorded individually. The digital data traces of the repetitions at the same point are later vertically stacked to improve the signal-to-noise ratio. The nominal energy of each shot is about 130 Joule. With help of an intelligent routine, the user can evaluate the data quality after each shot and finish the data acquisition at this position. Next, the hammer is decoupled from the tunnel wall (Relax). The entire Stretch-Shot-Relax procedure takes maximum five minutes, while it is completely operated and controlled remotely from a field tablet using a dedicated data acquisition and control software.

Figure 4. Easy to use data acquisition and control software on a field tablet.

2.2 The seismic source – Explosives vs TSP-Impact

With TSP, the seismic waves must be generated by a point source. Both, explosives, and TSP-Impact satisfy this requirement. However, the energy transferred by the explosives to the media is larger. Repeated hammer blows on the same spot help indirectly increase the energy transferred to the ground. The difference in energy leads to a more rapid attenuation of the waves as they pass through the medium, so that the penetration depth is lower when using TSP-Impact. When using TSP-Impact, prediction ranges of up to 100 m ahead of the face can be achieved, while up to 250 m are possible when using explosives.

Another difference is the signal bandwidth. Normally, explosives have a wider bandwidth from 100 Hz to 3,000 Hz, whereas with TSP-Impact the bandwidth can be between 100 Hz and 1,750 Hz. The frequency range of the useful signal has a major

influence on the spatial resolution. The higher the prevailing frequency, the higher the resolution, i.e., the ability to identify successive reflectors depending on the wavelength.

Figure 5 shows the amplitude spectrum of data recorded with explosives and TSP-Impact (left and right, respectively) with the same receiver at the same location in Switzerland's Hagerbach Test Gallery. Here, the lithology consists of competent schist. The bandwidths of the significant signals are 100 - 1,150 Hz and 100 - 850 Hz, respectively, with most of the energy around 500 Hz for both source types. Given the anelastic attenuation or absorption of seismic waves, the high frequency component of the signal generated by explosives may be rapidly attenuated by the medium, so the signal frequency of reflections from distant areas (e.g. > 20 - 50 m from the face) is likely to be in a similar range, i.e. 100 - 250 Hz. Therefore, a similar spatial resolution can be expected for both data sets, resulting in very similar results.

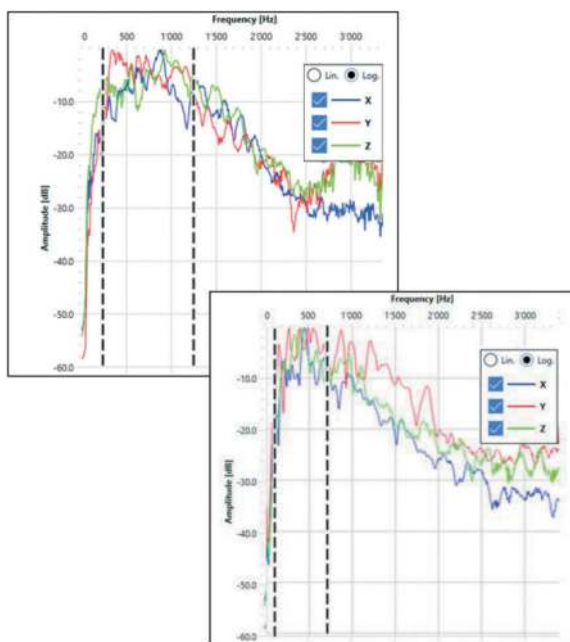

Figure 5. Amplitude spectrum, left: explosive; right: TSP-Impact.

2.3 Uninterrupted data acquisition and processing

To fully integrate geological prediction into mechanised tunnelling, the deployment of the measurement system and data acquisition must be carried out quickly so that the tunnelling cycle is not delayed. The use of a pneumatic impact hammer not only fulfils time and safety requirements, but also the demands for efficiency and prediction quality. Full integration of the system into the production cycle is achieved by installing the receivers at a specific location and using the TSP impact hammer during short breaks between each stroke (Figure 6). After a number of shot points have been recorded, the back receivers can be moved

forward in a roll-along fashion. This continuous use of the hammer in short breaks after each stroke always ensures a consistent geological prediction. Any downtime is reduced to a minimum.

As soon as twenty shot points have been recorded, the data can be sent to the processing centre via the cloud. Processing takes place immediately so that initial results are quickly available. If further data is collected at more shot points, it can be sent for processing and merged with previous data. In this way, the results are constantly regenerated, and the accuracy of the results is continuously improved.

Figure 6. Continuous data recording using TSP-Impact.

3 THE USE OF TSP 603-IMPACT IN THE RISHIKESH – KARNAPRAYAG RAILWAY LINE PROJECT

3.1 Project description

The Rishikesh - Karnaprayag Railway Line Project is a 125 km single-track railway line under construction in the Uttarakhand state of India (Figure 7). The project was commissioned by the national enterprise Rail Vikas Nigam Limited (RVNL) and it comprises the construction of 17 tunnels, 35 bridges and 12 stations. Tunnel Package 4 includes the excavation of two main tunnels of about 15 km and an escape tunnel of 0.7 km. 10.5 km of tunnels are currently under construction by two single shield TBMs for hard rock with a 9.1 m diameter each. The construction work is done by the Indian contractor Larsen and Toubro.

Figure 7. Project location overview.

3.2 Campaign selection and local geology

To date, more than 25 TSP campaigns have been carried out with the impact hammer source. The TSP hammer was installed in a special niche behind the TBM shield (see Figure 3). In this article, campaigns no. 7 and no. 8 are selected for further discussion. The face positions of those campaigns are at chainage 49,376 m and 49,445, respectively.

According to the Geotechnical Baseline Report and previous field work, a sheared/fault zone was expected along these chainages. The rock mass rating was estimated at $RMR < 20$ resulting in rock mass class V.

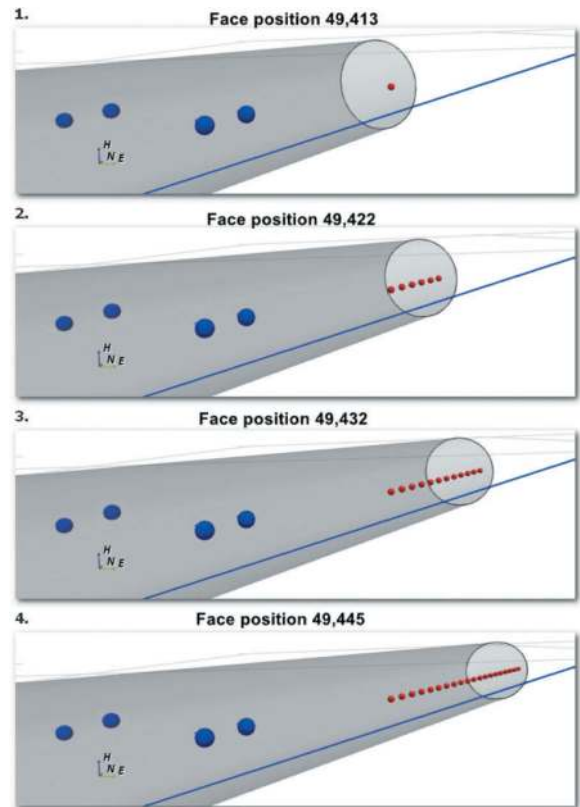

Figure 8. Tunnel model at 4 different face positions. Blue and red dots are receivers and shot points, respectively.

The inspection of the tunnel face during the excavation, which was carried out at two different stations before the problematic zones were encountered, revealed that it was a highly jointed and slightly weathered quartzite phyllite with strong to medium strength.

3.3 Tunnel definition in Amberg TSP Ease software

The TSP software makes it possible to take into account both planning information and the current tunnelling status. As soon as the tunnel axis has been entered in project coordinates, the tunnel model can be defined. Data acquisition begins at a specific position with the first blow of the hammer. The impact position refers to the current position of the tunnel face. Figure 8 shows the tunnel model in various positions of the tunnel face as the TBM moves forward.

After each TBM stroke of 1.7 metres, the next shot position is reached and the impact source can be coupled and seismic data recording proceeds. As segments are installed by the TBM or other tasks are carried out between each lift, seismic data acquisition does not cause any additional downtime, which means that the geological investigations are fully integrated into the production cycle.

3.4 Results

Seismic results can be obtained as tables, charts, and 2D/3D figures. Figure 9 shows the property charts of the seismic P- and S-wave velocities, V_p and V_s , respectively, and dynamic Young's Modulus (Edyn) of campaign #7. The position and the extent of the changes in the individual parameters are determined by the spatial position of the reflectors extracted by the software. The seismic reflectors correspond to boundaries at which a high acoustic impedance contrast exists. Hence, a large part of the wave energy was reflected to the receivers. The plane representing the boundary intersects with the tunnel axis. This correspond to the position where the change is expected along the prediction range. Decreasing values in seismic velocities or in the elastic parameters are commonly associated to weakness zones were for instance increasing fracturing, fault zones, cavities or any unfavourable ground condition might be expected.

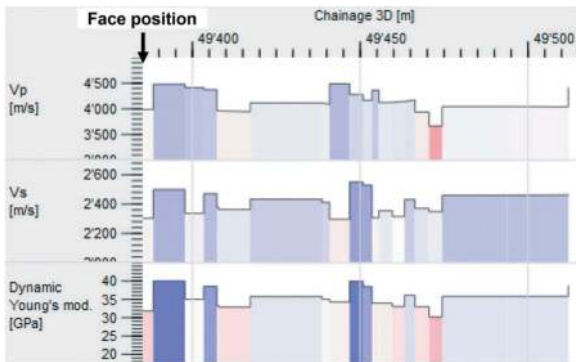

Figure 9. P and S-wave velocities and dynamic Young's modulus of campaign #7.

Figure 10 depicts longitudinal and horizontal planes from the 3D models of the V_p distribution for campaigns #7 and #8, top and bottom, respectively. On the upper part of each figure, Edyn charts are shown indicating the changes in GPa of the modulus. In campaign #7, Edyn values between 35 and 40 GPa dominate throughout most of the model. These values are related to the medium strong rock mass. Two anomalies in the velocity field are observed at the left-hand side of the tunnel axis, starting around 19 m from the axis, and extending for about 20 m, laterally. The reflectors defining the start of these two zones intercept the axis at chainage CH 49,407 and 49,466. The second anomaly has the lowest V_p and Edyn values: 3,630 m/s and 30 GPa, respectively. Lower Edyn values are associated with decrease in rock mass stiffness due to increasing fracturing, fault zones, etc.

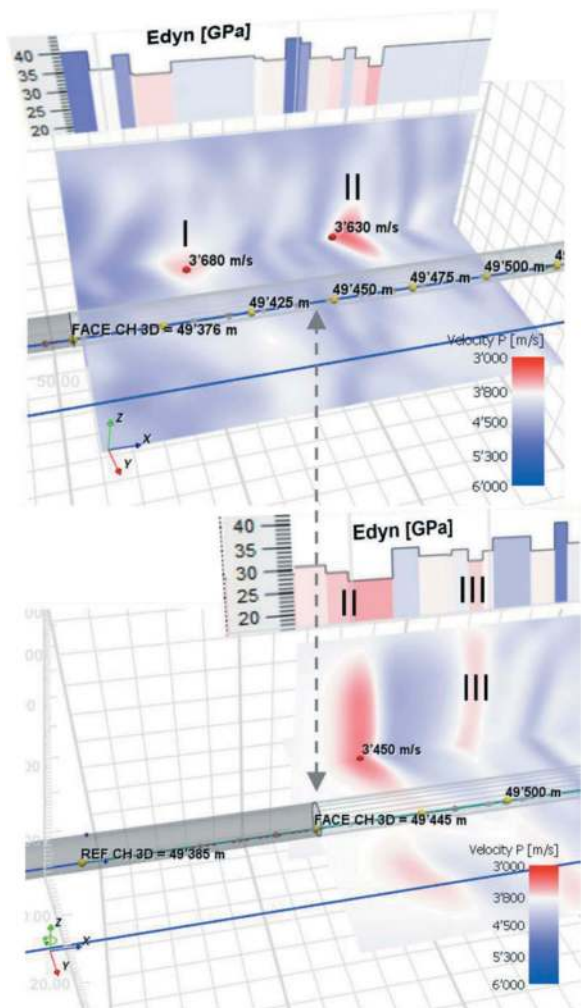

Figure 10. Longitudinal and horizontal 2D sections extracted from the 3D model of the V_p distribution. Top: campaign #7, bottom: campaign #8. On top of each figure, charts of Edyn variation in GPa are superimposed along the prediction range.

Campaign #8 was performed after 69 m excavation ahead of campaign #7, partially overlapping the prediction range of that campaign and shortly before the probable occurrence of the second anomaly. The result of campaign #8 not only confirmed the existence of a weak zone at the same location, but also enabled a more precise visualisation of the spatial distribution of the anomaly. According to the new result, the weakness zone reaches the tunnel section, and its influence area is two times larger at the tunnel level, 16 m instead of 8 m. The latter is based on the interception of the reflectors with the tunnel axis. Velocity and elastic values are slightly lower, $V_p= 3,450$ m/s and Edyn= 27 GPa.

Figure 11 shows the correlation between the TBM Contact Force (CF) and Edyn values obtained from Campaign #7 and #8 between chainages CH 49,440 and CH 49,500, approximately. According to the construction site personnel, CF has become an important parameter that allows conclusions to be drawn about the quality of the rock mass. Dropping

CF is an indicator of decreasing rock mass quality. For instance, $CF < 4,000$ KN is well correlated with poor rock mass. The lower the CF, the poorer the rock mass. In turn, increasing CF values are then associated with a rock mass of higher quality.

Along the selected chainages, the most significant CF drop is observed between CH 49,468 and CH 49,480, with CF values $< 3,000$ KN. This zone is in good agreement with the velocity anomaly (II) observed in the results of both TSP campaigns covering these chainages. Outside from this section, CF values $> 4,000$ KN dominate. Edyn values are in good agreement along most of the depicted section. However, in campaign #7 some opposite trend is observed between CH 49,452 and CH 49,464. Since this section lies in the far-field forecast of campaign #7 and is obviously embedded between two strong reflectors, one of which has a significant Edyn rise at around CH 49,446 and the largest drop from CH 49,466, sufficient resolution was not achieved to obtain reflectors that would better match this section. In fact, the influence of anomaly II can already distort the result for earlier chainages.

Figure 11. Diagram of TBM Contact Force versus Edyn as per Campaign #7 and #8 along selected chainages.

4 CONCLUSIONS

The new mechanised seismic source overcomes the current challenges posed by TBM tunnelling, namely the immediate identification of hazard zones and data acquisition without disrupting the production cycle and without downtime.

The percussion hammer is suitable for tunnelling with TBMs. It enables fast data acquisition during TBM stops for other activities.

In the present case study, critical areas such as shear/fault zones according to the GBR have not yet been encountered. However, areas with low to very low rock strength were encountered in these sections. These zones were correctly identified in various seismic campaigns and in some cases in exploratory boreholes and confirmed by the parameters logged by the TBM.

The information obtained from probe drills did not always match the TBM parameters, as was the case in some seismic campaigns, mainly due to the low to very low data quality.

Although much less energy is released into the ground with the impact hammer compared to explosives, sufficient spatial resolution is still achieved to identify geological structures that could be unfavourable for excavation. The penetration depth is naturally affected by this. However, this disadvantage is compensated for by uninterrupted data acquisition. This was demonstrated by the results of the two seismic measurements presented in this article. The first campaign made it possible to identify a possible weak zone in the far field about 90 metres before hitting it. In the subsequent campaign, which was carried out after about 70 metres of excavation, the weak zones were confirmed. The results of the second seismic campaign clarify the spatial extent and arrangement of this zone much better.

The TBM parameters, especially the contact force, corresponded well with the predicted zone of weakness.

ACKNOWLEDGMENTS

The authors would like to thank the site team of the contractor Larsen and Toubro, who actively supported the use of the TSP 603-Impact System in the Package 4 lot. The readiness for continuous operational use is in place and is also supported by the client RVNL.

Limits on the estimation of the EPB face pressure. A concrete example based on Kalman filter approach

ABSTRACT: The estimation of face pressure in urban tunnelling is a challenging task due to the complex geotechnical conditions and the need to protect existing infrastructures. This paper proposes a methodology to correct the geotechnical parameters (soil cohesion and friction angle) based on the measured pressure applied by the tunnel boring machine (TBM). The methodology is applied to a real case study of a 4 km tunnel excavated in soft soils in Paris. The results show that the proposed methodology can be used to calibrate the ranges of values for TBM face pressure and to provide possible design countermeasures despite the obvious discrepancies between the estimated and measured face pressures. These discrepancies can be attributed to the inherent complexity of TBM follow-up engineering in urban settings, where engineering decisions, predictions from analytical models, and contingent requirements may be incomparable.

Keywords: Tunnelling, TBM, Performance prediction, Face pressure, Kalman Filter

1 INTRODUCTION

In many cases, the excavation of urban tunnels has to deal with low overburden, soft soils, productive groundwater tables, and pre-existing or future constructions inside its geotechnical zone of influence. The envelope of these constraints results in the current adoption of closed mode tunnel boring machines (TBM) capable of managing the external geotechnical condition by the application of a confinement pressure at the face, as shown in Leca et al (2007), Zizka et al. (2016), and AFTES (2018). Moreover, in urban areas, where EPB are employed, the face pressure plays a fundamental role to control the surface settlements and possible problems on the existing infrastructures, in particular buildings.

The estimation of the face pressure, during the design stage is based on the geotechnical parameters, employing analytical or numerical models. In most cases the estimation of the geotechnical parameters is quite difficult and a small change in loads could lead to have different settlement estimations. During the construction, the face pressure is continuously monitored, normally referring the value to the tunnel crown, and compared with the designed value.

The aim of this paper is to:

- discuss a methodology to estimate the possible variation of the geotechnical parameters that play a fundamental role in the face pressure estimation based on the analytical formulation proposed.
- Apply the methodology to a real case, in order to assess the buoyancy and the limits of the findings and to establish also the possible variation of the parameters compared with the observed ones.
- Employ the so-called Unscented Kalman Filter (UKF) approach taking as reference the Face Pressure measured during the TBM tunnel execution.

The limits of this statistical method are then analysed.

2 DATASET AND METHODOLOGY

The real data used for comparison with the statistical models belong to an urban excavation for the city of Paris.

The utilized dataset comprises of all the TBM execution parameters, aggregated per lining ring, together with geomechanical information of the ground.

*Corresponding author: aflor@systra.com

The total number of rings is 2223 and the total length of the tunnel is approximately 4 km, with a cover of 15 meters on average, with minimum cover of 7 m and maximum cover of 21 meters.

The design confinement face pressure was evaluated along the alignment in an iterative way, as the minimum allowed pressure that guarantees tunnel face stability, contrast to waterhead in the chamber, and limitation of induced effects on pre-existing structures. Moreover, given the undrained behavior of the excavated soils, the confinement pressure also limits the insurgence of excess pore pressures and long-term subsidence induced by their consolidation.

The design process started with the assessment of the admissible volume loss every 20 m.

The confinement pressure was estimated according to this volume loss. The design pressure profile was then smoothened to obtain a constant value stretching on less than 75 m and a gradual pressure transition.

3 METHODOLOGY

In this work we propose a methodology that aims to correct the geotechnical parameters (soil cohesion and friction angle) based on the measured pressure applied by the TBM.

In the following paragraphs, the data of the already completed excavation are used to investigate the limits of validity of the proposed methodology. The discussion is a critical review of the effective application in an under-construction project.

The methodology process starts with the assessment of the admissible face pressure in undrained conditions. For this reason, the formula collected in Broms (1967) was used to establish the face design:

$$N = \frac{\sigma_s + \gamma h - \sigma_T}{c_u} \quad (1)$$

where:

N= stability number (minor than 2 to keep the deformations in the elastic field)

γ = Soil unit weight

h= tunnel cover

σ_s = is the surcharge on the top of the ground

σ_T = is the face EPB face pressure

c_u = undrained cohesion

Figure 1 shows the distribution of the face pressure according to Equation (1). It is possible to see the formula seems to have a quite good fit with the measured values for the first 1000 rings but does not show a good trend for the last 1000 rings approximately. For this reason, the application of the approach based on drained parameters was considered as well, employing the analytical formula collected in Kolymbas (1998) with approach shown in Amemiya et al. (2014).

Figure 1. Distribution of the face pressure vs measured along the alignment for undrained parameters.

The approach employed in this paper for the estimation of the face pressure is shown in equation (2).

$$pf = \alpha \left(\frac{\gamma h}{tg \left(45 + \frac{\varphi}{2} \right)} + c k_p \right) \quad (2)$$

where:

- pf is the applied face pressure,
- γ is the soil unit weight,
- h is the cover from the tunnel crown,
- c is the cohesion,
- φ is the friction angle.
- K_p is the passive earth coefficient
- α is a coefficient between 0.5 and 1.0.

By employing Equation (2), one can model in a very simple but effective manner both the soil properties (with c and φ) and the human factor (coefficient α). The proposed formula for the estimation of the front pressure could be further expanded to better reflect the different agents. In this simplest form it allows nonetheless to take into account choices that may not be dictated by calculations (for instance Client demands related to other factors).

The proposed procedure consists of three iterative steps:

1. Estimation of reference face pressure based on the Equation (2).
2. Variation of the values for the alfa factor, cohesion and friction angle and comparison with measured value.
3. Prediction of the new value of face pressure.

This methodology allows to calibrate the ranges of values for TBM face pressure and, so provide the possible designed countermeasures. For example, depending on the geological conditions, it is possible to vary the face pressure between lower and upper values.

4 KALMAN FILTER METHODOLOGY

The Kalman Filter is a mathematical tool for finding the best estimate for the state of a system in a discrete time process that is assumed as a linear stochastic differential equation (Salimi et al. (2016)). Following the approach of Innaurato (2001) we could consider the following discrete nonlinear time system:

$$x_{k+1} = f(x_k) + w_k \quad (3)$$

$$y_k = h(x_k) + v_k \quad (4)$$

Where $k \in \mathbb{R}$ labels the discrete timesteps, $x_k \in \mathbb{R}^{n_x}$ is the unknown state of the system and $y_k \in \mathbb{R}^{n_y}$ corresponds to the output data. In this paper x_k are:

- c_k : estimated cohesion;
- φ_k : estimated friction angle;
- α_k : estimated value of alfa.

Whereas y_k are the observed EPB face pressure values.

In order to provide an adequate initial model, all previous information on the input parameters x_k must be assessed. This previous information will come with an associated error of modelling w_k that can be represented probabilistically by means of a multivariable Gaussian probability density function with zero mean and covariance matrix Q_k .

On the other hand, the error related to face pressure values (v_k) is usually given by the manufacturer of the TBM, so it also turns out to be an independent and Gaussian random variable, with zero mean and covariance matrix R_k . The nonlinear functions f and h represent the dynamic process and the measurement model, respectively. The estimation of the state consists in elaborating an outlook of x_k employing y_k for each time k . For this reason, the interest of the user should be focused on obtaining the probability distribution function (PDF) of x_k conditioned to y_k or, in other words, the probability of reproducing the observed measurements (TBM face pressure) with a particular set of input parameters. The probability of a parameter set given the observations is:

$$p(x_k | \mathbb{Y}_{k-1}) = \int p(x_k | x_{k-1}) p(x_{k-1} | \mathbb{Y}_{k-1}) dx_{k-1} \quad (5)$$

The application of the Bayes Theorem to the observations leads to the updated equation of the parameters set, which is:

$$p(x_k | \mathbb{Y}_k) = \frac{p(y_k | x_k) p(x_k | \mathbb{Y}_{k-1})}{p(y_k | \mathbb{Y}_{k-1})} \quad (6)$$

Where:

$p(x_k | Y_k)$ is the probability of a certain estimation for the set of geotechnical parameters given the observed measures. This term is also known as the a-posteriori PDF.

$p(y_k | x_k)$ is the probability of computing the observed measures through the application Equation (2) given a certain set of geotechnical parameters.

$p(x_k | Y_{k-1})$ is the probability of a certain estimation for the set of geotechnical parameters given the previous observed measures. This term is also known as a-priori probability.

$p(x_k | Y_{k-1})$ in Equation (6) is the normalised probability or so-called scale factor so the $p(x_k | Y_k)$ could be between 0 and 1.

In this way expressions (5) and (6) represent the fundamental estimation of the Bayesian system of the Equations (3) and (4) depending on time k . The approach is depicted schematically below:

Figure 2. Principles of Bayesian Filter.

However, Equations (5) and (6) cannot be used in a simple way to find the PDF of a random vector belonging to a very nonlinear system, since a computationally demanding random sample simulation procedure must be adopted. This issue can be addressed by using the first two statistical moments (mean and covariance) of a Gaussian probability density function assumed for the parameter vector x_k . This procedure then aims for finding the PDF of the parameter's estimation. In this case the search problem is easier to solve by implementing the approach previously mentioned, with the unknown parameter standing for x_k at time k . The new equations (5) and (6) can be expressed in terms of the Kalman filter as the predictions:

$$\hat{x}(k|k-1) = E[f(x_{k-1} | \mathbb{Y}_{k-1})] \quad (7)$$

$$P_{(k|k-1)}^x = Cov[f(x_{k-1} | \mathbb{Y}_{k-1})] + Q \quad (8)$$

and the updated formulation can be expressed as:

$$\hat{y}(k|k-1) = E[h(x_k | \mathbb{Y}_{k-1})] \quad (9)$$

$$P_{(k|k-1)}^y = Cov[x_k | \mathbb{Y}_{k-1}] + R \quad (10)$$

$$P_{(k|k-1)}^{xy} = Cov[x_k, h(x_k) | (\mathbb{Y}_{k-1})] \quad (11)$$

$$\hat{x}(k|k) = \hat{x}(k|k-1) + P_{(k|k-1)}^{xy} (P_{(k|k-1)}^y)^{-1} (y_k - \hat{y}(k|k-1)) \quad (12)$$

$$\hat{x}(k|k) = \hat{x}(k|k-1) + P_{(k|k-1)}^{xy} (P_{(k|k-1)}^y)^{-1} (y_k - \hat{y}(k|k-1)) \quad (13)$$

As shown in Figure 3, the Kalman filter employs a recursive prediction-update procedure to obtain the mean and covariance of x_k from measurements. Equations (9)-(13) show how this implementation depends on the determination of the mean and covariance of the random state vector through the nonlinear functions $f(\cdot)$ and $h(\cdot)$.

Figure 3. Principle of Kalman Filter technique.

Nonlinear systems, such as those commonly encountered in geotechnical engineering, present a challenge for state estimation. However, significant research has been conducted in recent years, leading to the development of various Kalman Filter algorithms for nonlinear systems. Three of the most prominent algorithms are the Extended Kalman Filter (EKF), the Unscented Kalman Filter (UKF), and the Ensemble Kalman Filter (EnKF).

In this work, we use the UKF, which is a variant of the Kalman Filter that employs the Unscented Transform (UT) to propagate the state distribution through the nonlinear system (see for instance Julier (2004)).

The UT uses a set of deterministically chosen sigma points to represent the mean and covariance of the state distribution. These sigma points are propagated through the nonlinear system, and the resulting mean and covariance are calculated using a weighted average. To generate the sigma points, we consider the initial mean and covariance of the state distribution (red ellipse in Figure 4). The sigma points are then propagated through the nonlinear system to obtain a new set of points, which are used to calculate the mean (the "star" point at the right of Figure 4) and covariance (ellipse in Figure 4) of the transformed state distribution. The UKF is applied to both the prediction and update steps of the Kalman Filter algorithm. In the prediction step, the UKF is used to propagate the state distribution through the nonlinear process function f . In the update step, the UKF is used to update the state distribution based on the nonlinear measurement function h .

Figure 4. Uhlmann unscented transformation based on reference Julier (2004).

5 LIMITATIONS

The main drawback of the method is the assumption of normal distribution for the coefficients and the noise on the measured quantity (pressure) being white noise.

In practice both these assumptions are wrong since:

- Human intervention dictates the effective choice of TBM face pressure, be it because of buildings on the surface or other criteria.
- The encountered soil properties do not follow a normal distribution, as shown in Figure 5.

As an example, by looking at the design phase information of the soil cohesion, Figure 5, it is obvious that that the Normal distribution built on the parameters calculated on the samplings (mean and standard deviation, with amplitude proportional to the histogram area) and the normal distribution fitted on the data (amplitude, mean and standard as free parameters) are very different.

Figure 5. Distribution of designed values of cohesion.

On the other hand, the distribution of friction angle values shows that both the normal distributions (the optimized one and the one constructed with the original distribution parameters) (Figure 6). This means that the gaussian approximation is still valid for the friction angle.

6 RESULTS

Despite the limitation described in the previous paragraph, reference (the value applied during excavation) and estimated values for pressure are in good accord, see Figure 7.

Figure 6. Distribution of designed values of friction angle.

The main difference between the two sets of data is in the extreme values (both low and high). These differences are not of significant interest, as they are not due to limitations of the methodology, but to specific field conditions.

Figure 7. Correlation between measured and simulated face pressure.

Figure 8 shows the comparison between the reference face pressure and the estimated one where the small differences are always within the prescription established by the designer in terms of lower and upper threshold which normally are within a tolerance of ± 0.2 - 0.3 bar i.e. the natural pressure oscillation in the chamber of an EPB type TBM.

Figure 9 shows the absolute error expressed in % between the simulated and the measured face pressure values; it is possible to see how the majority of the values are within the 50 KPa which is the value normally recommended in the engineering practice. The absolute error is about zero for the first 200 rings approximately with some peaks between rings 1000 and 1800. These differences are due to particular conditions of EPB advancing with lower pressure in order not to damage the existing structures as it was a Client's requirement, and they could not be efficiently considered in a mathematical forecasting model.

Figure 8. Correlation between measured and simulated for all rings.

Figure 9. Measured face pressure absolute error (%) depending on the studied ring.

7 CONCLUSIONS

From the above considerations, the following conclusions can be drawn:

- The estimation of the TBM face pressure during the design stage is very important to efficiently forecast volume loss and hence the settlements onto the existing structures. The most employed methods are the analytical formulations which give a good estimation in almost ideal conditions.
- the estimation carried out in this paper, through the application of probabilistic estimators (Unscented Kalman Filter, UKF) showed that this technique constitutes a powerful and versatile calculation tool that allows to obtain very satisfactory adjustments. During the iteration process of the UKF, it has been possible to observe the special relevance of the maximum and minimum limits of each parameter to be estimated and entered in the filter.

The proposed Kalman filter methodology for estimating face pressure in urban tunnelling settings showed promising results in this case study based on a very simple analytical formulation. However, some limitations were apparent, with notable discrepancies between the estimated and measured face pressures. These discrepancies can be attributed to the inherent complexity of TBM follow-up engineering in urban settings, where engineering decisions, predictions from analytical models, and contingent requirements may be incomparable.

Despite these limitations, the proposed methodology has the potential to provide a more robust and reliable approach to face pressure estimation in urban tunnelling. Further testing on other datasets is warranted to validate its effectiveness in a wider range of conditions.

ABSTRACT: Bentonite and polymer-based drilling slurries are widely used in numerous geotechnical applications such as Slurry Shield TBM tunnelling, MicroTunnelling, Horizontal Directional Drilling and other trenchless technologies, piles and diaphragms constructions. In all cases, the rheological characteristics of the fluids must be correctly adjusted to ensure the stability of the excavation, proper lubrication and transportability of the excavated material. To date, there are several international standards and many best practices, empirical abacuses and indications for the definition of rheological properties of drilling fluids. However, there is often a lack of correlation between the results of different tests or measurements that can be carried out in laboratories using rheometers, viscometers and other sensitive and accurate equipment, and the rapid measurements that are widely used on site. The study presented in this paper involves the systematic performance of laboratory tests and rapid measurements on a natural bentonite used in the construction of tunnels and other underground works. The aim is to provide a broad overview of the rheological characteristics of drilling fluids prepared at different bentonite dosages, a series of correlations between the results of laboratory tests carried out using different mixing speed and mixing time. The results of the study support a better selection of the correct properties during drilling, an informed choice of the most appropriate measuring instruments and a more accurate measurement and control of the rheological properties of drilling fluids.

Keywords: Excavation, Viscosity, Marsh, Mixing, Rheology, Slurry

1 INTRODUCTION

Bentonite and polymer-based drilling slurries are used extensively in various geotechnical applications such as Slurry Shield TBM tunnelling, Micro-tunnelling, Horizontal Directional Drilling and other trenchless technologies, piles and diaphragms constructions. The crucial aspect in all these applications is to appropriately adjust the rheological properties of the fluids. This adjustment is necessary to guarantee excavation stability, adequate lubrication and the efficient transportation of the excavated materials.

Drilling fluids can be oil-based, synthetic-based and water-based: such fluids have different characteristics but, among them, water-based drilling fluids

are environmentally friendlier and cheaper than oil-based and synthetic ones (Liu et al., 2022).

Bentonite fluids are a particular type of water-based drilling fluids obtained by mixing water and bentonite, a natural volcanic clay. These fluids are commonly employed in tasks involving soil excavation as they are able to stabilize the hole walls by creating a protective barrier and ensuring the transportability of the excavated material (Chiarelli, 2014).

The essential element in the preparation of these fluids lies in the interactions between clay and water. When dry clay, which is composed of stacked plate-like structures, comes into contact with water, it undergoes a series of transformations. These transformations involve various stages, including hydration, dispersion, gelation,

*Corresponding author: diego.sebastiani@geeg.it

aggregation, and flocculation, as explained by Muller-Vonmoos et al. (1989).

Furthermore, these fluids typically exhibit pseudoplastic behaviour, although there are exceptions. Pseudoplasticity means that they require the application of a certain level of stress, known as the yield point or yield stress (represented as τ_0), to initiate flow. Below the yield stress the sample does not flow but behaves elastically (Steffe, 1996). When forces exceed the shear stress, the behaviour of the material can exhibit either pseudoplastic or Newtonian characteristics, as illustrated in Figure 1. Pseudoplasticity can be better understood by considering that the system is composed of molecules that can arrange themselves into lattice structures. To disrupt or “break” these structures, stress levels equal to or exceeding the yield point are required. This means that the material can transition between a solid-like and a liquid-like state depending on the applied stress. Whether this plasticity is reversible or not depends on the material capacity to re-establish the lattice structure after deformation (Luckham and Rossi, 1999).

Figure 1. Shear stress vs shear rate and main rheological behaviour of fluids (modified after Braun and Rosen, 1999).

The concentration of bentonite in fluid formulations is restricted because excessive amounts of powder can lead to issues such as the creation of a thick filter cake and formation damage. To address these challenges, the inclusion of polymers and other additives can be beneficial (Saboori et al., 2019). These additives serve multiple purposes, including the achievement of a thinner filter cake on the wellbore wall, reducing the potential for damage and fluid loss, and improving the rheological properties of the fluid (Song et al., 2016).

The intricate interaction between clay and water is of the utmost importance in the formulation of bentonite fluids. Its understanding plays a crucial role in tailoring these fluids for diverse applications, ranging from their use as drilling fluids in the oil industry to soil stabilization in civil engineering projects. The literature contains some information, including results from experimental tests and theoretical explanations,

that shed light on the rheological properties of bentonite drilling fluids (Ettahadi et al., 2022).

This study aims to offer supplementary insights into the rheological properties of bentonite drilling fluids. In particular the main objectives are: i) the investigation of the influence that mixing parameters adopted on site, such as time and rpm (round per minute), have on the properties of bentonite drilling fluids and ii) the definition of a correlation between the apparent viscosity and the results of easily accessible tests such as the Marsh cone, offering a valuable way to swiftly assess the parameter without resorting to more advanced instruments like rotational rheometers.

2 MATERIALS AND METHODS

To investigate the rheological properties, a natural bentonite was selected and different fluid samples were prepared by mixing it in varying concentrations with water.

The first step was the bentonite characterization in terms of Atterberg limits, water content, dry residue over 75 μm and swelling index; then different fluids were prepared adopting different mixing conditions, varying mixing speed and mixing time, and tested in terms of rheological parameters such as Marsh viscosity, API filtrate and filtercake. Also, a rheological analysis with a rotational rheometer was performed.

In the following paragraphs the testing methods and the models used are described.

2.1 Mixing and concentration

2.1.1 Bentonite sample characterization

Liquid limit values were determined with the Casagrande apparatus, following the ASTM D4318 (ASTM-D4318-17, 2017), in duplicate. The water content of the powder was measured using a thermobalance Gibertini mod. crystaltherm, at 105°C until constant weight of the dry sample. The dry residue over 75 μm was determined on the dry powder weighting the residue retained over a standard sieve of 200 Mesh, and calculated as (1):

$$\text{dry residue \%} = \frac{W_{\text{residue}}}{W_0} \cdot 100 \quad (1)$$

where W_0 is the initial weight of the powder, and W_{residue} is the residue retained after the sieving.

The wet residue was determined on a 5% solution of bentonite, passed through a standard sieve of 200 Mesh. The wet residue (2) was dried overnight at 105°C and weighted to obtain an indication on the insoluble minerals fraction, using the following formula:

$$\text{wet residue \%} = \frac{W_{\text{driedresidue}}}{W_0} \cdot 100 \quad (2)$$

where W_0 is the initial weight of the powder, and $W_{\text{dried residue}}$ is the residue retained after the sieving of the slurry and dried overnight.

The swelling index was determined following the standard ASTM D5890 (ASTM-D5890, 2019).

The pH of the bentonite slurry was determined using a pH test strip.

2.1.2 Bentonite slurries preparation

Different bentonite fluids were prepared at different rpm and mixing times using an orbital mixer Giorgio Bormac AM 20-D ARGOLab with a three-blade rotating stirrer positioned about 2 cm from the bottom of a 5 L plastic can with a 17 cm diameter. Every sample was prepared filling the can with tap water weighing 2500 g. The study can be divided into two main phases. The two different phases involved different concentration of bentonite as well as mixing parameters. In the first phase it was investigated the effect of different mixing parameter (Table 1) on the bentonite slurries properties described from the American Petroleum Institute (API-13B-RP1, 2015).

Table 1. Mixing parameters.

Bentonite weight %		5% wt	6% wt	7% wt
Fixed time: 15 min	Mixing speed (rpm)	750	✓	✓
		1000	✓	✓
		2000	✓	✓
Fixed rpm: 1500	Mixing time (min)	5	✓	✓
		10	✓	✓
		15	✓	✓

For the second phase the mixing parameters were fixed, (Table 2) varying only the bentonite concentration.

Table 2. Second phase mixing parameters.

Bentonite weight %		6.0% wt	6.5% wt	7.0% wt	7.5% wt
Fixed time: 20 min	Fixed rpm: 1500	✓	✓	✓	✓

2.2 Rheological tests

The bentonite slurries obtained at different dosages were subjected to the Marsh cone test at $t = 0$ h (immediately after the active mixing phase, T_0) after 1 hour, 3 hour and 24 hours of steady state. This assessment aimed to observe any distinct effects on the hydration phase of the bentonite slurry due to the different mixing parameters specified. The Marsh cone test was conducted following the guidelines outlined in API 13B-RP1 specifications. The retention capacity of the bentonite slurries was determined

by assessing the fluid loss both immediately after T_0 and after a 24-hour period, following the guidelines outlined in API 13B-RP1 specifications.

The rheological characteristics of bentonite fluids have been analysed using a rotational rheometer. A rotational rheometer is an instrument used to study the rheological properties of various types of fluids. These fluids are placed between a rotor and a stator, which can have different geometries. The fluid placed between the rotor and stator is set in motion by the rotation of the rotor. A second device measures the torque required to keep the plate in motion, and from this measurement, the applied stress on the fluid (shear stress, τ) can be determined. Meanwhile, the rotational speed provides information about the shear rate, $\dot{\gamma}$ (Sartori, 2013).

2.3 Common yield stress models for drilling fluids

Aqueous suspensions of clay that possess a relatively high particle concentration have traditionally been described according to Bingham's theory. The Bingham model is the simplest constitutive equation for viscoplastic fluids. Another model extensively adopted to describe the behavior of bentonite fluid viscosity is the Herschel-Bulkley (H-B) model. This model was used in this study to describe the rheological behaviour of the bentonite slurry.

Typically, the H-B model, described by eq. (3) and (4), is used for many suspensions since Newtonian plastic, shear thinning, shear-thickening and Bingham can be considered as a special case of the model.

$$\tau = \tau_0 + K \cdot \dot{\gamma}^n \quad (3)$$

$$\eta = \frac{K \cdot (\dot{\gamma})^n + \tau_0}{\dot{\gamma}} \quad (4)$$

Where τ is the shear stress; τ_0 is the yield stress or yield point; η is the viscosity; $\dot{\gamma}$ is the shear rate; n is the flow behaviour index and n is the consistency coefficient.

3 RESULTS AND DISCUSSION

3.1 Bentonite characterization

In the first part of the study, we characterized bentonite powder (Table 3), identifying its water content, residue at 75 microns both dry and wet. Regarding the water absorption properties of this bentonite, the liquidity limit and swelling index were analysed. The liquid limit is quite high, standing at around 430%.

The bentonite selected in this study can be categorized as a natural sodium bentonite. Generally, the higher the content of montmorillonite in the natural bentonite, the more the card-like structure can expand, resulting in a higher liquid limit (while the plastic limit remains relatively unchanged), thereby increasing the plasticity index (the range between the liquid limit and

Table 3. Bentonite characterization.

Type	Natural Sodium Bentonite	
Physical state	Powder	
Colour	Yellow	
Water Content	%	13.0
Dry residue over 75 microns	%	16.8
Wet residue over 75 microns	%	3.3
Swelling index	mL	25
Liquid limit	%	430
pH sol. 5% @25°C		9

the plastic limit). Consequently, bentonite with a higher capacity for water absorption requires less bentonite powder in the water mixture to achieve a specific viscosity. However, pure bentonites (with an exceptionally high montmorillonite content) are rare and expensive. It is well known (Madsen and Muller-Vonmoos, 1989) that due to their card-like structure, bentonites sol takes time to expand, and the particles require more time to disperse and swell. As a result, the viscosity increase over time is slow.

3.2 Mixing optimization

The preparation of a bentonite-based fluid initially involved the adoption of three different dosages of bentonite powder. In Figure 2 the results of Marsh viscosity are reported and the same behaviour on the API filtrate analysis can be observed.

Furthermore, it's important to note that extending the mixing time did not impact either the fluid loss or the thickness of the cake (Figure 3).

On the other hand, as rpm changes (mixing energy), there is a slight decrease in viscosity. The decreasing trend of viscosity with the increase of rpm adopted is in opposition to what expected (Figure 4) probably because the natural bentonite could be characterized by a low Na/Ca ratio as pointed out by the swelling analysis (25 mL). By enhancing the mixing efficiency there is a greater availability of Ca ions into solution. Such ions are recognized to have an adverse effect on the swelling and rheological properties of the bentonite fluid.

Using a typical electric motor curve as an example for a generic mixer, we generated a curve for the laboratory agitator based on the available data. To assess the laboratory findings, we compared them to the standard mixing speed and duration used in the field, taking into account the associated energy consumption taking as reference the previous part. Three scenarios were considered. The first scenario, representing the typical values used for on-site preparation, involved mixing at 1200 rpm for 20 minutes and re-mixing for 5 minutes. In the second scenario, mixing occurred at 1400 rpm for 10 minutes, followed by re-mixing for 2 minutes and 30 seconds.

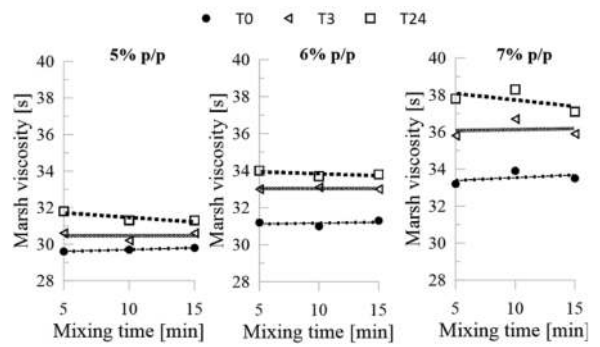

Figure 2. Marsh viscosity comparison immediately after mixing, hydrated 3 hours and 24 hours.

Figure 3. Fluid loss and cake thickness comparison for different %wt, immediately after mixing.

Figure 4. Marsh viscosity comparison immediately after mixing, hydrated 3 hours and 24 hours.

The third scenario involved mixing at 1600 rpm for 7 minutes and 30 seconds, with a subsequent re-mixing time of 2 minutes. It's worth noting that in Italy, the electricity cost for businesses typically falls within the range of 8 to 9 cents per kWh. The resulting percentage savings compared to the on-site preparation procedure are presented in Table 4.

The results show that it is possible to reduce the energy consumption optimising mixing time and mixing speed. It's important to notice that these results are obtained from laboratory apparatuses and they need to be adjusted if compared to field ones, taking into account specific field conditions.

Table 4. Cost options and savings.

	rpm	Time mix [min]	Remix time [min]	Cost [€]	Save [%]
1 st possibility	1200	20	5	0.15-0.17	0
2 nd possibility	1400	10	2.5	0.08-0.09	45%
3 rd possibility	1600	7.5	2	0.06-0.07	58%

3.3 Rheological measurement

To investigate the rheological characteristics of bentonite fluids they were subjected to progressively escalating shear rates, spanning from 250 s^{-1} to 2000 s^{-1} . The primary objective was to analyse the transformation of these fluids, transitioning from a gel-like state to a more liquid state, which occurs when the stress level exceeds the threshold causing the breakdown of the fluid’s network structure, ultimately resulting in a more gel-like consistency. In this instance, the aim was to attain a Marsh viscosity goal of 40 seconds Figure 5.

Figure 5. Individuation of the concentration to a marsh viscosity target of 40s.

The Herschel-Bulkley model was chosen as the best fit for characterizing the rheological properties of the studied bentonite fluids. This decision was based on minimizing errors between model-calculated and observed viscosities in experimental data. The suitability of this model is evident when analysing graphs of shear rate changes from 0 to 100 s^{-1} and back to 0 for various bentonite concentrations. The study examined different concentrations to understand how the thixotropic loop varies with increased bentonite powder content. During the decreasing shear rate phase, the Herschel-Bulkley model, supported by several studies (Yang, et al.) (Ren, et al., 2021) (Mellak, et al., 2014), effectively describes the fluids behaviour.

The fitting results, displayed in the Figure 6, demonstrate a strong alignment between the Herschel-Bulkley model and the experimental rheometer data.

An n value of less than 1 reveals the existence of pseudoplastic behaviour, signifying that viscosity rises as the shear rate diminishes.

Figure 6. H-B model applied to the experimental data.

Studying bentonite fluid behaviour beyond the initial gel structure breakdown is essential for understanding its thixotropic rheological properties. Traditional models like the Herschel-Bulkley model are insufficient to capture the complex behaviour observed when shear rates are gradually increased and then decreased in thixotropic fluids, leading to the creation of a “thixotropic loop” in shear stress-shear rate graphs (Franceschini, et al., 2022).

Figure 7. Hysteresis shear rate/shear stress cycle.

In the region of decreasing shear rates, the Herschel-Bulkley model is commonly used and referred to as the “steady state flow” zone. However, when examining the area of increasing shear rates, known as the “transient flow” zone, a different trend emerges (Franceschini, et al., 2022). Here, shear stress initially

rises linearly with shear rate, but as the shear rate continues to increase, shear stress decreases before returning to the steady state flow zone. This phenomenon is more pronounced with higher bentonite concentrations. The combination of transient flow and steady state flow forms the thixotropic loop, and its size grows with increasing bentonite content, indicating the materials degree of thixotropy (Yang, et al.) (Ren, et al., 2021). This degree of thixotropy is a measure of the energy required for bond dissociation per unit time and volume. The magnitude of the hysteresis area in the loop indicates whether the material has a gel-like structure under static conditions, resulting in increased rheological parameters and resistance to creep. In the case of bentonite fluids, the gel structure is related to swelling due to the insertion of water molecules between montmorillonite trilayer elements and particle interactions based on the electrical double layer theory (İşçia, et al.). At higher concentrations, particle aggregation into clusters occurs, forming a more complex network called a flocculate. The arrangements of particles contributing to the gel structure include edge-to-face and edge-edge arrangements, driven by electrostatic attractions or repulsions within the double layer. The transient flow zone is characterized by a “stress overshoot” peak, representing the elongation and resistance of the microstructure before its rupture due to increased shear rates (İşçia, et al.). Unlike the steady state flow zone, the transient flow zone is complex and challenging to describe with models like the Herschel-Bulkley model. It’s worth noting that the fluid cannot fully recover its original characteristics after being subjected to increased and then decreased shear rates, leading to changes in the shear force required for new flow. The hysteresis area increases as the bentonite content in the fluid rises, indicating higher thixotropy (Yang, et al.). Regarding the hysteresis areas (Table 5), as anticipated, their value increases as the bentonite content in the fluid increases because the material is more thixotropic.

Table 5. Values of hysteresis (thixotropy) areas for different concentrations of the Bentonite N.

Concentration	%	6.5	7.0	7.5
Area	J/m ³ s	551	644	651

After conducting a study on the rheological behaviour of bentonite fluids at different concentrations, an attempt was made to establish a correlation between the viscosity values measured with the Marsh cone (expressed in seconds) and the apparent viscosity values obtained with a rheometer. Based on literature studies (Pitt, 2000), it was established that the viscosity measured with the Marsh cone can be considered as the effective viscosity of a fluid subjected to a shear rate on the order of 2000 s⁻¹ (ranging from 1500 to 2500 s⁻¹). Therefore, all four

types of bentonite fluids at varying concentrations were subjected to a rotational rheometer at shear rates of 1000, 1500, and 2000 s⁻¹ to obtain measurements of apparent viscosity (Figure 8).

Subsequently, the obtained data points were analysed to establish a correlation with the Marsh cone times obtained in the previous phase of the study. The theoretical background for seeking a linear correlation is based on existing literature, which suggests that Marsh cone viscosity values expressed in seconds can be transformed into viscosity values (referred to as “effective viscosity”) expressed in cP using the following empirical expression:

$$\mu = \rho (t - 25) \quad (5)$$

Where μ effective viscosity in Centipoise [cP = mPa·s], ρ bentonite fluid density [g/cm³], t time to Marsh cone [s], 25 is a value that refers to the seconds it takes for a fluid with negligible viscosity at any density.

Figure 8. Correlation between Marsh viscosity and effective viscosity (μ) at different shear rate.

The expression suggests a linear relationship between viscosity and Marsh cone time. Table 6 presents the values obtained through rotational rheometer analysis of the optimally concentrated bentonite fluid, subjected to shear rates of 1000 s⁻¹, 1500 s⁻¹, and 2000 s⁻¹, resulting in apparent viscosity measurements.

Table 6. Apparent viscosity and Marsh time results for natural bentonite.

Shear rate [s ⁻¹]	Apparent viscosity [mPa s]	Marsh viscosity [s]
1000	35	40.0
1500	27	40.0
2000	21	40.0

4 CONCLUSIONS

The primary aim of this study was to further the body of knowledge related to the rheological properties of bentonite-based drilling fluids.

First, it was evaluated how operative conditions adopted during the mixing step as time and rpm influence the properties of bentonite drilling fluids. The main outcomes were that Marsh viscosity was almost constant at the increase of mixing time, similarly to the results of the fluid loss and the cake thickness. This allows to reduce the energy consumption associated with prolonged mixing operations.

Secondly, a good fit between the Herschel-Bulkley model and the experimental rheometer data was obtained. The n value lower than 1 revealed the occurrence of pseudoplastic behaviour as signifying that viscosity rises as the shear rate diminishes. The hysteresis area increased as the bentonite content in the fluid raised, indicating higher thixotropy of the materials.

Finally, a correlation between the apparent viscosity and the results of Marsh cone tests was investigated, offering a valuable way to swiftly assess the parameter with easily accessible tools.

ABSTRACT: Accurate identification of geological transitions during tunnel excavation is vital for ensuring safety and operational efficiency. Recognizing the significance of this critical issue, the present study developed an optimization system based on electrical exploration to analyze the characteristics of geological transitions in front of tunnel faces. The system employed an inverse analysis utilizing the harmony search algorithm to calculate essential attributes, including the distance between the tunnel face and geological transitions, as well as the electrical resistivity of the changing ground. To assess the applicability of the developed system, laboratory experiments were conducted using a soil chamber that simulated ground formations with geological transitions. The experimental findings confirm the system's effectiveness, demonstrating exceptional predictive capabilities within a relatively short data analysis timeframe. Notably, the system's ability to accurately predict the distance between the tunnel face and geological transitions highlights its efficacy in mitigating potential hazards arising from unforeseen geological transitions. As a result, the precise prediction of geological transitions achieved through the proposed method enables proactive implementation of risk management measures.

1 INTRODUCTION

Over the past few decades, there has been a significant increase in underground infrastructure construction driven by the growing demands for transportation, electricity, water supply, and sewage treatment. However, geological hazards during tunnel excavation can pose risks such as water inflow and collapse, which can severely impact both efficiency and safety (Zhao et al., 2007; Farrokh & Rostami, 2009; Zhao et al., 2014; Rafie et al., 2015; Bai et al., 2021; Xu et al., 2022). Particularly, geological transitions during tunnelling have the potential to induce ground settlement, face collapse, and sinkholes (Toth et al., 2013). Therefore, accurate predictions of these transitions are essential for effective risk management during tunnel construction (Yazdani-Chamzini, 2014).

At the tunnel design stage, geotechnical surveys often fall short in accurately identifying geological hazards along the tunnel route. Consequently, various non-destructive techniques have been developed,

including seismology, electromagnetic exploration, and ground-penetrating radar, to detect geological hazards ahead of tunnel construction (Dickmann & Sander, 1996; Grodner, 2001; McDowell et al., 2002; Gong et al., 2019; Caselle et al., 2020). Among these techniques, electrical methods, such as electrical resistivity tomography (ERT), stand out for their cost-effectiveness and efficiency in data analysis at tunnel sites (Kaus & Boening, 2008; Schaeffer & Mooney, 2016; Park et al., 2018; Kang et al., 2022; 2023; Mifkovic et al., 2021; Nie et al., 2023). Specifically, Park et al. (2016) developed a system that utilizes the harmony search (HS) optimization algorithm and electrical resistance measurements to predict anomalies ahead of a tunnel.

Building on prior research, this study aims to develop an optimization system to estimate geological transition attributes. These attributes include the distance from the transition point to the tunnel face and the electrical resistivity of the changing ground. In contrast to the approach taken by Park

*Corresponding author: dldnjfwp@korea.ac.kr

et al. (2016), this study employed the Wenner electrode array, renowned for its low earth resistance, to enhance measurement accuracy.

To validate the effectiveness of the developed system, laboratory-scale experiments were conducted, replicating the transition from rock to soil within a soil chamber. In addition, parametric studies were performed to investigate how prediction accuracy was affected by the characteristics of the geological transition. These characteristics encompassed variables such as the distance between the transition and the tunnel face and the electrical resistivity of the changing ground.

2 BACKGROUND

2.1 Electrical resistivity

An optimization system was developed to estimate the characteristics of geological transitions ahead of a tunnel face using electrical resistivity measurements. Electrical resistivity is a property that signifies a material's resistance to electrical current flow. In the context of soil and rock formations, various factors can lead to significant variations in electrical resistivity. These factors encompass porosity, clay content, weathering degree, saturation, as shown in Table 1 (Atkins and Smith, 1961; Brace and Orange, 1968; Timur et al., 1972; Rhoades et al., 1976; Parkhomenko, 2012). For instance, a decrease in porosity reduces electrical resistivity. Consequently, electrical resistivity has been widely employed to determine vital properties of rock and soil formations, as well as to infer the geological structures of ground formations.

Table 1. Correlation between soil conditions and resistivity.

Electrical resistivity of ground	Porosity	Clay content	Degree of weathering	Degree of saturation
High → Low	High → Low	Low → High	Low → High	Low → High

2.2 Analytical solution for geological transition

To accurately assess the attributes of a geological transition ahead of a tunnel face using inverse analysis, this study incorporated an analytical solution of electrical resistivity into an optimization algorithm. The well-known analytical solution for ground formations with a geological transition was employed, as represented by Equation 1 (refer to Figure 1) (Takahashi and Kawase, 1990).

$$\rho = \rho_g \left[1 + 4a \int_0^{\infty} \frac{\frac{\rho_{trans} - \rho_g}{\rho_{trans} + \rho_g} e^{-2\lambda d_{trans}}}{1 - \frac{\rho_{trans} - \rho_g}{\rho_{trans} + \rho_g} e^{-2\lambda d_{trans}}} (J_0(\lambda a) - J_0(2\lambda a)) d\lambda \right] \quad (1)$$

The analytical solution involves five variables, including both known and unknown variables. The known variables consist of the measured apparent electrical resistivity (ρ), the electrical resistivity of the surrounding ground (ρ_g), and the electrode spacing (a). On the other hand, the unknown variables comprise the electrical resistivity of the changing ground (ρ_{trans}), the distance between the geological transition and tunnel face (d_{trans}).

Figure 1. Schematic for the analytical solution of a geological transition.

3 OPTIMIZATION SYSTEM

3.1 System overview

This study developed an optimization system to determine geological transition characteristics, such as the electrical resistivity of the changing ground (ρ_{trans}), and the distance from the geological transition to the tunnel face (d_{trans}). The system incorporates an inverse analysis program based on the HS algorithm, which utilizes the analytical solution derived from Equation 1 to estimate these characteristic values of the geological transition. A detailed explanation of the inverse analysis process using the HS algorithm within the proposed system is provided in the subsequent section 3.2.

To enhance the prediction performance of the system, electrical resistivity was measured five times by changing the electrode spacings (a), and these measurements were integrated into the inverse analysis process. Consequently, the measurement equipment must be capable of measuring five electrical resistivity values corresponding to each electrode spacing.

In summary, the developed optimization system is composed of electrodes, a circuit board, a power supply, a measurement apparatus, and a control PC with the inverse analysis capability, as depicted in Figure 2.

3.2 Inverse analysis procedure

The developed optimization system utilizes the inverse analysis approach to estimate the unknown variables associated with the characteristics of the geological

Figure 2. Schematic of the proposed optimization system.

transition. This is achieved by inversely implementing the analytical solution in conjunction with the known variables (refer to Figure 3). To conduct the inverse analysis, the system employs the HS algorithm, which aims to find the optimal condition through a process resembling musical harmony improvisation (Geem et al., 2001).

Figure 3. Objectives of the inverse analysis.

The objective function ($f(x)$) of the HS algorithm was defined as the root mean square error (RMSE) between the analytical solution ($\rho_{analytical}$) and the measured electrical resistivity (ρ_a), as shown in Eq. 2. The HS algorithm aims to minimize the objective function values of the harmony memory, which includes the unknown variables. Finally, the characteristics of the geological transition can be obtained using the harmony memory with the minimum objective function. A detailed description of the HS algorithm procedure can be found in Geem et al. (2001).

$$f(x) = \sqrt{\sum \frac{1}{M} (\rho - \rho_{analytical})^2} \quad (2)$$

where M is the number of measurements with different electrode spacings.

4 LABORATORY EXPERIMENTS

4.1 Experimental setup

The developed system was validated through a lab-scale soil chamber test designed to simulate a geological transition in front of a tunnel face. A schematic of the experimental setup is shown in Figure 4. The experimental equipment comprised a soil chamber, electrodes, measuring apparatus, and a PC with the inverse analysis program. To enhance

prediction performance, five apparent electrical resistivities were measured with electrode spacings of 10, 15, 20, 25, and 30 mm. The experiment employed rock and soil formations such as granite, gravel, silica sand, and weathered granite soil to simulate ground conditions while considering geological transitions. The properties of these specimens are summarized in Table 2.s

Figure 4. Schematic diagram of the experimental setup.

Table 2. Properties of the rock and soil specimens.

Type	Property	Values
Gravel	Water content [%]	3.03
	Coefficient of uniformity (C_u)	0.6696
	Coefficient of curvature (C_c)	0.8673
	Dry unit weight (r_d) [kN/m^3]	14.396
	Soil type (USCS)	GP
	Electrical resistivity (ρ) [Ωm]	119.665
Silica sand	Water content [%]	31.26
	Coefficient of uniformity (C_u)	0.6384
	Coefficient of curvature (C_c)	1.1697
	Dry unit weight (r_d) [kN/m^3]	14.578
	Soil type (USCS)	SP
	Electrical resistivity (ρ) [Ωm]	76.29
Weathered granite soil	Water content [%]	22.42
	Coefficient of uniformity (C_u)	0.7382
	Coefficient of curvature (C_c)	1.0897
	Dry unit weight (r_d) [kN/m^3]	13.812
	Soil type (USCS)	SP
	Electrical resistivity (ρ) [Ωm]	133.34
Granite	Dry unit weight (r_d) [kN/m^3]	25.064
	Electrical resistivity (ρ) [Ωm]	303.89

Geological transitions were simulated in the soil chamber by filling it with silica sand, gravel, or weathered granite soil and stacking granite blocks. In this setup, the rock and soil formations were arranged in the upper and lower layers, respectively, as shown in Figure 5. Six experimental cases were performed, involving variations in the characteristics of the geological transition, such as the distance between the geological transition and the tunnel face (d_{trans}) and

the electrical resistivity of the changing ground (i.e., soil formations) (ρ_{trans}). Table 3 summarizes the characteristics of the geological transitions in each experimental case.

Figure 5. Illustration of the laboratory test cases for predicting geological transitions.

Table 3. Laboratory experimental cases for predicting geological transitions.

Considering the distance (d_{trans})	Values		
Distance [d_{trans}] (mm)	10	30	50
Electrical resistivity [ρ_{trans}] (Ωm)	119.67 (Gravel)		
Considering the changing ground (ρ_{trans})	Values		
Electrical resistivity [ρ_{trans}] (Ωm)	76.29 (Silica sand)	119.67 (Gravel)	133.34 (Weathered granite soil)
Distance [d_{trans}] (mm)	30		

4.2 Experimental results and discussion

The optimization results were analysed using two types of graphs: the prediction error graph and the convergence curves, as illustrated in Figures 6 and 7. Prediction errors were calculated by comparing the predicted results with the characteristic values of the simulated geological transition in the soil chamber. In addition, the convergence curves represented the objective function (i.e., Eq. 2) corresponding to each iteration, demonstrating the optimization performance of the developed system. A significant decrease in the convergence curves indicates the high optimization capacity of the system.

To assess the effect of the distance between the geological transition and the tunnel face, the electrical resistivity was measured while varying the distance from the geological transition to the tunnel face during the optimization process. The optimization results are compared in Figure 6. The experimental results show that the prediction error decreased as the tunnel face approached the geological transition, as shown in Figure 6(a). Furthermore, the convergence rate increased along with the shorter distance between the geological transition and the tunnel face (refer to Figure 6(b)). Thus, the geological transition ahead of a tunnel face can be detected more clearly when it is adjacent to the tunnel.

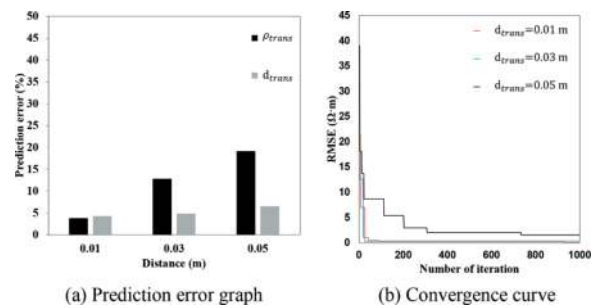

Figure 6. Effect of the distance between the geological transition and tunnel face on the optimization result.

To estimate the effect of the electrical resistivity of the changing ground on the optimization, inverse analysis was conducted using the electrical resistivity measurements corresponding to different materials of changing ground. The optimization results are compared in Figure 7, considering three substances of changing ground. The results showed that the effect of the changing ground on the optimization was negligible, as shown in Figure 7. Nevertheless, the prediction and convergence performance were sufficiently superior to predict the geological transition in front of a tunnel face, regardless of the changing ground.

Figure 7. Effect of the changing ground on the optimization result.

5 CONCLUSIONS

In this study, an optimization system was developed for predicting geological transitions ahead of

a tunnel face using inverse analysis combined with the HS algorithm. The developed system is capable of estimating important features, including the electrical resistivity of changing ground, and the distance between the geological transition and the tunnel face, which are crucial for implementing effective risk management strategies. To validate the system, a series of laboratory experiments were conducted, and the findings can be summarized as follows:

- 1) The developed system was successfully verified through laboratory-scale chamber experiments that simulated geological transitions ahead of a tunnel face. These experiments demonstrated the system's ability to accurately predict the two characteristics of the geological transition.
- 2) The prediction error of the system decreased when the tunnel face approached the geological transition in the experiments. Thus, tunnel operators can detect geological transitions more accurately when they are in close proximity to the tunnel face.
- 3) The prediction performance of the system was consistently significant, regardless of the changing ground. This capability enables the effective management of construction risks associated with unforeseen geological transitions by accurately predicting their characteristics.

High resolution resistivity imaging for assessment of geological conditions ahead of tunnel face in a complex geology

S.L. Kapil*

President, ISEG & Director DMR Hydro Engineering & Infrastructures Ltd., India

ABSTRACT: Assessment of subsurface geological conditions along tunnel alignment is the most challenging task for tunnelling projects. Extremely rugged, densely forested, and inaccessible topography provides limited scope for investigations, which becomes a cause of concern during execution of these projects. Therefore, a realistic geological prognosis based on a comprehensive survey and investigation is the backbone of any successful project.

Conventional geological mapping and exploration techniques like drilling-drifting are expensive, time-consuming, and provide very limited information. On the other hand, geophysical investigations are fast, economical, and capable of continuous area coverage. In the last two decades, developments in software and hardware have considerably improved the reliability and applicability of geophysical techniques, and now 2D/3D subsurface details can be generated in a fast and economical way. Now it is possible to apply advanced geophysical investigation tools in rugged topography as well as under high slope conditions ($> 45^\circ$).

Resistivity imaging is a newly developed advanced technique for generating 2D/3D resistivity images of subsurface geology and is capable of identifying the location and geometry of weak/fracture zones in a precise way. In this case study, resistivity imaging was utilized at one of the tunnelling projects in southern India. The investigation of the 6.71 km long tunnel was done utilizing more than 40 drill holes. In general, good quality rock mass consisting of granitic gneiss, biotite gneiss and migmatite with occasional pegmatite veins present in the area. After excavation of about 4 Km length, the tunnel face completely collapsed due to adverse geological conditions and construction was held up for more than two years. Resistivity imaging identified a highly poor rock mass of about 200 m length ahead of the tunnel face. These findings were used for planning the treatment and design of excavation methodology for the inferred zone and the same was crossed successfully.

Keywords: Investigation, Geophysical, Resistivity, Imaging

1 INTRODUCTION

Assessment of subsurface geological conditions along tunnel alignment is the most challenging owing to inaccessibility, thick vegetation cover, high super incumbent cover and geological complexity of the terrain. This results into time and cost overrun due to unforeseen geological conditions during execution. Therefore, realistic geological prognosis based on comprehensive survey and investigation is the backbone of any successful infrastructure project. Acquiring precise details of geotechnical parameters in the investigation stage of project development have great implication in selection of optimum alignment, preparation of cost estimate and design.

The conventional exploration techniques like drilling, drifting, pitting and trenching are expensive,

time consuming and provide very limited information. On the other hand, geophysical investigations are fast, economic and capable of continuous coverage of the project area. To minimize the uncertainties in investigation, emerging geophysical techniques are of immense help. These techniques provide precise details of subsurface rockmass conditions and can minimize uncertainties met during construction. Geophysical studies with appropriate technology covering all project components needs to be taken up for minimizing the adverse geological conditions often met during construction.

Two decades back, due to lack of advancements in hardware and software, the geophysical instruments especially for engineering applications were in development stage and relied on basic theories of homogeneous isotropic and sub-horizontal layered

*Corresponding author: shyamkapil@gmail.com

earth. Due to these unrealistic assumptions it was difficult to undertake geophysical surveys under undulated terrain and high slope areas. In the last two decades, development in software and hardware have considerably improved the reliability and applicability of geophysical techniques and now 2D/3D subsurface details can be generated in a fast, economic and precise way. Now it is possible to apply new age geophysical tools in rugged topography as well as on high slope area ($>45^\circ$). These non-invasive advanced geophysical investigation techniques like resistivity imaging, crosshole seismic tomography and seismic refraction tomography are extremely useful in optimizing and minimizing quantity and locations of direct investigations like drilling and are capable in developing more accurate sub surface geological model of the project components.

2 PROJECT LOCATION

The project is located near Munnar in Idduki district of Kerala and envisages transfer of water from Western Kallar River to the existing Sengulam Reservoir by constructing a 12m high and 80m long concrete gravity weir and a diversion tunnel of 3.5m diameter and 6.8 km length.

Project layout and location is shown in the Figure 1 and Figure 2 respectively. Geological investigations for this scheme were carried out doing extensive drilling along the diversion tunnel and along adits. During construction of tunnel highly poor rock mass was encountered from RD 4095.25m onwards and finally due to loose fall, over break and caving, tunnel face was completely collapsed at RD 4005.0m.

Efforts were made to negotiate the poor rock mass. However because of highly poor nature of rock mass work could not proceed for almost two years. Drilling from surface ahead of tunnel face was also planned. However due to difficult field conditions this could not be taken up. Tunnel face was at a depth of about 200m from surface. As such, in order to assess geological conditions ahead of tunnel face resistivity imaging along the tunnel alignment from surface was taken up.

Figure 1. Project layout.

Figure 2. Project location.

3 GEOLOGY OF PROJECT AREA

The project is located at Anachal near Munnar in Idduki district of Kerala along the western slope of the Western Ghats amidst ridges rising to a moderate level of EL 850M to EL 1100M. The hills are occupied by migmatite group of rocks essentially made up of granitic gneiss, biotite gneiss, migmatite with occasional pegmatite veins which are highly weathered at places. The tunnel is driven through hornblende biotite gneiss and granitic gneiss and intrusive pegmatite. The trend of foliation varies from $N 30^\circ$ to $60^\circ W$ - $S30^\circ$ to $60^\circ E$ and dip 60° to 70° towards NE.

4 RESISTIVITY IMAGING

Resistivity surveys have been used for many decades in hydrogeological, mining and geotechnical investigations with some limitations. The resistivity sounding method used since 1920's provides a one dimensional model of the subsurface. The greatest limitation of the resistivity sounding (1D) is that it does not take into account horizontal changes in the subsurface resistivity. A more accurate model of the subsurface is a 2D model where the resistivity changes in the vertical direction, as well as in the horizontal direction along the survey line can be determined. Accordingly, resistivity surveying method has undergone dramatic changes over the last two decades on account of rapid developments in hardware technology and interpretation software.

A major improvement in the early 1990's was the development of two-dimensional (2D) resistivity imaging method that provide a more realistic model of the subsurface in geologically complex areas. In 2D imaging large numbers of electrodes

Figure 3. Arrangement of electrodes for a 2D imaging survey for apparent resistivity pseudo section (Loke 2000).

placed over the surface are connected to the instrument through an electronic switching mechanism. Arrangement of electrodes for 2-D Resistivity imaging survey is detailed in the Figure 3.

Data is collected by the instrument automatically for several datum points as per the selected electrode configuration protocols viz. Wenner, Dipole-Dipole, Schlumberger etc. As large data is collected for several datum points, this can be inverted for generation of subsurface image in terms of resistivity. This 2D/3D resistivity image can be interpreted further for assessment of subsurface lithology and can provide fine details about the subsurface. The inversion software can handle resistivity variations in both horizontal as well as in vertical directions. With these developments resistivity imaging has become a powerful tool for geological exploration with more reliability.

Figure 4. Imaging cable crossing the highway.

5 DATA COLLECTION

The tunnel alignment on the surface was crossing the National Highway, NH-49 at number of places. This posed serious problem for laying the imaging cables and was negotiated by making the local arrangement at site by placing cable in between thick rubber sheet and angle iron tied with wire (Figure 4). This was further covered by placing soil sacks and soil. This arrangement helped in smooth data collection without any restriction to traffic movement.

Moreover, tunnel is passing through big boulders and dense plantations and it was very difficult to inject the current with the electrodes available with the imaging system. In order to make good contact with the ground special mild steel electrodes of 1.5m length were fabricated and these were used for data collection. Further, to increase the contact surface area of electrodes, these were driven with hammer in a small pit filled with bentonite, salt water mixture. This mixture was kept ready and poured in between measurements to keep the contact wet.

Figure 5. Installation of longer electrodes in dense forest area.

Resistivity Imaging data was collected in roll-along (Dahlin 1996) manner with four cables each of 200m length with a cumulative length of 800m using eighty-one electrodes with 10m interval. Initially it was planned to cover the entire tunnel length of 2900m in a single layout. However due site difficulties and restriction first imaging line (R1) was terminated after covering a length of 2200m from RD 4309m to RD 2109m. Another imaging line (R2) of 800m was taken up from RD2309m to RD1509m with a overlap of 200m. A total length of 2800m was covered.

ABEM Lund Imaging System was used for field data collection. Instrument was kept in the mid of layout for taking one set of data recording. After completion of one set of data recording first cable & 20 electrodes were shifted after the last cable and the position of instrument kept in the middle of layout and again data set was recorded and this procedure was continued till the requisite length was covered. Data collection in this manner helped in data overlap after every 200m for better depth and lateral resolution. Installation of electrodes in forest area and schematic diagram showing data collection in roll-along manner is shown Figure 5, Figure 6 respectively. Data collection was done utilizing Schlumberger and Dipole- Dipole. The work presented in this paper is from the investigation report (Kapil et al. 2017).

Figure 6. Data collection as per roll along method protocols.

6 DATA PROCESSING

Data was processed using RES2DINV software in which a finite difference or finite element model of subsurface resistivity distribution is automatically adjusted to minimise the residuals between the model response and measured data (Loke and Dahlin 2002). Two different optimisation methods were tried for data inversion, L2 norm and L1 norm. In L2 norm or least square inversion, square of differences between model response and measured data is minimised. This method gives smooth transitions in resistivity between zones of different resistivity. In L1 norm or robust inversion the absolute differences are minimised. This method is more robust against noise in the data, and gives sharper boundaries between zones of different resistivities (Loke et al. 2003). Data for both Schlumberger and Dipole-Dipole protocols was processed using least square and robust inversion. Schlumberger data did not provide the vertical resolution with clarity. However dipole-dipole data provided the boundaries of poor rockmass with clarity and therefore the same was used for final assessment of geological conditions ahead of tunnel face.

7 RESULTS

7.1 Imaging line (R1)

This 2200m long profile was conducted utilizing Dipole-Dipole, Schlumberger and Gradient protocols with 10m electrode spacing in roll-along manner covering the diversion tunnel length from tunnel RD 4309m to 2109m. However out of these protocols the expected poor rockmass boundaries were obtained in dipole-dipole electrode configuration with clarity and the same was used for geological assessment. Maximum penetration depth of about 250m has been achieved in this profile. The resistivity imaging section corresponding to Dipole-Dipole electrode protocol is shown in Figure 7.

Low/high resistivity values on the top are indicating the overburden, boulders and rockmass. Some higher resistivity values are also observed on ground surface in overburden area representing dry soil and boulders. A low resistivity zone having values of 80 to 200 ohm.m from RD 4069m to RD 3795m is clearly visible within the rockmass. This zone corresponds to completely weathered water saturated rockmass representing the location where tunnel face was collapsed. From tunnel face (RD 4005m) length of this zone is about 210m (RD 3795 m). In the balance length of tunnel, resistivity values varying from 600 ohm.m to 4500 ohm.m represents fair to good quality rockmass. Some zones are having resistivity values above 4500 ohm,m and this represents highly competent rockmass.

7.2 Imaging line (R2)

This 800m long profile was conducted utilizing Dipole-Dipole and Schlumberger protocols with 10m electrode spacing in roll-along manner covering the tunnel length from RD 2309m to RD 1509m with 200m overlapping with R1 profile. In this profile also poor rockmass boundaries were obtained in dipole-dipole protocol data with clarity and the same was

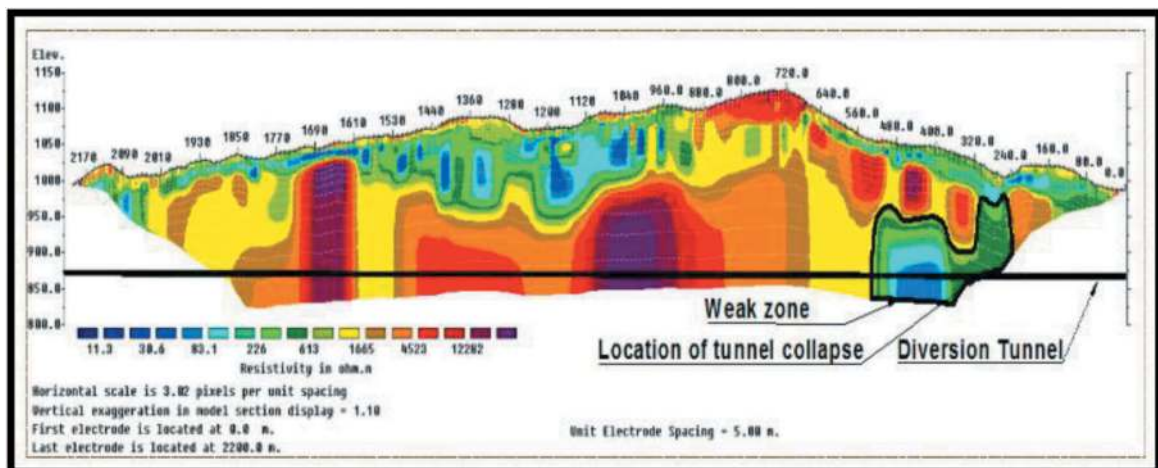

Figure 7. 2D resistivity imaging section along profile R1.

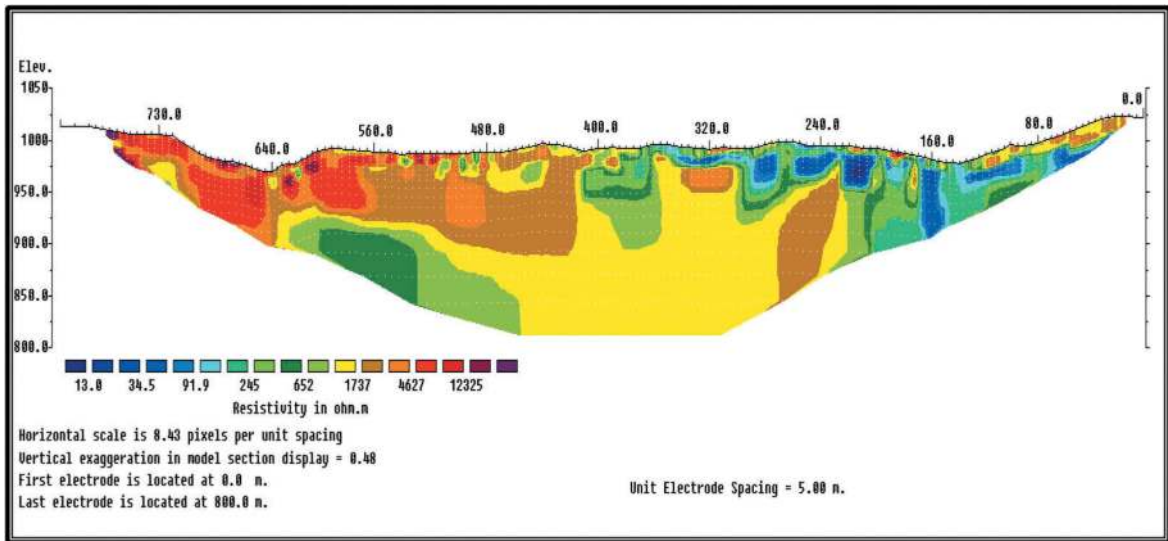

Figure 8. 2D resistivity imaging section along profile R2.

used for geological assessment. Maximum penetration depth of about 180m has been achieved in this profile.

The resistivity imaging section corresponding to this profile is shown in Figure 8.

Low/high resistivity values on the top in general corresponds to overburden representing dry soil, boulders and rockmass. A low resistivity zone of 97m length from RD 2149m to RD 2052m having values of 80 to 200 ohm.m is clearly visible within the rockmass. This zone corresponds to completely weathered, water saturated rockmass. In the balance length of tunnel, resistivity values are varying from 600 ohm.m to 4500 ohm.m representing fair to good quality rockmass. Some zones are having resistivity values above 4500 ohm,m representing highly competent rockmass.

7.3 Geological section

On the basis of results of the resistivity imaging profile R1 and R2 a Geological section was developed along tunnel alignment from RD 4039M to RD

Table 1. Anticipated geology in different zones.

Zone	Anticipated Lithology
Zone A	Top soil consisting slope wash material, boulders, weathered rockmass
Zone B	Completely weathered water saturated rockmass . This zone is expected to behave like soil with very loose Migmatite group of surrounding rock.
Zone C	Migmatite group of rock consisting of hornblende, biotite gneiss and granite gneiss with intrusive pegmatites. Moderately jointed fair quality rockmass.
Zone D	Migmatite group of rock consisting of hornblende, biotite gneiss and granite gneiss with intrusive pegmatites. Slightly jointed good quality rockmass.
Zone E	Migmatite group of rock consisting of hornblende, biotite gneiss and granite gneiss with intrusive pegmatites. Strong, massive very good Quality rockmass.

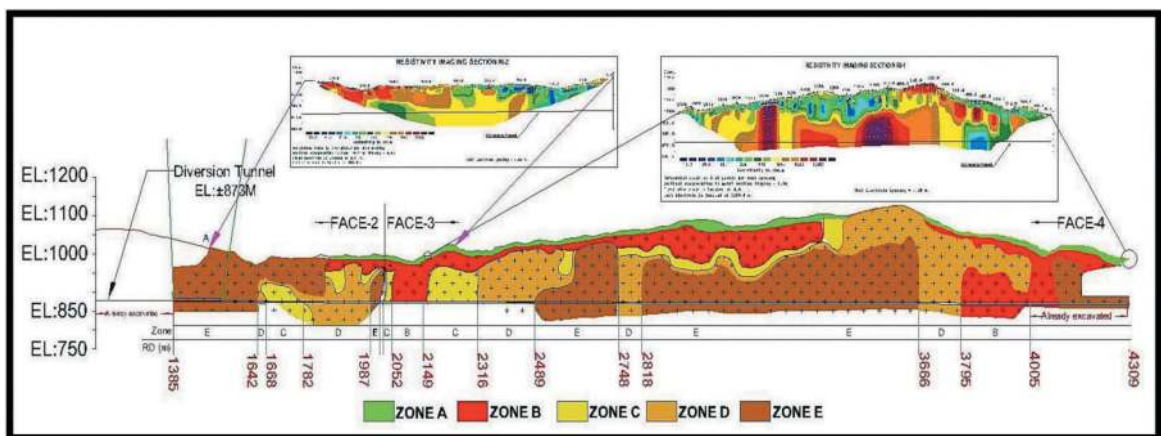

Figure 9. Geological section showing inferred zones.

1385M. Along the tunnel alignment anticipated lithology based on resistivity values has been divided into five zones Zone A, Zone B, Zone C, Zone D and Zone E. The detailed geological description of different zones is given in Table 1. The Geological section showing different zones is shown in Figure 9. Pie chart showing the percentage of different zones is shown in Figure 10.

Figure 10. Pie chart showing the % in different zones.

8 CONCLUSIONS

Investigation of the diversion tunnel was done with extensive drilling utilizing more than 40 drillholes. Good quality rockmass was expected as per the drilling data along most of the tunnel alignment at tunnel grade. However adverse geological conditions were met after excavation of about 4 Km tunnel length where good rock mass was predicted based on geological mapping and drilling data. Resistivity imaging from the surface was taken up for assessment of geological conditions ahead of collapsed tunnel face and along the balance tunnel alignment. Keeping in view the rugged topography and presence of large boulders along the tunnel route, longer electrodes of 1.5m length were fabricated and used for current injection. In addition to this for increasing the surface area, these electrodes were installed in a small diameter hole filled with a mixture of bentonite and salt. This arrangement provided a high quality data. Dipole- Dipole protocol data was processed with RES2DINV software using robust inversion. Penetration depth of more than 200m beyond tunnel grade was achieved along most the covered length from RD 4005m to 1385m. Two zones consisting highly weathered rockmass were inferred along the tunnel alignment. Zone 1 is inferred from RD 4005m to RD 3795m and Zone 2 is inferred from RD 2149m to RD 2052m (Figure 9). Zone 1 corresponds to the location where the tunnel face was collapsed completely.

Based on results of imaging survey data, planning & excavation methodology was finalized and tunnel excavation was restarted. The zone 1 was crossed successfully after taking adequate measures. Out of the predicted length of 210m of Zone 1, 185m length encountered highly weathered rock mass. This confirmed the reliability of imaging results. Resistivity imaging mapped the poor rock mass with proper location and geometry and this helped in starting the excavation which was pending for more than two years.

These results clearly indicate that resistivity imaging is a powerful tool and capable to provide the subsurface geological conditions in a fast and economic way with reliability. Moreover this also provide the complete details of the subsurface geology which is generally not possible by other methods nor even by drilling.

Qiang Li*, Weigang Yu & Song Lu

China Railway Southwest Research Institute Co., LTD. Chengdu, China

ABSTRACT: During tunnel construction in karst areas of China, geological hazards such as water or mud gushing pose substantial geological risks to tunnel construction. Improper handling of these hazards results in significant safety hazards during the operation stage. Therefore, it is of great significance to enable more accurate prediction and assessment of karst development degree in karst tunnels and thus minimize or prevent hazards in tunnel construction. In the above research, through the study of characteristics of karst forms and karst groundwater revealed in tunnel excavation, the characteristics and action mechanism of karst water-bearing media were unveiled, an assessment model of karst development degree based on hydrochemical kinetic parameters and fractal indexes of karst forms was established, and a hydrochemical kinetics-fractal index assessment technology of karst development degree was proposed. In engineering application in typical karst tunnels including Yaowanggu Tunnel on Jiuzhaigou-Mianyang Expressway, Xingaopo Tunnel on Xuyong-Bijie Railway and Shuangfengya Tunnel on Micang Avenue, the assessment technology of karst development degree based on hydrochemical kinetics and fractal theory was used according to different regional geological, hydrogeological and environmental conditions, and the corresponding hydrodynamic parameters and fractal assessment indexes were obtained for targeted prediction and assessment of karst development degree in tunnels. It played a positive guiding role in the project construction. The application of this technology in tunnel projects above has proved its potential for wider adoption and promotion in similar tunnel projects.

Keywords: Tunnel, Karst development degree, Groundwater chemical dynamics, Fractal theory, Evaluation technology

1 INTRODUCTION

China has the largest number of tunnels which more than 40,000 (Tian Siming et al., 2021), there are some instances of long and deep tunnels located in highly complex geological environments in mountainous regions. Especially, the construction of karst tunnels that traverse karst development areas often confronts geological hazards, including water or mud gushing of varying magnitudes, posing substantial risks to tunnel construction. Improper handling of these hazards will result in significant safety risks during the operation stage.

It is widely acknowledged that karst development necessitates specific conditions, namely the solubility and permeability of the rock, as well as the mobility and erosive properties of water (Zhang

Renquan et al., 2018). Hydrogeological conditions such as structure, lithology and karst development horizon are key factors controlling the development of karst water systems (Qin Xiaoqun et al., 2017). Karst water system is affected by tunnel construction, which results in different characteristics of groundwater recharge, runoff and discharge (Li Xiao et al., 2020). To date, how to accurately assess the development of karst and karst groundwater in karst tunnels remains a prevalent and challenging issue in tunnel construction. In the study of the hazard-inducing theory of karst tunnels, unfavorable geological bodies that adversely affect tunnel construction safety when disturbed by construction are defined as hazard-inducing karst structures (He Faliang, 2019). These structures can be categorized into different types, namely dissolution fissures,

*Corresponding author: liq019@qq.com

karst cave cavities, channels and underground rivers (Li Shucai et al., 2018). Many scholars have extensively investigated the hazard-inducing mechanisms of certain typical karst structures through case analyses (Liu Y et al., 2019), theories encompassing geochemistry and fracture mechanics (Wang Ying et al., 2004), as well as model experiments (Li Shucai et al., 2018), and unveiled the hazard-inducing mechanisms of water and mud gushing in karst tunnels. Through the analysis of hazard-inducing mechanisms, typical factors were selected as assessment indexes to establish different water gushing risk assessment models (Yingchao Wang et al., 2017). For assessment of the criticality level of water and mud gushing in tunnels (Mao Bangyan et al., 2010), various methods such as the hierarchical analysis method (Han Xingrui et al., 2018), the expert scoring method (Liu Jian et al., 2004), and the machine learning-based method (Bai Chenghao, 2021) were used and thus a range of risk assessment methods have been developed for evaluating the risk of water and mud gushing hazards in karst tunnels. The assessment technology of karst development degree based on hydrochemical kinetics and fractal theory was developed through the study of fractal characteristics of karst forms and hydrochemical kinetics (Li Cangsong et al., 2017a). The feasibility of this method was further verified based on the engineering applications carried out in recent years.

2 CHARACTERISTICS OF KARST KARST AQUIFER

2.1 *Hydrogeological characteristics of karst water storage structures*

Karst terrain in China has a vast distribution, encompassing a total area of approximately 3.44 million km² (Li Datong, 1985). Karst terrain exhibits a more pronounced presence in regions such as Guangxi, Guizhou, eastern Yunnan, and northern Guangdong. However, the extent of karst development and the characteristics of karst functional assemblage can widely differ from one location to another. Based on the analysis, these variations can primarily be attributed to different geological and climatic conditions including different karst geochemical background conditions such as topography, hydrology, vegetation coverage, as well as the intensity of karst dissolution or sedimentation. Generally, karst aquifers are divided into different karst water systems according to the spatial association relationship between aquifer and aquiclude formations, different combinations of surface hydrological network and deeply incised valleys, and the existence of surface and underground watersheds. Different karst water systems not only have different hydrogeological characteristics, but also have different karst water circulation and hydrochemical characteristics due to the different morphology of water storage structures. Generally, the hydraulic

connection between different karst water systems is weak or completely absent. From the perspective of water-bearing structure, tunnels traverse geological bodies of monoclinical strata, folds, fracture zones and composite strata. Tunnels that pass through syncline water-bearing structures or fracture structures are particularly susceptible to significant hazards like karst water or mud gushing. This vulnerability arises from the development of fissures within these structures where the existence of highly water-rich media, such as karst channels, is more prevalent. Additionally, based on engineering cases, long and deep tunnels, in particular, frequently encounter a wide range of karst water storage structures.

2.2 *Chemical action mechanism of karst water*

In terms of macroscopic karst landforms, the development and distribution patterns of karst exhibit variations that encompass peak clusters, peak forests, depressions, and dissolution valleys. Based on observations from various karst tunnels, several karst forms are commonly present including dissolution pores, dissolution fractures, dissolution grooves, dissolution channels, karst caves and karst underground rivers. The diverse range of karst forms fully shows the irregularity of karst forms. The karst forms revealed in tunnel excavation exhibit the characteristics of uncertainty and irregularity. When changing the observation scale and magnifying or reducing a karst form of a certain scale by multiplying it exponentially by a factor of 2, a remarkable similarity can be observed between images of large-scale dissolution fractures, pores, and underground river channels, and those of smaller-scale joints and fissures. This similarity indicates that the development of karst forms exhibits a significant characteristic of fractal imagery known as self-similarity. Upon confirming the self-similarity of karst forms, the observation scale and magnification factor were changed through image processing. It was found that the characteristics of each karst form remained unchanged. Consequently, the fractal dimensions of various karst forms can be determined. This finding suggests that karst development forms also exhibit the scale invariance characteristic of fractal images. Due to the properties of self-similarity and scale invariance exhibited by karst forms, the fractal theory can be applied to conduct an in-depth study on their characteristics, so as to explore the underlying laws governing karst development and distribution and integrate macroscopic and microscopic laws.

Based on the chemical kinetics theory of karst groundwater (Cao Yuqing et al., 2017), soluble rock and karst groundwater not only facilitate the dissolution of rock but also induce changes in the hydrochemical composition of karst groundwater through hydrodynamic and hydrochemical processes. The chemical composition of groundwater reflects the hydrogeochemical environment and various physical and chemical reactions or action mechanisms that groundwater undergoes as it migrates through karst

water-bearing media. It becomes a hydrogeological parameter capable of characterizing the process of water-rock interaction and the extent of such reactions.

According to the fractal theory, the hydrogeological characteristics of karst revealed in tunnels are affected by their hydrogeological environment, and there are differences in hydrochemical components, so the composition of hydrochemical ions is random. According to the complexation reaction theory in analytical chemistry, the formation of highly stable new ions through the combination of molecules or ions with metal ions is known as a complexation reaction. By integrating the principles of hydrochemical kinetics, ion pairs are defined through the combination and pairing of common ions in hydrochemical analysis. Subsequently, the cumulative percentage of ion pairs is statistically analyzed. According to paper (Li Cangsong et al., 2018), they also have two significant attributes, i.e. self-similarity and scale invariance of fractal images. This proves the applicability of fractal theory in the chemical composition analysis of karst groundwater.

3 ASSESSMENT TECHNOLOGY OF KARST DEVELOPMENT DEGREE

3.1 Assessment method based on hydrochemical kinetics-fractal indexes

The karst development degree can be viewed as varying stages and conditions of karst geological phenomena formed by the dissolution of soluble rocks under the influence of specific internal driving forces and external agents. It represents the ultimate outcome of karstification, yet remains a relative concept. Therefore, both qualitative and quantitative methods should be used for assessment of karst development extent. Finally, a comprehensive assessment index is utilized to describe the extent of karst development. The qualitative assessment coefficient C_{kDq} of karst development degree is determined according to the monograph Groundwater Chemical Kinetics and Fractal Characteristics of Karst Tunnel (Li Cangsong et al., 2017b). The present study primarily focuses on the fractal assessment index C_{kDF} for determining the extent of karst development using Formula (1). This mainly involves calculating hydrochemical fractal assessment index Q_w and microscopic karst form fractal assessment index Q_p .

$$C_{kDF} = \sqrt{Q_w \cdot Q_p} \quad (1)$$

The calculation steps for hydrochemical fractal assessment index Q_w are as follows:

1. collect water samples and analyze the conventional hydrochemical composition of the samples;

2. create the cumulative ion pair percentage - observation scale scatter diagram and the fractal dimension calculation curves;
3. perform regression analysis on the fractal dimension calculation curves; and
4. compute the hydrochemical fractal assessment index using the slope and correlation coefficient indicated in Q_w regression curves.

The calculation steps for microscopic karst form fractal assessment index Q_p are as follows:

1. obtain microscopic karst form photos by taking field photos or scanning rock samples under a microscope;
2. conduct "gray scale processing" of the images;
3. call in fractal images and compute the fractal dimensions using the prediction and assessment system of tunnel karst development degree V1.0 (software copyright No. 2019SR0236368);
4. plot the karst unit area percentage - observation scale scatter diagram curves, and perform regression analysis, and compute the fractal assessment index Q_p of karst development degree according to the fractal dimension and correlation coefficient of fractal curve.

3.2 Index system

As described above, karst development is special and complex, and karst forms encountered in tunnel excavation are random. Therefore, it is not easy to accurately define or assess the extent of karst development. So, the assessment index system of karst development degree consists of two parts: qualitative index and quantitative index. The qualitative assessment index (C_{kDq}) of karst development degree is based on the necessary conditions for karst development, and it is obtained by itemized scoring and summing as per assessment indexes by field technicians. The fractal assessment index (C_{kDF}) of karst development degree is computed by using the aforementioned method to analyze the fractal characteristics of both karst form and karst groundwater. For details, please refer to paper (Li Cangsong et al., 2018) and literature (Li Cangsong et al., 2017b).

The assessment model of karst development extent based on hydrochemical kinetics-fractal indexes is established as Formula (2):

$$C_{kD} = 0.3 \times C_{kDq} + 0.7 \times C_{kDF} \quad (2)$$

3.3 Assessment criteria

By fully considering the understanding or judgment experience of karst experts on the possibility of karst development, and based on the calculation results of the comprehensive assessment index C_{kD} of karst development degree, recommended assessment criteria for karst development degree are given in Table 1.

Table 1. Recommended assessment criteria for karst development extent.

Extent of karst development	Characteristics of surrounding rock and possibility of karst occurrence	C _{kD}
Not developed	The rock is hard, the rock mass is complete, the structure is not developed, and generally there is no occurrence of karst.	0.0~0.10
Slightly developed	A small number of small dissolution fractures, cracks or pores may be developed in places with good groundwater runoff conditions.	0.10~0.20
Relatively developed	Dissolution grooves and channels may be developed	0.20~0.40
Developed	Karst caves or underground rivers are very likely to develop is the lithology is soluble rock.	0.40~0.80
Very developed	Extra-large filled karst caves or extra-large underground rivers that may have a catastrophic safety impact on tunnels	0.80~1.00

4 ENGINEERING APPLICATION CASES

4.1 Yaowanggu tunnel

4.1.1 Project overview

Yaowanggu Tunnel is located in Beichuan County, Sichuan Province, China. The left tunnel is 2,030 m long and the right track is 1,994.5 m long. The tunnel site area is in the northwest of Sichuan Basin. Under the control of strata lithology and tectonic process, the topography and landforms in the tunnel site area exhibit distinct characteristics of medium-low mountains, characterized by prominent dissolution and denudation. The tunnel is situated at the southwest end of the water storage structure of Tangwangzhai flat-topped trap syncline. The tunnel body passes through the strata of the Middle Devonian Guanwushan Formation (D_{2gn}) limestone, the Middle Devonian Yangmaba Formation (D_{2y}) limestone, the Middle Devonian Ganxi Formation (D_{2g}) argillaceous sandstone, mudstone and shale in sequence.

4.1.2 Karst development degree

1. The karst form of soluble rock exposed in Yangmaba Formation in the tunnel site area, and Figure 1 shows the karst after numerical processing. The fractal dimension of karst in Figure 2 is calculated by the compiled fractal image calculation software. Scatter Diagram of Karst Unit Area Percentage-Observation Scale and Calculation Curve of Fractal Dimension after calculation. After regression analysis of the fractal dimension curve, the linear equation is $y = 0.471x + 3.016$, and the fractal assessment index (Q_p) of karst form is 0.68.

2. Chemical fractal dimension calculation of karst groundwater

Figure 1. Numerical processing of karst landform.

Figure 2. Calculation curve of fractal dimension.

According to the investigation of water samples, which hydrochemical compositions of groundwater points are similar, indicating that the hydrochemical process is mainly dominated by water-rock interaction and rainfall, and mainly controlled by carbonatite dissolution.

In this study, two groundwater sample points are taken as the chemical fractal samples of karst groundwater. The hydrochemical fractal assessment index Q_w of sample points is calculated respectively, and averaged to obtain the karst development assessment index value of karst strata exposed by the tunnel. After calculation, through linear regression

Table 2. Hydrochemical composition analysis of karst groundwater in tunnel.

No.	ph	K ⁺ +Na ⁺	Ca ²⁺	Mg ²⁺	NH ⁴⁺	Cl ⁻	SO ₄ ²⁻	HCO ₃ ⁻	CO ₃ ²⁻	NO ₃ ³⁻	TDS
		Unit: mg/L									
S01	7.72	8.46	39.14	5.56	0.28	9.21	9.73	139.36	0.00	2.95	145.02
S02	7.93	8.40	41.23	4.80	0.22	6.91	9.85	145.42	0.00	2.89	147.01

of the fractal dimension curve, the linear equation of two water sample is $y=0.966x-1.574$ (Figure 3), which indirectly proves that the karst water samples taken in this study have high homology. The fractal assessment index (Q_w) of karst form is 0.87. Therefore, the fractal assessment quantitative index C_{kDF} of karst development degree is obtained according to the formula:

$$C_{kDF} = \sqrt{Q_w \cdot Q_p} = \sqrt{0.87 \times 0.68} = 0.77$$

Figure 3. Calculation curve of S01 and S02.

According to the on-site geological survey and regional karst hydrogeological conditions, the tunnel body passing through limestone is the key mileage section for karst and karst groundwater development. According to the previous table, the qualitative assessment index (C_{kDq}) of karst development degree is calculated as 0.76. According to the classification standards for karst development degree of the constructed assessment model, the fractal assessment index C_{kD} of karst development degree is 0.77. Therefore, when the tunnel passes through this stratum section, the karst development degree is “developed”, and it is highly likely to develop karst caves or underground rivers.

$$C_{kD} = 0.3C_{kDq} + 0.7C_{kDF} = 0.77$$

4.1.3 Verification of construction reveal

In April 2022, the tunnel was excavated to the stratum of Yangmaba Formation at ZK199+306, revealing a karst cave. Then the tunnel was excavated to ZK199+312, revealing a large karst cave again. According to the advanced geological forecast of the tunnel, the karst is developed at ZK199+301~+355 section of the tunnel. In

combination with the tunnel excavation exposure, the karst cave extends towards the right line of the tunnel and passes through the vault of the right tunnel. The karst caves at ZK199+296~+306 section belong to the same system as those exposed in this study. In June 2022, the right line of the tunnel was excavated to the tunnel working face at K199+324, revealing a relatively soft rock stratum with extremely developed joints and fissures. The rock stratum is broken as a whole, with yellow mud in the vault and falling blocks. Geophysical prospecting shows that this section is a low-resistance section, and it is inferred that there is a karst or dissolution development zone. The above reveal fully verifies the accuracy of the prediction and assessment conclusions.

4.2 Shuangfengya Tunnel

4.2.1 Project overview

Shuangfengya Tunnel is located in Tiechang Township and Huitan Township, Nanjiang County, Bazhong City, with a total length of more than 8.5km. The tunnel site area is located in the northeast of Sichuan Basin and at the southern foot of the Micang Mountain in Daba Mountains. The landform is obviously controlled by geological structure and lithology, and is distributed in east-west direction. It belongs to the landform of tectonic denudation-dissolution high and medium mountains. The topographic slope changes greatly, generally ranging from 10° to 35° , and is nearly vertical locally in the form of scarps and cliffs. The exposed section is at one end of Guangwu Mountain, which is on one flank of the syncline and can be regarded as monoclinical karst water-bearing structure.

See Table 3 for the simple analysis data of investigated water samples, and the water sample points are moderately~weakly alkaline. The cations in the water samples are mainly Ca^{2+} , followed by Na^+K^+ , and Mg^{2+} is less. The anions are mainly HCO_3^- , followed by SO_4^{2-} , and Cl^- is less. The hydrochemical characteristics of the water sample points belong to bicarbonate and sulfate water with low TDS, short runoff path and good circulation conditions, maintaining a good state of natural freshwater resources.

Table 3. Hydrochemical composition analysis water points in tunnel site area.

No.	Sampling location	K^+Na^+	Ca^{2+}	Mg^{2+}	Cl^-	SO_4^{2-}	HCO_3^-	CO_3^{2-}	TDS
		mg/L							
A01	Underground river at ditch bottom	36.00	80.16	19.46	8.51	115.27	268.49	0.00	393.64
S01	Tunnel working face	78.00	117.84	6.32	14.18	169.07	341.71	0.00	556.26
S02	Tunnel working face	51.00	124.25	7.30	12.76	134.48	346.59	0.00	503.09

4.2.2 Karst development degree

According to the above method, and the calculation process will not be described in detail. The fractal dimension of karst calculated results are shown in Figure 4. After regression analysis of the fractal dimension curve, the linear equation is $y=0.663x+2.477$, and the fractal assessment index (Q_p) of karst form is 0.80.

Figure 4. Fractal dimension curve of karst form.

Figure 5. Hydrochemical fractal dimension curve.

According to the hydrochemical analysis data of groundwater samples taken, the calculation curves of fractal dimensions are shown in Figure 5, and their linear equations are $y=0.921x-1.533$, $y=1.029x-1.701$ and $y=1.187x-1.961$ respectively. The average value of fractal assessment index (Q_w) of karst form is 0.93. Therefore, according to the formula, the assessment quantitative index C_{kDF} of karst development degree is 0.86. According to the classification standards for the constructed karst development degree assessment model, the C_{kD} value is 0.83. When the tunnel passes through this stratum section, the karst development degree is “very developed”. If the passing lithology is soluble rock, it may cause catastrophic safety impact on the tunnel, such as extra-large filled karst caves or extra-large underground rivers.

4.2.3 Verification of construction reveal

(1) Geophysical prospecting forecast results

See Figure 6 for the slice map of HSP test results in ZK51+259~ZK51+159 section within the detection range. There is obvious wave impedance interface and wave velocity reduction in ZK51+259~ZK51+210 section. According to the analysis, within this section, the rock mass is broken, joints and fissures are developed, weak interlayers, fracture zones and karst (solution cracks, etc.) are relatively developed, groundwater is developed, mostly occurring in

a linear manner, and the stability of surrounding rock is poor. There is obvious wave impedance interface and wave velocity reduction in some sections of ZK51+305~ZK51+249 section. According to the analysis, within this section, the rock mass is broken, joints and fissures are developed, there are weak interlayers, fracture zones and karst (solution cracks, etc.) in ZK51+305~ZK51+285 and ZK51+260~ZK51+249, groundwater is developed, mostly occurring in a linear manner and increasing in rainy season, and the stability of surrounding rock is poor.

Figure 6. HSP analysis results.

(2) Site exposure

Since the exposure of karst caves at ZK51+258 at the exit of Shuangfengya Tunnel, three large-scale karst caves have been continuously exposed within a range of less than 50m of the tunnel alignment. The surrounding rocks in this section are light yellow and grayish black limestone and shale, which are relatively hard and broken in stratified structure, with developed karst, fracture zones and weak interlayers. There are indeed sinkholes on the surface, which are consistent with the design data. Three large-scale karst caves originate from the same water system, with chainages of ZK51+258, ZK51+240 and ZK51+220 respectively. The three exposed karst caves all run through the tunnel in a transverse manner and develop along both sides of the side wall and top of the tunnel. The occurrence of karst caves is basically consistent with that of rock strata, i.e. $3^\circ \angle 85^\circ$. The width of the karst cave revealed at ZK51+258 is about 4m, that at ZK51+240 is about 7m, and that at ZK51+220 is about 15m.

Figure 7. Karst cave revealed in tunnel.

4.3 Xingaopo Tunnel

4.3.1 Project overview

The Xingaopo Tunnel on Xuyong-Bijie Railway has a total length of 8,100m and a maximum burial depth of about 445m. Soluble rocks are mainly distributed in D3K300+106~D3K301+400 section, with a length of about 1,294m, including limestone inter-layers of Maocaopu Formation (T_{1m}), Feixianguan Formation (T_{1f}) and Changxing Formation (P_{2c}). The geological structure of the tunnel site area is complex, and the structural features such as faults and folds are mainly in east-west direction, intersecting with the tunnel alignment at a large angle. Due to strong tectonic action, the stratum rock mass is very broken. Affected by stratum uplift and river erosion, the water system in the tunnel site area is distributed in a dendritic shape, and most of the streams belong to seasonal running water. Lanjia River Gully at the entrance section, Shangyangtang River Gully at DK304+780 and Chashu River Gully at DK306+300 are the main surface water bodies in the tunnel site area, with relatively abundant water volume.

4.3.2 Karst development degree

The fractal dimension of karst is calculated by the compiled fractal image calculation software. After regression analysis of the fractal dimension curve, the linear equation is $y=0.579x+2.689$, and the fractal assessment index (Q_v) of karst form is 0.75.

According to the hydrochemical analysis data of groundwater samples taken, their linear equations of fractal dimensions curves are $y=0.897x-1.496$, $y=1.055x-1.779$ and $y=1.103x-1.806$ respectively. The average value of fractal assessment index (Q_w) of karst form is 0.92. The assessment quantitative index C_{kDF} of karst development degree is 0.83. Therefore, according to C_{kD} of 0.79, when the tunnel passes through this stratum section, the karst development degree is “developed”, and it is highly likely to develop karst caves or underground rivers.

4.3.3 Verification of construction reveal

Based on the prediction and assessment of karst development and forecast analysis, it is confirmed that joints and fissures are developed in rock mass at D3K300+354~D3K300+375 section of Xingaopo Tunnel, with “developed” karst. The tunnel encounters karst caves and cavities, so there is a great possibility of water and mud inrush in the tunnel. According to the comprehensive forecast conclusion, corresponding preventive measures have been taken during construction. When the tunnel working face was exposed to D3K300+364, a large unfilled karst cave with a major axis diameter of about 20m was observed. The karst cave is divided into upper and lower layers. The wall of the upper karst cave is dry and water-free, and its alignment is perpendicular to that of the tunnel. The wall of the lower karst cave is relatively wet and attached with a large number of

white carbonate crystals, and its alignment is oblique to that of the tunnel. The revealed karst cave is shown in Figure 8.

Figure 8. Revealed karst cave.

5 CONCLUSIONS

In this study, the hydrochemical kinetics-fractal index assessment technical method of karst development degree and its application in tunnel engineering are analyzed. The research results are as follows:

- (1) The water and mud inrush hazards in karst tunnels are the results of comprehensive action of stratum lithology, geological structure and karst groundwater. Its macroscopic karst form, microscopic dissolution traces and karst hydrochemical dynamic characteristics reflect the karst development degree. Therefore, it is feasible to use macroscopic surface karst forms and hydrochemical fractal characteristics of karst groundwater as quantitative assessment indexes of karst development degree.
- (2) The application practice of karst tunnels such as Yaowanggu Tunnel, Shuangfengya Tunnel and Xingaopo Tunnel shows that the assessment technology of karst development degree based on hydrochemical kinetics-fractal indexes can be combined with advanced geological forecast means on the basis of accurate identification of hazard-inducing structures in high-risk karst tunnels, and multiple methods are used for comprehensive assessment. In addition, based on the special geological investigation of karst risks, it is conducive to avoiding tunnel karst geological hazards during construction by evaluating potential risks and reasonably supplementing measures such as geological drilling and advanced drilling in the tunnel.

ABSTRACT: Splitting failure and zonal disintegration often occur in the high sidewall of the underground powerhouse due to excavation-induced unloading, which brings many adverse effects to the construction and support work of the tunnel. We carried out two true three-dimensional geomechanical model tests to investigate the splitting failure and zonal disintegration of rock tunnel with high sidewall under high in-situ stress. The tests result show that with the increase of in-situ stress, the failure mode of the surrounding rock has a tendency to change from splitting to zonal disintegration. The model tests result reveals the formation conditions and failure characteristics of splitting failure and zonal disintegration of high sidewall tunnel, which provides a solid test foundation for further study of the nonlinear deformation and failure mechanism of rock tunnel with high sidewall under high in-situ stress. Then, we proposed a numerical analysis method based on ABAQUS platform. The numerical simulation results effectively reveal the formation condition and failure mechanism of the high sidewall tunnel.

Keywords: High sidewall tunnel, Geomechanical model test, Splitting failure, Zonal disintegration, Finite element method

1 INTRODUCTION

With the growth of underground engineering projects, the depth of excavation has increased, resulting in more and more rock engineering constructions. High sidewall tunnels in brittle rock experience complex and discontinuous deformations during excavation and pose a threat to stability and the construction process. The two most common failure modes are splitting failure and zone disintegration. These specialized failures must be taken into consideration given the risks they pose on long-term stability.

In-situ observations have revealed noticeable differences between splitting failure and zonal disintegration in rock tunnels. Splitting failure refers to a vertical or subvertical fracture at the high sidewall, which manifests as parallel or nearly parallel split

cracks. In contrast, zonal disintegration is characterized by an annular layered fault, involving alternating zones of rupture and non-rupture in the surrounding rock of the deep tunnel. These findings highlight the importance of accurately distinguishing between these two phenomena, which could significantly impact the safety and stability of rock tunnels.

Previous studies (Reva, 2002; Li et al., 2008; Tan et al., 2012; Gao et al., 2019; Chanyshev and Belousova, 2018) have only focused on the zonal disintegration phenomenon in rock tunnels, ignoring any possible relationship between this phenomenon and splitting failure.

The geomechanical model test is a crucial tool in investigating the zonal disintegration of subterranean chambers, thanks to its capacity for visualization, intuition, and realism (Chen et al. 2013a, 2013b and

*Corresponding author: lifanll@foxmail.com

2013c; Gao et al., 2018b; Zhu et al. 2019). Additionally, numerical simulation is a computational analysis method that has gained extensive use through the application of computer technology (Zhou and Shou. 2013; Vtorushin, 2016; Gao et al., 2018a; Wu et al., 2019; Li et al., 2023). In our research, we have found that zonal disintegration typically occurs in deep tunnels with depths of over 1,000 meters, while splitting failure occurs in rock tunnels with high sidewalls and depths of several hundred meters. With increasing in-situ stress, does the failure mode of high sidewall rock tunnels shift from splitting failure to zonal disintegration? To test this hypothesis, we conducted two model tests on the failure mechanisms of high sidewall tunnels under high in-situ stress, using the main powerhouse of the Pubugou Hydropower Station as an example. In Model I, we replicated the splitting failure of high sidewall tunnels under high ground stress. Upon increasing the ground stress, we found that zonal disintegration occurred in Model II, confirming the previous hypothesis.

To further investigate this relationship, we propose a numerical analysis method based on ABAQUS platform, utilizing strain gradient theory and continuous damage mechanics to establish an elastic damage softening model and energy damage failure criterion. This method can effectively predict the failure modes of rock tunnels under different in-situ stress and temperature scenarios. These findings contribute to a better understanding of the failure mechanisms of rock tunnels and can serve as a useful reference for future engineering design and construction of such structures.

2 IMPLEMENTATION OF GEO-MECHANICAL MODEL TEST

2.1 The scheme of the geo-mechanical model

The Pubugou Hydropower Station's main powerhouse project serves as our engineering background. The underground powerhouse cavern is situated within the granite rock mass on the left bank downstream of the dam axis. The overlying rock mass measures 360m thick, and the main powerhouse's cross-section size is 26.8m x 70.1m. According to the similarity principle (Zhang et al. 2019a) and considering the scale of the main powerhouse and the size of the test system (0.7 m x 0.7 m x 0.7 m), the geometrical similarity of the model test is selected as $C_L=C_P/C_M=300$. Figure 1 displays the extent and in-situ stress as simulated by the model test. To investigate the correlation between high sidewall tunnels' splitting failure and zonal disintegration, we conducted two model tests. Model I involved normal excavation while Model II involved overloading post-excavation.

An iron-barites-silica cementation material (Zhang et al. 2019b), referred to as IBSCM, has been chosen as an analogous material for the purpose of this study. The mixture proportion of IBSCM, as well as the physical and mechanical parameters of both the granite and

Figure 1. Geo-mechanical model test loading scheme ($\sigma_1=27.30$ MPa, $\sigma_2=16.16$ MPa and $\sigma_3=15.25$ MPa).

the analogous material, are presented in Tables 1. To accurately measure the deformation and stress changes of the surrounding rock during the testing process, three typical monitoring sections, namely stress monitoring sections I and III (to monitor radial and tangential stress respectively), and deformation monitoring section II have been established. In Figure 2, five measurement lines have been arranged for each monitoring section, each of which comprises six measuring points. It is important to note that due to the size of the model, vertical measurement Line C only includes five measuring points. These monitoring sections and measuring lines have been established to ensure precise data collection and accurate analysis of the deformation and stress changes in the surrounding rock during testing.

2.2 Conduct geomechanical model tests

To ensure the consistency and stability of rock formations, a geomechanical model is created through layering, compacting and air-drying the material (Zhang et al. 2012, 2017, 2020; Wang et al. 2017). This methodology involves dividing the model into ten layers, each 70mm in span, and carving grooves in the model to implant sensors at designated elevations. To maintain cohesion and prevent detachment, each previous layer's surface is chiseled and moistened with alcohol before adding the subsequent layer. This ensures that the layers' interface remains rough and firm, thereby increasing the reliability and accuracy of the geomechanical model's performance.

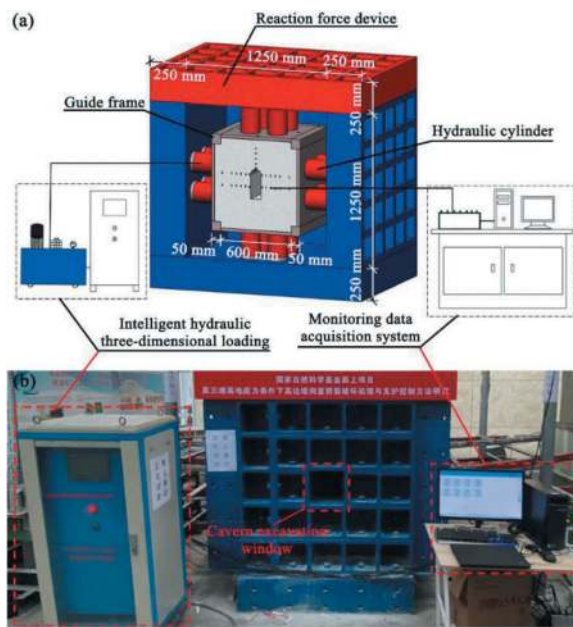

Figure 3. Three-dimensional loading system. (a) Internal schematic diagram; (b) Frontal photo of the system.

Model I is an experiment involving the excavation of a tunnel. To simulate the stress field in an actual engineering site, a self-developed true three-dimensional model test system is used to impose boundary loads on the model (Figure 3). The model is loaded step-by-step until it reaches the design value, after which the load is kept constant and stabilized for 24 hours using a servo-control mode. This process allows for the formation of an initial stress field that conforms to the in-situ field within the model. The subsequent step involves the excavation of the model tunnel. This experiment aims to provide valuable insights into the behavior and performance of tunnels under varying stress conditions, contributing to the development of effective and safe engineering practices.

Model II excavation stage is similar to Model I, but with an additional overloading test conducted after completion. During this geomechanical test,

incremental loads are applied to the model until its structural failure, simulating a progressive increase in buried depth. The gravity and tectonic stresses are increased stepwise, each at 0.1 times the initial in-situ stress. Following each loading stage, the model's boundary pressure is maintained for at least 15 minutes until data stabilization. Displacement and pressure of the surrounding rock are recorded at each stage. The overloading test continues until the loading reaches 2.2 times the in-situ stress, when significant tunnel collapse occurs and the test ceases. This experiment advances our understanding of underground conditions and offers insights into avoiding potential collapses in mining operations. It is intended to serve as a valuable reference for geotechnical engineers tasked with subterranean construction planning.

3 GEO-MECHANICAL MODEL TEST RESULTS

3.1 Model failure phenomenon

After completion of excavation, boundary loading is maintained for a period of time. The model frame is then disassembled and the model is cut perpendicular to the axis of the tunnel to compare the failure patterns of Model I (after excavation) and Model II (after unloading test), as demonstrated in Figure 4. Observations reveal that splitting failure occurs in the high sidewall tunnel after excavation (burial depth of 360m). However, when in-situ stress is increased to 2.2 times the initial in-situ stress (equivalent to a burial depth of 792m), zonal disintegration arises in the high sidewall tunnel. These findings illustrate the complex behavior of geological materials and the importance of considering various factors during excavation and post-excavation phases to avoid undesirable consequences. Such knowledge can contribute to the development of more efficient and safer underground constructions in the future.

The high sidewall tunnel depicted in Figure 4a shows severe damage due to splitting failure. The model tunnel's both sides display evident longitudinal cracks, whereas the vault exhibits no significant damage. Figure 4b depicts the typical zonal disintegration where the rupture zone and non-rupture zone appear sequentially like onion-skin. The sidewall region shows a twofold increase in the cracks, almost double the size of the excavation phase. Overloading intensifies the tunnel's damage, causing the sidewall area to experience serious collapse. The cracks parallel to the tunnel wall still exist, indicating a hypothesis that with the increase in in-situ stress, the high sidewall tunnel undergoes a failure mode shift from splitting failure to zonal disintegration.

Based on the observation that the high sidewall tunnel's zonal disintegration failure mode is caused

by high in-situ stress. When under extreme stress, the surrounding rock fails abruptly and can cause catastrophic damage. The splitting failure displayed in Figure 4a is characteristic of moderately fractured rock masses with a lower in-situ stress concentration. At this stage, the vault remained intact, and only the sidewall suffered damage. Given that the tunnel remained unaffected by the stress earlier, overloading significantly amplified the sidewall's damage.

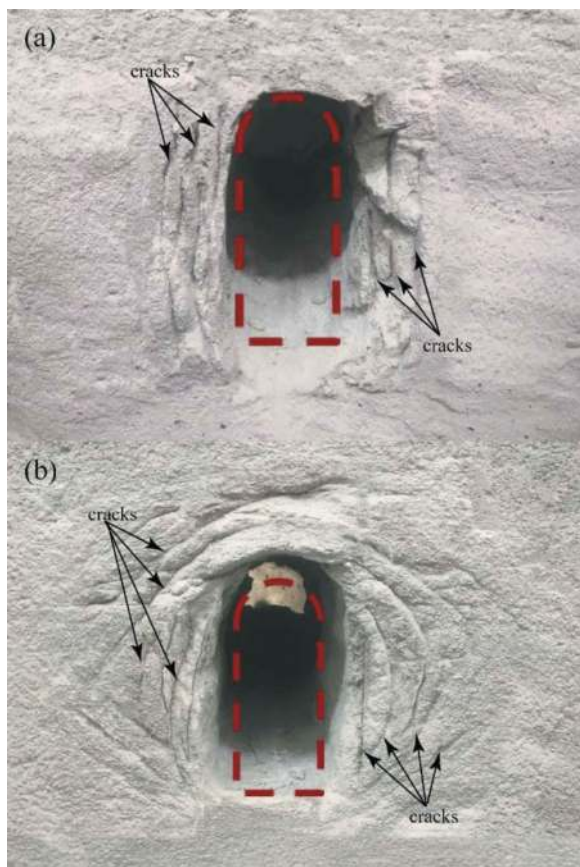

Figure 4. Fracture patterns around the tunnel with high sidewall. (a) Model I; (b) Model II.

In summary, the high sidewall tunnel subjected to a gradual increase in in-situ stress appeared to undergo a failure mode shift from splitting failure to zonal disintegration. In the case of higher stress levels, the material experienced a catastrophic failure leading to severe damage to the tunnel. The findings of this study can be crucial for understanding the mechanics of rock mass failures and preventing catastrophic tunnel damage.

3.2 Displacement monitoring results

In this section, the model test results have been transformed into the prototype based on the principles of similitude. The positive value of the convergence displacement towards the tunnel is defined. The radial displacement variation around the tunnel can be derived by joining the data of each measurement point with a smooth curve (Figure 5).

Figure 5 illustrates that:

Figure 5. Radial displacement around the tunnel after the excavation and overloading test.

After excavation (as depicted by the red squares in Figure 5), there was noticeable deformation in the circumference of the tunnel, which was directed towards its interior. The nearest measuring point displayed relatively significant displacement, suggesting that the surrounding rock's broken area was consistent with the damage observed during the test. Conversely, the measuring point farthest away from the tunnel sidewall exhibited significantly less displacement compared to other measuring points on the same line, indicating minimal excavation disturbance on the high sidewall tunnel situated 3L away from the tunnel. The measured displacement on lines A, B, D, and E showed a generally oscillating attenuation pattern, which differed greatly from the displacement variations around the shallow tunnel. In contrast, each measuring point's displacement on vertical Line C displayed a monotonic attenuation trend, distinctly contrasting the pattern observed on the horizontal lines. At this stage, the test data did not significantly differ from Model I, demonstrating the occurrence of splitting failure.

The results of our overloading test (indicated by blue circles in Figure 4b) showed that the maximum displacement around the tunnel was 3.7 times larger than in the excavation stage. This suggests that the deformation rate of the surrounding rock is greater than the rate of load increase and that rupture of the surrounding rock is more likely to occur. We observed that the displacement variation of the measuring points on the horizontal lines was consistent with that observed during the excavation stage, undergoing oscillation attenuation, but with a larger vibration amplitude, about three times that of the excavation stage. However, we observed different variation in the vertical displacement of the tunnel vault, which changed into oscillation attenuation. We discovered that zonal disintegration, in which annular layered fractures alternated between the rupture zone and the non-rupture zone, occurred in the high sidewall tunnel. These findings are important for understanding the behavior of surrounding rocks in tunnels under

overloading conditions and can inform the design of future underground structures.

3.3 Stress monitoring results

Connecting data from measurement points during excavation and overload stages with smooth curves allows for obtaining changes in radial and tangential stresses around the tunnel, as shown in Figure 6. We can find that:

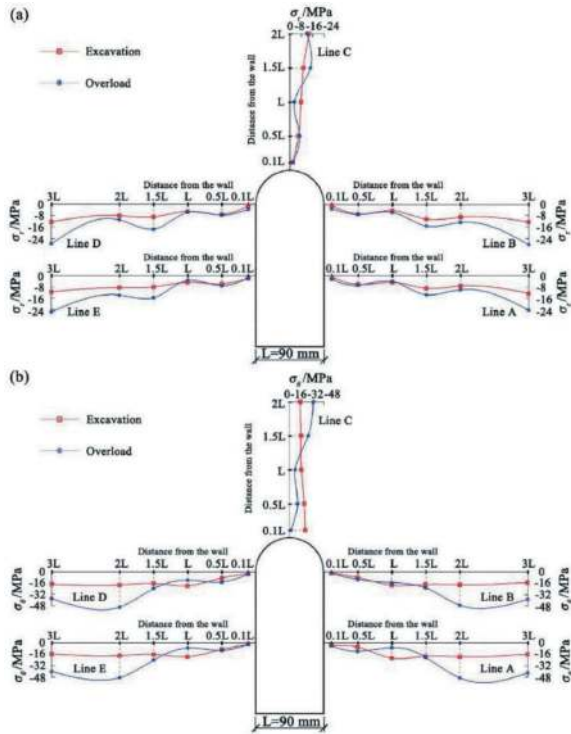

Figure 6. (a) Radial stress around the tunnel after the excavation and overloading test; (b) Tangential stress around the tunnel after the excavation and overloading test.

Following the excavation, the stress release around the tunnel leads to deformation that is focused towards the tunnel. As a result, radial stress around the tunnel decreases, as can be observed from the red squares in Figure 6a. During this phase, the changes in the radial stress data are consistent with Model I, indicating the occurrence of a splitting failure. As in-situ stress increases, damage to the surrounding rock increases, resulting in an increase in the release of radial stress. The farther away from the tunnel sidewall, the less damage occurs to the surrounding rock, resulting in an increased difference between the monitoring data after excavation and overload. During the overload stage, changes in the radial stress of the vault are more prominent. The stress values at 0.1L, 0.5L, and 2L away from the wall remain largely unchanged, while the radial stress decreases as the distance increases from the wall and increases at 1.5L. This change in radial stress from

a monotonous increase during excavation (red squares in Figure 6a) to vibration during overload (blue circles in Figure 6a) coincides with zonal disintegration. Overall, these findings suggest that the damage around the tunnel increases with the increase of in-situ stress, and the release of radial stress is concentrated towards the tunnel.

Regarding displacement and radial stress, the change of tangential stress after excavation is similar to that of Model I. During the overload phase, the plastic area around the tunnel expands, causing points L and 1.5L away from the sidewall to enter the plastic phase and decrease their tangential stress. The rock 2L away from the wall remains in the elastic stage, where the tangential stress is still concentrated. In addition, the surrounding rock of the vault also enters the plastic stage from the elastic stage, leading to a release of the tangential stress. The plastic zone extends from the tunnel sidewall to the vault and takes on an approximately circular shape, which aligns with the variation in zonal disintegration. Overall, these findings have important implications for understanding the response of rock masses around tunnels to excavation-induced stress changes, underscored by the stress-induced rock failure patterns, which can help inform the design and safety of underground engineering structures.

4 NUMERICAL SIMULATION OF FAILURE MODE

We have developed a simulation program that utilizes the finite element method to replicate splitting failure and zonal disintegration in the rock surroundings of a tunnel with high sidewalls under high stress conditions. The program incorporates an elastic damage softening model and an energy damage failure criterion, both of which are based on the strain gradient theory and continuous damage mechanics. This section provides an introduction to the simulation program and compares the simulation results with those from the geo-mechanical model test. The aim of this program is to improve our understanding of rock mechanics and to enhance our ability to predict and prevent catastrophic rock failures.

4.1 Development of the simulation program

In this section, the model test results have been transformed into the prototype based on the principles of similitude. The positive value of the convergence displacement towards the tunnel is defined. The radial displacement variation around the tunnel can be derived by joining the data of each measurement point with a smooth curve (Figure 5).

When dealing with the elastic damage softening model and simulating splitting failure and zonal disintegration numerically, the influence of strain gradient must be taken into account. However, in general finite element analysis, the element shape function only

achieves first-order continuity, and the second-order derivative value of the displacement within the element after interpolation becomes zero. As a result, applying such a unit analysis does not reflect the impact of strain gradient. Therefore, it is crucial to build the element with higher order continuity, which is required to maintain C^1 order continuity of the displacement of the node and its first derivative. Hermite interpolation function has been used to construct high-order hexahedral elements, from which both the shape function and stiffness matrix of the element have been derived (Zhang, 2015; Li et al. 2021, 2022). This technical advancement forms the basis for considering strain gradient effects in numerical simulation. Our simulation program is developed on the platform of ABAQUS finite element software.

To determine the distribution of the failure zone in the surrounding rock, a criterion must be established to identify element failure. In numerical simulations, two criteria are commonly utilized: the maximum tensile strain criterion and the energy damage failure criterion. The maximum tensile strain of the unit is calculated using equation (1). If the maximum tensile strain ε_{max} is greater than or equal to the ultimate tensile strain ε_{tu} , the element is deemed to have undergone tensile failure. To ensure that the entire calculation remains coherent and continuous throughout the simulation, a residual elastic modulus E_C is applied to the rock mass element where tensile failure has occurred. It is crucial to establish the criterion for determining element failure to accurately obtain the distribution of the failure zone in surrounding rock.

$$\varepsilon_{max} = \frac{2}{\sqrt{3}} \sqrt{|J_2'|} \cos\left(\omega - \frac{\pi}{3}\right) + \frac{I_1'}{3} \quad (1)$$

where

$$\omega = \frac{1}{3} \arccos\left(-\frac{3\sqrt{3}}{2} \frac{J_3'}{|J_2'| \sqrt{|J_2'|}}\right) \quad (2)$$

$$\begin{cases} I_1' = \varepsilon_x + \varepsilon_y + \varepsilon_z \\ J_2' = -(e_1 e_2 + e_2 e_3 + e_1 e_3) \\ J_3' = e_1 e_2 e_3 \end{cases} \quad (3)$$

$$\begin{cases} e_1 = \frac{2}{3} \varepsilon_x - \frac{1}{3} (\varepsilon_y + \varepsilon_z) \\ e_2 = \frac{2}{3} \varepsilon_y - \frac{1}{3} (\varepsilon_x + \varepsilon_z) \\ e_3 = \frac{2}{3} \varepsilon_z - \frac{1}{3} (\varepsilon_x + \varepsilon_y) \end{cases} \quad (4)$$

Where ε_x , ε_y and ε_z are strains in X, Y and Z directions respectively.

If the maximum level of tensile strain experienced by a particular element falls below the ultimate tensile strain, then that unit will not undergo tensile

failure. In such cases, the failure criterion of the element is based on the energy damage caused by strain gradient. To account for the influence of the strain gradient term, a formula for calculating the strain energy density of the element has been proposed. This formula is believed to effectively measure the strain energy density of the element, helping experts accurately predict whether or not that element will fail under tensile conditions.

$$\frac{dW}{dV} = \int_0^{\varepsilon_{ij}} \sigma_{ij} d\varepsilon_{ij} + \frac{1}{8} G l^2 \left(4\eta_{ijj}\eta_{ikk} + 4\eta_{iik}\eta_{kjj} + 4\eta_{iik}\eta_{jjk} + 7\eta_{ijk}\eta_{ijk} + 2\eta_{ijk}\eta_{kji}\right) \quad (5)$$

where σ_{ij} is two order Cauchy stress tensor, ε_{ij} is Eulerian strain tensor, G is the lame constant, l is the internal length parameter, η_{ijk} is strain gradient tensor.

The calculation formulas of elastic strain energy density $(dW/dV)_s$, critical strain energy density $(dW/dV)_c$ and ultimate strain energy density $(dW/dV)_u$ are as follows:

$$\begin{cases} \left(\frac{dW}{dV}\right)_s = \int_0^{\varepsilon_s} \sigma_{ij} d\varepsilon_{ij} \\ \left(\frac{dW}{dV}\right)_c = \int_0^{\varepsilon_o} \sigma_{ij} d\varepsilon_{ij} \\ \left(\frac{dW}{dV}\right)_u = \int_0^{\varepsilon_u} \sigma_{ij} d\varepsilon_{ij} \end{cases} \quad (6)$$

Where ε_s is the yield strain in the process of loading, ε_o is the residual strain in the process of loading, ε_u is the ultimate strain in the process of loading.

The energy damage failure criterion is defined by the variation in strain energy density (dW/dV) . When $(dW/dV) < (dW/dV)_s$ (ε_s is the yield strain in the process of loading), it remains in the linear elastic phase with no internal damage. Upon exceeding $(dW/dV)_s$ and entering the plastic damage regime, the damage variable d is triggered, leading to the formation of micro-cracks within the material which then begin to propagate as the loading increases. When $(dW/dV) \geq (dW/dV)_c$, the micro-cracks transition into macroscopic cracks, with the rock mass entering its residual stage while still retaining some of its bearing capacity. Once the ultimate strain threshold $(dW/dV)_u$ is reached, the rock mass is no longer able to bear the load, resulting in its failure. As with tensile failure, the failure element is assigned a residual elastic modulus E_s to maintain the overall integrity and continuity of the calculation. It is worth noting that this approach can predict the strength and deformation behavior of materials under complex loading conditions, which is particularly relevant when evaluating the stability of underground structures or geotechnical engineering projects.

4.2 Establishment of numerical models

The numerical model's range aligns with that of the physical model delineated in Section 2.1. Figure 7

portrays the numerical model's scales along the X, Y, and Z axes, all of which are 210 m. The three-dimensional computational grid comprises 60000 elements and 67769 nodes. The external loads applied to the numerical model, which appear in Figure 7, reflect consistency with the physical model's boundary conditions and tunnel construction process.

Figure 7. Numerical model generated for the simulation of high sidewall tunnel the excavation and overload.

4.3 Numerical models' results

The external loads depicted in Figure 7 are applied to the numerical model. After equilibrating, the nodes' displacement and strain parameters are established at zero to initiate the in-situ stress field. The tunnel is then excavated, and the stress, strain, and displacement fields of the rock surrounding it are calculated. These results are then transformed to the cylindrical coordinate system to visually communicate the distribution of radial stress, strain, and displacement of the rock around the tunnel, as shown in Figures 8 and 9.

The Figures 8 and 9 demonstrate the emergence of spaced apart rupture zones in the surrounding rock. In Figure 8, the rupture zone is distributed on either side of the tunnel, running parallel to the tunnel sidewall. In Figure 9, the rupture zone is shaped like a ring around the tunnel. The numerical simulations of the damage zone range, average radius, and average width were found to closely correspond with the results of the model tests.

The displacement, strain, and stress around the tunnel also reveal the appearance of three layers of rupture zones. Deformation is concentrated in the middle of the sidewall near the tunnel rupture zone, and stress is aligned parallel to the height of the tunnel sidewall. This finding is consistent with Figure 4b, where a vertical crack appears parallel to the wall near the tunnel. Although the two rupture zones forming a ring shape outside the tunnel were similar to the test results shown in Figure 4b, there were two cracks on the vault and four cracks on the sidewall in the model test, indicating greater damage to the surrounding rock

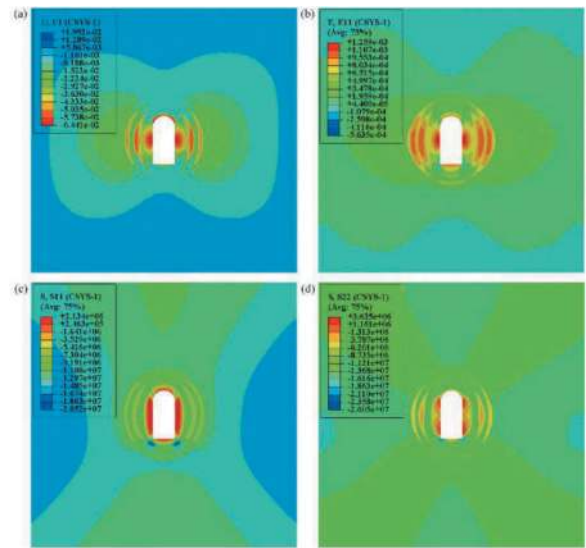

Figure 8. Simulation splitting failure results in terms of the contour of: (a) Radial displacement; (b) Radial strain; (c) Radial stress; and (d) Tangential stress in the surrounding rock of the tunnel.

than in the numerical simulation. This may be due to the constitutive model used in the numerical calculation, which does not account for the damage effect of excavation on the surrounding rock.

The numerical model reveals that the surrounding rock's radial displacement exhibits an oscillating pattern, characterized by the alternating wave crest and trough. These observations correspond with the radial displacement variation measured by the model test. This validation attests to the robustness of the elastic damage softening model and the ABAQUS-based numerical analysis methodology utilized in this study.

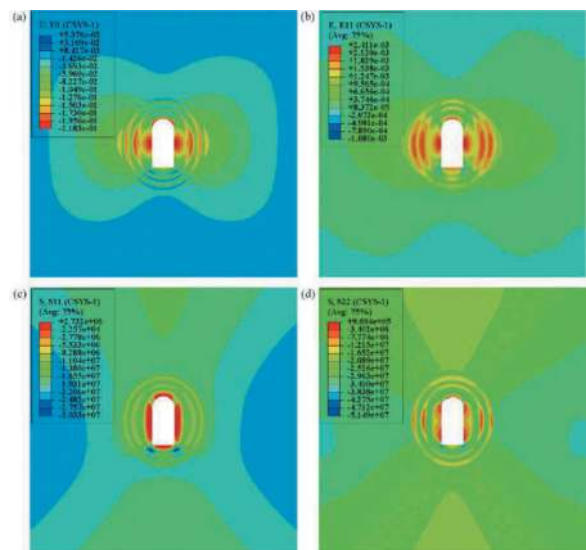

Figure 9. Simulation zonal disintegration results in terms of the contour of: (a) Radial displacement; (b) Radial strain; (c) Radial stress; and (d) Tangential stress in the surrounding rock of the tunnel.

Through numerical simulation, it has been observed that the unloading of an excavation can cause the surrounding rock to rupture. The resulting stress wave from the rock fracture moves away from the tunnel wall, thus creating a new stress field in the adjacent rock. Upon overlaying the original rock mass' stress field, further fracturing may occur, leading to the formation of ruptured and non-ruptured zones. Crack propagation is likely to extend along the direction of maximum principal stress, or the direction of tangential stress. Ultimately, a ring-shaped fracture will form at the elasto-plastic boundary. These observations have significant implications for understanding the behavior of rock masses when subjected to excavation activities.

5 CONCLUSIONS

Using the Pubugou Hydropower Station's main powerhouse as our engineering background, we conducted 3D geo-mechanical model tests on the failure of rock tunnels with high sidewalls due to excavation and overloading. Our research revealed that the failure of high sidewall tunnels would transform from splitting failure to zonal disintegration as in-situ stress increased. During the excavation stage, the displacement and stress of the surrounding rock at the side wall of the tunnel would exhibit oscillation attenuation, while the vault showed a trend of monotonic attenuation. However, in the overload stage, the displacement and stress of the surrounding rock of the high sidewall tunnel underwent wave-like changes in the distribution of peaks and troughs. Finally, we confirmed the zonal disintegration of the high sidewall tunnel by cutting the model body after the overloading test.

Using the elastic damage softening model and energy damage failure criterion, established through strain gradient theory and continuous damage mechanics, we developed a numerical simulation program to analyze the splitting failure and zonal disintegration of high-stress surrounding rock in sidewall tunnels. Our simulation results are in agreement with model test results. The study shows that excavation unloading causes stress redistribution in the surrounding rock, leading to renewed rock mass breakage and newly defined ruptured and non-ruptured zones. Crack propagation occurs along the maximum principal stress direction, forming annular cracks at the elastic-plastic boundary.

Development and test of directional coring drilling system for advanced geological exploration

Jun Liu*

China Railway Construction Heavy Industry Corporation Limited, Changsha, China

ABSTRACT: Directional coring drilling system is an effective tool for advanced geological exploration in tunnel construction, which can realized the directional drilling and continuous coring, so as to obtain effective geological information. Its key technologies include the design of directional drilling trajectory, and the design of deflection tool which can realize the coring function. A directional drilling trajectory design software is developed. According to the deviation between actual drilling trajectory and design trajectory, the trajectory to be drilled is designed in the form of “arc segment + straight segment”, and the appropriate tool face angle and build-up distance of the deflection tool are calculated. Based on the working principle of static Point-the-Bit Rotary Steering System, an deflection tool integrating the functions of guiding, steering, and coring — directional coring tool is developed. Finally, the feasibility of this directional coring drilling system is verified by test. The test results show that this system can realize the effective control of drilling trajectory, achieve the continuous coring in the whole hole section of directional drilling, with low water consumption and high coring rate, and thus it has certain promotion and application value.

Keywords: directional drilling, coring, geological exploration, drilling trajectory design, deflection tool

1 INTRODUCTION

Directional coring drilling system is a high-tech precision drilling system for underground spaces integrating the functions of guiding, steering, and coring. It can realize directional drilling according to the predetermined trajectory and obtain rock core samples continuously. As an indispensable advanced geological exploration tool in major national infrastructure projects such as long mountain tunnels and subsea tunnels, it can accurately obtain the location information of surrounding rock and water area of the rock strata in a tunnel trajectory area, effectively reduce the tunnel construction risks, and provide effective data support for the design and construction decisions of super-long major engineering tunnels.

At present, the directional drilling technology is relatively mature in petroleum industry. Some companies such as Baker Hughes, Schlumberger and Halliburton have their rotary steering drilling tools, the working mechanism of which is to realize the steerable drilling by offsetting the drill bit or main shaft with an offset mechanism^[1]. According to different steering modes, rotary steering drilling tools can be divided

into two types: Push-the-Bit and Point-the-Bit. Push-the-Bit type means that the offset mechanism offsets the drill bit near the bit to directly provide lateral force to the drill bit. Point-the-bit type means that the offset mechanism directly or indirectly offsets the main shaft connecting with the drill bit to bend it so that the drill bit points the direction of well trajectory control. According to different offset modes, rotary steering drilling tools can be divided into static offset type and dynamic offset type: the static offset means that the offset mechanism does not rotate with the drill string in the process of drilling, and can provide a fixed lateral force in one direction. Dynamic offset type means that the offset mechanism rotates with the drill string in the process of drilling, extends directionally and periodically at a certain position by the control system, and provides steering force by virtue of the supporting reaction. However,, their diameters are large, and these rotary steering drilling tools can only realize the function of directional drilling but not coring.

In the field of geological exploration, drilling and coring in front of the tunnel face with drilling equipment can directly reveal the formation lithology, structure, groundwater, karst, weak interlayer and

*Corresponding author: liujun1@crchi.com

other geological bodies in front of the tunnel face and their properties, being one of the most direct and effective methods of advanced geological prediction [2-3]. However, if the traditional linear coring tool is used, due to the influence of gravity and surrounding rock anisotropy, the drilling trajectory longer than 300 m will be significantly bent, which is difficult to truly reflect the geological characteristics of the tunnel crossing area [4]. Therefore, a directional coring drilling system is required. At present, the directional coring drilling system mainly uses screw drilling tool to realize directional drilling, and then uses traditional linear coring tool to realize coring, that is, discontinuous coring cannot obtain the core of the whole hole section. The working principle of a screw motor is to carry out the directional drilling in cooperation with bend joint and bottom-hole survey tool by using a bottom-hole motor with high-pressure flushing fluid as the power source [5]. Limited by the working principle, the motor is installed at the near bit end, and thus cannot realize the coring function. DEVICO in Norway has mastered the directional coring drilling technology, which can realize continuous coring [6]. However, the company strictly keeps relevant technologies confidential, and only provides technical services without selling products. Its product DeviDrill has realized long-distance directional drilling and continuous coring in Hong Kong [7-9]. But the measurement of actual drilling trajectory cannot be directly obtained by the MWD (measurement-while-drilling) system in the directional coring tool, requiring the combination with other measuring tools.

The composition of directional coring drilling system for advanced geological exploration is introduced, including the directional drilling trajectory design software and directional coring drilling equipment. The software can, according to the deviation between actual drilling trajectory and design trajectory, design the trajectory to be drilled in the form of "arc segment + straight segment", and calculate the appropriate tool face angle and build-up distance of the deflection tool. Based on the working principle of static Point-the-Bit Rotary Steering System, an deflection tool integrating the functions of guiding, steering, and coring — directional coring drilling device is developed. The device can obtain information such as azimuth angle and inclination angle required for the calculation of actual drilling trajectory through its own MWD tool. Finally, the feasibility of the directional coring drilling system for advanced geological exploration is verified by test.

2 DIRECTIONAL DRILLING TRAJECTORY DESIGN SOFTWARE

The calculation of actual drilling trajectory and the design of track to be drilled are characterized by heavy calculation workload, many complicated formulas, and error-prone calculation process, bringing

great difficulties to the on-site drilling guidance. In order to keep the deviation between the drilling trajectory and the design trajectory in a small value, it is necessary to calculate the actual trajectory of a borehole according to the data measured by MWD tool, design the trajectory to be drilled according to the deviation between the actual trajectory and the design trajectory, and provide reference values for the proper tool face angle and deflection distance of deflection tool in directional drilling, so as to guide the directional drilling process. Based on MATLAB App Designer, the trajectory design and calculation analysis system of directional coring tool is developed, realizing the functions including the calculation of actual drilling trajectory, the design of trajectory to be drilled, and the visualization of borehole trajectory, etc. The application of the system in directional drilling practice can effectively improve the drilling efficiency and reach the target point faster.

2.1 Calculation of actual drilling trajectory

The actual drilling trajectory is a curved form of the borehole axis, presenting a spatial curve. The parameters required for the calculation of actual drilling trajectory include borehole depth, borehole inclination angle and azimuth angle [10], and the calculation methods include tangential method, mean-angle full range method, balanced tangential method, radius of curvature method and minimum curvature method [11]. With mean-angle full range method as the example for introduction, as shown in Figure 1, in the geodetic coordinate system NEG, N is the magnetic north direction, E is the magnetic east direction and G is the gravity direction. O and A are two measuring points. Given the distance L_A from O to A, local geomagnetic declination λ , and coordinates (X_O, Y_O, Z_O) of point O, the azimuth angles of point O and point A α_O and α_A , and the inclination angles θ_O and θ_A , the calculation of the three-dimensional coordinates of point A is shown in Formula 1. Generally, the orifice coordinates are set to $(0, 0, 0)$, and by analogy and iteration according to Formula 1, the three-dimensional coordinates of all measuring points can be obtained, thus the actual drilling trajectory is obtained.

$$XA = LA \sin \frac{\theta_o + \theta_A}{2} \cos \left(\frac{\alpha_o + \alpha_A}{2} - \lambda \right) + X_O \quad (1)$$

$$YA = LA \sin \frac{\theta_o + \theta_A}{2} \sin \left(\frac{\alpha_o + \alpha_A}{2} - \lambda \right) + Y_O \quad (2)$$

$$ZA = LA \cos \frac{\theta_o + \theta_A}{2} + Z_O \quad (3)$$

Figure 1. Schematic diagram of actual drilling trajectory calculation.

2.2 Design of trajectory to be drilled

In order to reduce the deviation between the actual drilling trajectory and the design trajectory, the trajectory to be drilled is designed in the form of “arc section + straight section”, of which the arc section is drilled by directional coring tool, while the straight section is drilled by conventional coring tool. Based on the principle of arc section + straight section as the shortest distance, the optimal trajectory to be drilled is selected, and the tool face angle and deflection distance required for deflection tool are calculated for the guidance of directional drilling.

In the paper, the inclined plane method is used to design the trajectory to be drilled in three-dimensional space, i.e. the design of drilling trajectory on a inclined plane in the space, where the inclined plane is determined by the tangent line of the starting point of deviation correction and the ending point of deviation correction, the radius of curvature R of the curved section is constant and is determined by the build-up rate of deflection tool [11]. As shown in Figure 2, given the coordinates of point a (the end of actual drilling trajectory), inclination angle θ_a and azimuth angle α_a , radius of curvature R of the deflection tool, and the coordinates of target point c, then the angle γ , the distance L_{bc} between point b and c, the coordinates of point m and b, the inclination angle θ_b and azimuth angle α_b at point b can be solved, with the formulas as below. It should be noted that the coordinates of point c are on the design trajectory, and based on the principle of arc section + straight section as the shortest distance, the final coordinates are determined by optimization algorithm.

Figure 2. Schematic diagram for calculation of trajectory to be drilled by inclined plane method.

$$\gamma = 2 \tan^{-1} \frac{D - \sqrt{D^2 + S^2 - 2RS}}{2R - S} \quad (4)$$

$$L_{bc} = \sqrt{D^2 + S^2 - 2RS} \quad (5)$$

Where

$$D = L_{ac} \cos \angle mac \quad (6)$$

$$S = L_{ac} \sin \angle mac \quad (7)$$

$$L_{ac} = \sqrt{(X_c - X_a)^2 + (Y_c - Y_a)^2 + (Z_c - Z_a)^2} \quad (8)$$

$$\angle mac = \cos^{-1} \frac{(Z_c - Z_a) \cos \theta_a + (X_c - X_a) \sin \theta_a \cos \alpha_a + (Y_c - Y_a) \sin \theta_a \sin \alpha_a}{L_{ac}} \quad (9)$$

The coordinates of point m are calculated as below:

$$Z_m = Z_a + R \tan \frac{\gamma}{2} \cos \theta_a \quad (10)$$

$$X_m = X_a + R \tan \frac{\gamma}{2} \sin \theta_a \cos \alpha_a \quad (11)$$

$$Y_m = X_a + R \tan \frac{\gamma}{2} \sin \theta_a \sin \alpha_a \quad (12)$$

The inclination angle, azimuth angle and three-dimensional coordinates of point b are calculated as below:

$$\theta_b = \cos^{-1} \left(\frac{Z_c - Z_m}{\sqrt{(Z_c - Z_m)^2 + (Y_c - Y_m)^2 + (X_c - X_m)^2}} \right) \quad (13)$$

$$\alpha_b = \begin{cases} \tan^{-1} \left(\frac{Y_c - Y_m}{X_c - X_m} \right), & \text{if } X_c > X_m \\ \tan^{-1} \left(\frac{Y_c - Y_m}{X_c - X_m} \right) + \pi, & \text{if } X_c < X_m \end{cases} \quad (14)$$

$$Z_b = Z_a + R \tan \frac{\gamma}{2} (\cos \theta_a + \cos \theta_b) \quad (15)$$

$$Y_b = Y_a + R \tan \frac{\gamma}{2} (\sin \theta_a \cos \alpha_a + \sin \theta_b \cos \alpha_b) \quad (16)$$

$$X_b = X_a + R \tan \frac{\gamma}{2} (\sin \theta_a \sin \alpha_a + \sin \theta_b \sin \alpha_b) \quad (17)$$

According to the above conditions, the formulas for the calculation of tool face angle ω and deflection

distance L of the deflection tool can be obtained as follows [12].

$$\tan \frac{\omega}{2} = \frac{\sin \gamma \cos(\alpha_b - \alpha_a) - \text{SGN}(\theta_b - \theta_a) \sqrt{\sin^2 \gamma - \sin^2 \theta_a \sin^2(\alpha_b - \alpha_a)}}{\sin(\alpha_b - \alpha_a) \sin(\theta_b - \gamma)} \quad (18)$$

$$L = \gamma R \quad (19)$$

Where

- If $x > 0$, $\text{SGN } x = 1$;
- If $x = 0$, $\text{SGN } x = 0$;
- If $x < 0$, $\text{SGN } x = -1$;

2.3 Software interface and application cases

Based on the above theoretical calculations, a directional coring tool trajectory design and analysis system is developed by using MATLAB App Designer, realizing the functions of parameter input, automatic selection of effective data of the MWD tool, calculation of actual build-up rate and display of calculation results, calculation of actual drilling trajectory and visualization of calculation results, design and calculation of trajectory to be drilled and the visualization of results, calculation and display of actual drilling trajectory end point deviation, calculation and display of recommended deflection tool face angle and deflection distance, etc. The software interface is shown in Figure 3.

With the actual drilling trajectory as the example, the software is tested to verify the feasibility of the software. The design trajectory is a straight line, and it is expected that the initial azimuth angle of 330° and inclination angle of 90° will be maintained in the whole process of drilling, with a final hole in 800 m deep. As shown in Figure 3, the red line is the theoretical design track, and the area surrounded by the blue line is a cylindrical target area with a radius of 5 m. An actual drilling trajectory not exceeding this target area is expected. Input the local magnetic declination, build-up rate of the deflection tool and the measured data of actual drilling trajectory, and click START CALCULATION to obtain deviation between the end point of actual drilling trajectory and the design trajectory of 4.576 m. If the deviation correction is started at this time, the recommended tool face angle of the deflection tool is 341.7° , the deflection distance is 46.94 m, and the distance between the target point and orifice on design trajectory is 283 m. In addition, the software can visually show the actual drilling trajectory and the trajectory to be drilled in three-dimensional space (NEG coordinate system), where the black one is the actual drilling trajectory and the blue one is the design trajectory of "arc section + straight section". The output results of the software can effectively guide directional drilling process.

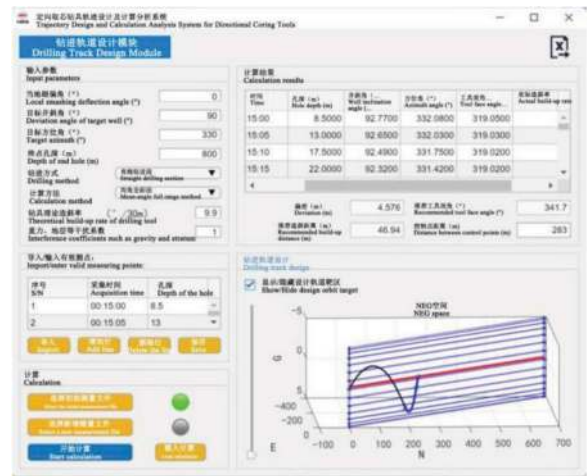

Figure 3. Software interface.

3 INTRODUCTION AND TEST OF DIRECTIONAL CORING DRILLING SYSTEM

3.1 System introduction

The directional coring drilling system includes software and hardware. The software has been introduced above. The hardware mainly includes drilling rig, linear coring tool, directional coring tool, mud pump, hydraulic pump station, source of water, and source of electricity, as shown in Figure 4. The drilling rig is mainly driven by the hydraulic pump station to provide rotary power and propulsion power for the drilling tools. The mud pump is used to provide flushing water for drilling tools for slag removal and cooling in the process of drilling. The drilling tools are the core equipment of the whole system, used for coring. It should be noted that the linear coring tool is only functioned by coring, with relatively mature technology at present. Directional coring drilling tools have the functions of both coring, guiding and correcting deviation, which is an important and difficult point in directional core drilling system.

Figure 4. Schematic diagram of directional coring drilling system.

Based on the working principle of static Point-the-Bit Rotary Steering System in the field of petroleum, an deflection tool integrating the functions of guiding, steering, and coring — directional coring tool is developed, with the working principle as below.

The acceleration value is measured by accelerometer. The magnetic force value is measured by magnetometer. The MWD tool integrating accelerometer and magnetometer is connected to the rear end of the inner pipe assembly. The measured data are stored in the MWD inclinometer. The MWD tool can be lowered and refloats along with the inner pipe assembly. After refloating, the measured data is read: azimuth angle α , inclination angle θ and tool face angle γ . In combination with the drilling depth of each measuring point, the actual drilling trajectory can be solved by the directional drilling trajectory design software. Of them, the tool face angle γ represents the degree of rotation of the deflection tool around its own axis, and is an important reference for directional drilling.

(2) Steering principle

The steering principle of directional coring tool refers to the static Point-the-Bit Rotary Steering System, and the schematic diagram is shown in Figure 5. Of them, the eccentric mechanism, thrust bearing and joint bearing determine the deflection deformation of the center shaft, tilting the drill bit connected with the center shaft. Lower it to the bottom of the hole and rotate the whole directional coring tool to change the inclination direction of the drill bit, and ensure the correct inclination direction of the drill bit in combination with the tool face angle measured by the MWD tool. During the formal drilling, the hydraulic anti-rotating mechanism is used to prevent rotation. Finally, the casing will not rotate, but only the drill pipe, center shaft and bit rotate to ensure an unchanged drilling direction.

Figure 5. Steering principle of the directional coring tool.

(3) Coring principle

Wireline coring is adopted for the directional coring tool to reduce the time of bit lifting and tripping, and improve the drilling efficiency [13]. The coring principle is the same as that of conventional linear coring tool: the inner pipe assembly is lowered by water pressure in place, then the elastic part enters the locking coupling, and the water pressure rises; during normal drilling, the core enters the inner pipe through the core lifter; when coring is required, the overshot is lowered with water pressure and connected to the inner pipe

assembly, then the overshot is lifted upward, forcing the elastic part to contract, disengaging the inner pipe from the outer pipe, and lifting the inner pipe assembly [14].

Based on the above principle, the technical parameters of directional coring tool developed in this paper are shown in Table 1. In the whole drilling process of directional coring drilling, linear coring tool and directional coring tool are used alternately. When it is found that the actual drilling trajectory exceeds the allowable error, the directional coring tool is used for deviation correction. After the completion of deviation correction, linear coring tool is used to continue to drill, so as to ensure that the actual drilling trajectory does not exceed the target area.

Table 1. Technical parameters of directional coring tool.

Parameter Description	Parameter Value	Parameter Description	Parameter Value
Borehole diameter (mm)	76	Maximum build-up rate ($^{\circ}$ /30m)	>3
Core diameter (mm)	31.5	Measurement parameters and errors	Azimuth angle $< \pm 1^{\circ}$ Inclination angle $< \pm 0.2^{\circ}$ Tool face angle $< \pm 0.2^{\circ}$
Single coring length (m)	3	Maximum drilling speed (m/h)	>1

3.2 Engineering test

Testing verification is carried out to verify whether the directional coring drilling system can realize the functions of guiding, steering, and coring in actual working conditions. Aiming at the actual drilling trajectory formed by the directional coring drilling system, MWD tool is used for measurement. The actual drilling trajectory is calculated in combination with the directional drilling trajectory design software. The calculation results are compared with the measurement results of laser tracker (accuracy: 0.01 mm). The accuracy of the measurement results is verified, that is, the guiding function is verified. The actual drilling trajectory is measured by laser tracker, and the direction of deviation correction and the radius of curvature are fitted with Matlab to verify the steering function of directional coring device. In addition, in the test, the drilling rate and core sampling rate of directional coring tool are tested to verify its coring function.

3.2.1 Test methods

The directional coring drilling test is carried out with two 4.2m concrete blocks in the plant. The test methods are as follows:

- (1) The conventional NQ linear coring tool was used to drill for not less than 2m first, so as to ensure that the anti-rotating mechanism of directional coring tool was already in the borehole and could play an anti-rotating function. In the process of linear coring drilling, the set bit pressure was about 10 kN, the rotating speed was about 304 rpm, and the flow rate was about 55 l/min.
- (2) Then the drilling function of directional coring tool was tested. The directional coring tool was carried on a qualified drilling rig after commissioning, and the eccentricity of the eccentric mechanism was adjusted to tilt the drill bit. In order to eliminate the influence of gravity, the directional coring tool was lowered to the hole bottom in a way that the drill bit deflected to the right. Flushing water was supplied, and the anti-rotating mechanism prevented the casing from rotating. In the process of directional coring drilling, the bit pressure was 16-20 KN, the rotating speed was 210-305 rpm, and the flow rate was about 28-35 l/min.
- (3) After the completion of drilling, the actual drilling trajectory was obtained by using MWD tool and laser tracker in combination with directional drilling trajectory design software. A comparison for consistency between the direction of actual drilling trajectory and the expectation was carried out. The actual build-up rate was calculated and concluded.

Figure 6. Directional coring drilling engineering test.

3.2.2 Test results

Verification of guiding function: The data of MWD tool was input as the directional drilling trajectory design software. The calculated actual drilling trajectory results are shown in Figure 7(a), and the measurement results of laser tracker are shown in Figure 7(b). It can be seen that the data of MWD tool fluctuates more than laser tracker data in xy plane, which may be caused by large measurement error of azimuth angle of MWD tool. In yz plane, the distance between the starting point and the ending point of the borehole as measured by the MWD tool on the vertical plane is

about 20.5mm, which is only 2.5% of difference in comparison with the distance of 20mm between the starting point and the ending point as measured by the laser tracker on the vertical plane, indicating a small measurement error of MWD tool in inclination angle.

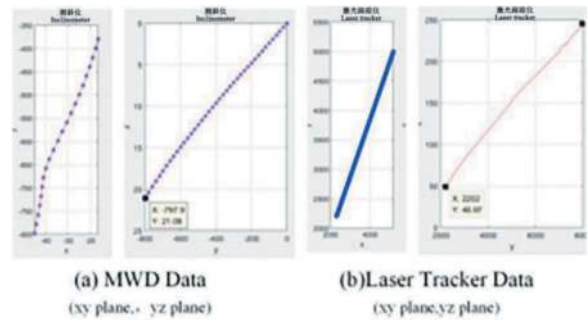

Figure 7. Measurement results of borehole trajectory.

Verification of steering function: The measurement results of laser tracker in horizontal plane are shown in Figure 8(a), with totally 602 measuring points. The last 100 measuring points of the laser tracker were extracted, i.e. about 1.3 m of directional drilling trajectory. The local enlarged view is shown in Figure 8(b). It can be seen that the drilling trajectory tends to deviate to the right from the starting point to the ending point of the borehole, which is consistent with the set direction. Fitting the circle with matlab, as shown in Figure 8(c), the radius of curvature is about 114m, and the corresponding build-up rate reaches $15^\circ/30m$. Moreover, it can be seen from Figure 8(c) that the direction of circle center is on the right side of the trajectory, which is consistent with the expected drilling direction.

Figure 8. Deviation correction results.

Verification of coring function: The actual boreholes and the cores obtained are shown in Figure 9. As can be seen from the figure,

- (1) In the process of drilling, the water returned from the flushing fluid to the outside of the hole is turbid, indicating a high drilling speed.
- (2) The geology in the concrete is very uneven, while the hole wall formed by coring drilling is

smooth, requiring high anti-rotating ability of directional coring tool.

- (3) Directional coring tool can be directly put into the borehole formed by linear coring tool, without reaming process or replacing mud pumps and other equipment, thus greatly improving the drilling efficiency.
- (4) The diameter of the core from linear drilling is 47.3 mm, and that from directional drilling is 31.45 mm. In comparison with the core from linear drilling, the core from directional drilling is more broken. It may be because the core from directional drilling is smaller in diameter and easy to fracture.
- (5) In the process of linear coring drilling, the drilling rate was about 2 m/h. In the process of directional coring drilling, the drilling rate was about 1.06-1.18m/h and the coring rate was higher than 90%, realizing continuous coring in the whole hole section.

Figure 9. Coring results.

4 CONCLUSION

Aiming at the drilling needs of directional continuous coring in advanced geological exploration, a directional drilling trajectory design software is developed, which can implement the calculation and visualization of actual drilling trajectory and trajectory to be drilled, the calculation of appropriate tool face angle and deflection distance of deflection tools, effectively guiding the directional drilling process.

In addition, the hardware of directional coring drilling system is introduced, and a deflection tool integrating the functions of guiding, steering, and coring — directional coring tool is developed. Finally, the feasibility of directional coring drilling system is verified by test. As shown by the test results, the directional coring drilling system can effectively control the borehole trajectory and implement continuous coring in the whole hole section of directional drilling. In comparison with screw drilling tool, it consumes less water, requires

no special mud pump, saving the equipment replacement time and improving the drilling efficiency. Therefore, it has certain promotion and application value.

Geological risks in TBM tunneling and its prediction by HSP method

Song Lu*, Yang Xiao & Xu Wang

China Railway Southwest Research Institute Co., Ltd., Chengdu

ABSTRACT: In order to realize the real-time prevention and control of geological risks in TBM tunneling, and taking into consideration the construction technology of TBM tunnels and structural characteristics of the TBM machine, the unfavorable geological bodies affecting the construction of TBM tunnels, such as karst, boulder, bedrock relief and structural fracture zone were analyzed so as to develop an advanced geological prediction technology based on HSP method, which uses the rock-breaking vibration of the TBM machine as the seismic source. By developing the software system with the functions of one-click design of parameters, automatic acquisition of wave field information, real-time data processing, detection of geophysical anomalies, and intelligent interpretation of prediction results, we put forward the optimization design scheme for the hardware and software of HSP system, so that the HSP system can be mounted on the TBM machine, and the goal of “real-time geological exploration and reporting while TBM tunneling” can be achieved. This technology has been applied in Guiyang Metro Line 3, Guangzhou Metro Line 18, Fuzhou Metro Line 4, Qingdao Metro Line 8 and other projects, and the karst, boulder, bedrock relief and other unfavorable geological bodies with elastic wave impedance difference have been well predicted. The HSP method-based geological prediction technology, which is based on the “passive source” of TBM construction environment, provides a solution for the real-time perception of geological state in the process of TBM tunneling, making the real-time fusion analysis of geological and construction information possible, and promoting the development of intelligent TBM construction.

Keywords: TBM Construction, HSP method, Rock-breaking Seismic Source, Intelligent identification

1 INTRODUCTION

Urban rail transit, which operates through subterranean tunnels, has gained popularity due to its fast speed, high transportation capacity and low environmental impact. It has become an essential mode of transportation for people to travel. Tunnel Boring Machine (TBM) construction is a prevalent technique in urban rail transit construction and has also been applied to underground infrastructure projects, including underground pipe galleries and pipelines. As urban transportation and underground space construction continue to develop, the need for effective management of geological risks and optimization of engineering design has increased. Consequently, the standards for density and accuracy of geological exploration have become more stringent. Exploration methods primarily based on drilling and in-situ testing are limited in terms of location and number of holes due to site structures, transportation and other constraints. Moreover, the accuracy of surface investigation may not meet the requirements for high-precision investigation due to factors such as time period and funding. Additionally, frequent geological disasters occur due to uncertain

geological conditions^[1, 2]. While existing geophysical exploration technologies have resolved many engineering problems within their respective detection capabilities, traditional geophysical exploration methods still could not identify the distribution of unfavorable geological conditions (bodies) in TBM construction or adapt to TBM construction scenarios. Furthermore, the unique structure and construction characteristics of TBM will also impact the safety and progress of TBM construction, particularly in complex geological conditions and environments. Hence, ensuring effective management of geological risks during TBM construction is essential for the efficient implementation of the metro construction project using the TBM method.

Based on the technological characteristics of TBM construction, this paper examines significant geological hazards that impact TBM construction, such as karst, boulder and bedrock relief. It discusses geological prediction technology that employs the HSP method which utilizes the rock-breaking vibration of the TBM as the seismic source. Additionally, the paper presents several prediction cases to provide guidance for future TBM construction projects with similar geological conditions.

2 TECHNOLOGICAL CHARACTERISTICS OF TBM CONSTRUCTION

The TBM method is a highly mechanized tunnel construction technique that employs a TBM to excavate underground. The TBM performs tunneling and mucking while simultaneously controlling the excavation face and surrounding rock to prevent collapse and destabilization. Additionally, the TBM assembles pipe segments to form the lining and carries out grouting behind the wall to construct the tunnel without disturbing the surrounding rocks, as illustrated in Figure 1. The primary principle is to minimize the impact on surface buildings, transportation facilities, and underground pipelines by completing tunneling and lining works to the greatest extent possible without disturbing the surrounding rocks. To attain this objective, the earth or slurry pressure within the pressure chamber is frequently utilized to balance the earth pressure and water pressure exerted on the excavation surface, thereby actively regulating the release of stress and deformation of the surrounding rocks. This aspect constitutes a crucial element of TBM technology.

Figure 1. Schematic diagram of TBM construction.

3 ANALYSIS ON GEOLOGICAL RISKS OF TBM CONSTRUCTION

3.1 Cases of disasters faced by TBM construction

In TBM construction, safety incidents frequently arise as a result of unfavorable geological conditions. For instance, in one engineering project, a water-earth consolidated block obstructed the screw conveyor, rendering the TBM inoperable. Upon opening the observation hole to address the issue, sand and water surged through the opening of the screw conveyor. In another project, the sudden release of gas in the local formation gap created a groundwater channel, causing the confined water behind the TBM to surge along the channel and into the hole, resulting in a significant collapse of the ground and the TBM being buried. It is evident that determining geological conditions is a crucial aspect of TBM construction for metro lines. Therefore, significant emphasis shall be placed on geological conditions, and geological exploration work shall be carried out beforehand for TBM construction sections. Typical geological hazards that may arise during TBM construction include karst, boulder, bedrock relief, and water-rich structural zone.

3.2 Risk of karst or dissolution zone

Based on varying geological conditions and levels of karst development or hazards, karst zones can be categorized into high- and low-risk zones. A geological area that features a rock-soil interface (primarily defined by a heavily weathered rock stratum beneath a soil layer) located within 10 m below the structural floor is classified as a high-risk karst zone. The high-risk karst zone is typically considered to be bounded by a plane range of 3 m away from the main structure boundary, while all other zones are considered low-risk karst zones.

In areas where karst develops, large-scale karst/soil cave groups are typically formed, and the distribution pattern of karst is often irregular. The individual shapes of the karst caves vary. The fillings of the karst/soil caves are mostly rheoplastic or soft plastic, which exhibit low stability. If the groundwater is abundant or flows actively, ground collapse may occur easily [3]. Under such circumstances, TBM construction may result in structural damage, leading to issues such as sinking, “kowtow” and deflection of the TBM, or sudden mud burst or water gushing in the tunnel.

3.3 Risk of boulders

The spheroidal weathering of rock mass commonly creates boulders and poses a significant challenge to TBM construction. If an unknown boulder is encountered during TBM excavation, it may act as a major obstacle, akin to a “tiger blocking the road,” as illustrated in Figure 3. This will make excavation exceedingly difficult, with the cutterhead frequently getting stuck. The TBM’s posture will become challenging to control, and the cutter holder and cutterhead will be deformed easily, significantly impeding the efficiency of TBM construction.

Figure 2. Boulder.

Figure 3. Geological risk of boulder.

3.4 Risk of bedrock relief

The bedrock surface is characterized by undulations, often forming distinct strata with a soft top and hard bottom, as illustrated in Figure 4. When the TBM advances to cut the rock stratum at the bottom, severe wear will be caused around the cutterhead, and the TBM posture control will also become difficult. There have been instances where the shield was worn out by the cutterhead.

Figure 4. Geological section of an engineering project.

3.5 Risk of geological structural zones

The lithology on either side of the fracture zone exhibits significant differences. The fracture zone itself is characterized by a substantial amount of breccia. Shallow fracture zones are typically filled with clay, which has a relatively high stickiness, leading to the formation of mud cakes. If groundwater is abundant, gushing may occur easily during TBM excavation. Furthermore, due to the uneven bedrock surface and the impact of hydrothermal process, the rock strata on either side of the fracture zone may become silicified. Silicified rock is known for its high strength, but it can also cause excessive wear on the cutterhead, as well as cracking of the cutter ring and bolt fracture. For instance, in a previous project, TBM excavation encountered a fracture zone, resulting in slow progress and a 39-day suspension due to a fractured scraper bolt.

3.6 Other risks

During urban metro construction, TBM construction often encounters existing structures such as foundation piles and anchor cables that intrude into the construction area. These structures will act as roadblocks, impeding TBM progress and leading to significant wear and tear around the cutterhead. In some cases, they can even make the TBM get stuck or affect the structural safety of nearby buildings.

4 ANALYSIS ON GEOLOGICAL PREDICTION FOR TBM CONSTRUCTION

4.1 Environmental characteristics of TBM construction

(1) Space characteristics of TBM construction

The TBM construction environment is highly intricate. Since the TBM occupies a significant portion of the tunnel space behind the working face, the

observation space for advance geological prediction is extremely narrow, and the room for laying out geological prediction equipment is insufficient, as illustrated in Figure 5. Consequently, the application of advance prediction methods used in traditional drilling and blasting (D&B) tunnel construction in the TBM construction environment is challenging.

Figure 5. Environment of TBM construction.

(2) Impact of shield segments

Shield segments are the primary assembly components used in TBM construction. Typically, they are constructed from high-strength, impermeable reinforced concrete, with a high reinforcement ratio, high strength and thickness ranging from 30 cm to 50 cm, to ensure reliable load-bearing capacity and waterproof performance. Once the TBM has excavated a distance of one ring, the erector operator assembles single-layer lining segments using the erector, enabling the tunnel to be formed in one go, as illustrated in Figure 6. However, the complete coverage of the tunnel wall by segments limits the arrangement of geophysical exploration receiving devices, such as geophones and electrodes.

Figure 6. Tunnel segment support.

(3) Environmental noise interference

Vibration interference: Compared with the D&B method, the vibration, noise and other environmental hazards generated by TBM construction are less harmful, but its vibration and noise will still have a certain impact on advance geological prediction. The main sources of vibration and noise include: 1) Large vibration caused by large collision when the cutterhead cuts soil during

TBM tunneling; 2) the mucking mechanism of TBM, including mainly screw conveyor and belt conveyor; 3) several links of the TBM construction involving auxiliary equipment and the treatment and transportation of raw materials and muck. Transportation work involving segment transport trolleys, slurry carts, muck carts and bentonite carts can generate varying degrees of vibration and noise.

Electromagnetic field interference: As described by Maxwell's Electromagnetic Theory, changing magnetic fields can excite vortex electric fields, and changing electric fields can excite vortex magnetic fields. Electronic devices inherently generate electromagnetic fields in their surrounding space. The TBM construction site is equipped with intensive electric equipment, complex electrical circuits and numerous metal components. Its power distribution systems range from high voltage to low voltage and from strong current to weak current, featuring extremely intricate structures and functions. All of these factors contribute to the production of significant electromagnetic interference, which can significantly affect the accuracy of advance geological prediction through electromagnetic methods.

4.2 Technical requirements for the geological prediction for TBM construction

Scenario adaptability of prediction methods The TBM construction environment poses limitations or challenges to the implementation of commonly used prediction methods for mine tunneling, such as TSP, geological radar method and transient electromagnetic method [4]. The implementation of the geological radar method and the transient electromagnetic method, which involve laying survey lines on the tunnel face, is not feasible. Similarly, the TSP method, which requires blasting source holes and receiving holes in the side walls, is affected by the segments, and the use of explosive sources poses safety risks for the TBM. Therefore, a suitable prediction method for TBM construction scenarios shall consider factors such as field source excitation, measuring point arrangement and noise disturbance capability.

Figure 7. Influence of TBM construction environment on geophysical prediction.

(3) Detection range

The TBM method offers significant advantages over traditional underground excavation methods in terms of engineering progress. Through analysis of statistical data from TBM construction sections of Beijing Metro Lines 5, 4, and 10, as well as Beijing Airport Express, and by disregarding non-advancing operations and solely comparing normal tunneling conditions in TBM construction sections, it is evident that the maximum and average tunneling speeds in TBM construction sections are significantly higher. In fact, they are approximately 5 to 10 times faster than those of the mine tunneling method, as illustrated in Figure 6. In this case, the detection range of the prediction method must meet the requirements of the tunneling speed.

Figure 8. Comparison of tunneling speed between TBM construction and mine tunneling method.

5 GEOLOGICAL PREDICTION METHODS SUITABLE FOR TBM CONSTRUCTION

In TBM construction, conventional advance geological prediction methods primarily include the surface drilling method, geophysical exploration method, and analysis of rock-machine sensing parameters and muck behavior in the tunnel. Each method has its unique characteristics and limitations. For instance, the drilling method's hole layout is restricted by surface buildings and structures. Similarly, the surface geophysical exploration method is susceptible to interference from underground pipelines and urban geophysical exploration sources, which will affect the quality of field source signal reception. Additionally, the rock-machine sensing parameter analysis is typically more accurate when an anomaly is imminent, making it challenging to predict unfavorable geological conditions in advance and gain valuable time for treatment. This paper introduces a real-time advance geological prediction method (HSP method) which uses the rock-breaking vibration of the TBM as the seismic source.

5.1 Technical principles of HSP method

This method is based on the elastic wave theory, which utilizes the vibration signals generated by the disc cutter during TBM tunneling as seismic sources [5, 6]. By creating virtual seismic sources [7, 8] through interference phenomena, reflection imaging is performed for geological bodies with differences in elastic wave

impedance (i.e., the product of density and velocity) in front. Unfavorable geological bodies, such as faults, weathered fracture zones, karst and groundwater enrichment zones, exhibit distinct characteristics from surrounding rocks. The reflection characteristics of the wave field propagation are as follows:

$$R_{12} = \frac{\rho_2 v_2 - \rho_1 v_1}{\rho_2 v_2 + \rho_1 v_1}$$

Where, R_{12} is the reflection coefficient, ρ is the medium density, and v is the longitudinal wave velocity of medium.

Figure 9. Geological Prediction with rock-breaking vibration as the seismic source.

5.2 On-site implementation process of HSP method

In the implementation process, geophone points are arranged along the tunnel contour. While fixed positions are not necessary, it is important to meet minimum offset requirements to ensure accurate geophone point position data entry into the software system. Rock-breaking vibration signals are continuously collected during TBM excavation to ensure sufficient data volume, typically not less than 8 minutes. The collected data undergoes time-frequency analysis^[9], interference analysis, reflection imaging^[10, 11], time-depth conversion, anomaly extraction, and geological interpretation to determine the spatial location and range of unfavorable geological conditions (bodies) ahead. This process enables accurate geological prediction.

5.3 Onboard HSP217T real-time geological prediction system

Incorporating onboard geological prediction equipment that is suitable for TBM construction environments is an effective approach to enhance the intelligent sensing capabilities for TBM construction. The acquisition control is performed using the industrial control computer located in the TBM control room. The acquisition host is modularized and integrated into the TBM host room, while the large receiving cable is integrated with the TBM structure to form a complete set of onboard prediction equipment. See Figure 10 for further details.

Figure 10. Onboard prediction system.

With a modular design, the software component of the system comprises three distinct modules: (i) the host control and parameter design module, which includes host acquisition control, position parameters of receiving and sending points, data processing parameters, and other relevant parameters that can be set rapidly and efficiently; (ii) the information acquisition, storage and imaging module, which performs data acquisition, processing, and inversion imaging based on the design parameter information, as illustrated in Figure 11, and completes the mapping of geophysical exploration images, abnormal areas and presumed geological risks; and (iii) the anomaly identification and geological interpretation module, which identifies and interprets anomalies in the result images and performs iterative approximation analysis of multiple detections. See Figure 12 for further details on the iterative approximation analysis.

Figure 11. Inversion imaging display interface.

Figure 12. Iterative approximation analysis of multiple detections.

6 CASE ANALYSIS OF PREDICTION BY HSP METHOD

6.1 Karst prediction

TBM cluster construction is adopted for Guiyang Metro Line 3. However, due to the presence of a karst zone, risks such as deviation, water burst and mud gushing may be encountered during TBM construction. To mitigate these risks, the HSP method was employed for geological prediction along the entire line. The prediction analysis focused on ZDK24+687 in the Sifanghe Road Station–Zaojiaoqing Station Section. In this project, 200 data were collected, with a total of 1,600 channels. Each channel lasted for 0.256 s and the whole process took 15 minutes. The data were processed by interference imaging, as illustrated in Figure 14. The analysis predicted five areas of abnormal reflection. When the TBM entered these areas, excavation parameters and mucking amount became abnormal.

Figure 13. Results of Detection at ZDK24+687 (top view).

6.2 Boulder prediction

In Section K6+939~K6+869 of Guangzhou Metro Line 18, the TBM needed to pass through an intensely weathered zone of granite. Preliminary survey data showed that there were boulders in the area. In this case, HSP method was used to perform test at K6+939 of the tunnel face. A total of 300 data were collected, totaling 2,400 channels. Each channel lasted for 0.256 s, and the whole process took 18 minutes. The data were processed by interference imaging, as illustrated in Figure 15. Based on the prediction results, numerous abnormal reflection areas were identified. When the TBM entered these areas, a loud abnormal sound was detected in front of the tunnel face, which was confirmed to be the sound of boulder breakage caused by the cutterhead. The screw conveyor brought out small pieces of boulders, leading to damage of the cutting tools and belts, and necessitating the shutdown of the TBM for maintenance. Multiple spheroidal weathered blocks of granite appeared in the muck. See Figure 14 for detection results.

Figure 14. Results of detection at K6+939 (top view).

6.3 Prediction of bedrock relief

The Linpu Station–Chengmen Station Section of Fuzhou Metro Line 4 comprises primarily of torso mountains, hilly landform units, and Quaternary deposits as its geomorphic units. The terrain of the torso mountains and hilly landform units exhibits significant fluctuations, and the TBM crossing area is characterized by numerous bedrock intrusions into the tunnel design space. In this test, 300 data were collected at K42+700 of the tunnel face, with a total of 2,400 channels. Each channel lasted for 0.256 s, and the whole process took 18 minutes. The data were processed by interference imaging, as illustrated in Figure 16. Based on the prediction results, one abnormal reflection area was identified. When the TBM entered the area, tunneling was carried out under challenging conditions, including broken stones and bedrock relief, which led to the TBM's shutdown for handling. The specific situation of surrounding rock excavation and exposure is shown in Figure 15.

Figure 15. Results of Detection at K42+700 (top view).

6.4 Prediction of structural fracture zones

The pilot tunnel in the Dayang Station–Qingdaobei Station Section of Qingdao Metro Line 8 was constructed using dual-mode TBM. The tunnel's top has a minimum cover depth of 29.49 m, and the maximum burial depth of the overburden is 52.49 m (57.94 m below sea level). The overburden primarily comprises of weakly weathered tuff and weakly weathered andesite. To mitigate the construction risks associated with the cross-sea tunnel, the project team defined the chainage for optimal mode conversion and conducted advance geological prediction using the HSP method. Specifically, two anomalies were identified through the prediction process at K1+473, including a minor reflection anomaly and a major anomaly area, as illustrated in Figure 16. During the tunneling process towards the minor anomaly in the hard rock mode, joint fissures emerged within a 2-meter tunnel length range in the direction of 12 o'clock to 1 o'clock, accompanied by localized water seepage. As the tunneling progressed towards the major anomaly, an advance horizontal drilling operation was conducted by the TBM at a distance of 7 meters, revealing a broken stratum ahead. Based on the drilling and prediction outcomes, the TBM mode was appropriately adjusted, enabling it to pass smoothly through the structural fracture zone.

Figure 16. Results of detection at K1+473 (top view).

Figure 17. Photos of exposure by excavation.

Figure 18. Photos of exposure by excavation.

7 CONCLUSIONS

TBM construction is frequently impeded by unfavorable geological conditions, such as karst, boulders, bedrock relief and fault fracture zones, which may result in TBM entrapment, adversely affecting construction efficiency and safety. However, the implementation of conventional advance geological prediction methods in tunnels is hindered by the space environment, geophysical exploration source interference, and segment support mode.

By analyzing the common geological risks and characteristics of TBM construction, this paper discusses an advanced geological prediction technology based on HSP method which uses the rock-breaking vibration of the TBM as the seismic source. Additionally, various cases of unfavorable geological condition prediction are introduced and analyzed. The application results demonstrate that the HSP method can effectively predict common unfavorable

geological conditions in the TBM construction environment. Furthermore, since shutdown is not required, this method provides a solution for the real-time perception of geological state in the process of TBM tunneling, making the real-time fusion analysis of geological and construction information possible, and promoting the development of intelligent TBM construction.

Rock abrasiveness in the studies of São Paulo Metro: Tests, classification systems, parameters obtained from various lithotypes and their relationship with weathering degree

Marcelo D. Monteiro*, Hugo C. Rocha, Guilherme B. Robbe & Audrey Melchert de Almeida
Companhia do Metropolitano de São Paulo - Metrô, Brazil

ABSTRACT: The assessment of the abrasivity effects exerted by rocks on cutting tools is of great importance. The consumption of these tools needs to be carefully analyzed, as it can result in increased costs and delays in schedules. In this regard, the São Paulo Metro conducts detailed studies to better understand the factors that condition abrasive properties in rocks found in the São Paulo Metropolitan Region.

These studies are carried out through petrographic analysis of rocks, uniaxial compressive strength tests, CERCHAR abrasivity tests and drillability tests. The results are reported using internationally recognized classification systems, such as the equivalent quartz content (eQc), the CERCHAR abrasivity index (CAI), and the rock abrasivity index (RAI).

An aspect of major relevance in the studies was the evaluation of the weathering degree of the rocks and its influence on the results of the abrasivity tests. It was observed that as the weathering degree increases, the abrasivity parameters show lower values. This information is crucial for a proper evaluation of abrasivity. Solely considering mineralogical aspects is not sufficient. It is necessary to take into account the specific geo-mechanical conditions of the rocks.

Finally, based on the CERCHAR and RAI indexes, estimates of the consumption of cutting tools were made for the studied rocks. The Cantareira Granite proved to be more abrasive, resulting in higher tool consumption compared to the granitic and gneissic rocks of the Embu Complex.

Keywords: abrasivity, cerchar, weathering, cutting tools

1 INTRODUCTION

The study of parameters related to the abrasiveness of rocks and soils is of great importance in the execution of works in rock masses, both for drilling & fire blasting excavations, as well as those mechanized with tunnel boring machines (TBM) or road header machine mainly for assessment of wear on cutting tools and their associated costs. Since the expansion projects for the metro lines in São Paulo (Brazil) started to intercept the rock masses that constitute the basement of the Metropolitan Region of São Paulo, the São Paulo Metro started to develop a line of studies related to abrasivity of rocks and their effects on the consumption of cutting tools, trying to fill the existing gap in knowledge on the subject, both in São Paulo and in Brazil. The studies carried out showed behavior of the local lithotypes that were quite different from those observed in classical studies carried out on the European continent, in particular due to the

different physical and chemical conditions of the tropical climate with a temperate climate and a different degree of action of external dynamics.

2 GEOLOGICAL CONTEXT AND SAMPLE SELECTION

The samples for the study were collected throughout the geological-geotechnical investigation campaigns of the Basic and Executive Project phases of the São Paulo Metro, Lines 2, 4, 5 and 6. In the evaluations, we sought to identify the representative lithotypes at depths of interaction with underground excavations.

The geology of the São Paulo Metropolitan Region (RMSP) is represented by three compartments: in stratigraphic order, the Precambrian basement, the Paleogene to Neogene sediments of the São Paulo Basin and the Quaternary covers. As for lithotypes, the geological framework of the RMSP is

*Corresponding author: mdmonteiro@metrosp.com.br

basically made up of metamorphic and igneous rocks, associated with the Embu Complex and the São Roque and Serra do Itaberaba Groups, in addition to bodies of intrusive granitoid rocks.

The Embu Complex is the unit with the highest occurrence in the basement of the RMSP, occurring in its central-southern portion and occupying a range of outcrops with a NE-SW direction, represented by gneisses, amphibolites, migmatites and granite-gneisses (Monteiro et al., 2012).

The intrusive granitoids, in this study represented by the Cantareira Granite, occur as rocks of granodioritic to granitic composition and appear as a large number of batholiths that outcrop in the region, some partially covered by the sediments of the São Paulo Basin. The greater resistance to weathering has caused these rocks to sustain morphological highs (Coutinho 1980, apud Juliani 1992). These rocks are marked by high values of uniaxial compressive strength. Samples of hydrothermalized archosean sandstone from the Resende Formation were selected from the sedimentary soil packages. These were included in this study due to their frequent occurrence in studies. They are sandstones with strong cementation, which makes excavation difficult in relation to the rest of the sedimentary package. These rocks are located next to fault zones, from where they receive input from hydrothermal fluids, especially in the east zone of São Paulo.

3 ABRASIVENESS ASSESSMENT

Historically, abrasiveness studies were restricted to mineralogy and were based only on the amount of quartz mineral present in the samples, based on the Mohs hardness scale (relative) and the Rosiwal hardness scale (absolute), the latter of which supported the development of quartz-equivalent content. Plinninger (2010) mentions that exclusive approaches to these indices based only on the mineralogy of the rock proved to be limited as they did not consider other important characteristics (such as grain size and mechanical resistance); This scenario provided the development and application of other tests and indices to better evaluate the abrasive properties of rocks and soils.

In the international literature, in addition to mineralogical approaches, there are a large number of parameters and tests to evaluate the abrasive properties of soils and rocks (all tests and indices developed have applications depending on specific approaches). In studies carried out in Brazil, the equivalent quartz content (eQc) and the CERCHAR abrasiveness index (CAI) have been used more frequently. In recent years, the application of the drilling rate index (DRI) has been increasing.

3.1 Equivalent Quartz Content (EQC)

It is an index developed to indicate the abrasive potential of rocks based on the presence of abrasive minerals. Quartz equivalent is a parameter obtained from petrographic analysis carried out on slides from

rock samples in which the percentage of minerals is determined; the value obtained is multiplied by the Rosiwal abrasivity of each mineral.

Equivalent quartz is used by excavation equipment manufacturers and research professionals to identify tool consumption problems.

3.2 Cerchar Abrasiveness Index (CAI)

The CERCHAR abrasiveness index is obtained from the homonymous test, developed in the 1970s. The test consists of fixing a rock sample over which a tip made of material with known hardness is slid. The tip is subjected to a weight of 7 kg, which provides a load of 70 N. The surface of the sample where the tip friction is applied is obtained naturally through fresh flat fractures or artificially, in this case, using diamond saw. The friction of the tip with the test surface creates a groove in the sample, leading to wear of the tip, which represents the CERCHAR Abrasive Index (CAI). Values below 1.0 are considered slightly abrasive, values between 1.0 and 2.0 are considered medium abrasive, values between 2.0 and 4.0 are considered very abrasive and values between 4.0 and 6.0 are considered extremely abrasive. In practice, we can assume that CERCHAR evaluates primary wear. This is the wear that cutting tools suffer in direct contact with the rock mass and is the most discussed in studies focused on the consumption of these tools.

3.3 Rock Abrasiveness Index (RAI)

The rock abrasiveness index (RAI) represents a modification of the quartz-equivalent content (eQc) and is applicable not only to sound rocks, but also to weathered rocks. The RAI is calculated by multiplying the simple compressive strength (RCU) by the equivalent quartz content (eQc), being defined as an index that combines the presence of abrasive minerals with the mechanical properties of the rock (Plinninger, 2010). The RAI stands out for its practicality in obtaining it, since petrography data and RCU tests are usually available in good geological-geotechnical investigation campaigns. Even so, Plinninger (2010) mentions that in the absence of these parameters, eQc can be replaced by X-ray diffractometry and RCU by the point load test. In the rating scale for RAI there are no upper and lower limits. Values below 10.0 are considered as non-abrasive, values between 10.0 and 30.0 are considered as little abrasive, values between 30.0 and 60.0 are considered abrasive, values between 60.0 and 120.0 are considered considered as very abrasive and values above 120.0 are considered as extremely abrasive.

The highest RAI values recorded were in quartzites in South Africa (RAI of 360) and Germany (RAI around 200), but experience indicates that values of up to 400 are admitted as plausible for this parameter. The lowest values are attributed to highly weathered rocks, with low mechanical resistance (Plinninger, 2010).

RAI has been used successfully in Europe, contributing significantly to the assessment of the

abrasive properties of rocks and the prediction of cutting tool consumption.

4 RESULTS AND IMPLICATIONS FOR EXCAVATIONS

Below are presented the results obtained for the evaluated parameters (equivalent quartz - eQc, the CERCHAR abrasivity index - CAI and the rock abrasivity index - RAI), the correlations between these parameters, the influence of the degree of alteration and the application of these in predicting the consumption of cutting tools in underground excavation works in rock masses.

4.1 Equivalent quartz content results

The granite units are predominantly within the same occurrence range, between 40% and 50%. These units have a main mineralogical profile represented by quartz (20 – 25%), feldspars (30 – 40% for Cantareira and 40 – 50% for the Embu Complex) and biotite (10 – 20%). Secondary and accessory mineralogy includes zircon, titanite, apatite, epidote, tourmaline, chlorite, sericite, muscovite and opaque minerals. Some samples of these granites presented quartz-equivalent values that differ from the average profile, these are credited to specific variations, such as sample 6175B with 8% tourmaline, contributing to an eQc of 59.30% (Cantareira Granite) and sample 5719 with 6% hornblende and about 35% quartz, resulting in an eQc of 53.33%. At the other extreme, counts of 20% biotite (sample 6115) and the combination of 20% quartz with high amounts of biotite, muscovite and chlorite (sample 5653A) provided eQc values of 43.80% and 40.90%.

The gneisses of the Embu Complex are in a similar range to the granites, however, with a predominant occurrence range of up to 60%. The mineralogical profile of these rocks is more diverse, presenting a wide variety in the quantities of the main mineralogy (quartz, feldspars, amphiboles and biotite). Despite this great variability, the lithotype reaches higher average values than the granitic units. Discrepant occurrences are also observed in this unit; sample 5595B has 15% garnet, a mineral with a high weight for abrasiveness, contributing to an eQc of 58.69%. For sample 5207A, the low amount of quartz (20%) and 28% biotite contributed to the eQc value of 40.07%. Even so, looking at the average values of the three units, it is clear that they are very close. The Cantareira Granite has an average value of 47.96%, the granites of the Embu Complex have 46.94% and the gneisses of the Embu Complex have 52.90%.

For the other lithotypes with more restricted occurrence, an eQc of 99.57% was recorded in the quartz vein sample (5595). This is the highest value among all the samples analyzed in this study and is consistent with what is expected for a sample with 99.5% quartz and 0.5% opaque minerals. High values of eQc are also recorded (and were expected) in the hydrothermalized

arkose sandstones of the Resende Formation, with values from 63.18% to 77.00%. These high values occur due to quantities of quartz + feldspars exceeding 80%. Amphibolite samples from the Embu Complex have low eQc values due to the reduced amount of quartz (below 6%), combined with a greater amount of amphibole (between 50 and 60%). For this unit, the average eQc value is 27.70%, the lowest of all units analyzed.

Figure 1. Values of equivalent-quartz content.

4.2 Cerchar abrasiveness index results

The unit with the highest CERCHAR values is that of the Embu Complex granites, which have a higher frequency of results between 4 and 6 (extremely abrasive). The Cantareira Granite, with a smaller number of samples, presents results concentrated in relatively close ranges (ranges 4 to 5), indicating compatibility between the granite samples. Despite widespread occurrence among almost all ranges of results, the gneisses from the Embu Complex present a higher frequency of results between ranges 2 and 4 (very abrasive). In relation to the other lithotypes studied, it is possible to observe that the hydrothermalized arkosean sandstones present lower values (ranges 0 to 1), being predominantly considered as little abrasive. The amphibolite samples from the Embu Complex had results in ranges 2 and 3 (medium to very abrasive abrasiveness) and the mylonite sample showed high abrasivity, with a value of 4.9. For granite units, in Cantareira the largest number of results above their average is evident. Within this unit, the low value of 3.3 obtained for sample 6116 represents an exception to its standard behavior. The Embu Complex has samples with higher CERCHAR values. Sample 5622, located in the region of the Ponte Grande neighborhood - municipality of Guarulhos, presented a value of 5.7. This is the sample with the highest CERCHAR value recorded in the studies. In general, the two granitic units have CERCHAR abrasiveness results profiles within similar results ranges, with the Embu Complex having higher values between the two units. The hydrothermalized sandstones of the Resende Formation, despite the small number of samples tested, at the 3 different sampling points the results varied from 0.5 to 1.1. It should be noted that these are samples with high quartz-equivalent content (eQc) values. The values for the granitic units are in accordance with the typical CAI values indicated for these rocks in the study by Plinninger et al. (2003).

Figure 2. Values of CAI.

4.3 Comparison between EQC and Cerchar

Among all the samples used in this study, 44 have quartz-equivalent and CERCHAR results, 24 of which are from igneous rocks, 17 from metamorphic rocks and 3 from sedimentary rocks; This made it possible to compare these parameters. The comparison between the eQc and CERCHAR results obtained on the same samples allowed us to identify the lack of correlation between these parameters, which indicates that abrasive mineralogy is not the only factor that influences the CERCHAR test. Arkosean sandstone samples have high quartz-equivalent values, however, low CERCHAR values. Similar cases also occur in other lithotypes. These results are in agreement with the evolution of this study. Previous initial work with samples from the Metropolitan Region of São Paulo (Monteiro et al., 2011 and Monteiro et al., 2012) already indicated the lack of correlation between these two parameters and this is completely in agreement with the observations of reference works in the European continent, such as Kasling (2000) and Plinninger et al. (2004). In this way, the premise is assumed that just the presence of large quantities of quartz and other abrasive minerals does not necessarily imply the ability to significantly consume cutting tools. The observations of West (1989) and Bieniawski et al. were not confirmed.

Figure 3. Comparison between eQc and CAI.

4.4 Influence of weathering alteration degree

The studies by Monteiro et al. (2011, 2012) suggest that one of the reasons for the lack of compatibility for the eQc and CERCHAR parameters would be the action of weathering, an agent of external dynamics, which causes changes in rocks, reducing their

mechanical resistance, but having little influence on the quartz content-equivalent. This low influence on quartz-equivalent is due to the fact that quartz, the most abundant high-hardness mineral in rocks in this geological context, is significantly resistant to weathering. For the CERCHAR abrasiveness index, rocks with a degree of alteration A1 (sound lithotype geomechanical conditions) presented 80% of results considered as extremely abrasive (ranges 4 to 6) and 20% as very abrasive (ranges 2 to 4). At this degree of change, low abrasive results (ranges 0 to 1) or medium abrasiveness (ranges 1 to 2) are not observed.

When evaluating the results of rocks with alteration degree A2 (little altered rock), it is observed that the percentage of extremely abrasive rocks drops to 67%, while very abrasive rocks increase to 33%. In rocks with degree of alteration A3 (moderately altered rock), the change is even more significant, extremely abrasive rocks drop to 27%, very abrasive rocks remain at 33% and low abrasive and medium abrasive results appear which together total 40% of the results. For the rock abrasiveness index (RAI), a very similar behavior occurs. With rocks in degree of alteration A1, 36% of very abrasive results were recorded (RAI between 60 and 120), 57% of abrasive rocks (RAI between 30 and 60) and 7% of slightly abrasive rocks (RAI between 10 and 30). Moving to the degree of alteration A2, the percentage of very abrasive rocks fell to 8%, abrasive rocks fell to 54% and the percentage of low-abrasive rocks rose to 38%. With the degree of alteration A3, results from very abrasive rocks are no longer recorded, abrasive rocks drop to 20% and the percentage of low-abrasive rocks rises sharply to 80% of the results. By evaluating the average CERCHAR and RAI results for the different degrees of change, the data presented above is consolidated. For CERCHAR there is a small reduction in the average between grades A1 and A2, with a significant drop for grade A3. In the RAI results there is a significant drop across the three degrees of change. These results are compelling and confirm the hypothesis that the action of weathering, through the alteration of rocks, is an incisive and preponderant factor in the loss of abrasive conditions. The degree of change also explains the reason for the lack of similarity in the behavior of eQc versus CERCHAR in studies carried out in São Paulo, compared to studies carried out with rocks from the European continent.

5 CONCLUSIONS

This study applied some of the abrasiveness assessment indices most used by tunnel engineering to rock samples from the São Paulo Metropolitan Region. The quartz-equivalent content (eQc) and the CERCHAR abrasiveness index (CAI) were evaluated. Regarding the evaluated indices, the quartz-equivalent showed that the three main lithotypes are found in approximately the same result range, which is in line with what was expected for all the lithotypes evaluated. For CERCHAR, compatibility was observed between the

granite samples and a large dispersion of values for the gneisses. • No correlation was found between quartz-equivalent and CERCHAR, which indicates that just the presence of abrasive minerals does not necessarily imply an abrasive behavior of the rock (taking into account primary wear). • The mechanical resistance of the rock plays a fundamental role; In this context, the action of alteration on the rocks becomes important, which reduces their geomechanical conditions, but does little to alter the quartz-equivalent content. • CERCHAR values decrease as the degree of rock alteration increases, showing that the evaluation of alteration is fundamental for the study of abrasivity. Rock dismantling in an excavation process begins with the friction of the cutting tool against the rock mass in order to detach a rock fragment (chip). For tools, this is the primary wear and CERCHAR adequately evaluates the action of abrasiveness in this process. After the fragment is released from the mass, it remains under conditions of free friction with the cutting tool and, subsequently, with the internal part of the excavation chamber and with the excavated material transport system. This is secondary wear and the quartz equivalent becomes its best indicator at this stage of the process.

Phased prediction method for construction period of secondary lining construction time of tunnel in squeezed rocks

Li Ning*

China Railway First Survey and Design Institute Group Co. Ltd, Xi'an, Shanxi, China

ABSTRACT: The construction time of the secondary lining of the tunnel is often judged by the deformation rate, but in practical engineering, it is often difficult to obtain the later deformation rate after the waterproof board is laid, so it is impossible to accurately judge. In order to obtain the construction time of secondary lining of squeezing surrounding rock tunnel and make the construction of secondary lining more operable, based on the limit value of deformation rate, this paper fits and statistically analyzes the deformation measurement data of 412 squeezing surrounding rock tunnel sections, and obtains the deformation stability time range value of different deformation grades and the prediction method of construction time of secondary lining in stages during construction period. The specific conclusions are as follows: (1) A deformation data processing method is proposed, which can predict the stability of the deformation (u) and the final stability time (t') in the stability stage. (2) Through statistical analysis, the stable range of deformation stability time (t') under different deformation levels and different span conditions is determined, which is used to preliminarily determine the timing of secondary lining construction in the design stage. (3) The stable range value of deformation stabilization time (t') from excavation under different deformation levels and different span conditions is proposed, which can be used to preliminarily determine the construction time of secondary lining in the design stage. (4) Through the test of measured deformation data, the prediction results can be accepted by the project by using the staged prediction method of secondary lining construction time. (5) The construction time prediction method of secondary lining of squeezing surrounding rock tunnel with the stability time (t') of staged deformation as the discriminant index has strong operability, which avoids the operation trouble when the deformation rate is used as the discriminant index and can directly serve the engineering practice.

Keywords: Squeezing rock, Railway tunnel, Construction timing of secondary lining, Deformation classification, Deformation stabilization time, Statistical analysis

1 INTRODUCTION

With the advancement of infrastructure construction in western China, the problem of large deformation of squeezing surrounding rock has become a prominent problem for tunnel builders. Squeezing rocks is a rock mass with significant plastic deformation or rheology in a certain range around the tunnel under high ground stress environment, which has the remarkable characteristics of high ground stress, low strength and strong rheology. Under the action of high ground stress, the squeezing surrounding rock tunnel is prone to large deformation, resulting in support cracking, steel frame distortion, deformation intrusion and even lining cracking and falling block.

Under the condition of large deformation, the construction of secondary lining too early or too late will affect the safety of tunnel construction and structural stability. Therefore, the timing of secondary lining construction is always a hot issue in the study of squeezing surrounding rock tunnel. Taking

Wushaoling tunnel as an example, Liu et al. (2008) proposed two discriminant indexes for the timing of secondary lining construction with different deformation levels, that is, the daily deformation and total deformation measured on site based on the ultimate displacement of the tunnel. The slight large, medium and severe large deformation sections reached the secondary lining construction standard after 45-55d, 55-60d and 80-90d of tunnel excavation respectively, which was proposed by Guo et al. (2020). Taking Zhegushan Tunnel as an example, Meng et al. (2017) proposed that it is more appropriate to apply secondary lining after the initial support deformation is 65%-70% of the final convergence value.

Many scholars have also carried out a lot of research work on the time characteristics of tunnel deformation. Zhang et al. (2001) analyzed the displacement-time relationship curve of the whole process of surrounding rock deformation according to the field monitoring data. Yang et al. (2006) carried out curve analysis on the convergence measurement

*Corresponding author: 406639508@qq.com

data of tunnel surrounding rock and summarized the characteristics of deformation aging. Zuo et al. (2018) combined with field monitoring data, according to the classification of surrounding rock, the deformation-time characteristic curve of surrounding rock is divided into three stages of 'bow' type and four stages of 'step' type. Sun et al. (2008) divided the deformation curve of surrounding rock according to the deformation rate of surrounding rock. Based on the field measured data, Liu et al. (2009) analyzed the relationship between the deformation stability time and the surrounding rock grade.

In summary, there are few studies on the timeliness and deformation prediction of surrounding rock applied to the construction timing of tunnel secondary lining. In this paper, through the statistical analysis of the deformation monitoring data of 412 squeezing surrounding rock tunnel sections, the deformation stability time range values of squeezing surrounding rock tunnels with different deformation grades are obtained. Based on the final deformation stability time statistics, a phased secondary lining construction timing prediction method is proposed. The phased deformation stability time is used as the discriminant index of the construction timing of the secondary lining, which provides a reference for the construction timing of the secondary lining of the squeezing surrounding rock tunnel.

2 DEFORMATION CLASSIFICATION STANDARD AND STATISTICAL SAMPLES

2.1 Deformation classification standard of squeezing surrounding rock tunnel

Based on the geological conditions and in-situ stress of squeezing surrounding rock tunnel, the

classification standard of deformation potential of squeezing surrounding rock in China is shown in Table 1 (Liu et al., 2020), and the deformation potential is divided into four grades: slight, medium, serious and extremely serious.

Table 1. Classification standard of deformation potential of tunnel in squeezing rock.

Deformation grade (S)	Deformation potential	$G_n=R_{cm}/\sigma_{max}$	Relative deformation ($\epsilon/\%$)
I	Slight	0.3~0.2	2~4
II	Medium	0.2~0.15	4~6
III	Serious	0.15~0.1	6~8
IV	Extremely serious	<0.1	>8

2.2 Statistical sample

The measured data of convergence deformation of 412 squeezing surrounding rock tunnels at home and abroad were investigated and counted, including 55 foreign samples (Kimura et al., 1987; Panet et al., 1996; Brox et al., 1999; Phienweij et al., 2007; Barla et al., 2009, 2010, 2001; Atgar et al., 2020), accounting for 13 %. There are 357 domestic samples, accounting for 87%, including Liangshui tunnel, (2013a), (2013b), (2018); Muzhailing tunnel, (2017); Wushaoling tunnel (2005); Xinchengzi tunnel, (2016); Lanzhou-Chongqing tunnel, (2018) The excavation span of the tunnel is divided according to the Industry standard of The People's Republic of China (2002): the small and medium span is 5-12 m, and the large span and above is greater than 12 m. The specific sample statistics are shown in Table 2.

Table 2. Summary of statistical samples of measured deformation curve of tunnel in squeezing rock.

Order number	Excavation span	Tunnel name	Nationality	Grade				Total	
				I	II	III	IV		
1	medium and small span (5-12m)	Wushaoling tunnel	China	20	17	13	38	88	
2		Muzhailing tunnel	China	5	4	2	5	16	
3		Maoxian Tunnel	China	8	8	7	15	38	
4		Changping Tunnel	China	3	4	4	3	14	
5		Jiazhuqing tunnel	China	2	5	3	4	14	
6		Saint Martin Tunnel	Italy	3	2	4	8	17	
7		Large span and more (>12m)	Liangshui tunnel	China	2	14	28	4	48
8			Maoyushan tunnel	China	2	6	8	2	18

13			Frejus Tunnel	France	2	3	2	1	8
14		Enasan Tunnel II	Japan	1	1	6	4	12	
		Aggregate		56	106	141	109	412	

Note: The deformation samples are all sidewall convergence data.

3 DEFORMATION DATA PROCESSING METHOD

3.1 Deformation time history curve fitting and stable time value method

From Figure 1, it can be seen that the measured data of surrounding rock is the deformation from the element buried to the laying of waterproof board. The fitting curve of surrounding rock deformation is $u=f(t)$, and the fitting curve of deformation rate is $v=f'(t)$. Observing the deformation rate $v=f'(t)$ curve, t takes day as the unit. When the deformation rate decreases obviously and tends to be relaxed, the t corresponding to the first point A' of the relaxation section along the time coordinate $v < v_l$ is the stable time t_s . At this time, the point corresponding to the deformation fitting curve $u = f(t)$ is point A , and the corresponding u of point A is the stable deformation u_s .

Figure 1. Deformation-time curve of rock.

3.2 Deformation stability time criterion

In the squeezing surrounding rock tunnel, the following regulations are formed in the Technical Specification for Railway Squeezing Surrounding Rock Tunnel: the construction of secondary lining should be carried out after the deformation of surrounding rock and initial support is basically stable, and the deformation rate decreases obviously and tends to be moderate. When there is no experience, it can be carried out according to the deformation rate (7d average value). The small span is less than 1 mm/d, and the large span and above are less than 2mm/d, and the secondary lining is strengthened. That is, for small and medium span, $v_f=1\text{mm/d}$; for large span and above, $v_f=2\text{mm/d}$. The engineering practice shows that the tunnel constructed according to this criterion has no lining cracking problem due to extrusion deformation.

3.3 Deformation prediction in stable stage

The optimal curve fitting method is used to predict the deformation of surrounding rock in the stable stage, and three typical fault planes are selected to explain the deformation prediction method. Taking the most unstable section 1 of deformation

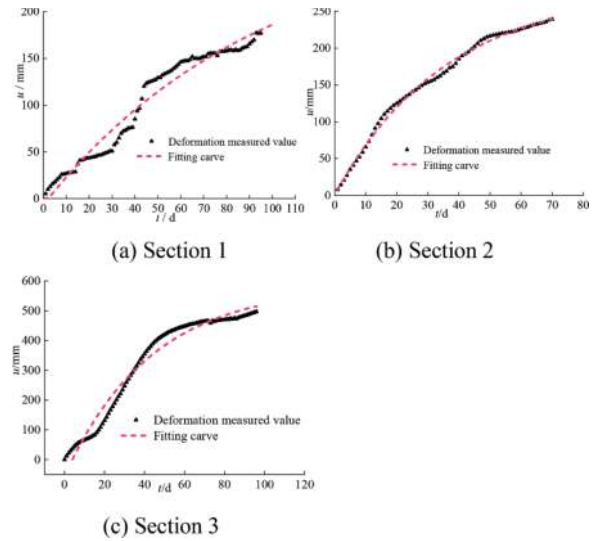

Figure 2. Deformation-time curve of typical section.

development as an example, based on the analysis of curve characteristics, five function forms are selected for fitting, as shown in Table 3.

Table 3. Deformation-time curve function of section 1.

Function forms	Fitting expression	Correlation coefficient
Power	$u = 4.303 \cdot t^{0.830}$	0.949
Polynomial	$u = -7.57 + 3.07t - 0.01t^2$	0.964
Logarithm	$u = -941.08 + 220.23 \ln(t + 70)$	0.958
Exponential 1	$u = 332.32e^{-66.72/(t+13.33)}$	0.961
Exponential 2	$u = 290.30 - 296.87e^{-t/95.36}$	0.968

It can be seen from Table 3 that the exponential 2 function form with the largest correlation coefficient can obtain the same results as the other two sections. Therefore, the fitting function form is

$$u = f(x) = A_1 + A_2 \cdot e^{-t/A_3} \quad (1)$$

In the formula, u is the deformation of surrounding rock (mm); $f(x)$ is in the form of function; t is the measurement time (d); e is a natural constant; A_1 , A_2 and A_3 are fitting constants.

In order to predict the deformation u_s and the stability time t_s of the surrounding rock in the stable stage, the function form of the deformation rate curve is obtained according to Formula (1), that is,

$$v = f'(x) = (-A_2/A_3) \cdot e^{-t/A_3} \quad (2)$$

In the formula, v is the deformation rate of surrounding rock (mm/d); $f'(x)$ is the derivative of $f(x)$.

For $v=v_l$ in Equation (2), the value of t can be obtained.

$$t = -A_3 \cdot \ln(-v_1 \cdot A_3/A_2) \quad (3)$$

The t obtained by the formula (3) is rounded, and the stability time t_s is obtained.

Substituting $t=t_s$ into formula (2), the stable deformation rate of surrounding rock can be obtained.

$$v_s = (-A_2/A_3) \cdot e^{-t_s/A_3} \quad (4)$$

Substituting $t=t_s$ into formula (1), the deformation of surrounding rock in stable stage can be obtained.

$$u_s = A_1 + A_2 e^{-t_s/A_3} \quad (5)$$

Sections 1-3 are medium and small span tunnels, and the $v_s=1\text{mm}$. According to the formula (3)-(5), the deformation prediction results of section 1-3 can be calculated and shown in Table 4.

Table 4. Deformation prediction results of typical sections.

Section	Fitting expression	t_s/d	u_s/mm	$v_s/(\text{mm}\cdot\text{d}^{-1})$
1	$u = 290.30 - 296.87e^{-t/95.36}$	109	195.64	0.993
2	$u = 278.548 - 278.058e^{-t/35.664}$	74	243.63	0.979
3	$u = 584.61 - 639.77e^{-t/43.25}$	117	541.84	0.989

4 DEFORMATION STABILITY TIME STATISTICS BASED ON DEFORMATION CLASSIFICATION

In the above deformation prediction method, A_1 , A_2 and A_3 have different values in the fitting curves of different sections. In order to establish the relationship between the deformation stability time t_s and the relative deformation of surrounding rock ε_s ($\varepsilon_s = u_s/a$) in the statistical sense, 412 sets of t_s and ε_s data were statistically analyzed. The t_s obtained by the above prediction is calculated from the component embedding. According to the statistical results of Liu et al. (2008), the time from tunnel excavation to component embedding is 1-3 days. In order to obtain the time from excavation to deformation stability and ensure the safety of secondary lining construction, the time of early loss of displacement is increased by 3 days on the basis of the above predicted t_s , that is,

$$t'_s = t_s + 3 \quad (6)$$

In the formula, t'_s is the deformation stability time (d) from excavation; t_s is the deformation stabilization time (d) from the time of the embedded element.

4.1 Abnormal data elimination method

The following is a statistical score of the data in the two cases of small and medium span and large span.

In the statistical samples, due to the limitations of on-site construction environment, measurement methods, downtime and other conditions, the statistical data are very discrete. For example, Figure 3 is a scatter plot of the relationship between the deformation stability time and the corresponding relative deformation of 187 small and medium span sections.

Figure 3. t'_s - ε_s relationship scatter chart of medium and small span tunnel (data before elimination).

In order to ensure the credibility of statistical data, it is necessary to eliminate abnormal data. Based on the deformation classification standard in Table 1, the relative deformation distribution of small and medium-sized tunnel sections is divided into four sections. The coverage rates of 90% and 10% are used as the upper and lower limits of the stability time of the surrounding rock in each section, and the data outside the boundary are eliminated as abnormal data. The upper and lower limits of the four sections are shown in Figure 4.

Figure 4. Data processing of deformation stability time of each section of medium and small span tunnel.

The relationship between the deformation stability time and the relative deformation of the small and medium span tunnel after eliminating the abnormal data is shown in Figure 5.

Figure 5. t'_s - ε_s relationship scatter chart of medium and small span tunnel (data after elimination).

After the same method is used to eliminate the abnormal data for 225 large-span and above tunnel sections, the scatter diagram of the relationship between the deformation stability time and the relative deformation of large-span and above tunnels is shown in Figure 6.

Figure 6. t'_s - ε_s relationship scatter chart of large-span and above tunnel (data after elimination).

4.2 Statistical analysis of deformation stability time

The scatter results of the relationship between the deformation stability time and the relative deformation of small and medium-sized and large-span and above tunnels are summarized as shown in Figure 7.

Figure 7. t'_s - ε_s relationship scatter chart of all sections.

It can be seen from Figure 7 that although the relationship between t_s and ε_s is relatively discrete, in general, the deformation stability time of small and medium span and large span and above tunnels increases with the increase of relative deformation. For large-span and above tunnels, the deformation

stability time range of each grade is obtained according to the same treatment method, and the deformation stability time of each grade of small and medium-span and large-span and above tunnels is summarized. The results are shown in Table 5.

Table 5. Statistical results of deformation stability time t'_s s (construction time of secondary lining) of different deformation grades (unit:d).

Deformation grade	Relative deformation	Span	
		Medium and small span	Large spans and above
I	$2 \leq \varepsilon < 4$	$38 \leq t < 65$	$43 \leq t < 70$
II	$4 \leq \varepsilon < 6$	$54 \leq t < 90$	$59 \leq t < 98$
III	$6 \leq \varepsilon < 8$	$72 \leq t < 107$	$72 \leq t < 112$
IV	$8 \leq \varepsilon$	$t \geq 93$	$t \geq 93$

Note: When the surrounding rock conditions are good, the relative deformation value is small, and the support stiffness and control measures are relatively strong, the smaller value of the numerical range in the table is taken, otherwise the larger value is taken.

It can be seen from Table 5 that the deformation stability time range of each grade of squeezing surrounding rock tunnel with small and medium span and large span and above is not much different, and the deformation stability time is positively correlated with the relative deformation.

5 PREDICTION OF CONSTRUCTION TIMING OF STAGED SECONDARY LINING DURING CONSTRUCTION PERIOD

5.1 Prediction method for construction timing of staged secondary lining during construction period

In the above analysis, ε at different stages of each section corresponds to a t'_s . For this reason, the ε of 20d, 30d, 40d and final stable stage were extracted in stages, and the relationship between ε and t'_s is sought, as shown in Figure 8.

The obtained scatter relationship is fitted by curve fitting, and the exponential 2 function form in Table 3 is also selected. Due to the limitation of various construction conditions on site, the distribution of each scatter point in Figure 8 is observed. It is found that the t'_s corresponding to the same ε is still a range value of a certain interval. The median value of the scatter point is taken to fit the curve, extending to the upper and lower sides and ensuring that the 85% coverage rate takes the range value, as shown in Table 6.

Table 6 can be used to realize the prediction and discrimination of the construction time of the secondary lining in stages. The discrimination method does not consider the deformation grade. The

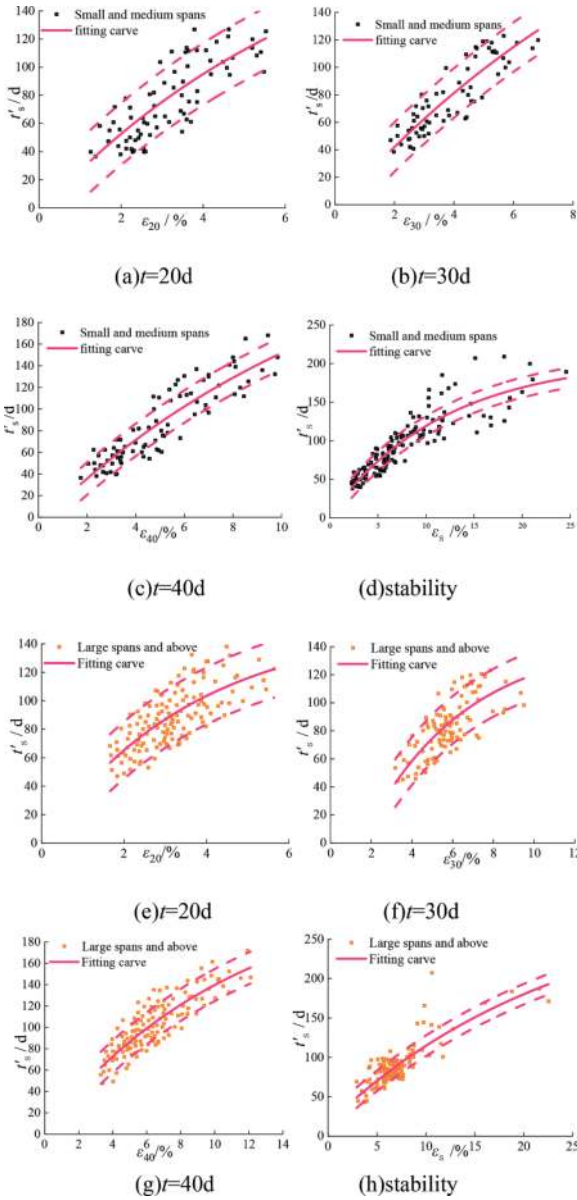

Figure 8. t'_s - ε_s relationship scatter chart of different stages of construction period.

Table 6. Prediction method of construction timing of secondary lining by stages in construction period based on stability time statistics.

Span	Measurement time /d	Fitting expression
Medium and small span	20	$t'_s = 228.58 - 232.07e^{-\varepsilon_{20}/7.231} \pm 22$
	30	$t'_s = 304.62 - 308.92e^{-\varepsilon_{30}/13.37} \pm 18$
	40	$t'_s = 295.53 - 301.33e^{-\varepsilon_{40}/14.81} \pm 15$
	Stability	$t'_s = 207.01 - 203.15e^{-\varepsilon_s/12.99} \pm 13$
Large spans and above	20	$t'_s = 155.17 - 156.19e^{-\varepsilon_{20}/3.62} \pm 20$
	30	$t'_s = 146.05 - 197.51e^{-\varepsilon_{30}/4.92} \pm 17$
	40	$t'_s = 235.84 - 232.32e^{-\varepsilon_{40}/11.33} \pm 15$
	Stability	$t'_s = 307.99 - 292.51e^{-\varepsilon_s/24.18} \pm 12$

difference of different deformation grades is reflected in the actual value of ε in each stage. The deformation grade is high, the value of ε is large, and the predicted t'_s is large.

5.2 Application test

The section YDK176+641 of a medium and small span tunnel is selected for inspection. The final stable deformation time of the section is 62d, the final stable deformation is 311.55 mm, and the hole diameter is 6.4 m. According to the measured deformation data of the section, the final stability time is predicted in stages. The measured deformation data of the four stages are converted into relative deformation, and then substituted into the fitting expression of Table 6 respectively, so as to obtain the predicted deformation stability time t'_s of each stage. The test results are shown in Table 7.

Table 7. Test results of prediction method for construction timing of secondary lining by stages during construction period.

Measurement time /d	Measured deformation / mm	Relative deformation / %	Predicted value /d
20	196.41	3.07	76.8±22
30	245.41	3.83	72.6±18
40	276.75	4.32	70.4±15
Stability	311.55	4.87	67.3±13

It can be seen from Table 7 that the predicted deformation stabilization time of the four stages of YDK176+641 section is within the range of the above four intervals, among which the predicted deformation time at stabilization is the closest to the actual deformation stabilization time, and the predicted error values of the four stages can be accepted by the project.

6 CONCLUSION

- (1) A deformation data processing method is proposed, which can predict the deformation u_s and the final stability time t'_s in the stable stage.
- (2) The exponential function $u = f(x) = A_1 + A_2 \cdot e^{-t/A_3}$ can fully reflect the characteristics of the deformation time history curve of the squeezing surrounding rock tunnel and obtain the maximum fitting correlation coefficient.
- (3) The stable range value of deformation stability time t'_s from excavation under different deformation grades and different span conditions is proposed, which can be used to preliminarily determine the construction time of secondary lining in the design stage.

- (4) A method for predicting the construction time of secondary lining in stages during construction period based on deformation stability time statistics is proposed. According to the measured relative deformation, the construction time of secondary lining can be predicted in stages and finally determined.
- (5) Through the test of measured deformation data, the prediction method of staged secondary lining construction is adopted, and the prediction results can be accepted by the project.

Because there are some differences in the geological conditions, support stiffness, control measures and construction methods of each tunnel in the statistical samples of this paper, the statistical results have a large range of values, and the specific implementation should be reasonably valued according to the engineering conditions.

ABSTRACT: Sydney Metro West will double rail capacity between Greater Parramatta and the Sydney CBD, transforming Sydney for generations to come. This once-in-a-century infrastructure investment will have a target travel time of about 20 minutes between Parramatta and the Sydney CBD, link new communities to rail services and support employment growth and housing supply. The Sydney Metro West corridor, encompassing nine stations at Westmead, Parramatta, Sydney Olympic Park, North Strathfield, Burwood North, Five Dock, The Bays, Pyrmont, and Hunter Street in the Sydney CBD, four cross-over caverns, two turnback junction cavern and associated stub tunnels, two service facilities, one dive, and a stabling and maintenance facility at Clyde, is strategically located near other major infrastructure within the geological region known as the Sydney Basin. This basin is characterised by extensive structural and topographic features, including a thick sequence of sediments deposited under both fluvial and marine conditions. The bedrock geology along the Sydney Metro West rail corridor predominantly comprises various soils overlaying the Wianamatta Group shale, predominantly the Ashfield Shale. This formation, in turn, rests atop the Mittagong Formation, which overlays the Hawkesbury Sandstone. However, the corridor is also known to harbour several vertical linear fault zones that cut across both the Ashfield Shale and the Hawkesbury Sandstone. Additionally, dykes ranging from clay to high-strength basalt or dolerite have been identified in the vicinity of the proposed rail corridor, with several likely to intersect with the alignment. Employing rigorous best practices, our team has gathered a wealth of geophysical and geotechnical data to characterise the subsurface geotechnical units beneath various harbour and bay crossings, as well as the stratigraphy aligning with the westward-heading tunnels. This comprehensive analysis has helped identify key geotechnical risks that could arise during the construction of the tunnels and other related underground infrastructure along this corridor.

Keywords: Sydney, Geology, Tunnelling, Geological Structure, Metro, Characterisation

1 INTRODUCTION

Sydney Metro West will provide a direct connection between the CBDs of Parramatta and Sydney, linking

new communities to rail services as well as supporting employment growth and housing supply (Figure 1). This state-of-the-art railway helps address Sydney's rapid growth, with the city's population to increase

*Corresponding author: David.Och@wsp.com

above 6 million in the next 20 years. The Sydney Metro West corridor, encompassing nine stations at Westmead, Parramatta, Sydney Olympic Park, North Strathfield, Burwood North, Five Dock, The Bays, Pyrmont, and Hunter Street in the Sydney CBD, four cross-over caverns, two turnback junction cavern and associated stub tunnels, two service facilities, one dive, and a stabling and maintenance facility at Clyde, is strategically located near other major infrastructure within the geological region known as the Sydney Basin. As such, detailed geophysical and geotechnical investigations to facilitate early planning and design work were undertaken on behalf of the Sydney Metro.

The scoping, delivery management and interpretation of the ground investigation and the development of the tunnel alignment design was undertaken by the Technical Advisor (WSP AECOM design joint venture) in collaboration with TfNSW over several stages, namely the Scoping Design, Definition Design, and finally the Early Contractor Involvement (ECI), which the WSP AECOM JV only focused on the ECI delivery of the Central Tunnelling Package (CTP) tender defining the completion of their Technical Advisor appointment.

Tunnelling design and delivery for the project has been separated into three separate packages -; Westmead Station to Sydney Olympic Park Station – Western Tunnel Package (WTP); Sydney Olympic Park Station to The Bays Station – Central Tunnel Package (CTP), and The Bays Station to the Sydney

CBD defines the Eastern Tunnel Package (ETP). Several alignment and design options were considered along the length of the corridor that were mainly defined horizontally and vertically by existing infrastructure assets and geological constraints, respectively. The design was predicated on full rock face excavation on the main tunnels heading west by Tunnel Boring Machine (TBM), with the possible use of mixed face TBM excavation heading east.

Following an assessment of the reliance of the historical geotechnical data sourced from earlier iterations of this project, local councils, and other government agencies a staged targeted site investigations based on gaps in geological knowledge was conducted concurrently with the concept design options. This allowed for these boreholes to be adjusted as the geological interpretation and the design developed. The land investigations included cored boreholes and cone penetration testing (CPT) in alluvial lowland areas, along with seismic refraction surveys in areas inaccessible by drilling equipment.

All major boreholes had specific lab testing carried out, along with water pressure and permeability testing (packer and slug testing), down-hole optical and acoustic televiewer of the cored rock to measure defects and in specific key boreholes in-situ stress testing (HSM and over-coring) were undertaken.

The marine intrusive investigations were carried out on Darling Harbour, Johnstone Bay and Iron Cove Bay and included cored boreholes completed

Figure 1. Geological map defining the Sydney Metro West corridor (Colquhoun et al., 2018; Herbert, 1983a; Och et al., 2009).

from jack-up barges. This also included continuous sediment sampling and in-situ tests noted above.

Marine geophysical investigation included seismic refraction and reflection surveys, magnetometer, and side-scan sonar surveys.

These data collected during the investigations allowed both the rock and soil formations along the corridor to be characterised and defined into geotechnical units.

The interpretation of these units and rock head was critical to design development and the identification of the geotechnical risks that could be realised whilst tunnelling below these environments.

This paper describes the site investigation and then focuses on an unknown geological interpretation of ground conditions near to Sydney Olympic Park to inform and influence the design development.

2 REGIONAL GEOLOGY

The project area is situated within the geological region known as the Sydney Basin. During the Permian and Triassic Periods, which occurred approximately 298 to 200 million years ago, the Sydney Basin experienced the deposition of a thick sequence of sediments in both fluvial and marine environments.

At the end of the Late Triassic, there was minor deformation and warping of the basin, followed by a period of tectonic activity from the Jurassic to the Palaeogene. These geological processes contributed to the formation of joints, faults, and the intrusion of igneous dykes (Och et al., 2009).

As a result of these structural weaknesses, major river systems eroded the uplifted eastern margin of the basin, forming deeply incised valleys. During the Pleistocene, there was a rise in sea levels, leading to the infilling of these valleys with sediment.

Subsequently, there was a period of lower sea levels, which resulted in the erosion of most of the Pleistocene valley infill, except for the upper portions of the valleys. In the more recent Holocene era, another sea-level rise occurred, leading to the infilling of the valleys with Holocene sediments. These sediments rest upon the underlying Pleistocene sediments.

Along the proposed Sydney Metro West alignment, the dominant geological units are depicted in Figure 1 and consist of the following formations (Colquhoun et al., 2018; Herbert, 1983a): anthropogenic fill (reclaimed areas), Holocene sediments, Pleistocene sediments, Triassic-age sedimentary rocks of the Ashfield Shale, Mittagong Formation, Hawkesbury Sandstone, and localised igneous dykes.

2.1 Local geological conditions

The regional geological units in the project area are shown in Figure 1 and include the following:

- Fill: Reclaimed areas near the harbour and some parklands.

- Holocene sediments: Under-consolidated sediments.
- Pleistocene sediments: Over-consolidated sediments, often sandy clays.
- Residual soils: Weathered siltstone and sandstone rock.
- Wianamatta Group: Ashfield Shale - Claystone, mudstone, siltstone, laminites, and fine-grained lithic sandstone.
- Mittagong Formation: Interbedded shale and fine-grained sandstone.
- Hawkesbury Sandstone: Medium to coarse-grained quartz sandstone.

2.1.1 Anthropogenic

Major areas of fill are associated with reclamation works near the harbor foreshores, pond sites, and brick pits. Unnatural topography, such as the Pyramid in Sydney Olympic Park, indicates substantial infilled areas at White Bay, Sydney Olympic Park, Silverwater, and Rosehill (Figure 1). The Johnstons Bay area has a deeper section of fill due to land reclamation, approximately 30m above the alignment. Station boxes, portals, dives, shafts, and Clyde MSF will likely be impacted by fill. Fill material varies from good quality ripped sandstone to poor-quality refuse, such as boiler ash or chemical to putrescible waste material. It can consist of gravels, sands, clays, and may range in consistency from loose to very stiff cohesive material. Asphalt and concrete are also classified as fill.

2.1.2 Quaternary deposits

Quaternary deposits are commonly found along the alignment and comprise sands, silts, and clays with varying amounts of organic matter. Some station boxes, dives, and shafts will be impacted by alluvium. Major alluvial areas include The Bays, Powell Creek, Haslams Creek in Sydney Olympic Park, Clyde, Rosehill, and Parramatta. Parramatta has alluvial clays and sands extending from the river into the township with varying layers of fill. Parramatta Park has a small shallow alluvial channel defined by a northerly running creek.

2.1.3 Bays and Harbour

Sediments within Darling Harbour, Johnstons Bay, Iron Cove Bay, and the adjoining Parramatta River areas are expected to consist of sands, silts, and clays with shell fragments, organic matter, and anthropogenic content. These sediments result from marine and fluvial processes during the Pleistocene, Holocene, and present age. The sedimentary sequence within the Port Jackson part of Sydney Harbour has been described by (Roy, 1980), (Pells and Wong, 1990) and (Och et al., 2017):

“Pleistocene sediments dominate boreholes in the harbour palaeovalleys and comprise over-consolidated marine sediments. These upper sediments consist of well-sorted medium dense to dense medium-grained sand overlying a thick layer of stiff

silty clay to clay, including shell hash zones. Fluvially derived sediments, including sandy clays, minor sand, and gravel with charcoal layers, are found below and appear to be associated with locally derived slope colluvial deposits.

Holocene sediments consist of loose/soft clayey silt interbedded with fine to medium-grained silty sand and shells. They overlay the relatively flat Pleistocene deposits and fill incised channels formed during the last glacial maximum”.

2.1.4 Residual

Residual soils develop from in-situ weathering of the parent bedrock and are typically found as a mantle over the weathered bedrock profile on low-relief, gently inclined natural surfaces. Residual soil derived from weathering of shale material consists of medium to high plasticity silty clay, gravelly clay, sandy clay, and silt, with variable consistencies ranging from firm to hard.

The residual Hawkesbury Sandstone soils are thin, typically less than 2m thick, and comprise medium plasticity silty clay to sandy clay. The residual Ashfield Shale soils are around 1.0 to 3.0m thick on ridge tops and thicker below valley floors and river channels. Unlike Extremely Weathered (EW) rock, the Ashfield Shale lacks relict structure and exhibits soil-like properties when remoulded by hand.

2.1.5 Wianamatta Group

The Wianamatta Group comprises the Bringelly Shale, Minchinbury Sandstone, and Ashfield Shale. The Sydney Metro West corridor is located within the Ashfield Shale and lower formations.

2.1.5.1 Ashfield Shale

This formation is up to 50 m in thickness at Sydney Olympic Park comprising the four members defined by Herbert and Helby (1980) and Herbert (1983b). The tunnels only align in this formation on approach to stations and service shafts or in areas of major faulting (Homebush Bay Fault Zone – Figure 1) then transition into the lower geological formations between North Strathfield and Westmead. The full profile of the Ashfield Shale members is only encountered at Westmead (partial) and Sydney Olympic Park, but other locations where Ashfield Shale is encountered the profile is defined by the topography and pervading geological structure. The Ashfield Shale encountered along the Sydney Metro West Corridor are characterised below:

- Mulgoa Laminite Member: Up to 11.0 m thick, dark grey siltstone and fine light grey sandstone laminations. Upper levels show micro cross beds and small burrows. Boundary with Minchinbury Sandstone is sharp but not found in this area.
- Regentville Siltstone Member: Up to 15.0 m thick, dark grey sideritic-banded siltstone beneath Mulgoa Laminite. Base is sharp.
- Kellyville Laminite Member: 6.5 m to 9.0 m thick, light-grey siltstone and fine to medium-grained

sandstone laminations. Features include micro-crossbeds, coarsening of grain size, and inclined beds. Base is gradational in some boreholes.

- Rouse Hill Siltstone Member: Average thickness of 6m, dark grey to black sideritic claystone-siltstone. Faint pale laminations increase towards the top. Lower 3 m has a ubiquitous light grey-white marker lamination (Och et al., 2020). Basal contact generally grades into Mittagong Formation, but some boreholes show discrete unconformities into the Hawkesbury Sandstone.

The Ashfield Shale generally has a UCS (unconfined compressive strength) ranging from 5 to 40MPa, with a mean value of approximately 25MPa when fresh and normal to bedding. These laminated rocks exhibit high anisotropy, with lower strength parallel to bedding.

2.1.6 Mittagong Formation

The Mittagong Formation consists of alternating dark shale and sandstone beds and laminae of varying thickness. It is challenging to map this formation due to its variable thickness and weathered surface occurrence, making it difficult to distinguish from other formations at the published scale.

2.1.7 Hawkesbury Sandstone

The Hawkesbury Sandstone is a medium to coarse-grained sandstone. Petrographic analysis shows that it is composed of quartz grains (50% to 80%), clay matrix (5% to 40%), quartz cement (up to 20%), and carbonate cement (0% to 15%, up to 35%) (Cole et al., 2020; Franklin, 2000). The sandstone exhibits three facies' types: massive sandstone, cross bedded or sheet facies, and shale/siltstone interbed “mudstone” facies (Herbert and Helby, 1980).

The cross-bedded facies consists of sets of cross-bedded strata with variable dip angles, typically dipping towards the northeast. Massive sandstone facies lacks crossbedding and may contain channelized erosional features and concentrated shale clasts. The Mudstone Facies includes lenses and continuous beds of shale, siltstone, and laminites within the sandstone, with variable thickness.

2.1.8 Geological structure

Deeper weathering and palaeovalleys in the in the upper Triassic formations described above reflects faulting/shear zones, stress relief areas, and valley bulging (Gray, 1982; McNally, 1981). Many variably thick dykes have been encountered cross cutting the alignment (Figure 1) and vary from high strengths through to clays. The contact zones can also result in slight rock strength variabilities at the contact boundaries (contact metamorphism), ranging from highly altered and strong to highly weathered and weak due to preferential weathering across the host rock along with chilling associated cooling during dyke emplacement (Dale, 1989; Dale et al., 1997).

3 GROUND INVESTIGATIONS

During the initial Scoping Design phase through to the Tender stage of the Sydney Metro West project, several tranches of land and bay/harbour geotechnical and geophysical investigations (Table 1) were carried out for the proposed running tunnel alignment options. The vertical alignment of the tunnels was critical as the geology along this corridor were in locations that had very limited sub surface knowledge as it would potentially govern station depths and tunnelling methodology. The ground investigations were based on assessments of historical borehole information and data and the investigations were targeted in areas that were deemed important to the alignment. In areas where no access (swamp lowlands or residential constraints) was available some land-based refraction surveys were undertaken to supplement the knowledge gained from nearby boreholes. Across water crossings geophysical surveys (reflection and refraction) were carried out prior to intrusive investigations being undertaken to assess for any anomalies to allow for better targeting.

4 RESULTS

The tunnel alignment spanning from North Strathfield Station to Sydney Olympic Park Station and Parramatta Station traverses diverse geological formations. The elevation profile fluctuates along this path, with Sydney Olympic Park Station being the highest point at 21 m AHD and Newington at 14 m AHD. The tunnel reaches its deepest point beneath Silverwater. The region is characterized by Homebush Bay catchment, where the topography follows undulating patterns with lower areas around Rosehill and Duck Creek (Figure 1).

Geologically, the upper layers consist of reclaimed alluvial plains with varying fill depths overlying interbedded clay, sandy clay, and sand formations. These transitions are especially pronounced

around the Ashfield Shale layer, with fill depths ranging up to 6m. The Mittagong Formation, encountered at depth, has alternating siltstones and fine to medium-grained sandstones with layers of shale or sandstone, eventually overlaying the Hawkesbury Sandstone.

The tunnel corridor’s geological nature is anticipated to vertically align through Ashfield Shale, progressing to Mittagong Formation, and finally Hawkesbury Sandstone. Throughout, the presence of geological structures like joints, faults, and buried palaeovalleys is evident, possibly influencing the excavation of cross passages. The Homebush Bay Fault Zone (Och et al., 2009) and secondary faults contribute to vertical variations in rock formations, indicating fault displacement and the development of a negative flower fault structure and that splays into a discrete strike-slip fault system to the NNE and SSW shaping the region’s lowlands (Figure 2). Similar structures have been identified in projects such as the M4-M5 (Lyons and Grasso, 2022) and M8 (Baxter-Crawford and Lippet, 2023) but are more related to flower-type structures associated with a strike-slip fault system (Woodcock and Rickards, 2003).

5 TBM AND TUNNEL CONSIDERATIONS

The geological characteristics of harbours and lowland swamps along the Sydney Metro West alignment exerted a significant influence on both the horizontal and vertical alignment of the designed tunnel and associated cross passages, as well as the selection of Tunnel Boring Machines (TBMs). The in-house design team worked closely with geological experts to navigate these challenges and optimise the tunnel’s alignment and construction methodologies.

Selection of TBMs considers the machine could handle different ground conditions during tunnel driving, including soft sediments, clay, and rock formations. Slurry TBMs was assessed to be the appropriate TBM for the Eastern Tunnel Package (ETP) due to the depth and uncertainties in geological conditions below the Johnstons Bay and Darling Harbour. Double shield TBM technology for both the Central and Western Tunnel Packages (CTP and WTP) was adopted as the design team considered the depth of the TBMs vertically below the lowland areas, namely Iron Cove Bay, Powell Creek, Haslams Creek in Sydney Olympic Park, Clyde, Rosehill, and Parramatta (Figure 1). The full length of tunnelling would be through the described varying rock formations (Figure 2), and therefore, these hard rock TBMs were chosen to ensure safe and efficient excavation and reduced wear on the cutting tools.

6 DISCUSSION

Geological findings significantly influenced tunnel design considerations. The varying geological

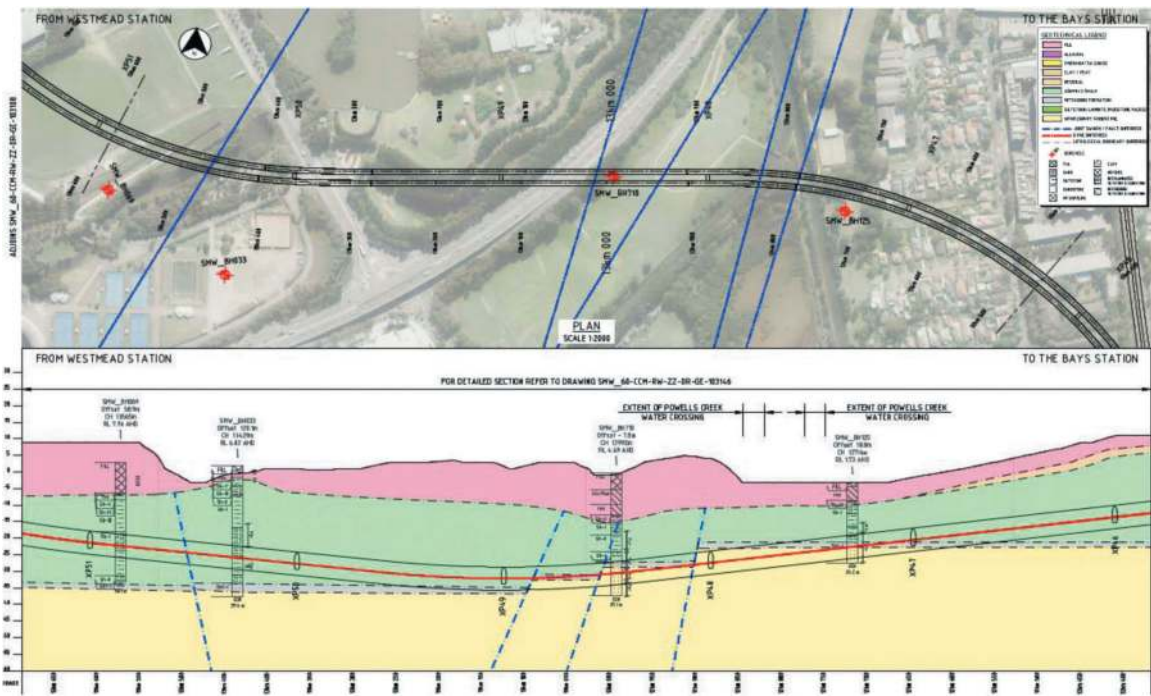

Figure 2. Geological long section highlighting the displacement of the upper Triassic sedimentary rocks of the Sydney basin across the Homebush Fault Zone (Och et al., 2009) across the Powells Creek lowlands between Sydney Olympic Park and North Strathfield.

Figure 3. A cross-sectional 3D relief (long axis - north) pictorial depicting associated topography across the Sydney Olympic Park – North Strathfield area with an underlying interpretation of a negative flower structure and geological displacement of the Triassic stratigraphy across the Homebush Bay Fault Zone.

formations necessitated adaptation of tunnelling methodologies and support systems. The presence of major fault systems and other geological structures and hydrogeology introduced complexities for the in-house design team in aligning the tunnels along this corridor. The study of analogous projects informed the understanding of fault systems and their impact on future tunnel construction. Ongoing scientific studies aim to enhance our understanding of subsurface relationships in the Sydney Basin due to the geological and engineering significance of

these fault systems (McMillan et al., 2021; McMillan, 2021; Och et al., 2009).

7 CONCLUSION

The success of the Sydney Metro West project hinged on the pivotal roles played by thorough ground investigations across very sensitive areas and the expertise of the in-house design team. Geological complexities, especially in harbours and lowland swamps, underscored the necessity for precise tunnel alignment and TBM selection. The collaborative efforts between geological experts and the design team ensured optimised designs that navigated diverse ground conditions, ensuring both structural integrity and environmental stewardship. The synergy between comprehensive ground investigations and in-house design expertise was instrumental in achieving the project's goals.

ACKNOWLEDGMENTS

The authors extend their gratitude to the Sydney Metro for approving this article, and all the contributors Jonathon Chan, Julian Singh, David McIntyre, Matthias Rheinlander, Peter Dowbiggin, Geoff Bateman, Ben Seaford, Brendan O’Kane, Stuart Allabush, Stephen Roberts, and others who all worked well as a team to facilitate the integration of the

earlier ground investigations into the tunnel design process. The collaborative efforts of the Technical Advisor (WSP AECOM JV) Ground Investigations team (Golder Associates (WSP) - Douglas Partners) and TfNSW team were instrumental in achieving these results.

Chengdu-Guiyang High-speed railway—Yujingshan Mountain Tunnel crossing Giant Karst cave and underground river

Weichen Qing*, Yu Yu, Jieyuan Zheng, Yong Zhu & Yong Wang
China Railway Eryuan Engineering Group Co. Ltd, Chengdu, Sichuan, China

ABSTRACT: Yujingshan Mountain Tunnel, with a total length of 6,306m, is a key part of the Chengdu-Guiyang High-speed Railway Project with a design speed of 250km/h. A giant karst cave was discovered when the tunnel was excavated to about 2km from the entrance. The karst cave is 95m long, 230m wide, and 50m-120m high. Its volume is about 1 million cubic meters. A large underground river develops at the bottom of the cave, with a width of 5-15m, and a flow of 70m³/s in the rainy season. As Yujingshan Mountain Tunnel is 110m perpendicular to the water surface of the underground river, the project faces four major challenges: construction safety, operation safety, construction period, and environment protection. In order to overcome the challenges, firstly, the underground river was relocated to the outside to maintain the original water channel; secondly, the method of layer-by-layer and zone-by-zone backfilling is adopted to realize quick backfilling; thirdly, a 430 m² tunnel with super-large cross section was built in the spoil body; fourthly, a 184m double-track high-speed railway bridge was built in the tunnel. By adopting the above measures, about 1 million cubic meters of spoil was used to backfill the cave, which saves a lot of land; the underground river was relocated to the outside, which maintains the original water channel and protects the original ecosystem; a new structure of integrated tunnel and bridge was created, which ensures the operational safety. The successful construction of this project has shortened the travel time between Chengdu and Guiyang, the two major provincial capitals in southwest China, from 14h to 3h. Meanwhile, it has also accumulated valuable experience of tunnels passing through large karst caves, which is a model of coordinated development of environmental protection and economic construction. The project received the Overcoming the Challenge of ITA Awards 2020.

Keywords: Giant karst cave, Underground river, Tunnel with super-large cross section, Bridge crossing, Environment protection

1 INTRODUCTION

The karsts are widely distributed in China, and the area with karst accounts for about one-third of the country's land area. Karst geology is quite common, and only in Yunnan, Guizhou, and Guangxi provinces, the exposed area of carbonate rocks accounts for about half of the total area of the three provinces. Therefore, karst-fissure-cavities, karst valleys, karst caves, karst channels, underground rivers, etc. might be encountered when tunnels are constructed in karst areas, which pose serious safety hazards to tunnel construction and operation, and may cause structural deformation, water and mud inrush, collapse, and top chip off-falling^[1-3].

When tunnels are constructed in karst areas, in order to ensure the safety of the railway, geological exploration measures should be taken first to explore the karst area^[4-7], and try to avoid possible karst caves ahead^[8]. If it is impossible to avoid them,

reasonable treatment measures will be taken. Common treatment methods include bridge or piled raft crossing, shotcrete-bolt support, backfilling/replacement, grouting reinforcement, etc. Two technical schemes, namely curtain grouting, pipe shed and pipe-jacking culvert, were proposed for the karst cave section filled with soft plastic gray brown silty clay under the new Wulong drainage tunnel of Chongqing-Huaihua Railway^[9]. During the construction process of a mountain tunnel of Qianjiang-Changde Railway, a giant karst cave was discovered. The internal situation of the cave was complex, and its overall stability was poor. After comparing multiple schemes, the treatment plan of backfilling the cave with spoils and upper grouting reinforcement was finally selected^[10]. A super large karst caves developed at ZK250+135~+166 section of Yanwan Tunnel, which were treated with measures including backfilling with spoils, bridge crossing, and arch protection^[11]. A beam span structure was proposed to cross karst fissures and sections

damaged by karst caves of Xiaosanxia Tunnel on Zhengzhou - Chongqing HSR [12].

The paper takes the construction process of the Yujingshan Tunnel as the research object, which encountered a giant karst cave and an underground river. The karst cave had giant internal space and complex accumulations at the bottom. The railway was located high near the roof of the cave and had a long distance to cross the cave. There is still limited research on crossing this type of karst cave. This paper extensively compares and demonstrates the treatment plans for crossing karst caves, in order to determine the optimal technical solution.

2 PROJECT PROFILE

The Yujingshan Tunnel is located in the Xingwen - Weixin section of Chengdu-Guizhou Railway, within the territory of Weixin County, Yunnan Province. The tunnel has an entrance mileage of D3K277+860 and an exit mileage of D3K284+164, with a total length of approximately 6,306m and a maximum burial depth of 350m. When it was excavated towards the small mileage end of the transverse gallery work area to the D3K279+948 mileage, the upper bench excavation revealed the development of a giant karst cave in front of the lower part of the tunnel face. The karst cave was shaped like a dome and was located about 60m below the ground level. With a plan shape of a broad bean shape, the karst cave is 95m along the route, 230m wide laterally, and 50m-120m high. The sediment at the bottom of the karst cave is 30-90m thick, with a cross slope of 30-40°. It is high on the right side of the route and low on the left side, and a large underground river develops on the low side of the cross slope. The river is 5-15m wide, with a total length of 18km and a flow rate of 70m³/s in the rainy season. The D3K279+855~+960 section of the railway is suspended near the roof of the karst cave, 40m away from its bottom, and 110m perpendicular to the surface of the underground river. The plane position relationship between the railway and the cave is shown in Figure 1.

Figure 1. Plane position of relationship between tunnel and cave.

It is rarely seen in the world for a tunnel to pass through such a large and complex karst cave. There are many difficulties in engineering construction, mainly including four major challenges:

- (1) It is found by site investigation that the walls of the karst cave are medium to thick layered limestone. Generally the integrity of rock mass is good, but the rock mass is fragmented in some areas, which is extremely unfavorable for the stability of the cave wall, leading to the risk of falling and collapsing on the roof and walls of the cave. As shown in Figure 2, multiple collapsed accumulations are found at the bottom of the cave, with residual sliding marks of collapsed rocks sliding on the surface. The scars in some sections of the cave roof are fresh, which indicates that recent collapses have occurred in the cave. According to the actual measurement of a single boulder at the bottom of the cave, the maximum size of the stone block reaches 8×4×15m, which directly threatens the safety of workers and mechanical equipment inside the tunnel. Therefore, how to ensure the construction safety of the structure crossing giant karst cave is the first challenge.

Figure 2. Cave roof wedge.

- (2) The tunnel is 40m above the bottom of the karst cave, with a suspended length of 90m. There is a thick accumulation body at the bottom of the cave, mainly composed of fragmented stones. According to exploration, there are weak interlayers such as soft clay and silt with a thickness of 0-15m distributed among them, with poor regularity. Which reliable structural form should be adopted to meet the strict requirements of the high-speed railway for track settlement control is the second challenge.
- (3) Faced with such a rare giant karst cave, no matter what treatment plan is adopted, the difficulty of engineering treatment is extraordinary. In addition, there are only 3 years to the planned opening of Chengdu-Guizhou High-speed Railway. How to

quickly determine the treatment plan and efficiently organize construction to ensure the scheduled opening of Chengdu-Guizhou High-speed Railway is the third challenge.

- (4) The water resources in the project location are poor, and the underground river in the karst cave is the main source of production and domestic water for downstream villages, as well as the only water source for downstream hydroelectric power stations. How to maintain the water flow of the underground river, sustain the balance of the existing groundwater network, and protect the original ecosystem is the fourth challenge.

3 RESEARCH ON THE TREATMENT PLANS FOR THE GIANT KARST CAVE

In order to overcome the four major challenges mentioned above, ensure the smooth crossing of the tunnel through the karst cave and guarantee the safety of high-speed rail operation in the later stage, various schemes have been studied and compared, including preliminary comparison of route relocation and in-situ crossing, detailed design of subgrade backfilling, arch bridge crossing, bridge crossing and light protection, bridge crossing and tunnel protection, etc., and eventually the final plan is formed, which consists of diversion of the underground river, backfilling of the giant karst cave, excavation of the backfill body for tunnel construction, and construction of a bridge in the tunnel.

3.1 Preliminary plans

Based on previous research and experience, two preliminary plans have been proposed: route relocation and in-situ crossing. In the route relocation plan, in order to avoid the karst cave, the route will be shifted to the right with a length of 5.5km, whose construction period is no less than 3.5 years. Works worth of CNY 431 million will be abandoned and the investment will be increased by CNY 445 million. In addition, geological surveys will be conducted again, which does not rule out the possibility of encountering large-scale karst again. Taken into account the project schedule, investment, and engineering risks, the route relocation plan is not recommended. Therefore, it is suggested to focus on studying the in-situ crossing plan.

3.2 Detailed design

After the in-situ crossing plan is determined, in-depth research is conducted on schemes such as subgrade backfilling, arch bridge crossing, bridge crossing and light protection, bridge crossing and tunnel protection treatment, etc., whose specific measures are:

(1) Subgrade backfilling

Firstly, the soft soil on the surface of the accumulated material at the bottom of the karst cave is

removed, and the lower side is backfilled. A work platform is provided to reinforce the lower accumulation layer with bored piles. Then the karst cave is backfilled in layers, with a 1:1 slope on both sides of the subgrade. Within the 1:1 slope range of the filling body, grouting pipes are horizontally embedded to solidify the filling material. After the grouting is completed, the outer filling continues, as shown in Figure 3(a).

(2) Arch bridge crossing

Firstly, the cave is backfilled in layers. After it is backfilled to a certain height at the bottom of the beam, to ensure the safety of bridge construction, the upper roof in the bridge construction range above the karst cave is protected before the bridge construction proceeds. Finally, an open-cut tunnel is constructed on the upper part of the bridge to ensure the safety of train operation, as shown in Figure 3(b).

(3) Bridge crossing and light protection

Firstly, the cave is backfilled in layers. After the backfilling is completed, the backfilling body is excavated by sloping and a U-shaped retaining wall is provided at the bottom. To ensure the safety of bridge construction and operation, anchor mesh shotcrete combined with anchor cables is used to strengthen protection on the top wall of the karst cave and improve the self-supporting capacity of the surrounding rock at the cave top. To prevent the peeling of the surface layer of sprayed concrete from affecting operational safety, a lightweight steel structure is installed on the bridge, as shown in Figure 3(c).

(4) Bridge crossing and tunnel protection

The plan of bridge crossing and light protection is relatively mature and feasible. However, to ensure the safe operation of high-speed railway, reduce the rockfall threat of karst cave roof to the track and bridge structure, and minimize safety risks, a treatment plan of bridge crossing and tunnel protection which separates bridge and tunnel has been proposed combined with construction practice. Namely, the karst cave is first backfilled in layers. After the backfilling is completed, the upper benches are excavated, which are used as the construction platform for anchor mesh shotcrete on the upper roof and anchor cable protection, and both sides of the backfill body are grouted and reinforced. Then, the lower benches of the tunnel are excavated. After the completion of tunnel construction, under the protection of the tunnel structure, the bridge is constructed as the bearing structure of train and track during operation, as shown in Figure 3(d).

As shown in Table 1, the main advantages and disadvantages of the four schemes mentioned above were compared. The bridge crossing and tunnel protection scheme has the advantages of bridge and tunnel combination, dynamic and static separation, relatively low construction risk, controllable construction cost, and short construction period. It avoids the disadvantages of difficult control of settlement and

(a) Subgrade backfilling (b) Arch bridge crossing

(c) Bridge crossing and light protection

(d) Bridge crossing and tunnel protection

Figure 3. Schematic design.

differential settlement in the subgrade backfilling scheme, difficulty and large amount of foundation excavation of the arch bridge crossing scheme, and low stability of the upper roof of the bridge crossing and light protection scheme. Although this plan also faces the challenges of large tunnel sections and complex construction, the construction technology for tunnels with super-large section is relatively mature and

the risks are controllable. Therefore, the bridge crossing and tunnel protection scheme is determined as the implementation plan.

4 TECHNICAL SOLUTION FOR TREATMENT OF GIANT KARST CAVE

4.1 General technical road map

Based on the above scheme study, the final solution which includes underground river diversion, backfilling of giant karst cave, excavation of bridge in the backfill body and construction of bridge in tunnels has been formed. The overall principle is to prioritize the diversion of underground rivers, build a work platform for backfilling the karst cave, then excavate a tunnel with super large cross section, and finally construct a bridge under the protection of the tunnel. The overall technical road map is shown in Figure 4.

4.2 Underground river diversion

In order to maintain the original underground water system, the underground river inside the cave is relocated to the outside of the cave before the backfilling of the giant karst cave. A detour drain cavern is set up along the direction of the underground river water flow and 30-50 m away from the right side of the cave wall at the foot of the cave slope, to divert the upstream water of the underground river to the downstream. The drain cavern is about 450m long, as shown in Figure 5. In addition, large block stones are backfilled as a three-dimensional seepage layer for backfilling construction within the range of 3m around the karst cave and 20m at the bottom of the original underground river, to introduce the bedrock fissure water around the cave into the underground river system.

Table 1. Comparison of in-situ crossing schemes.

S.N.	Main Engineering Measures	Advantages	Disadvantages	Additional Investment (CNY 100 million)	Construction Period (years)
1	Subgrade backfilling	the economic cost is relatively low, and the construction period is relatively short	Settlement is difficult to control and it can cause differential settlement, which affects operational safety	3	3
2	Arch bridge crossing	It has good feasibility; Estimated construction period of 42 months	Large amount of tunnel expansion and under cut engineering, long affected section length, causing certain difficulties in construction; The excavation of bridge foundations is difficult and carries high risks	4	3.5
3	Bridge crossing and light protection	It has High feasibility; Estimated construction period of 43 months	Unable to completely solve the stability problem of the upper roof, and there is a potential risk of arch block falling	3.6	3.5
4	Bridge crossing and tunnel protection	relatively low construction risks; Estimated construction period of 41 months	The tunnel excavation has a large cross section and the construction is complex	3.4	3

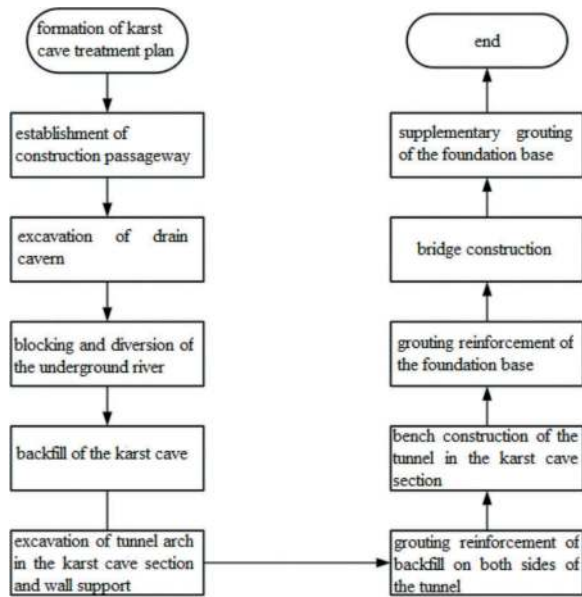

Figure 4. Diagram of underground river diversion.

4.3 Backfilling of giant karst cave

Figure 5. Diagram of backfill section of karst cave.

Based on the geological and hydrological conditions of the giant karst cave in the Yujingshan Tunnel and the characteristics of the cavity structure, a multi-channel layered backfilling scheme is proposed to safely and efficiently complete the backfilling with a height of 120m and a total volume of 1.08 million cubic meters, as shown in Figure 6.

- (1) The vertical spatial height of the giant karst cave varies from 50m to 120m. Five backfill channels are built vertically inside the cave, with a height difference of 20m between adjacent channels, namely: Channel 4 at 988m elevation, Channel 6 at 1008m elevation, Channel 7 at 1028m elevation, Channel 1 at 1048m elevation, and the upper bench channel at the large mileage end of the tunnel at 1082m elevation.

- (2) The hierarchic backfilling scheme is adopted, which means that the giant karst cave is back-filled layer by layer in 5 levels from bottom according to the height difference of every 20m by the 5 backfilling channels.
- (3) The backfilling surface is compacted and leveled with construction machinery after every 3m of backfilling to ensure that the backfill material has a certain degree of compaction.

Figure 6. Diagram of backfill section of karst cave.

4.4 Excavation of the backfill body for tunnel construction

Bridge crossing is adopted for the D3K279+813~D3K280+010 section of Yujingshan Tunnel. Type A lining structure is used for D3K279+813~+872 and D3K279+958~D3K280+010 sections to meet the requirement of bridge structure, construction and maintenance, and in accordance with the relative position relationship between the tunnel and the cave, as shown in Figure 7(a). D3K279+872~+958 section is located in the backfill body, and adopts the Type B protective structure, as shown in Figure 7(b). The minimum distance between the tunnel floor and the bridge floor is 1.5m, leaving a maintenance space of 1.5m below the bridge floor.

Type A lining section is mainly located at the front and rear positions outside the karst cave along the mileage direction (as shown in Figure 3), and it is constructed by four-bench method, in which controlled blasting is adopted for the first and second benches, and mechanical excavation is used for the third and fourth benches. The supporting measures are as follows: spray C25 concrete with a thickness of 4cm, lay steel mesh and anchor rod, erect I20b steel frame, and sett anchor pipes with lock feet, re-spray concrete to 28cm, and use C35 reinforced concrete for the secondary lining with a thickness of 1 m.

Type B protective structure is located in the backfill body, with an excavation area of 430m². The support of the excavated stratum has large deformation and high risk of instability, so it is necessary to solve the instability problem in the excavation

(a) Type A lining

(c) Type B lining

Figure 7. Diagram of different types of lining section (Unit: cm).

process and restrain the deformation of the initial support.

- (1) First, the first bench is excavated in the karst cave range, with anchor net spraying and anchor cable protection. In order to ensure the safety of subsequent construction, both sides of backfill body should be reinforced by grouting, as shown in Figure 8.
- (2) After the grouting of the backfill body achieves the effect, the lower backfill body is excavated by the bench method, as shown in Figure 9.
- (3) Considering the uneven composition of backfill body and the uneven settlement of tunnel foundation, steel pipe grouting is adopted at the tunnel bottom to improve the integrity of backfill body, as shown in Figure 10.
- (4) A reinforced concrete tunnel protection bridge is set in the karst cave section, and its initial support is C30 sprayed concrete with a thickness of 40cm, the secondary lining is C35 reinforced concrete, the arch wall of the secondary lining is a variable cross-section with a thickness of 75cm and the bottom plate is 3m thick, as shown in Figure 11.
- (5) In order to adapt to the uneven settlement and deformation of the foundation that may occur in the later period and ensure the safety of operation, the tunnel structure is divided into sections every

5m, and wide deformation joints with a width of 2cm are set between adjacent sections.

Figure 8. Diagram of the pre-grouting and reinforcement of the backfill body.

Figure 9. Diagram of bench method construction.

4.5 Bridge crossing in the tunnel

The bridge structure adopts (38.85m+108m+38.85m) short-side span prestressed concrete continuous beam, and the concrete strength grade of the beam body is C55. The line on the bridge is a double-track line, with a line spacing of 4.6m, a gradient of +30.00‰ and a design running speed of 250km/h. The ratio of side to mid span of continuous beam is 0.352. The continuous beam is a box girder with a single box, single cell, variable height and variable cross section, and a total length of 185.7m. The 4m long beam section at the mid span near the fulcrum and the full beam section at the side span are of the same beam height, which is 8.8m.

Figure 10. Diagram of tunnel bottom grouting reinforcement.

Figure 11. Reinforced concrete protective structure (tunnel).

The beam section with a span of 10m is of equal height, with a beam height of 5m. The schematic diagram of the mid-span section of the bridge is shown in Figure 12, and the bottom edge of the rest of the beams is changed according to Formula (1).

$$y = 5 + \frac{3.8x^2}{2025} \quad (1)$$

The side span, abutment and pier of the bridge are located in the type A cross-section (non-cave backfill

Figure 12. Diagram of midspan section (Unit: cm).

section), and the 108m long mid span crosses the backfill area in the cave. After the tunnel lining in the backfill area, a continuous beam is constructed. The beam body is divided into 0# block, 1# segment, 2# segment and mid-span closure segment (see Figure 13 for details). Continuous beam is constructed by cast-in-place support. First, the cast-in-place bracket is erected below the position of 0# block, after full preloading, the concrete of beam section 0# is poured, then the beam sections 1# and 2# are symmetrically constructed on both sides, and finally the bracket for the mid-span closure section is installed to pour the mid-span closure section, and the corresponding steel beams are tensioned. After the cast-in-place brackets are dismantled, the whole continuous beam system is formed.

Figure 13. Sectional Layout Profile of Beam.

5 STRUCTURAL SAFETY ANALYSIS AND MONITORING OF SUPER-LARGE SECTION TUNNEL

5.1 Computational model

Because it is necessary to excavate a super-large section tunnel (25.21m high and 17.22m wide) in the backfill body, the construction risk is high. The construction process of tunnel mileage D3K279+820~+980 is numerically calculated using finite difference numerical software FLAC3D, and the calculation model is shown in Figure 14.

5.2 Calculation parameter

According to the field survey data, the physical mechanics parameters of the stratum and backfill materials are shown in Table 2. C30 high strength shotcrete is used for the initial shotcrete, and C35 reinforced concrete is used for the second lining. See Table 3 for the parameters.

Figure 14. Numerical calculation model.

Table 2. Physical mechanics parameters of rock and soil.

Type	Unit weight γ (kN/m ³)	Elastic modulus E(MPa)	Poisson's ratio ν	Internal friction angle ϕ (°)	Cohesion c(kPa)
Limestone	23.5	6000	0.25	35	3000
Backfill body	23.0	65	0.25	30	200
Soft clay	20.5	15	0.30	7	24
Rock and soil fragments	22.5	60	0.28	36	15
Silty-fine sand	18.0	30	0.35	32	18

Table 3. Material parameters for primary support and secondary lining.

Support type	Unit weight γ (kN/m ³)	Elastic modulus E(GPa)	Poisson's ratio ν
Initial support	25.0	28	0.2
Secondary lining	25.5	31.5	0.2

5.3 Calculation result

The internal force values of the initial support of the D3K279+915 section are listed in Table 4, and the safety factor of the initial support structure of the tunnel is checked based on the Code for Design of Railway Tunnel^[13]. As shown in the table, because the cave itself is relatively stable, the initial supporting structure is less stressed and the safety factor is larger at the vault. The maximum internal force of

the initial supporting structure appears at the foot of left wall the tunnel. The maximum bending moment and axial force are -48.5 kN m and -967.3kN respectively, and the safety factor is 11.14.

Table 4. Maximum vault settlement at different sections.

Measure point	Bending moment value/ kN·m	Axial force value /kN	Safety factor	Whether it meets the requirements
Vault	2.9	103.4	117.82	yes
Left arch foot	-30.2	-272.6	29.96	yes
Right arch foot	-27.3	-186.6	38.33	yes
Left wall	46.6	-808.2	12.82	yes
Right wall	38.0	-756.1	14.24	yes
Foot of left wall	-48.5	-967.3	11.14	yes
Foot of right wall	-35.8	-825.3	13.53	yes
Baseplate midpoint	12.2	-627.6	20.46	yes

The internal force values and safety factor of the secondary lining of D3K279+915 section are listed in Table 5. The maximum internal force of the secondary lining structure also appears at the foot of the left wall. The maximum bending moment and axial force are -22.5 kN m and -440.1kN respectively, and the safety factor is 18.65, which meets the specification requirements. Combined with the calculation of internal force and safety factor of the primary support and secondary lining structure, it can be seen that the tunnel structure is reliable and can fully ensure the structural safety during operation.

Table 5. Maximum horizontal convergence at different sections.

Measure point	Bending moment value/ kN·m	Axial force value /kN	Safety factor	Whether it meets the requirements
Vault	1.6	32.5	135.29	yes
Left arch foot	-13.4	-162.3	44.68	yes
Right arch foot	-11.5	-186.6	42.03	yes
Left wall	22.1	-286.4	25.69	yes
Right wall	20.7	-265.3	27.79	yes
Foot of left wall	-22.5	-440.1	18.65	yes
Foot of right wall	-18.1	-429.5	19.76	yes
Baseplate midpoint	-7.8	-527.6	18.18	yes

5.4 Situation of field monitoring

(1) At present, the maximum settlement of tunnel bottom is 9.11mm, locating at the large mileage end of the right side of D3K279+885 section, which appears almost 40m away from the profile where the tunnel crosses the cave, mainly because the tunnels on the left and right sides have not entered the karst cave along the profile direction of the tunnel, and the surrounding rock at the bottom of some sections is bedrock, the basement settlement value is small. From the distance of 40m from the profile the bottom of the tunnel is backfill body, which means that the tunnel starts to completely cross the backfill body near this section, so the settlement of the basement is much larger than that of the tunnel bottom located on bedrock.

(2) Due to the uneven soil mass at the lower part of the high fill backfill body, uneven settlement occurs when the tunnel passes through the karst cave. The maximum longitudinal differential settlement at the tunnel bottom appears on the right side of K279+885 section, which is 2.95mm. The settlement on the right side of the tunnel bottom is slightly larger than that on the left side. At present, the maximum left-right differential settlement is 6.94mm at the large mileage end of D3K279+885 section, which meets the design requirements.

6 CONCLUSION AND DISCUSSION

In this paper, the treatment scheme of high-speed railway tunnel crossing giant karst caves is thoroughly studied. By comparing and selecting four in-situ crossing schemes: subgrade backfilling, arch bridge crossing, bridge crossing and light protection, bridge crossing and tunnel protection, the comprehensive plan is proposed, which consists of diversion of the underground river, backfilling of the giant karst cave, excavation of the backfill body for tunnel construction, and construction of a bridge in the tunnel. Combined with field construction, monitoring and operation verification, the plan has achieved good treatment effect, with various indicators meeting the requirements. Since the operation of the railway at the end of 2019, the tunnel settlement is controllable and the structure is stable, which fully guarantees the safety of high-speed rail operation and fully proves the practicability and reliability of this innovative scheme.

(1) Because the net height of the karst cave is 120m, and the accumulations at the bottom are unstable, it is not only difficult to construct the railway structure after the traditional scaffold platform is used to protect the karst cave, but also the construction period is long, and the safety is not guaranteed as it requires a large number of operating personnel. In this project, a multi-channel layered backfill scheme is proposed, and the spoil of this tunnel is skillfully used to backfill the karst cave completely, which adapts to local conditions and turns waste into treasure. Moreover, the construction

is simple and cost-effective as fewer operating personnel is needed. In addition, no casualties and mechanical equipment damage accidents occurred during the construction period.

(2) In order to solve the structural problem of the high-speed railway crossing the giant karst cave, firstly, a 432m² super-large section tunnel was built in the backfill body, and then a 38m+108m+38m three-span continuous beam was erected in the tunnel as the track bearing structure, which perfectly combined the advantages of the bridge and tunnel structure and embodied the combined design idea of complementary functions.

(3) In order to build a 432m² super-large section tunnel in soft backfill, high-pressure grouting is firstly used to reinforce the backfill around the tunnel, and then bench method is adopted with five benches from top to bottom. To adapt to the uneven settlement and deformation of the foundation that may occur in the later period, the tunnel structure is divided into sections every 5m, and wide deformation joints are set between adjacent sections, imitating the animal spine structure. Numerical simulated calculation is carried out for the construction and structure of super-large section tunnel, and the deformation and stress of tunnel in karst cave section are within the allowable range of specification and design. At the same time, since the operation, the measured maximum settlement at the tunnel bottom is 9mm, which meets the structural safety requirements.

(4) In order to maintain the original underground water system, a three-dimensional drainage system for underground water is constructed. Before backfilling construction, the underground river in the cave will be diverted to the outside of the cave; In the backfill construction, large stones are used to backfill around the cave and the bottom of the original underground river to form a three-dimensional seepage layer, and the bedrock fissure water around the cave is introduced into the underground river system. Since the operation, the quantity of underground river in the lower reaches is stable, which meets the demand of local villages for production and domestic water and hydropower generation.

(5) The successful construction of this project has broken through the technical bottleneck of tunnel construction in karst areas, developed the construction technology of tunnel passing through giant karst caves, and improved the freedom of high-speed railway line selection in karst areas, which has important guiding significance for railway construction in karst areas.

Tunnel behavior in soft soils subjected to pore water pressure drawdown

Alan Santos*, Raimundo Pérez-Léon & Juan Rodríguez-Rebolledo

Universidade de Brasília, Brasília, Brazil

Bernardo Caicedo

Universidad de Los Andes, Bogotá, Colombia

ABSTRACT: Constructing tunnels in soft soils presents significant challenges due to their unfavorable mechanical properties, which can result in excessive strains and potential damage to the tunnel and surrounding structures. In cities such as Bogotá, Mexico City, Shanghai, Singapore, and Tokyo, an additional phenomenon arises from the consolidation process of the soft soil caused by the reduction in pore water pressure resulting from deep water pumping. This phenomenon alters the total stresses acting on the tunnel lining during operation, leading to increased bending moments, compression, and shear forces. To investigate the behavior of tunnels under these challenging conditions, a numerical simulation using the Finite Element Method (FEM) was conducted and compared with a physical model tested in a geotechnical centrifuge. Two scenarios were simulated: one with the tunnel at the bottom of a compressible layer, resting on the hard layer (Model 1), and another in the middle (Model 2). The Hardening Soil (HS) model was utilized to simulate the behavior of the compressible soil. The results demonstrate agreement between the numerical and physical models. All models indicate an increase in vertical total stress at the top and bottom of the tunnel. Conversely, different patterns of earth pressure at the side walls were observed in each simulation. Furthermore, FEM simulations aided in assessing the influence of the initial stress state on the behavior of the tunnel lining during pore water pressure drawdown.

Keywords: Lowering, Regional subsidence, Geotechnical centrifuge, Hardening soil

1 INTRODUCTION

The consolidation process occurring in clayey soil due to piezometric drawdown from water pumping in underlying aquifers can lead to regional subsidence. According to Kusakabe & Ariizumi (2005) and Rodríguez-Rebolledo et al. (2013), this phenomenon causes an increase in vertical total stress at the top (crown) of a tunnel liner and a decrease in horizontal total stress at its sides. This redistribution of stress results in a significant increase in bending moments and compression forces within the tunnel lining structure.

To investigate the behavior of tunnels under these challenging conditions, a numerical simulation using the Finite Element Method (FEM, Plaxis 2D) was conducted. The findings from this analysis were compared with the results of a physical simulation performed in a geotechnical centrifuge by Pérez-Léon (2023). Additionally, the influence of the initial stress state on the behavior of the tunnel lining during pore water pressure drawdown was evaluated.

Two scenarios were examined: one with the tunnel located at the bottom of a compressible layer, resting on the hard layer (Model 1), and another positioned in the middle (Model 2).

2 PROTOTYPE DEFINITION

The prototype for this study was defined as a reference case, based on the subsoil conditions in the cities of Bogotá and Mexico. Typically, tunnels in these conditions consist of two linings: a primary lining composed of precast segments and a secondary lining made of cast-in-place reinforced concrete.

For the tunnel prototype, an external diameter of 6.0 m, a total thickness of 50 cm (including both linings), and a concrete compression strength of 35 MPa were considered. Figure 1 illustrates the overall characteristics of the prototype used for both the physical and numerical modeling analyses.

3 PHYSICAL MODELLING

3.1 Centrifuge model

The physical models were developed and conducted by Pérez-Léon (2023) at the geotechnical centrifuge of *Universidad de Los Andes*, Colombia.

A beam-type geotechnical centrifuge with the following specifications was utilized: a rotation radius

*Corresponding author: alanrmsbs@gmail.com

Figure 1. General characteristics of the prototype (dimensions in m).

of 1.90 m (1.70 m effective radius), maximum acceleration of 200 g, maximum model weight of 400 kg, nominal power of 298.3 kW, and data acquisition with 50 channels.

Centrifuge modeling aims to replicate the stress state of the prototype by increasing acceleration N times, resulting in a scaled model $1/N$ times in the centrifuge (NG, 2014). In addition to replicating in-situ stresses in a reduced model, the geotechnical centrifuge offers the advantage of reducing consolidation time up to $1/N^2$ times.

Considering the dimensions of the prototype (Figure 1) and a flight acceleration of 80 g ($N = 80$ g), two models were constructed for the geotechnical centrifuge: one with the tunnel at the bottom of the soft soil supported by the hard layer (Model 1, Figure 2.a), and another with the tunnel in the middle of the soft soil (Model 2, Figure 2.b). The model box for the geotechnical centrifuge had dimensions of 0.15 m wide, 0.55 m long, and 0.58 m high, with a front wall made of acrylic measuring 0.064 m thick. Ten holes were drilled on the right side of the box to install pore water pressure transducers at different depths. Another hole was added at the bottom to connect a horizontal water reservoir for water drainage during testing (pore water pressure drawdown). To maintain the water level in the model, a hole was added on the lower left side of the box connected to a vertical water reservoir.

To facilitate water drainage and reduce consolidation time, the superficial part of the soft soil was replaced with a sand layer. Two flexible hoses were added to drain the sand layer through the bottom sand drain (Figure 2). These modifications allowed for maintaining pore water pressure drawdown conditions and reducing the consolidation time from 49 to 16 hours in the model (equivalent to 36 to 12 years in the prototype).

Also, to represent the behavior of lacustrine soft soils more realistically and comply with the maximum permitted daily continuous operating time of 9 hours for the equipment, laboratory reconstituted clay was used. The clay consisted of a mixture of 50% kaolin clay (Caomin P055, a commercial

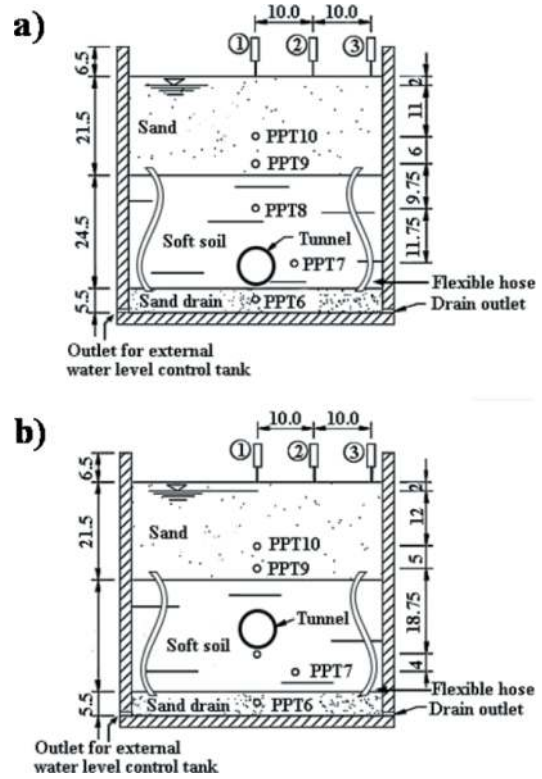

Figure 2. Dimensions and instrumentation for the centrifuge models: a) model 1, tunnel supported by the hard layer; and model 2, tunnel in the middle of the soft soil (dimensions in cm, from rodriguez-rebolledo et al., 2022).

product available in Bogota, Colombia) and 50% diatomaceous soil (50K-50DS) from Bogota ($G_s = 2.49$, $\gamma = 13.9$ kN/m³, $e_0 = 2.70$, $C_c = 0.707$, $C_u = 0.110$, $c_v = 28.16$ m²/year and $k = 7.74 \times 10^{-7}$ cm/s) (Rodríguez-Rebolledo et al., 2022; Pérez-Léon et al., 2022b).

In summary, the following materials were used in the physical models:

- Bottom sand drain: composed of coarse sand ($D_{50} = 3.0$ mm, $C_u = 1.89$, $C_c = 1.02$ and $k = 8.2 \times 10^{-2}$ cm/s).
- Upper sand layer: composed of medium sand ($D_{50} = 0.70$ mm, $C_u = 2.35$, $C_c = 0.92$, $\gamma_{max} = 15.3$ kN/m³, $\gamma_{min} = 14.8$ kN/m³, $\gamma_{sat} = 19.1$ kN/m³, $e_{max} = 0.94$, $e_{min} = 0.56$ and $k = 2.9 \times 10^{-3}$ cm/s).
- Soft soil: laboratory reconstituted clay composed by 50% kaolin clay and 50% diatomaceous soil.
- Tunnel: aluminum tube with an external diameter of 7.5 cm, 4.85 mm thick and a length of 12 cm (density of 27 kN/m³, Young's modulus of 70 GPa and Poisson's ratio of 0.33).

3.2 Diatomaceous soil

According to Ovalle and Arenaldi-Perisic (2020) and Zulaga-Astudillo et al. (2022), diatoms are unicellular algae with a hard and porous cell wall called frustule, composed mainly of silica. When diatoms die, their frustules settle and form diatomaceous soil

(DS), which is present in various aquatic environments worldwide.

Several authors (Zuluaga-Astudillo et al., 2022; Arenaldi-Perisic et al., 2019; Caicedo et al., 2019; Slebi-Acevedo et al., 2021) state that DS has low density, high surface area, elevated porosity, and a high initial void ratio. These characteristics, along with its double porosity (voids between and inside frustules), make DS highly capable of storing water (Palomino et al., 2011; Ovalle and Arenaldi-Perisic, 2020).

Despite the high-water storage capacity of DS, which results in high liquid and plastic limits, it exhibits relatively high values of effective shear strength compared to other fine soils, as reported by Caicedo et al. (2018). Ovalle and Arenaldi-Perisic (2020) explain that this is due to the interlocking of frustules and the highly frictional nature of the contact between them, characterized by their rough and hard surfaces.

3.3 Model instrumentation

According to Figure 2, the soil was instrumented with five pore pressure transducers (PPT6 to PPT10) to measure pore water pressure variations along the soil profile, and three Linear Variable Differential Transformers (LVDT's) on the model surface to measure settlements.

For the tunnel lining, as shown in Figure 3, eight earth pressure cells (C) were installed to measure total stresses, one LVDT for vertical convergence, sixteen strain gauges (SG) to quantify strains, moments and axial forces, and five piezometers (PPT) to compute the pore pressure variations around the tunnel.

Figure 3. Tunnel lining instrumentation (dimensions in cm, from Pérez-Léon, 2023).

4 NUMERICAL MODELLING

4.1 General characteristics

The numerical models were developed using the Finite Element Method (FEM) with Plaxis 2D software, considering plane strain analysis and utilizing

15-node triangular elements. Due to the problem's symmetry, only half of the model was simulated.

For simulating the soft soil (50K-50DS), the Hardening Soil (HS) constitutive model was employed. The HS model, introduced in the Plaxis software, is based on the theory of plasticity (Schanz et al., 1999; Brinkgreve et al., 2014, 2015). In this model, total strains are calculated using stress-dependent stiffness, which differs for loading and unloading/reloading conditions. Failure is defined by the Mohr-Coulomb failure criterion and incorporates shear hardening and compression hardening. Shear hardening follows a non-associated flow rule, while compression hardening has its own associated flow rule.

4.2 Material properties

The mechanical parameters for the 50K-50DS reconstituted soil were obtained, calibrated, and validated for the HS model based on laboratory test results by Pérez-Léon et al. (2022a), as presented in Table 1. To simulate the consolidation process, the drainage condition "Undrained A" was selected, representing undrained material behavior with effective values defining stiffness and strength. The soil was considered incompressible by applying a large bulk stiffness for water, and pore pressures were calculated (Plaxis, 2022).

Table 1. Material properties for 50K-50DS (from Pérez-Léon et al., 2022a).

Parameter	Name	Value	Unit
Drainage type	Type	Undrained A	
Unit weight	γ	13.9	kN/m ³
Secant stiffness in standard drained triaxial test	E_{50}^{ref}	4.2	MPa
Tangent stiffness for primary oedometer loading	E_{oed}^{ref}	2.4	MPa
Unloading/reloading stiffness	E_{ur}^{ref}	18	MPa
Poisson's ratio	ν_{ur}	0.2	-
Power for stress-level dependency of stiffness	m	0.5	-
Cohesion	c'_{ref}	20	kPa
Friction angle	ϕ'_{ref}	28°	°
Dilatancy angle	ψ	0	°
K_{σ} -value for normal consolidation	K_0^{nc}	0.53	-
Failure ratio	R_f	0.9	-
Reference stress for stiffnesses	p_{ref}	100	kPa
K_{σ} -value	K_0	0.53	-
Over-consolidation ratio	OCR	1	-

As shown in Table 2, the hard layer (HL) and crust were simulated by the Mohr-Coulomb model. The properties of the aluminum tube used in the centrifuge model were considered for the tunnel lining (Table 3), employing a liner-elastic model. Additionally, a strength reduction factor of 1 was assumed for

the lining-soil interface, considering the properties of the surrounding soil.

Table 2. Material properties for hard layer (HL) and crust.

Parameter	Name	Value		Unit
		HL	Crust	
Drainage type	Type	Drained		
Unit weight	γ	18	16	kN/m ³
Young's modulus	E'_{ref}	50	12	MPa
Poisson's ratio	ν	0.33	0.3	-
Cohesion	c'_{ref}	10	24	kPa
Friction angle	ϕ'	45	28°	°
Dilatancy angle	ψ	0	0	°
K_0 -value	K_0	0.29	0.53	-

Table 3. Material properties for the tunnel lining and interface.

Parameter	Name	Value		Unit
		Non-porous		
Drainage type	Type			
Unit weight	γ	27		kN/m ³
Young's modulus	E'_{ref}	70		GPa
Poisson's ratio	ν	0.33		-
Strength reduction factor	R_{inter}	1.0		-

4.3 FEM mesh

The FEM mesh was generated automatically by the software (Figure 4), with the general element distribution set to fine and a refined region around the tunnel (coarseness factor = 0.3). This resulted in a total of 2,866 elements and 23,638 nodes (Model 1).

Figure 4. FEM mesh for model 1.

4.4 Simulation stages

Three stages were considered for the numerical simulation:

- I. Initial phase: During this stage, the initial stress state was determined using the K_0 procedure, and the initial pore water pressure was calculated assuming hydrostatic conditions (phreatic level at a depth of 6.6 m).
- II. Tunnel construction: in this stage the tunnel was excavated, and the lining and the interface were activated. The plastic calculation type was applied, neglecting the undrained behavior of soft soil.
- III. Pore water pressure drawdown: This stage involved simulating the drawdown of hydrostatic initial conditions to induce regional subsidence. A fully coupled flow-deformation analysis was performed, allowing for a time-dependent analysis of deformations and pore pressure (Plaxis, 2022).

For Stage III, the flow boundary conditions were defined based on hydraulic head, using data obtained from instrumentation of the physical model. Pérez-Léon (2023) noted that complete dissipation of initial hydrostatic conditions was not achieved during physical modeling, as the water level in the horizontal outlet tank resulted in a remaining hydraulic head at the bottom of the model. Consequently, in the numerical modeling, hydraulic heads were adjusted to match the subsidence values obtained in the physical model through superficial LVDT's. The subsidence value obtained for both centrifuge models was approximately 0.75 m. As depicted in Figure 5, for maximum drawdown condition, hydraulic heads of -26.0 m and -6.6 m were defined at the bottom and

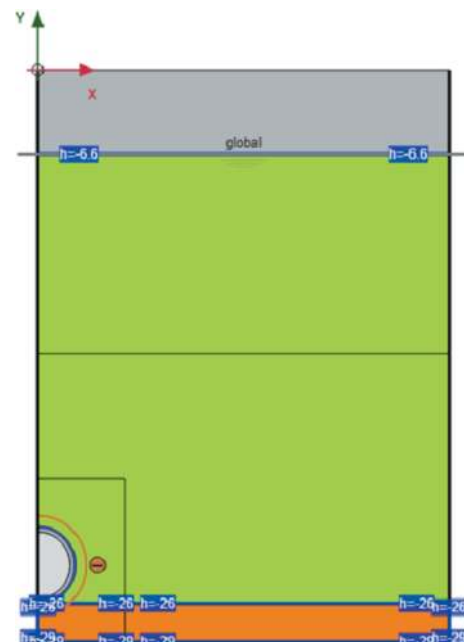

Figure 5. Flow boundary conditions (model 1).

top of the soft soil layer, respectively. Figure 6 illustrates the subsidence versus time curves obtained for both physical and numerical models.

Figure 6. Subsidence along the simulation time (red curves: model 1; blue curves: model 2).

To evaluate the influence of the initial stress state on the tunnel behavior, an additional simulation was held considering for the initial phase the stress calculation by the gravity loading procedure. The results were compared with those obtained by K_0 procedure.

5 RESULTS

5.1 Piezometric conditions

Figure 7 illustrates the piezometric profiles obtained for both Model 1 and Model 2, as well as for the physical and numerical simulations. In general, there is a similar behavior observed between the physical and numerical models. However, a notable difference is observed in the final drawdown condition ($U = 100\%$), where the numerical model shows higher pore pressure values (u) near the sand layer. This discrepancy is also evident in the U versus u graphs (Figure 8) for PPT7 and PPT8 (refer to Figure 2). Initially, the u values (for $U = 0\%$) are reasonably similar between models, but a significant difference develops during the consolidation process's final stage ($U = 100\%$) for the deeper piezometers. Nonetheless, these differences do not appear to impact the final magnitude of subsidence, as demonstrated earlier (Figure 6), where similar values were obtained between models.

5.2 Earth pressure

Figures 9 and 10 present the earth pressure (P_0) developed around the tunnel lining during the pore water pressure drawdown (U), for the physical and numerical Models 1 and 2, respectively.

For the physical models, not all earth pressure transducers worked properly or gave consistent results, so, considering the symmetry of the problem, only the results from half of the tunnel lining were included. For the numerical model, P_0 values were obtained at the stress points located in the same positions of the transducers.

As depicted in Figures 9 and 10, there is a notable disparity between the measurements obtained from numerical and physical models during the initial phase of consolidation ($U = 0\%$), likely attributed to the diverse methodologies employed in representing tunnel installation. However, as the pore pressure dissipates entirely and the total and effective stresses

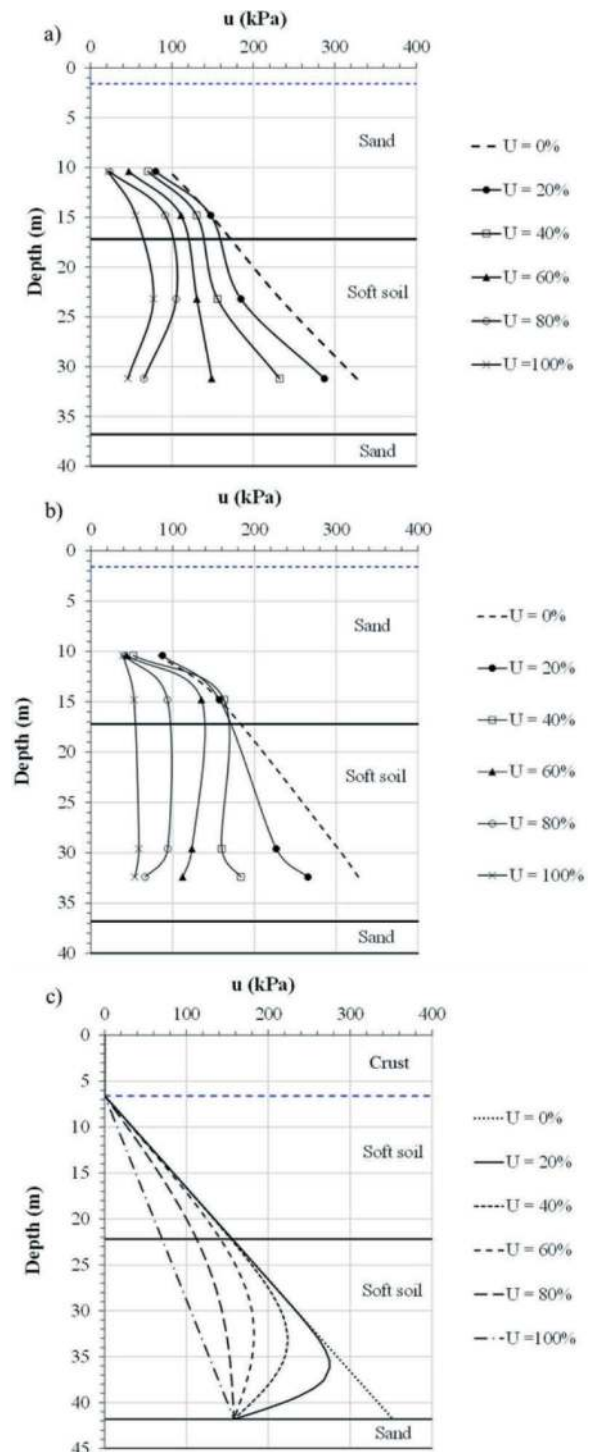

Figure 7. Piezometric profiles for: a) physical model 1, b) physical model 2, and c) numerical modeling.

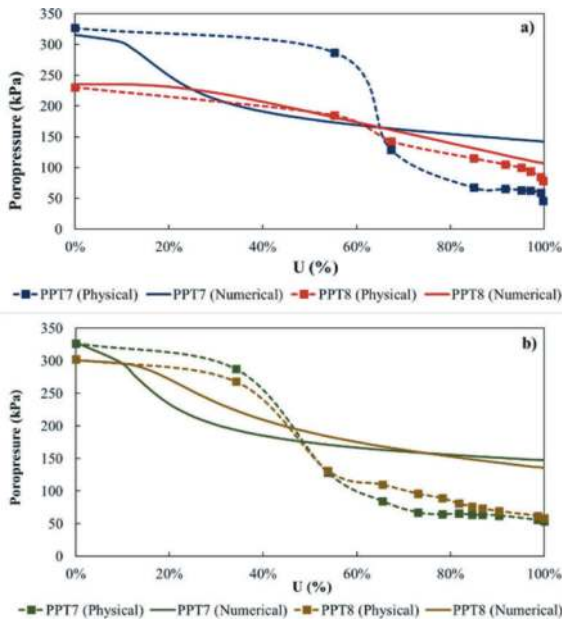

Figure 8. Pore water pressure (u) versus degree of consolidation (U) for PPT7 and PPT8, and for: a) model 1 and b) model 2.

become equivalent ($U = 100\%$), a higher degree of concurrence is observed in the outcomes.

For $U = 100\%$, the results indicate a significant increase in pressure at cell C5 when the tunnel is supported by the hard layer (Model 1, Figure 9) compared to when it is located within the compressible layer (Model 2, Figure 10). The pressure rises from 285 to 1410 kPa in the physical model (Figures 10a and 9a), and from 574.8 to 1468.8 kPa in the numerical model (Figures 10b and 9b). This can be attributed to the restriction of vertical tunnel movement caused by the hard layer, which also leads to higher pressures at the top of the lining (cell C1): an increase from 500 to 600 kPa in the physical model, and from 487.2 to 593.8 kPa in the numerical model. Moreover, there is congruence between the behavior and magnitude of results obtained from both numerical and physical tools at these two points. Just cell C5 of the physical model (Figure 10a) presents a significant difference with the numerical one, which will be explained later.

On the other hand, cell C3 records the lowest magnitude of earth pressure among all models, as the pressures at this location are primarily influenced by total horizontal stresses. It is noteworthy that physical models demonstrate an increase in lateral pressure during piezometric drawdown, whereas numerical models indicate a decrease. Kusakabe and Ariizumi (2005) published results from a centrifuge model with similar conditions, showing that lateral pressure also decreases during drawdown. However, in that model, the tunnel was fixed to the walls, restricting its vertical displacement. In another experiment conducted by Ma et al. (2010), where half of the tunnel was longitudinally supported by soft clay and the other half by rigid clay, lateral pressures decreased in the case of soft soil but increased for rigid soil.

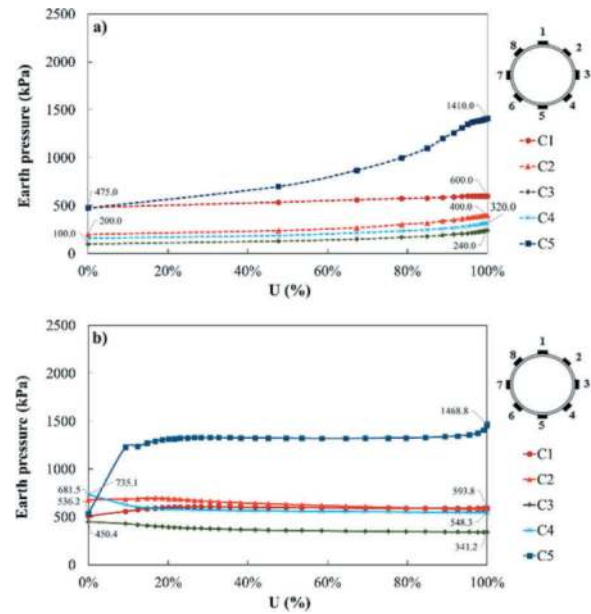

Figure 9. Earth pressures (P_0) versus U , for: a) physical model 1 and b) numerical model 1.

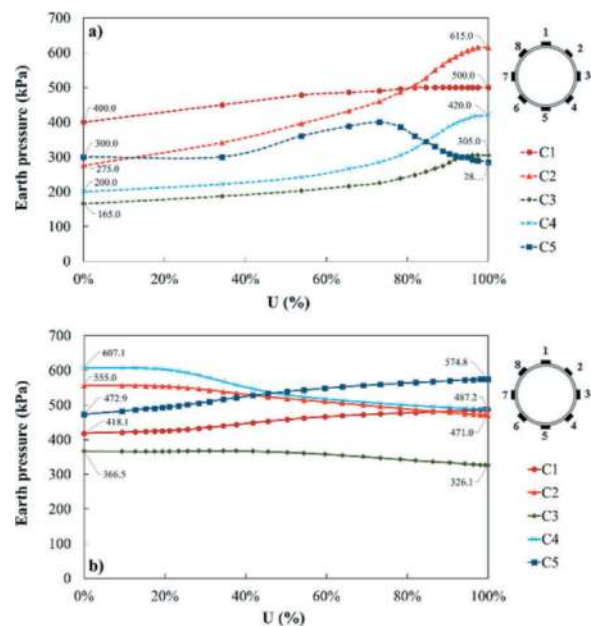

Figure 10. Earth pressures (P_0) versus U , for: a) physical model 2 and b) numerical model 2.

In addition to total horizontal stress, horizontal earth pressure acting in the laterals of the tunnel lining is influenced by the lateral pressure generated by lining deformation. Several factors contribute to the development of this lateral pressure, including: the compression and bending stiffness of the lining, the value of the lateral earth pressure coefficient, and the soil's Poisson's ratio and stiffness. Due to its complexity and to the lack of congruence among the results obtained from various studies, this topic is under investigation.

In physical Model 2, there is a significant increase in pressure in cell C2 during the piezometric drawdown

(Figure 10a). This can be attributed to the tunnel being influenced by the boundary conditions of the model, as it did not descend freely. The decrease in pressure observed in cell C5 during drawdown confirms this, indicating that the soil is unloaded beneath the tunnel. In the study by Kusakabe and Ariizumi (2005), where the tunnel was fixed to the model walls, this trend is consistent for both C2 (increases) and C5 (decreases). The stiffness of the tunnel, being higher than that of the surrounding soil, prevents it from moving vertically in sync with the soil during piezometric drawdown. As a result, negative skin friction develops at the top of the lining where cell C2 is located, as the soil tends to drag down the tunnel. The greater the limitation of the tunnel to move vertically, the greater the magnitude of this negative friction.

5.3 Initial conditions analysis

Figure 11 Presents the results obtained for numerical models 1 and 2, where the initial stress state was generated using the gravity loading method. By comparing the results of Model 1 under two different initial stress conditions (Figures 9b and 11a), it is evident that cell C5 exhibit the highest variation. At $U = 0\%$, C5 shows an increase of up to 207%. The other cells display smaller variations ranging from 0.5% to 21% (C2 and C4, respectively). At $U = 100\%$, the variation in C5 decreases significantly to 54%, while the other cells depict smaller alterations. These findings indicate that the support point of the tunnel in the hard layer is highly sensitive to the initial stress conditions. When employing the gravity loading method, the tunnel is installed since the beginning of the analysis, so the tunnel lining's weight and the forces generated by soil self-weight consolidation on top of the lining (negative friction) exert additional pressure on cell C5.

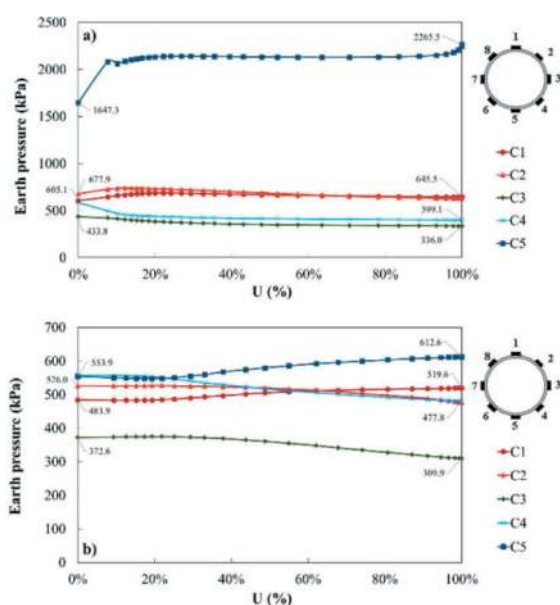

Figure 11. Earth pressures (P_0) versus U , using initial gravity loading procedure for: a) model 1 and b) model 2.

For Model 2 (Figures 10b and 11b), the variations decrease considerably. At $U = 0\%$, C5 exhibits a variation of only 17%, while the other cells range from 1.7% to 16% (C3 and C1, respectively). Under full settlement conditions ($U = 100\%$), instruments experience maximum variations of only 6.7% (C1). These results confirm that for Model 2, the methodology used to calculate initial stresses does not significantly affect the magnitudes of pressures acting on the lining. Furthermore, the obtained variations for $U = 0\%$ tend to decrease during pore water pressure dissipation.

In conclusion, despite significant differences in initial pressures between physical and numerical models (considering K_0 procedure), there is a notable similarity at the end of the consolidation process. This similarity can be attributed to the dissipation of excess pore pressure generated during tunnel installation over time. Consequently, all models reach a similar state when total stresses are equivalent to effective stresses.

6 CONCLUSIONS

This paper presents an investigation into the behavior of tunnels in soft soil subjected to regional subsidence. A numerical simulation using the Finite Element Method (FEM) with Plaxis 2D software is performed. The results of this analysis are compared to a physical simulation conducted by Pérez-León (2023) in a geotechnical centrifuge. Moreover, the influence of the initial stress state on the behavior of the tunnel lining during pore water pressure drawdown is assessed. Two scenarios are considered: one with the tunnel located at the bottom of a compressible layer, resting on a hard layer (Model 1), and another positioned in the middle (Model 2).

Flow boundary conditions were established by utilizing hydraulic head data gathered from instrumentation of the physical model. In the numerical modelling phase, hydraulic heads were modified to align with the subsidence values obtained from the physical model. A significant disparity was observed in the ultimate drawdown condition ($U = 100\%$), where the numerical model exhibited elevated pore pressure values near the sand layer. However, these discrepancies do not seem to have an impact on the overall subsidence magnitude, which remained consistent at approximately 0.75 m for all models.

It seems that there was initially a difference between the measurements obtained from the physical and numerical models in terms of earth pressure around the tunnel lining during pore water pressure drawdown. However, as the pore pressure dissipated and the stresses transitioned, there was a higher degree of agreement in the outcomes. Similar conclusions were reached in the numerical simulation when evaluating the

influence of the initial stress state on tunnel behavior, considering gravity loading and the K_0 procedures.

ABSTRACT: According to the characteristics of sandy soft soil layer in Hangzhou, soft soil with different sand content is prepared artificially, triaxial shear experiments are carried out to establish the constitutive equations of different sand content, and the safety characteristics of disturbed deformation of foundation pit excavation in different sandy soil layers are revealed. Combined with the actual project of excavation pit above the existing subway, the three-dimensional numerical simulation technology is used to analyze the influence process of pit excavation on the subway below, and the reasonableness of the simulation method is verified by comparing with the measured values. The influence of excavation depth, excavation width and excavation process on existing underground tunnels in different sand-bearing layers is further analyzed, which can optimize the excavation scheme and provide reference for similar projects in the future.

Keywords: soft soil with different sand content, triaxial shear experiment, foundation pit, tunnel deformation

1 INTRODUCTION

The rheology of soft soil refers to the phenomenon in which the deformation of soft soil changes over time under the influence of external forces. The rheology of soft soil is the primary cause of disturbance and progressive failure during foundation pit excavation, and it also significantly influences the time and spatial deformation effects. The rheological mechanism is very complex, involving creep, relaxation, elastic after-effect and more. The creep test is relatively easy to implement. Therefore, the creep constitutive equation, which can reflect the stress state, is often constructed to simulate the rheological effect. The rheological deformation in consolidation during construction can be regarded as the combination of instantaneous elasto-plastic deformation and creep deformation (creep deformation caused by time effect of soft soil under

different stress states), so the full creep constitutive equation that can reflect different stress states can be used to simulate the rheological deformation during construction. During the construction period, the load changes greatly, and the total rheological deformation (because the creep constitutive model is used to simulate the rheological deformation in this paper, the total rheological deformation is collectively referred to as creep deformation) is also obvious. During the operation period, the load is basically unchanged. At this time, the total rheological deformation is mainly the traditional creep deformation, and the overall deformation is relatively slow.

The newly excavated waterway in Hangzhou passes over the Hangzhou Metro Line 1 that has been put into operation. The waterway is located above the existing metro tunnel. The elevation of the crown of the prefabricated segment of the metro

*Corresponding author: 530356828@qq.com

tunnel structure is -9.30m (The ground elevation of the area where the excavation channel is located is 5m), and the minimum distance between the bottom of the foundation pit and the top surface of the tunnel structure is only 4.9m.

Figure 1. The relationship between the new waterway and existing metro tunnels.

According to the technical code for the safety protection of urban rail transit structures (CJJ/T202-2013), the relative relationship between the newly excavated channel and the subway tunnel is very close: $<1.0D$ ($D=6.2\text{m}$), and the channel excavation is located directly above the subway, which belongs to the strongly affected area: within $0.7h_1$ ($h_1=9.4\text{m}$) directly above and outside the structure, and the impact of channel construction on the subway is special. Excavation disturbance control has become the primary technical problem of construction safety control [1-3].

According to the as-built information, the subway tunnel passes through multiple layers of soft soil with varying sand contents, and the excavation disturbance above the subway tunnel in soft soil has obvious time effect on the surrounding ground and tunnel. Currently, numerous researches being conducted on soft soil, focusing on the deformation and failure caused by creep.

Xu F R [4] et al. (2012) proposed a mechanical model for the creep instability of honeycomb soft clay microstructure to predict the creep deformation characteristics of the soft clay, and found that the deformation instability of soft clay microstructure is related to its stress state, geometry, size and other factors.

Wang Y H [5] et al. (2014) simulated the triaxial creep test of dense sand and loose sand through DEM, and studied the micromechanics involved in the creep process.

Xu R Q [6] et al. (2015) obtained the microstructure data of Zijiangang soft soil in the Hangzhou area through SEM (Scanning Electron Microscope) image scanning, studied the pore characteristics of the soft soil, developed a three-dimensional pore calculation model using Image Pro Plus analysis software, and examined the impact of various factors on the calculation of three-dimensional porosity.

Sun M Q [7] (2016) determined the microstructure factor that can indicate the change of soft soil microstructure through the analysis of orientation degree and orientation fractal dimension in soft soil microstructure. By combining the microstructure factor with the one-dimensional creep consolidation differential equation, the one-dimensional creep consolidation differential equation was established.

Ming X [8] et al. (2018) utilized the discrete element method to investigate the creep and stress relaxation process of rockfill. The parameters and appropriate macro responses are derived from the experimental results. The relationship between macro and micro responses is discussed. The micro mechanism of the observed non isochronous phenomenon is also studied.

It can be seen that the creep characteristics of soft soil have a great relationship with the structure of soft soil, and different sand content has great impact on the structure of soft soil [9-11]. Therefore, according to the characteristics of different sand content in the stratum, a creep constitutive model is developed to depict the time effect of excavation construction and The time effect of the operation period; the disturbance influence law of different excavation length, different excavation depth, different excavation sequence and different creep characteristics on the existing subway is simulated and analyzed; the influencing factors and laws of excavation disturbance in the strong influence area above the existing subway are revealed, which provides a reference for the optimization of construction scheme.

2 CONSTRUCTION OF 3D NUMERICAL MODEL BASED ON PROGRESSIVE FAILURE THEORY

2.1 Establishment of geometric model and working condition determination

The core area utilizes the sloping+portal reinforcement scheme, and the specific construction sequence is as follows:

- (1) Cement mixing piles are used for foundation stabilization in different areas. After the initial setting of cement mixing piles is completed, all bored piles (including uplift piles, retaining piles and column piles+lattice columns) are driven. The cement mixing pile is reinforced in six areas. The unconfined compressive strength in the weak reinforcement area is greater than 0.6MPa, and the unconfined compressive strength in the strong reinforcement area is greater than 1.5MPa. The zoning reinforcement diagram of the core area is depicted in Figure 2. The uplift pile is $\phi 600@1250$ Bored piles, $l=40\text{m}$, 256 in total; The single row of retaining piles parallel to the subway are $\phi 800@1000$ 133 bored piles, $l=23.5\text{m}$; The outer side of the double row retaining piles directly above the subway is ϕ

800@2000 Bored pile with inner side ϕ 800@1000 67 bored piles, $l=9.8\text{m}$; The outer side of the double row retaining piles above the subway side is ϕ 800@2000 Bored pile with inner side ϕ 800@1000 Bored piles, $l=18.5\text{M}$, 64 in total; Column pile is ϕ 800@10000 18 bored piles, $l=40\text{m}$; Lattice column size is $450 \times 450 \times 8400$ (mm), embedded in the lower column pile. The schematic diagram of bored Piles in the core area is shown in Figure 2.

Figure 2. Schematic diagram of reinforcement area of core area.

- (2) The core area is divided into seven blocks symmetrically along the direction of the subway tunnel, each with a width of 10m. For each sub pit, first excavate the slope from 3.0m to 1.0m, then excavate pit A to -4.4m elevation, and section steel reinforced concrete (1 m) is poured. The excavation and pouring of pit B have been completed. Excavating the D1 pit to -4.4m elevation, pour plain concrete bedding, and lay section steel reinforcing cages on the base slab. During this period, C1 is excavated synchronously and the above operations are repeated. The 1m section of steel reinforced concrete base layer for pits C1 and D1 was poured as a whole. The later sub pit construction is the same as described above, and the construction sequence is illustrated in Figure 3.

Figure 3. Construction sequence diagram of core area.

The simplified numerical simulation model of foundation pit excavation in the channel core area is shown in the following Figure.

Figure 4. Numerical simulation model diagram of channel excavation above tunnel.

2.2 Progressive failure simulation method based on creep model and determination of constitutive model parameters

The progressive failure of soil is the process of soil deformation over time, including short-term sudden failure and long-term slow deformation failure. In order to simulate the entire process of deformation of the channel above the existing subway tunnel during excavation, the generalized exponential creep model is used to replicate the long-term progressive failure deformation of the strata with varying sand content. After determining the equivalent stress of the strata with varying sand content, the creep constitutive equation is adjusted by using the instantaneous equivalent strain corresponding to the equivalent stress as the initial instantaneous strain of the creep constitutive model.

The soft soil parameters in the core area are presented in Table 1 below.

Table 1. Soft soil parameters in core area.

Formation	E_s / MPa	Poisson's ratio	Density / $\text{kg}\cdot\text{m}^{-3}$	Cohesion / kPa	ϕ / °
①Silty soil	10.21	0.4	1891	11	29.2
②Silty sand	10.61	0.35	1902	6.6	31.3
③Silty clay	10.65	0.29	1831	1.9	16.2
④Clay	10	0.26	1802	28.1	17.9
⑤Silty clay	10.06	0.23	1871	27.8	17.2
⑥Silty sand	10.69	0.25	1862	6	33.1

The parameters of the retaining structure of the foundation pit in the core area are presented in Table 2 below.

The improved equivalent creep model is utilized to simulate the time effect of the excavation process and operation period. The implicit equation 3 in ANSYS is a commonly used generalized exponential

Table 2. Parameters of foundation pit retaining structure.

Structure	E / MPa	Poisson's ratio	Density / kg·m ⁻³	Cohesion / kPa	φ / °
Semi reinforced soil	90	0.24	2100	3150	45
Reinforced soil	120	0.24	2200	5500	55
Diaphragm wall	17700	0.24	2500	8010	94
Top beam	45000	0.26	2500	8010	94
Coupling beam	30000	0.26	2500	8010	94
Column pile	17700	0.24	2500	8010	94
Lattice column	2780	0.30	2500	8010	94
Uplift pile	5590	0.24	2500	8010	94
Brace	33800	0.26	2500	8010	94
Pier	30000	0.26	2500	8010	94
Cushion	30000	0.24	2500	5020	50

strain rate creep model. The constitutive equation is as follows:

$$\dot{\epsilon}e = C_1 C_5 e^{(-C_4/T)} \sigma e^{C_2+C_3} e^{[-C_5 \sigma e^{C_3} e^{(-C_4/T)} t]} \quad (1)$$

Where: C₁-C₅ represent unknown parameters obtained through fitting. σe is the von Mises equivalent stress and εe is the equivalent strain, and the calculation formula is as follows:

$$\sigma e = \left[\frac{(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2}{2} \right]^{\frac{1}{2}} \quad (2)$$

$$\epsilon e = \frac{1}{1+\nu'} \left(\frac{1}{2} [(\epsilon_1 - \epsilon_2)^2 + (\epsilon_2 - \epsilon_3)^2 + (\epsilon_3 - \epsilon_1)^2] \right)^{\frac{1}{2}} \quad (3)$$

When the creep constitutive parameters are obtained by fitting the creep strain rate duration curve equation, temperature and other effects are not considered. In Formula (2.2-1) C₂ = 1, C₃ = C₄ = 0, the implicit creep equation is rewritten as:

$$\dot{\epsilon}e = C_1 C_5 \sigma e \cdot e^{(-C_5 t)} \quad (4)$$

The strain corresponding to the equivalent stress of the formation with varying sand content, as obtained by Formula (σ_e = (1 - K₀)σ₁) is utilized as the initial strain for the creep equation of the formation with different sand content. The creep test curve has been modified, and the creep fitting results of the formation with different sand content are shown in Figure 5.

The specific construction steps and numerical simulation construction sequence of the foundation pit in the core area are presented in Table 3 below.

Figure 5. Creep fitting results of each formation.

3 ANALYSIS ON INFLUENCE LAW OF EXCAVATION LENGTH IN CORE AREA OF CREEP UNIFORM FORMATION ON TUNNEL SAFETY

Assuming that the excavation length of the foundation pit in the core area (other parameters are the same) is 36m (condition 2-1), 40m (condition 2-2) and 44m (condition 2-3), the displacement variation law of the key points of the subway tunnel structure under different excavation lengths of the foundation pit is analyzed. The schedule for excavation construction is shown in Table 4.

Table 4. The schedule of excavation construction.

Construction sequence	Time
Tunnel operation for 7 years and shutdown stage	2800 days
Construction of Zone II and Zone VI	2953 days
Construction of Zone I, Zone III, Zone IV, Zone V and bored piles	3175 days
Excavation of the first layer of soil and construction of retaining structure	3242 days
Pit and block excavation of foundation pit in core area	3308 days

The upward line of the tunnel is located under the center of the foundation pit in the core area. The Y-direction displacement curve of the crown and invert of the tunnel with time during the construction period is depicted in Figure 6.

(a) Crown during construction

(b) Invert during construction

Figure 6. Curve of Y-direction displacement versus time of tunnel crown and invert during construction period.

As can be seen from Figure 6:

In the core area I, III, IV and V and the bored pile construction stage (3175 days), after the reinforcement

of the area where the foundation pit in the core area was not reinforced in the previous stage, the Y-direction displacement of the tunnel crown and invert decreased significantly, and the settlement increased significantly compared with the previous stage. Compared to the previous stage (2953 days), the settlement of the tunnel crown with excavation lengths of $l=36$, 40 and 44m (GK2-1, 2-2 and 2-3) in the core area was 22.587mm, 23.387mm and 24.141mm respectively, and that of the invert was 21.984mm, 22.789mm and 23.551mm respectively. As the core excavation length L and the area of the reinforced area increase, the settlement of the tunnel crown and invert caused by the reinforcement increases with the increase of the core excavation length L .

Combined with the above figure, it is found that during the second step of excavation, the change in uplift value has exceeded the change of settlement value caused by the reinforcement of the core area. After that, the y-direction displacement of the tunnel with the excavation length of $l=44$ m (GK2-3) in the core area is the largest, followed by $l=40$ m (GK2-2), and $l=36$ m (GK2-1) is the smallest. Although the entire core area has been reinforced, with the increase of the excavation length of the core area, the size of the core area, and the scope of the reinforcement area also increases, but the increase of the excavation scope of the core area leads to the increase of soil rebound deformation caused by excavation, and the reinforcement of the core area is not enough to inhibit the increase in rebound deformation.

The maximum Y-direction displacement of zone 2 and zone 6 after construction was 5.683, 5.730 and 5.776mm (2953 days), which was reduced by 0.404, 0.410 and 0.416mm respectively compared with the previous stage (2800 days). At this time, the variation in the maximum Y-direction displacements increased as the increase of excavation length L . After excavating the first layer of soil and constructing the retaining structure, the maximum Y-direction displacement of 2.681, 2.558 and 2.460mm increased by 2.328, 2.486 and 2.647mm respectively compared with the previous stage (3175 days). At this time, the variation in the maximum Y-direction displacement increased with the increase of the excavation length L ; Compared with the previous stage (3242 days), the maximum Y-direction displacement after pit and block excavation in the core area was 15.262, 16.892 and 18.512mm, which increased by 12.581, 14.334 and 16.052mm respectively. At this time, the variation of the maximum Y-direction displacement increased with the increase of excavation length L .

4 ANALYSIS OF INFLUENCE OF EXCAVATION DISTURBANCE ABOVE TUNNEL UNDER DIFFERENT EXCAVATION DEPTHS

Assuming that the excavation depth of the foundation pit is 8.4m (working condition 4-1), 9.4m

(working condition 4-2) and 10.4m (working condition 4-3) respectively, the impact of the excavation depth of the foundation pit on the deformation of the tunnel below is analyzed.

The displacement duration curve of the key points on the lining structure of the subway tunnel is mainly analyzed (the key points include the arch crown, invert (arch bottom) and left and right arch waist of the tunnel below the center of the foundation pit in the core area). The construction time for numerical simulation is shown in Table 4.

- (1) During the excavation of the first layer of soil and the construction of the retaining structure (3242 days), the tunnel crown and invert have rebound deformation due to the influence of excavation. Compared with the previous stage (3175 days), the tunnel crown with excavation depths of 8.4, 9.4, and 10.4m (GK4-1, 4-2, and 4-3) in the core area were 10.712mm, 10.705mm, and 10.706mm, respectively; Compared with the previous stage (3175 days), the uplift values of invert are 10.076mm, 10.068mm and 10.070mm respectively. At this time, although the excavation was carried out, only the soil layer within 2m below the ground surface was excavated under the three working conditions, so the uplift values of the tunnel crown and invert under the three working conditions were almost the same.
- (2) After 3308 days of pit and block excavation in the core area, the tunnel arch crown and invert experienced rebound deformation, with Y-direction displacement continuing to increase throughout the excavation process. The uplift value also increased significantly. Compared to the previous stage (3242 days), the uplift values of the tunnel arch crown with the excavation depths of 8.4, 9.4, 10.4m (GK4-1, 4-2, 4-3) in the core area are 22.980mm, 27.519mm, 33.349mm respectively; Compared with the previous stage (3242 days), the uplift values of the invert are 21.776mm, 26.267mm and 31.810mm respectively. The uplift value of the tunnel crown and invert caused by excavation increases with the increase of excavation depth in the core area.

Combining with Figure 7, it can be observed that during the process of step-by-step excavation, the uplift value of the tunnel crown and invert caused by excavation increases with the increase of excavation depth in the core area, and the variation of uplift value with the excavation depth in the core area is not linear, and the variation of uplift value increases with the increase of excavation depth.

Under the influence of creep, the minimum Y-direction displacement of the subway during the 7-year operation and shutdown period is 0.333, 0.334, 0.333mm (2800 days), the maximum Y-direction displacement is 6.135, 6.135, 6.135mm (2800 days), and the maximum differential settlement is about 5.8mm.

After completing the pit and block excavation of the foundation pit in the core area, the maximum

Y-direction displacement of the three working conditions are 12.478, 17.013 and 22.701mm respectively, which are increased by 10.005, 14.539 and 20.227mm respectively compared with the previous stage (3242 days). At this time, the variation in the maximum Y-direction displacement increases with the increase of the excavation depth.

5 ANALYSIS OF DISTURBANCE EFFECT OF DIFFERENT EXCAVATION SEQUENCE ON EXISTING TUNNEL UNDER FOUNDATION PIT

Assuming that the excavation sequence of the foundation pit in the core area of the channel is different (other parameters remain the same), the impact of the construction scheme on the subway tunnel below is predicted. This paper primarily analyzes the displacement duration curve of the key points on the subway tunnel, which include the arch crown, invert (arch bottom) and the left and right arch waist of the tunnel under the center of the foundation pit in the core area). It also analyzes the changing trends of the x-direction and Y-direction displacement at the

selected positions. The schematic diagram of the block excavation area is depicted in Figure 8, and the excavation sequence parameters for the core area are presented in Table 5.

The three excavation sequences have obvious effects on the displacement curves of the tunnel arch crown and invert over time during the construction period. However, due to the viscoelastic model used in this paper, it can not accurately reflect the cumulative effect of plastic deformation. The excavation sequence is the same for the total deformation of the tunnel crown and invert after excavation, but the real situation is that the plastic deformation of the surrounding rock in the subway tunnel is large due to the excavation disturbance of the soft soil layer. Therefore, in terms of controlling the deformation of the subway tunnel below, different excavation sequences should be optimized and analyzed.

Figure 8. Schematic diagram of block excavation area.

Table 5. Excavation sequence parameters of core area.

Working condition	Excavation sequence
5-1	1, 2→3, 4→5, 6→7, 8→9, 10→11, 12→13, 14
5-2	1, 2→13, 14→4, 12→3, 11→6, 10→5, 9→7, 8
5-3	1, 2, 13, 14→3, 4, 11, 12→5, 6, 9, 10→7, 8

The upward line of the tunnel is located below the center of the foundation pit in the core area. The curve of Y-direction displacement versus time of the arch crown and invert (arch bottom) of the tunnel (s1062 section) during the construction period is shown in Figure 9.

(1) GK5-1 is excavated in a unilateral way, from pit 1 and 2 to pit 13 and 14, and is divided into 7 strips for step-by-step excavation. From the above figure, it can be found that during the excavation of GK5-1 in the core area pit sub-pit and block excavation, the tunnel arch has been bulged by 1.939, 3.324, 5.201, 6.276, 5.447, 3.396, 1.930mm compared to the previous step of excavation, and the tunnel superelevation arch has been bulged by 1.925, 3.290, 4.975, 5.587,

5.130, 5.587, 4.975, 5.587, 5.130, 5.587, 4.975, 4.975, 5.975, 4.975 and 5.975mm respectively, 5.587, 5.130, 3.409, and 1.945 mm, respectively. The uplift values of the tunnel arch and the super-elevation arch increased from the edge of the pit in the core area towards the center of the pit and then decreased away from the pit.

- (2) During the pit and block excavation of the foundation pit in the core area of GK5-2, the crown of the tunnel was 1.939, 1.936, 4.090, 2.552, 6.699, 3.758 and 6.545mm higher than in the previous excavation. Additionally, the invert of the tunnel was 1.925, 1.922, 4.033, 2.542, 6.281, 3.730 and 5.833mm higher than in the previous excavation. The uplift value of the tunnel crown and invert was the smallest at the edge of the foundation pit in the core area. In the subsequent process of dividing a sub pit into two sides and excavating towards the center of the foundation pit at the same time, the tunnel heave caused by the excavation of the entire sub pit is effectively reduced.
- (3) During the pit and block excavation of the foundation pit in the core area of GK5-3, the crown of the tunnel was raised by 3.875, 6.642, 10.457 and 6.545mm respectively, compared with the previous excavation. Additionally, the invert of the tunnel was raised by 3.848, 6.575, 10.012 and 5.833mm respectively, compared with the previous excavation. When a pit is excavated to the center of the foundation pit at the same time without dividing it into two sides, the tunnel uplift value caused by excavation increases significantly, which adversely impacts tunnel deformation control.

The horizontal displacement curve of the arch crown and invert (arch bottom) of the tunnel located below the foundation pit center in the core area during the construction period is shown in Figure 10.

- (1) During the pit and block excavation of the foundation pit in the core area of GK5-1, the crown of the tunnel was displaced by -0.019, -0.091, -0.210, -0.292, -0.237, -0.099, -0.007mm respectively compared with the previous excavation, and the invert of the tunnel was raised by -0.068, -0.192, -0.323, -0.361, -0.334, -0.205, -0.070mm respectively compared with the previous excavation. When excavating unilaterally, the horizontal displacement direction of the subway tunnel on the upward line is in the downward line direction.
- (2) During the pit and block excavation of the foundation pit in the core area of GK5-2, the displacement of the tunnel crown was -0.019, -0.019, 0.096, -0.274, 0.267, -0.684, -0.321mm respectively compared with the previous excavation, and the displacement of the tunnel invert was -0.068, -0.068, 0.257, -0.637, 0.272, -0.914, -0.395mm respectively compared with the previous excavation. The horizontal displacement of

(a) Crown during construction

(b) Invert during construction

Figure 9. Curve of Y-direction displacement versus time of tunnel crown and invert during construction period.

the tunnel crown and invert was the smallest at the edge of the foundation pit in the core area.

(3) During the pit and block excavation of the foundation pit in the core area of GK5-3, the displacement of the tunnel crown was -0.039, -0.178, -0.418, -0.321mm respectively compared with the previous excavation, and the displacement of the tunnel invert was -0.137, -0.380, -0.642, -0.395mm respectively compared with the previous excavation. When excavating both sides simultaneously, the horizontal displacement direction of the uplink metro tunnel is in the downward travel direction. The horizontal displacement variation of the crown and invert of the subway tunnel increases from the edge of the foundation pit in the core area to the center of the foundation pit.

By analyzing the Y-direction displacement versus time curve of the tunnel crown and invert during the construction period, it is evident that the maximum variation in vertical and horizontal displacement occurs when excavating the sub pits (7 and 8 sub

(a) Crown during construction

(b) Invert during construction

Figure 10. Curve of horizontal displacement versus time of tunnel arch crown and invert during construction period.

pits) in the center of the foundation pit in the core area during the unilateral excavation (GK5-1), and when excavating the sub pits (5, 6, 9 and 10 sub pits) on both sides at the same time (GK5-3), The variation of vertical displacement and horizontal displacement reaches the maximum. When a sub pit is divided into two sides and excavated at the same time (GK5-2), the variation of vertical displacement reaches its maximum when excavating the sub pits on both sides of the foundation pit center in the core area on one side of the subway tunnel on the uplink (6 and 10 sub pits). The variation of horizontal displacement reaches its maximum when excavating the sub pits on both sides of the foundation pit center in the core area on one side of the subway tunnel on the downlink (5 and 9 sub pits), The excavation method of GK5-2 effectively avoids the simultaneous maximum variation of vertical and horizontal displacement, greatly improving tunnel deformation.

In summary, the analysis demonstrates that the excavation depth of the channel core area has a greater impact on tunnel deformation compared to the excavation length of the channel core area.

Therefore, the priority should be given the influence of the excavation depth of the core area on tunnel deformation. Given that the bottom of the channel core area features a steel reinforced concrete composite bottom plate, which belongs to the navigation section that is not easy to be rebuilt, in order to facilitate the navigation of large tonnage ships in the future, the elevation of the foundation pit bottom in the channel core area is finally taken as -4.4m, and the excavation depth is taken as 9.4m.

6 CONCLUSION

In this paper, according to the characteristics of different sand content in the stratum, the generalized exponential creep constitutive model and parameter determination method of soft soil with different sand content are proposed, and the three-dimensional numerical simulation model of rheological deformation of the whole process of excavation of the foundation pit above the subway tunnel in different sand content strata is established, which reveals the influence of different excavation depth, excavation length and excavation sequence of the foundation pit above the subway tunnel on the deformation of the subway tunnel below in the creep soft soil layer. The main conclusions are as follows:

The sequence of excavating the foundation pit above the existing subway tunnel affects the deformation of the existing subway tunnel below. The sequence of excavation for the foundation pit affects the deformation process of the tunnel when the pit is excavated by pit and block. When a pit is divided into two sides and excavated toward the center of the foundation pit simultaneously, it effectively avoids the simultaneous maximum variation of vertical and horizontal displacement, leading to significant improvement in tunnel deformation.

Non-invasive tunnelling investigations using Muon tomography

Chris Steer & Lee F. Thompson*

Geoptic Infrastructure Investigations Ltd, Beechcroft Barn, South Warnborough, Hants, UK

ABSTRACT: Muon tomography is a technique that harnesses natural radiation to image large-scale objects in a non-invasive and non-destructive way. This paper reports on the successful application of muon tomography to the imaging of railway tunnels on the UK rail network. The muon tomography is described and a brief resume of the recent and past history of applications of muon tomography is presented. This is followed by a detailed description of the technique to the imaging of railway tunnels. The methods involved in extracting visualisations of the tunnel overburden are outlined and examples of results from recent tunnel surveys are presented. The paper concludes with an outlook of possible future applications of muon tomography to the tunnelling sector.

Keywords: Imaging, Surveying, Mapping

1 INTRODUCTION TO MUON TOMOGRAPHY

Muon tomography is a technique which exploits naturally-occurring radiation in the form of muons. Muons are fundamental particles that are created in the upper atmosphere, they have properties similar to that of a heavy electron (they have approximately 200 times the mass of the electron) which makes them highly penetrating particles capable of passing through tens to hundreds of metres of rock with ease. This, coupled with their relative abundance (at sea level there is 10,000 per m² per minute), leads to their suitability for tomographic imaging.

The muon tomography method is analogous to a medical X-ray. With an X-ray, the density information in an object of interest (e.g. a bone in a patient's arm or the root canal system in a patient's tooth) is images by passing a beam of X-rays through the object which are observed by a "detector" (X-ray film) on the other side of the object.

Muon tomography works in the same way except that a muon-sensitive detection system is needed to detect the muons. The key points here however are that muon tomography is a non-invasive and non-destructive method - capable of returning vital information on the structural integrity of objects at a distance and without the need to interact with the object. Furthermore, in the same way as an X-ray can diagnose issues that are otherwise hidden, muon tomography can identify features in, e.g. a tunnel overburden that would otherwise be invisible.

2 MUON TOMOGRAPHY, HISTORY AND APPLICATIONS

Muon tomography isn't a new method, its first documented application was in 1955 when it was used to measure the overburden in a tunnel system around a hydro-electric power station in New South Wales (George, 1955). The technique has most famously been used to identify hidden chambers in pyramids - as depicted in Figure 1 (Morishima et al., 2017).

Muon tomography has also been used in other applications such as imaging volcanos (Tanaka et al., 2014) and imaging sections of the Xi'an's ancient city walls (Liu et al., 2023). A summary of the broad

Figure 1. Depiction of voids found in Egyptian pyramid using the muon tomography method.

range of muon tomography applications has recently been published by the International Atomic Energy Authority (IAEA, 2022).

3 HIDDEN SHAFT LOCATION USING MUON TOMOGRAPHY

The background to this problem lies in the fact that much of the railway infrastructure in the United Kingdom dates back to the Victorian era. The period between the 1850s and early 1900s saw an enormous increase in the UK rail network with a proliferation of track, bridges, tunnels and viaducts being built during this period. Tunnel building methods at that time often involved several additional shafts being created along the length of the tunnel, these were constructed to speed up the construction of the tunnel and were used either to deploy personnel and/or to remove spoil. Importantly, what happened to these shafts when the tunnel was complete is somewhat arbitrary. In some cases the shafts were left open, in others they were bricked over in both the tunnel and on the surface, other shafts have a combination of these approaches.

Due to the age of these tunnels vital documentation on the location of hidden shafts is often incomplete or lost. It is a priority for the UK rail network operator, Network Rail, to have as full an understanding as possible of these hidden shafts since they have potential for dramatic consequences, as evidenced in an event which took place near Manchester in the early 1950s resulting in a loss of life.

Muon tomography is well-suited to the identification, characterisation and, if required, the long-term monitoring of railway tunnel infrastructure since it is capable not only of locating areas of under-density in an overburden but can pinpoint that density deficit and return valuable information on the opacity (effectively the integrated density along the column height above the tunnel) - information which can educate tunnel asset managers and help them to prioritise remedial works.

The potential of muon tomography to return valuable tunnel asset information is highlighted in the following two cases studies.

3.1 Case study: Alfreton Old Tunnel

The muon tomography technique was first demonstrated to Network Rail (UK) at the so-called Alfreton Old Tunnel - a disused railway tunnel located in Nottinghamshire, UK. Alfreton Old Tunnel has 3 open shafts to the surface and so is an ideal tunnel for a “proof of principle” application of muon tomography.

Muon sensors, consisting of plastic scintillator, coupled to photomultiplier tubes (light detection devices) were constructed. When a muon passes through the scintillator material a light pulse (“signal”) is created that is detected by the

photomultiplier. The size and exact time (to a few tens of billionths of a second) are recorded, enabling so-called “co-incidences”, i.e. instances of signals seen in two or more sensors separately but at the same time are identified as a muon passing through the system. The exact combination of which sensors see signals give additional information on the trajectory of the detected muon.

This muon detection system was deployed in the Alfreton Old Tunnel and a series of readings taken at regular 5 metre intervals along the tunnel. A full report of the tunnel survey is published in Thompson et al. 2020.

Figure 2. Results of muon tomography scan of Alfreton tunnel.

Figure 2 shows the results of scanning the entire length of the tunnel at 5 metre intervals and with just 30 minutes of data at each point. The “inferred rate” is that predicted to be seen in the muon sensor system (via computer simulations) assuming a certain geology for the tunnel. The 3 open shafts (indicated by blue vertical lines) are clearly visible in the data, a highly significant excess of muons compared to that which would be expected with a full overburden is observed in each case.

Figure 3. Muon sensor system data around open shaft.

Figure 3 shows a zoom in of the data around 220 metres, here the statistical significance of the open shaft observation is very high - 11 standard deviations, with just 30 minutes of data. Figure 2 shows other features visible in the data: the discontinuity at approx. 350 metres was due to a system replacement

and is understood, there is also some indication of an elevated muon rate around 650-700 metres which may reflect incorrect modelling of the overburden close to the tunnel portal. However, of particular interest is the deviation in the data around 80 metres, which is illustrated in greater detail in Figure 4.

Figure 4. Data from the suspected hidden shaft region.

The elevated muon rate in this region is indicative of a hidden shaft. When reported back to Network Rail it was confirmed that there is a suspected hidden shaft in the area - information that wasn't provided to the Geoptic team prior to reporting the results of the field trial. Having identified a hidden shaft Geoptic were subsequently contracted to take further measurements around this point. The results from this second study are depicted in Figure 5 which indicates that the hidden shaft is centred at the tunnel crown with a diameter of approximately 3.5 metres, the data also indicates that the overburden of the shaft is equivalent to 1 metre of standard density rock (5 metres of rock at 1 standard deviation), which suggests that the feature is highly likely to be a hidden shaft with minimal backfill material.

Figure 5. Visualisation of the hidden void in the Alfreton tunnel.

This case study ably demonstrates the potential for muon tomography not only to identify objects of interest but to characterise them also. Muon

tomography is also capable of longer-term monitoring of a region of interest to determine, for example, if water ingress is taking place since this would result in density changes that the muon sensors would detect.

4 INSTRUMENTATION AND DATA VISUALISATION

Since this initial project with Network Rail, Geoptic has been contracted to perform studies of many other tunnels across the UK. In total over the past year, we have spent more than 120 days or nights in tunnels performing imaging surveys using muon tomography. These programmes of work have resulted in improvements to instrumentation and also a more refined data analysis and reporting system.

Figure 6. Image of two muon systems on railway tracks.

In terms of instrumentation, as depicted in Figure 6 above, Geoptic has developed a ruggedised IP68 TRL9 system that can be deployed directly onto a Permaquip trolley and rolled into a rail tunnel. In addition to the above, borehole instrumentation is also available.

Since the initial body of work at Alfreton, Geoptic's software techniques - used both in the initial stages of any tunnel visualisation project to educate measurement times, and in the data-processing phase of any project - have undergone considerable refinements and improvements. This is exemplified in Figure 7 which illustrates results from a recent tunnel campaign where a number of features were identified and visualised. Figure 7 is a 2D slide through a 3D image of the area of interest.

5 OTHER TUNNELLING APPLICATIONS

To date, from a civil engineering perspective, Geoptic has applied the muon tomography

Figure 7. 2D slice through a 3D tunnel overburden density reconstruction.

technique to the location and characterisation of hidden shafts in the UK's railway infrastructure. However, it is clear that a non-invasive imaging tool such as this has many applications in the broader engineering sector and, indeed, studies into applications such as the use of muon tomography for safety and safeguarding in the nuclear waste sector are underway. In the context of the World Tunnel Congress we see applications in areas such as: TBM look ahead, long-term monitoring of voids post detection, structural evaluation of viaducts and bridges, detection and delineation of underground mine workings adjacent to rail lines (using the borehole sensors mentioned in Section 4), identification of geological voids, sinkhole detection and monitoring, determination and evaluation of hydrological conditions.

6 SUMMARY

Muon tomography is a powerful non-invasive imaging technique capable of returning detail on density changes in an overburden without the need to make contact with the object of interest. Geoptic has successfully pioneered the application of muon tomography to the identification and characterisation of hidden shafts and voids in railway tunnels on the UK's rail network. A number of other potential applications are outlined.

Empirical correlations between ground's mechanical properties and I-system

Chiraag Upadhye* & Sandeep Potnis
MIT World Peace University, India

Bineshian Hoss
Amberg Engineering AG, Australia

ABSTRACT: Design procedure for underground structures, particularly tunnels, relies on engineering classifications as a significant part of empirical and observational approach. Every system, technique, or method has specific scope and limitations due to the vast complexity of natural and physical characteristics of ground i.e., soil mass, rock mass or mixed ground. The Index of Ground-Structure abbreviated as I-System is a comprehensive approach for the classification and characterization of ground. It provides recommendations for support systems, excavation techniques, instrumentation techniques, prevention techniques, forecasting techniques, and design considerations. Using I-system, hundred number of cases are computed. It involves data collection for project located in Indian subcontinent in the Himalayas to evaluate parameters such as the Armature Index, Configuration Index, Hydro Index, Properties Index, Strength Index, Dynamic Forces Impact, and Excavation Technique Impact. This data is computed using I-System Software to obtain ground characterization parameters. Parametric study of the equations of the (I)-GC parameters is interpreted by regression analysis. The results obtained from I-system are compared with Geo-mechanical properties derived from the lab test results on samples. This analysis leads to improve the accuracy of the existing correlations.

Keywords: I-System, (I)-GC, Geomechanical Properties, Regression Analysis

1 INTRODUCTION

Mega projects such as tunnel construction involves number of activities, which are to be carried out at various stages of project. While infrastructure projects like tunnels are proposed, a Detailed Project Report is prepared to check its feasibility. Numerous investigations are conducted to analyse the ground i.e., the medium through which tunnels are constructed. Also, additional geological as well as geo-technical investigations are carried out in the further stages of the project. All this process is performed with the sole purpose of defining the ground in terms of its properties, strength, and character.

For the same reason there has been a development of rock mass classification such as RQD, RMR, Q, and most recently I-System (Bineshian, 2019, 2021). These systems particularly RMR, Q, and I-System include information on strength of the intact rock material, the condition of discontinuities, the orientation and frequency of discontinuities, the influence of subsurface groundwater. All these systems are based

on the empirical approach and were primarily developed for classification of ground and estimation of supports for the underground structures; however, I-System unlike other systems is applicable for underground, semi-surface, and surface structures in rock and soil providing classification as well as characterisation of ground.

2 I-SYSTEM – A BRIEF OVERVIEW

The “Index of Ground-Structure” or I-System (Bineshian, 2019, 2021) is a comprehensive classification and characterization system for ground (rock and soil). It differs conceptually from other classifications due to its applicability to a wide range of ground conditions and structures, as well as its comprehensiveness in providing accurate and precise prediction of ground behaviour based on several geomechanical hazards (failure mechanisms) studied during development.

Its design and practice range includes underground structures (caverns, deep or underground metro

*Corresponding author: sharmachiraag98@gmail.com

stations, exploration and grouting galleries, mine stopes, shafts, tunnels of any type or method, underground spaces, underground storages, wells, and so on), semi-surface structures, and surface structures. It is the first classification that takes into account the problematical and structural configurations of the ground, the scale effect of openings, the negative effect of earthquakes, and the influence of excavation techniques (Bineshian, 2021). Furthermore, it is the first classification that carefully predicts special ground behaviour such as Squeezing, Swelling, and Heaving (SSH), Time Dependent (TD), Viscoelastic Plastic (VP), fully plastic, gravity driven (GD), and Burst Prone (BP) condition.

2.1 I-System input data

Figure 1. I-System's indices and impact factors.

I-System contain important indices that will allow for comprehensive modelling of ground-structure behaviour. It has five indices that define the mechanical response of ground to the structure. It also contains two impact variables that characterise the influence of Dynamic Forces (DF_i) and Excavation Technique (ET_i) on structure. In I-System Figure 1 indices and impact factors are based on easily derivable main properties (i.e., key geomechanical, geostructural, geohydrological, geotechnical, geophysical, and geometrical features) and determinant seismic and excavation factors affecting ground-structure response. Eq 1 depicts I-System mathematically as “(I)”. The indices and impact factors for (I) are defined in Eq 2 to 8 as follows:

$$(I) = (A_i + C_i + H_i + P_i + S_i) \times DF_i \times ET_i \quad (1)$$

$$A_i = (a_{dn} + a_{ds} + a_{di}) \times a_{da} \times a_{dd} \times a_{df} \times a_{dp} \quad (2)$$

$$C_i = C_{pc} \times C_{sc} \quad (3)$$

$$H_i = h_{gc} \times h_{gs} \quad (4)$$

$$P_i = \left[p_{cc} + p_{dc} + (p_{ps} \times p_{pm}) \right] \times p_{bw} \& p_{bw} = f(V_p, V_s) \quad (5)$$

$$S_i = S_{cs} \times S_{se} \quad (6)$$

$$DF_i = f(PGA_{SD}, ERZ, MSK) \& PGA_{SD} \\ = f(PGA, SF, MSF) \quad (7)$$

$$ET_i = f(ET, PPV) \quad (8)$$

2.2 I-System's value

I-System value ranges from 0 to 100 and categorizes the ground-structure interaction into ten classes as (I)-01 to (I)-10, from worst to Best. The indices A_i , C_i , H_i , P_i , and S_i account for 20% of the overall score of 100. (DF_i) and (ET_i) are variables with values ranging from 1 to 0.75 and 1 to 0.50, respectively, that influence the sum of indices Figure 2.

Figure 2. I-System's indices and impact factors.

I-System is distinctive due to its outputs that is (I)-Class and (I)-GC Figure 3

Figure 3. I-System's classification output.

2.3 (I)-GC; I-System's ground characterization

I-System's Ground Characterisation abbreviated as “(I)-GC” characterises the mechanical properties of ground (rock or soil mass) by evaluating most important ground properties including Modulus of Deformation (E_g), Poisson's Ratio (v_g), Unconfined Compressive Strength (σ_{cg}), Uniaxial Tensile Strength (σ_{tg}), Cohesion (C_g), and Internal Friction Angle (ϕ_g). Quantified values provided as output of (I)-GC are estimations based on empirical correlations. (I)-GC's output provides most important input values required in design approach and procedure for underground structures. These empirical equations are developed and examined by author for several cases.

$$E_g = e^{0.05 \times (I)} - 1 \quad (9)$$

$$\nu_g = 0.5 - 0.004 \times (I) \quad (10)$$

$$\sigma_{cg} = 0.007 \times \sigma_c \times e^{0.05 \times (I)} \quad (11)$$

$$\sigma_{tg} = -\sigma_{cg} \times e^{(0.04 \times (I) - 4)} \quad (12)$$

$$C_g = 0.002 \times \sigma_{cg} \times e^{0.05 \times (I)} \quad (13)$$

$$\Phi_g = 15 + 0.55 \times (I) \quad (14)$$

This study improvises the accuracy of the (I)-GC's parameters and adopts specific methodology. The Parameters include three Geo-mechanical properties of the ground as follows:

- i. Modulus of Deformation of the ground (E_g),
- ii. Cohesion of the ground (C_g), and
- iii. Internal Friction Angle of the ground (ϕ_g).

The author of I-System mentioned in his study that the empirical equations which are developed are examined by author for several cases. However, the author stated that the accuracy of these empirical equations may be improvised for better results. As any empirical study depends on the frequency and variety of the cases, the more they are the better results shall be obtained. Assessing the point, the paper focuses to improve the accuracy of the results of the following ground properties.

3 DATA COLLECTION

The USBRL-T01 (Udhampur Srinagar Baramulla Rail Line Tunnel-01) Project is one of the most critical tunnel projects in India where currently I-System is being implemented and hence was selected for the data collection. The T01 Tunnel has two portals viz. P1 and P2. Portal P1 is located at the start of the project i.e., towards Udhampur side and portal P2 on the other side. The overview of the project is described in Section 2.1.

A unique set of procedure is developed to execute the research in this research. Initially, a thorough study to understand I-System's definition, structure, chronology and procedure is accomplished. A framework of process shown in Figure 4 is planned in order to compare the results of I-System and the actual results of the on-site data of the ground properties collected from the reference documents of the project.

For the derivation of the I-Value, the inputs parameters in terms of five indices and two impacting factors are decided based on the actual ground condition. The Table 1 below shows different documents referred for deriving inputs of indices.

Figure 4. Framework.

3.1 USBRL – T01

Tunnel T01 is an important segment of the Udhampur - Srinagar - Baramulla Railway Project (USBRLP) as Indian Railways 'most challenging project. USBRLP with 326 km railway line will provide an alternative and a reliable transportation system to union territory of Jammu and Kashmir (J & K) with the Indian Railway network from Jammu to Baramulla. It has been declared as a project of national importance and the largest project in the construction of a mountain railway since independence of India. It passes through the young Himalayas with tectonized zones including major thrust faults. The client for USBRLP project is Northern Railway (NR) and the project is in the last stage of progress in the balance length from Katra to Banihal.

Figure 5. Longitudinal tunnel profile T01.

Figure 6. USBRL T01 regional topography.

Tunnel T01 includes a single tube tunnel as critical part of the project that has been assigned to Konkan Railway Corporation Limited (KRCL). T01 is crossing the Reasi Thrust (RT) at its 336 m length between CH31804 to CH32140. RT is part of Main Boundary Thrust (MBT) of lower Himalayas. MBT is an active fault zone as one of the major Himalayan thrusts, which is incorporated within the Himalayan over - critical thrust wedge. It is displaced above the Indian lithosphere. The displacement is along the most of MBT's length. T01 with 3209 m length is the most challenging and hazardous tunnel in USBRLP with portal one (P1) chainage at CH29950 and portal two (P2) chainage at CH33159. T01 along its length, crosses through claystone, dolomite, limestone, mudstone, sandstone, shale, siltstone, and scree, alluvium, and colluvium materials in a clayey and silty matrix. Claystone, mudstone, sandstone, shale, and siltstone in T01 contains mica family minerals including muscovite.

Figure 7. T01 P2 tunnel face.

They mechanically deform non - uniformly, which resulting in convergence as a proof of squeezing behaviour.

Figure 8. Crushed dolomite mixed with PU-2C grout.

The construction work of the tunnel T01 is in progress from both the ends. From Km 30/000 to 31/822 rock mass strata is interbedded Sandstone and clay stone after that 31/768 to up-to face is highly fractured and crushed dolomite. From km 33/159 (T1P2) in the initial stretch, the rock mass strata are represented by highly jointed and fractured greyish/whitish cherty dolomite up to km 32/159. After these strata got deteriorated represented by highly sheared greyish/whitish cherty dolomite. When the excavation reached at Chainage 32/140 on 28 August 2016 first collapse occurred with huge flow of water along with material of sheared rock mass. Part of face at this Chainage towards left side had intact rock mass and highly sheared and fractured rock mass in the centre and towards the right side of the face. Probably this was the beginning of the shear zone. Approximately 5000 cum material along with water moved towards portal from the face.

Figure 9. Face butt at T01 P1 tunnel face.

During the excavation from both P1 and P2 end some minor over-break/small cavity have been

recorded in face logs after each round length at various locations and some major failure/large cavity/collapses have also been recorded at both the ends.

3.2 Creation of data pair

The Data pairs created for the USBRL T01 project are abbreviated as **TDP** (T01 Data Pairs). A total of 100 number of cases are selected for computation and analysed after purification of the data pairs. The next procedure is to obtain the values of the geomechanical properties of the corresponding chainages of 100 cases from the Geotechnical Investigation Report (GIR) and Geological Face Maps of the project which are Uniaxial compressive strength of Intact rock (UCS), Rock Quality Designation (RQD), Geological Strength Index (GSI), Hoek and Brown Constant (m_i), Disturbance Factor (D), Intact Modulus (E_i), Unit Weight (γ_{rm}).

3.3 Purification of data pair

A total of 100 cases of TDP data pairs were plotted in a scatter plot between (I)-Value vs geomechanical property. The plot highlighted the data pairs not following the trend. As per the principles of rock mechanics the value of geomechanical property included in this study that are (Eg, Cg, ϕ_g) shall always increase with increase in strength of the ground. This means that the values of these geomechanical properties should increase/decrease with increase/decrease in (I)-Value.

Based on such conditions a purification technique was applied to eliminate the data pairs.

- i. The data pairs representing lower value than the previous data pair were eliminated in an increasing trend and vice versa if necessary.
- ii. The data pairs far away from the trend were eliminated.
- iii. For the data pairs showing different Y values for same X values, the Data pairs obtaining better Coefficient of Multiple Determination (R^2) value were selected.

4 COMPUTATION OF DATA PAIRS

4.1 Evaluation of data pairs for modulus of deformation of the ground (Eg)

The Data pairs created for the USBRL T01 project are abbreviated as TDP (T01 Data Pairs). A total of 100 number of cases are selected for computation and are analysed after purification of the data pairs.

The Figure 10 is the window of I-System's Software in which the input parameters are seen for the underground structure. The window also has options to refer to the nomenclature for better understanding and be confusion free while selecting the input

Figure 10. I-system's software input window for representation.

parameters. Once all the inputs are checked as accepted by the user the compute button will become active. By clicking on the compute button, the window of computation will be generated by the software as shown in Figure 11

Figure 11. I-system's software output window for representation.

I-System's software calculates the values of six geomechanical properties as shown in the Table 2 which is the report generated by the software. It also plots the graphs for whole range of I-Value i.e., from (0-100) as described in Figure 12 defined by the original Eq. 9 - 14

To derive the actual rockmass parameters of the site, RSDData Software by Rocscience which is based on Generalized Hoek and Brown Failure Criterion is used.

Table 2. Input and output parameters for RS Data.

Input Parameters	Output Parameters
Material type	Tensile strength (MPa)
Intact Modulus (MPa)	Uniaxial Compressive strength (MPa)
UCS of Intact rock (MPa)	Modulus of Deformation (GPa)
GSI	Cohesion (MPa)
(Hoek and Brown constant) m_i	
Disturbance Factor (D)	

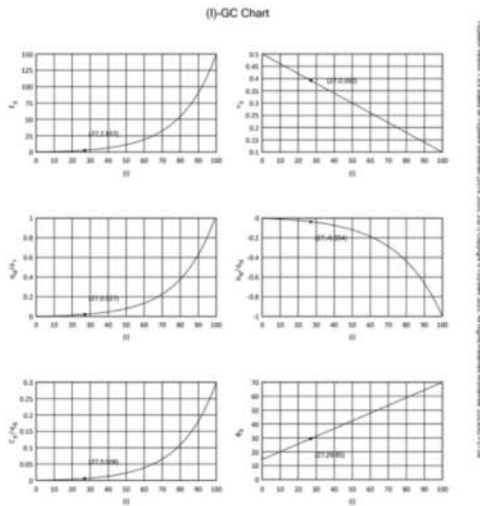

Figure 12. I-system’s software I-(GC) graphs for representation.

The data pairs are in the form of (X, Y) where X represents the (I)-Value and Y represents Modulus of Deformation of the ground (E_g).

The range of X i.e. (I)-Value varies from (20-40).

The range of Y i.e. Modulus of Deformation of the ground (E_g) varies from (1.0 - 5.0 GPa). The TDP data pairs are sorted as per the ascending (I)-Value.

Table 3. TDP Data Pair Summary.

Modulus of Deformation of the ground E_g TDP Summary

(I)-Value	E_g (GPa) I-System	E_g (GPa) RS Data	Total Data Pairs
24	2.320	1.204	1
26	2.669	2.409	13
27	2.857	1.204	19
27	2.857	3.392	6
27	2.857	4.752	2
30	3.482	3.392	5
30	3.482	4.752	47
Total Data Pairs			100

The Table 3 summarizes total case count of 100 cases for the Modulus of Deformation of the ground (E_g) based on the (I)-Value and sorted as purified and un-purified in black and red colour respectively. Out of 100 cases 39 cases were eliminated and 61 cases were selected for regression analysis with maximum coefficient of multiple determination value (R^2) as 0.999

4.2 Evaluation of data pairs for cohesion of the ground (C_g)

The initial chainages of the USBRL project were constructed with conventional as well as NATM

methods. Both the methods produced numerous failures and collapsed for several times. Due to termination of various agencies, the project has insufficient data for evaluation of Cohesion of the ground from the site and hence a modification or correlation cannot be established using the TDP data pairs. Though the need to modify the original equation due to ultra conservative output by the (I)-GC for the Cohesion of the ground (C_g) expressed by Eq. 15 is assessed.

To propose the modification to improve the accuracy of the original equation of Cohesion of the ground (C_g), the source data presented in Table 4 has been obtained from the standard reference notes and geotechnical references.

Table 4. Reference data for cohesion of the ground.

(I)-Value	(I)-Class	Cohesion C_g (KPa)
100 – 91	(I) - 01	1101 – 1350 or greater
90 – 81	(I) - 02	876 – 1100
80 – 71	(I) - 03	676 – 875
70 – 61	(I) - 04	501 – 675
60 – 51	(I) - 05	351 – 500
50 – 41	(I) - 06	226 – 350
40 – 31	(I) - 07	126 – 225
30 – 21	(I) - 08	76 – 125
20 – 11	(I) - 09	51 – 75
10 – 0	(I) - 10	25 – 50 or lesser

The data pairs for performing regression analysis are formed using the data presented in the Table 4. The data pairs are in the form of (X, Y) where X represents the mean (I)-Value of the range presented in the Table 5 and Y represents the mean value of the Cohesion of the ground (C_g) in KPa. The range of X i.e. (I)-Value varies from (0-100). The range of Y i.e., Cohesion of the ground (C_g) varies from (25.0 - 1350.0) KPa.

Table 5. Data pairs for cohesion of the ground.

(I)-Value X	Cohesion of the ground C_g (KPa) Y
95.50	1225.50
85.50	988.00
75.50	775.50
65.50	588.00
55.50	425.50
45.50	225.50
35.50	175.50
25.50	100.50
15.50	63.00
5.00	37.50

4.3 Evaluation of data pairs for friction angle of the ground (ϕ_g)

The original Equation of the (I)-GC for the Friction angle of the ground has produced very accurate and precise results when compared with the actual value of the geotechnical references. Hence, after the thorough assessment and the analysis of the results the original equation and the constants are kept same represented in the Eq. 17

$$\Phi_g = 15 + 0.55 \times (I) \quad (17)$$

The data pairs for performing regression analysis are formed using the data presented in the Table 4. The data pairs are in the form of (X, Y) where X represents the mean (I)-Value and Y represents Friction angle of the ground (ϕ_g) in degrees. The range of X i.e. (I)-Value varies from (0-100). The range of Y i.e., Cohesion of the ground (C_g) varies from (15°-70°).

Table 6. Data Pairs for Friction angle of the ground.

(I)-Value X	Friction angle of the ground ϕ_g (°) Y
100	70.00
90	64.50
380	59.00
70	53.50
60	48.00

5 ANALYSIS AND RESULTS

In this study, DataFit 9.1 software is used to perform data plotting, regression analysis and statistical analysis. It is a science and engineering tool that simplifies the tasks of data plotting, regression analysis (curve fitting) and statistical analysis. It reports the general as well as statistical information about each solved regression model automatically.

Plotting of Scatter Data using DataFit 9.1 software

Figure 13. Scatter data plot for Eg Unpurified data pairs.

The next process after formation of the Data Pairs viz. TDP was the sorting and plotting of the of the Scatter Data as shown in the Figure 4 for the Modulus of Deformation (E_g). The Scatter Data plot highlights the need to for the purification of the data pairs. As some TDP data pairs do not follow the trend are tending to create diversion of the relation. The purification of TDP data pairs is executed as per the conditions mention in section. 2.3.

5.1 Regression analysis of TDP data pairs for modulus of deformation of the ground (E_g)

The regression analysis performed using DataFit 9.1 software has yielded that in the range of (I)-Value (24 - 27) corresponding to (I)-Class - 03 which represents poor ground conditions, the value derived from the RS Data software represented by red colour plot in Figure 14 for the Modulus of Deformation of the ground is representing conservative value than the result derive from the original (I)-GC's Equation of (E_g), represented by black colour plot in Figure 14. The original and new constants are described in the Table 7 derived as the result of the regression analysis performed using Non-linear Model in the form of exponential curve.

Table 7. Equation details for E_g .

Eg-Modulus of the Deformation of the ground (GPa)		Original Constant		Proposed New Constant		R ² Value
Sr. No.	Data Pair	a	b	a	b	
1	TDP 61	0.05	1.00	0.07	4.50	0.999

Figure 14. New equation Vs original equation plot for E_g .

5.2 Regression analysis of data pairs for cohesion of the ground (C_g)

The regression analysis performed on the data pairs described in Table 8 using Non-linear Model in the

form of exponential curve plotted in red colour shown in Figure 15.

Table 8. Equation details for C_g.

C _g -Cohesion of the ground (KPa)			Y=Exp (a*x)*b				
Sr. No.	Data Pair	Case Count	Original Constant		Proposed New Constant		R ² Value
			a	b	a	b	
1	Ref	10	0.05	0.002	0.03	73.0	0.981

Figure 15. New equation Plot for C_g.

5.3 Regression analysis of data pairs for friction angle of the ground (ϕ_g)

The regression analysis performed on the data pairs described in Table 9 using linear Model and plotted in black colour shown in Figure 16.

Table 9. Equation details for ϕ_g .

C _g -Cohesion of the ground (KPa)			Y=Exp (a*x)*b		
Sr. No.	Data Pair	Case Count	Original Constant		R ² Value
			a	b	
1	TDP	11	0.55	15.00	1.00

6 CONCLUSION OF THE STUDY

6.1 Deriving new constant

The original equations of the (I)-GC's properties in I-System are in exponential as well as linear form mentioned in the Eq. (18-20).

Figure 16. Original equation plot for ϕ_g .

Table 10. Statistical summary of the analysis.

Sr. No.	Properties	Constants a	b	Coefficient of Multiple Determination (R ²)
1.	Modulus of Deformation of the ground (E _g)	0.07	4.50	0.999
2.	Cohesion of the ground (C _g)	0.03	73.00	0.981
3.	Friction angle of the ground (ϕ_g)	0.55	15.00	1.00

$$E_g = e^{0.05 \times (I)} - 1 \quad (18)$$

$$C_g = 0.002 \times \sigma_{cg} \times e^{0.05 \times (I)} \quad (19)$$

$$\Phi_g = 15 + 0.55 \times (I) \quad (20)$$

After the thorough analysis and its interpretation, the New Equation for the (I)-GC's Modulus of Deformation of the ground (E_g) proposed for the (I)-Value ranging between 20-40 is

$$E_g = e^{0.07 \times (I)} - 4.50 \quad (21)$$

After the thorough analysis and its interpretation, the New Equation for the (I)-GC's Cohesion of the ground (C_g) proposed for the (I)-Value ranging between 0-100 is

$$C_g = e^{0.03 \times (I)} \times 73.00 \quad (22)$$

After the thorough analysis and its interpretation, the Original Equation for the (I)-GC's Internal Friction Angle of the ground (ϕ_g) proposed to keep same for the (I)-Value ranging between 0-100 is

$$\Phi_g = 15 + 0.55 \times (I) \quad (23)$$

ACKNOWLEDGMENTS

Expressing my sincere gratitude to inventor of I-System, Dr Bineshian Hoss and all his team of USBRL T01 for their immense support and guidance. Also thanking Dr Sandeep Potnis for his continuous guidance and strong support. Lastly to my colleague Mr Karan Lakhani for being together in this journey.

ABSTRACT: In order to solve the design problem of the long tunnel of the water-rich karst platform in the compound syncline basin, the long tunnel with strong karst development – Yuanguping Tunnel is taken as an engineering example, the karst hydrogeology and surrounding environment topography and geomorphology are fully verified, and the comprehensive treatment of the karst in Yuanguping Tunnel is carried out for a long time by the method of engineering analogy, so as to ensure the safety of the tunnel construction and operation. The key design technologies are as follows: (1) The key design technologies such as drainage tunnel, drainage branch tunnel and grouting water plugging are adopted to solve the water gushing problem of the karst tunnel; (2) Drainage tunnels are set on both sides of the tunnels to solve the problem of groundwater backfilling tunnels in Huangyuxi Reservoir and Baiyangping Depression; (3) Combined construction of flue and drainage tunnel is adopted, with the upper layer as the smoke drainage area and the lower layer as the water drainage area to solve the problem of disaster prevention and smoke drainage in the long tunnel. The design case of this paper can be used as a reference for similar tunnels.

Keywords: Syncline, Karst, Rich water, Drainage tunnel, Back irrigation

1 INTRODUCTION

Karst is one of the common diseases when building highway tunnels in limestone areas. Its surface morphology is mainly characterized by solution cracks, solution grooves, sinkholes, and corroded depressions, and locally, there are karst funnels, skylights, shafts, karst trough valleys, and compound development of different karst forms. The development forms of underground karst are mainly joint fissures, dissolution, karst fissures, karst caves and karst water passages. The degree of karst development is controlled by lithology, folds, faults, groundwater and topography. It can be divided into three grades: strong, medium and weak. At present, the karst development grade of highway karst tunnels built in China is mostly weak or medium, the design treatment cost is not high, and the treatment measures are relatively mature (Zhao et al., 2022, Li et al., 2020, Wu et al., 2021). For tunnels with large karst bodies and strong karst development in general, there is still a lack of experience in engineering

treatment. At present, a lot of research has been carried out on the problem of karst in the industry, mainly focusing on the advanced prediction of single karst (Zhang et al., 2020, Cheng, 2020, Yan, 2021, Zhou et al., 2017) and the treatment measures of karst (Zhu and Zhu, 2021, Guan and Yang, 2018, Wang et al., 2020, Jiang and Zhang, 2022). However, there are few research reports on the comprehensive treatment measures that are mainly karst and accompanied by other problems such as high pressure and rich water.

Yuanguping Tunnel of Zhangguan Expressway passes through Wuling Mountain area. The surrounding rock of the whole tunnel is mainly argillaceous limestone, and the overall karst development is very strong. In addition, the groundwater in the tunnel area is very rich, which is a high-pressure water-rich zone. The tunnel passes through 8 folds and 7 fault zones, and the geological conditions are very complicated. In summary, the Yuanguping Tunnel of Zhangguan Expressway faces many problems such as strong karst, high pressure and rich water, and complex geological

*Corresponding author: 253484901@qq.com

conditions. Its key design and treatment technology are worthy of reference for similar projects in the future.

2 ENGINEERING OVERVIEW AND RISK ANALYSIS

Yuanguiping Tunnel is one of the control projects of Zhangjiajie-Guanzhuang Expressway. The highway belongs to the section of the national highway G59 Hohhot-Beihai Expressway. It is located in the northwest of Hunan Province and spans the Wuling Mountain area. The terrain is undulating and the geological conditions are complex. The tunnel is located at the junction of Yuanguiping Town and Jinyan Tujia Township in Yongding District, Zhangjiajie City, Hunan Province. The entrance of the tunnel is located at 600 meters to the south of Quanjiayu in Jinyan Township, and the exit of the tunnel is located at about 150 meters to the northwest of Ganxiwan in Yuanguiping Town. The Yuanguiping Tunnel is arranged in a double-hole separated layout. The pile number of the left line is ZK14 + 178 ~ ZK19 + 329, with a length of 5151 m, and the pile number of the right line is K14 + 185 ~ K19 + 312, with a length of 5127 m. It is an extra-long tunnel with a longitudinal slope of 8 ‰ and a maximum burial depth of 423 m. The surrounding rock of the tunnel area is mainly argillaceous limestone. At present, the plane line of the tunnel is basically set along the groundwater watershed, and the amount of water is relatively small. And the tunnel line position is basically perpendicular to the direction of the maximum horizontal ground stress, which is conducive to tunnel support and surrounding rock stability, as shown in Figure 1. Although the route selection has been fully considered, the design and construction risk of Yuanguiping Tunnel is still huge.

Figure 1. The plane of the tunnel.

2.1 Topography

The site of the tunnel is a medium-low mountain tectonic dissolution karst platform landform. The mountain is ridge-shaped, with some peak-shaped and hilly mountains, including micro-topography such as upland, karst, hills and flats. The mountain area accounts for more than 80 % of the total area. Various external dynamic geological processes denuded and accumulated the ground in the tunnel site area, forming an approximately flat uniform surface, which formed a relatively flat karst platform landform with steep cliffs around the top of the mountain, as shown in Figure 2. The surrounding rock of the whole tunnel is mainly argillaceous limestone, and the overall karst development is strong. The average line karst rate is 21.3 %, as shown in Figure 3.

Figure 2. Karst terrace.

Figure 3. Strong karst.

2.2 Compound syncline and large water inflow

A total of 8 folds are developed in the Yuanguiping Tunnel. Among them, the Guojiajie syncline (f23) is the largest, which is a regional controlled fold, and the rest are secondary folds, which are caused by the influence of locally developed fault structures, and the development scale is slightly smaller. Most of the area of the tunnel is located in a large composite syncline tectonic belt composed of several sub-level anticlines and synclines, as shown in Figure 4.

Figure 4. Compound syncline.

The water system of the working area belongs to the Yuanshui River system, a tributary of the Yangtze River. The main rivers are Quankou Creek (Gaojia Creek), Chixi River and Leigong Creek. Most of the rivers flow from northwest to southeast. Due to the wide distribution of carbonate rocks, the surface streams are mostly recharged by springs and underground river outlets, showing the characteristics of alternating distribution of open and ambush streams. Most of the tunnel site is in a water-rich area, and the surrounding surface has long-term running water. The slope catchment area is large, and the surface runoff dissipates quickly during rainfall. Most of the surface runoff flows into vertical karst pipelines such as karst funnels and sinkholes, and then discharges through horizontal karst pipelines. There is surface water in the depression ponds and gullies along the Dahu Village in the northwest of the working area. A small part of surface runoff, such as Mula River and Hanshui River, flows into Lishui River from southeast to northwest. Seasonal water flow exists on both sides of the tunnel and in the gullies at the foot of the slope at the inlet and outlet ends.

2.3 Surface reservoirs and karst depressions

In addition to the surface streams, the upper Huangyuxi Reservoir and the lower Huangyuxi Reservoir are located on the left side of the ZK15 + 150-890 section of the Yuanguping Tunnel, which is 0.6 km away from the left line of the tunnel entrance section. The reservoir capacity of the upper Huangyuxi Reservoir is 138,000 m³, which is discharged through the lower Huangyuxi Reservoir. The reservoir capacity of the lower Huangyuxi Reservoir is 547,000 m³. The two reservoirs are mainly irrigated and have benefits such as flood control and fish farming. The total irrigated area is 650 mu and approximately 450 people are protected. The F2 fault developed at ZK15 + 660 of tunnel strikes northeast and crosses Huangyuxi Reservoir and Yuanguping Tunnel. Geological survey shows that the fault bandwidth is 2-5 m. The influence bandwidth of the fault is tens of meters, and the rock mass on both sides is nearly vertical, and the rock mass in the zone is broken, and the joint fissures are developed. This zone is easy to become a water gushing channel for tunnels and reservoirs. The flood level of the upper Huangyuxi Reservoir is 804.74 m, which is discharged through the lower Huangyuxi Reservoir. The dam crest elevation of the lower Huangyuxi Reservoir is 788.65 m, and the flood level is 788.32 m. The design elevation of the tunnel is about 510 m, and the head difference is about 279 m, as shown in Figure 5 and Figure 6. The reservoir will pose a potential threat to the construction and later operation of the tunnel. Under the action of fault F2, the cracks generated by it will establish a hydraulic connection between the lower Huangyuxi Reservoir and the lower aquifer, which will increase the risk of water gushing in the tunnel.

Figure 5. Head height difference.

Figure 6. Huangyuxi Reservoir.

Figure 7. Baiyangping Depression.

Baiyangping Village on the southwest side of the K17 + 000-K18 + 00 section of the right line of the tunnel is the main catchment area of groundwater in the right area of the tunnel, as shown in Figure 7. The river is about 3km long, and there are many sinkholes, F3, F4 fault zones and joint cracks. Water flows into the river all the year round. The catchment depression area in Baiyangping Village is large. The lowest groundwater level elevation is 575m, about 1.5km from the right line of the tunnel. The design elevation of the tunnel is about 508m, and the water level difference is 67m.

2.4 Risk analysis of Yuanguping Tunnel

The tunnel stratum is dominated by carbonate rocks. The tunnel site area is a typical karst platform landform. The karst development is strong, and the possibility of hall-type karst caves is very large. It crosses the Guojiajie compound syncline water storage structure, and the groundwater in the core section of the syncline is rich and the pressure is large. The Yuanguping Tunnel is a water-rich karst platform tunnel with a compound syncline basin structure. The water-rich volume is huge, which is easy to cause mud and water inrush. The design and construction

risk is large, and the tunnel construction is extremely likely to expose karst pipeline water or underground river. The horizontal distance between the left line of the tunnel entrance and Huangyuxi Creek is about 780 m, and the head difference is 278 m, with high head pressure. The F2 fault developed at K15 + 660 on the left side of the tunnel entrance passes through the Huangyuxi Reservoir and Yuanguping Tunnel. The geological survey shows that the fault bandwidth is 2-5 m, and the influence bandwidth of the fault is tens of meters. The rock mass on both sides is nearly vertical, and the rock mass in the zone is broken, and the joints and fissures are developed. This zone is easy to become a water gushing channel between the tunnel and the reservoir. The reservoir water of Huangyuxi Reservoir is easy to flow backward along the fault zone, forming a major water gushing accident. The catchment depression area in Baiyangping Village on the right side of K17 + 000-K18 + 00 section of the tunnel exit is large, and the water volume increases sharply and the discharge is not smooth in the rainy season. Under natural conditions, because the tunnel is located in the underground watershed, the groundwater flows from the tunnel to both sides. However, after the tunnel excavation, the groundwater on both sides of the tunnel can pour into the tunnel along the groundwater pipeline, F3 and F4 fault zones and joint fissures, forming a huge water gushing in the tunnel. Yuanguping Tunnel should focus on solving the problem of high pressure and rich water; in addition, the length of Yuanguping Tunnel is more than 5000 m, so it is necessary to solve the problem of disaster prevention and smoke exhaust. In

general, the main problems solved by Yuanguping extra-long tunnel are karst, high pressure and rich water, disaster prevention and smoke exhaust.

3 KEY DESIGN TECHNOLOGIES OF YUANGUPING EXTRA-LONG TUNNEL

3.1 Treatment of karst water

3.1.1 Drainage tunnel

The high-pressure water-rich tunnel structure can be directly subjected to high water pressure by anti-water pressure lining, or the high water head can be avoided by reducing the water head. The strong karst development section of Yuanguping Tunnel accounts for a high proportion of the total length of the tunnel, and through the syncline core, and the tunnel water inflow is 270,000 m³/d. If the anti-water pressure lining structure is adopted, the tunnel structure will bear a high water head of 50-250 m. The cost of the anti-water pressure lining is shown in Table 1.

According to the head pressure of each section of Yuanguping Tunnel, if the anti-water pressure lining of 'mainly blocking' is adopted, the tunnel needs to be equipped with 800m long KSY-2.5 lining, 400m long KSY-2.0 lining, 1100m long KSY-1.5 lining and 1000m long KSY-0.7 lining. It is expected that the whole tunnel will increase the investment of 574 million yuan, and the economic and energy-saving benefits will be reduced. Moreover, there are many engineering cases of serious diseases or even structural damage after the completion of high-head tunnels at home and abroad. For example, the Yuanliangshan Tunnel of the Chongqing-Huaihua Railway adopts a lining structure with thickness of 1.2 m, and a double-layer rail is set inside to strengthen the

Table 1. Investment risk table of anti-water pressure lining.

Serial number	Lining name	Design head height	Secondary lining thickness	Single hole linear meter cost of the main structure (considering full head anti-water pressure lining during operation)	Estimate of single tunnel linear meter for surrounding rock reinforcement measures (encountered in the construction of high water pressure)	Single hole estimation extension index (lining + grouting)
1	KSY-0.7	70m	65/70cm	118000	—	118000
2	KSY-1.0	100m	75cm	153000	—	153000
3	KSY-1.5	150m	100cm	154000	3.5 m reinforcement ring 0.15 filling rate 34000 (radial grouting)	208000
4	KSY-2.0	200m	115cm	193000	4 m reinforcement ring 0.15 filling rate 40000 (radial grouting)	233000
5	KSY-2.5	250m	145cm	208000	4.5 m reinforcement ring 0.15 filling rate 48000 (radial grouting)	256000

stiffness of the tunnel structure, but the lining cracks and leaks seriously after completion. After the completion of Huayingshan Tunnel of Guanglin Expressway, a sudden mud gushing and water inrush accident occurred, resulting in the interruption of traffic in this direction of the tunnel. The Smart Tunnel in Malaysia passes through the karst area, and is closed after two years of operation due to structural damage. Hundreds of large-scale water and mud gushing occurred in the construction of the new Dabashan Tunnel on the second line of Xiangyu, which caused many shutdowns on site. Finally, a drainage tunnel was added to reduce the potential energy pressure and reduce the influence of high water head on the lining structure.

It can be seen that the risk of failure of the anti-water pressure lining structure is large, and the cost of anti-water pressure lining is high, so the economy of large-scale use in this project is unreasonable. It is proposed to adopt the scheme of “discharge-based and limited discharge.” On the premise of not changing the regional hydrology, the hydrodynamic pressure of groundwater around the tunnel is reduced by parallel discharge tunnels, as shown in Figure 8. So as to solve the problem of water gushing (mud inrush) caused by uncovering karst pipelines or karst development sections in tunnel construction or insufficient drainage capacity of tunnel central ditch in the operation stage, so as to solve the problem of high pressure and rich water in Yuanguping Tunnel. Horizontal branch holes are set up in the strongly developed karst section to assist drainage, as shown in Figure 9.

Figure 8. Drainage holes.

Figure 9. Drainage branch holes.

The transverse branch tunnel is set at the connection part between the discharge tunnel and the main tunnel. The discharge tunnel is connected to the main tunnel by the lower connection mode, which is perpendicular to the main tunnel and the discharge tunnel. The transverse branch tunnel is located below the inverted arch of the main tunnel, forming a separated interchange structure with the main tunnel. The central ditch of the main tunnel can be discharged into the transverse branch tunnel through the shaft, and the maintenance and repair of the discharge tunnel can enter the discharge tunnel from the ladder that perpendicularly intersects the main tunnel.

3.1.2 Drainage tunnel size

The control factors of the discharge tunnel section are as follows: ① The maximum drainage volume is determined according to the rainstorm condition of 270,000 square/d; ② The construction requirements of the discharge tunnel are determined according to the operation size of the medium-sized slag skimmer. In addition to considering the drainage capacity, the convenience and mechanization level of construction should also be considered. Considering the current mechanical application of mine engineering, it is proposed to use the slag skimmer with the dump truck to carry out the slag discharge construction. At present, the construction space generally required by the medium-sized crawler slag skimmer is about 4×4m. Combined with the requirements of dump truck transportation, the section to be adopted in this project is an arched section of 4.8m×5m (width × height). The standard discharge tunnel adopts a straight wall circular arch section with a cross-sectional area of 22 square meters. The longitudinal slope of the discharge tunnel is 0.4%. The discharge capacity is greater than the maximum water inflow of the Yuanguping Tunnel, which is 270,000 m³/d, and has a certain surplus to meet the drainage requirements. The size of the drainage branch tunnel is set at 2.4m×2.9m. Since the transverse tunnel is short, it can be constructed by small machinery.

3.1.3 Pre-design of grouting scheme

After advanced geological prediction, in view of the water-rich areas such as filling large karst caves and water-rich joint fissure dense zones where water inrush (mud) may occur, measures such as full-section deep hole pre-grouting and surrounding grouting after excavation can be taken in combination with the actual situation to carry out grouting and water plugging reinforcement treatment. The tunnel passes through a large filled karst cave or cave with poor self-stability, a contact zone between soluble rock and non-soluble rock, a dense zone of water-rich joint fissures, and a bedrock section with extremely developed groundwater. There are 2/3 full holes in the advanced exploration hole or the total water output is greater than 15m³/h. Combined with the core and water pressure analysis, it is determined that when there is a possibility of mud and water inrush, the grouting reinforcement measures of the full section surrounding rock 6m ahead of the excavation line are adopted, as shown in Figure 12. The tunnel passes through the dense zone of water-rich joint fissures and the bedrock area where groundwater is extremely developed. Through the advanced geological prediction results, it is judged that there is no possibility of water inrush in the tunnel, but the surrounding rock is weak and the self-stabilizing ability is poor, which is prone to collapse accidents. After excavation, the full-ring radial grouting reinforcement of 3m outside the excavation line is adopted, as shown in Figure 13.

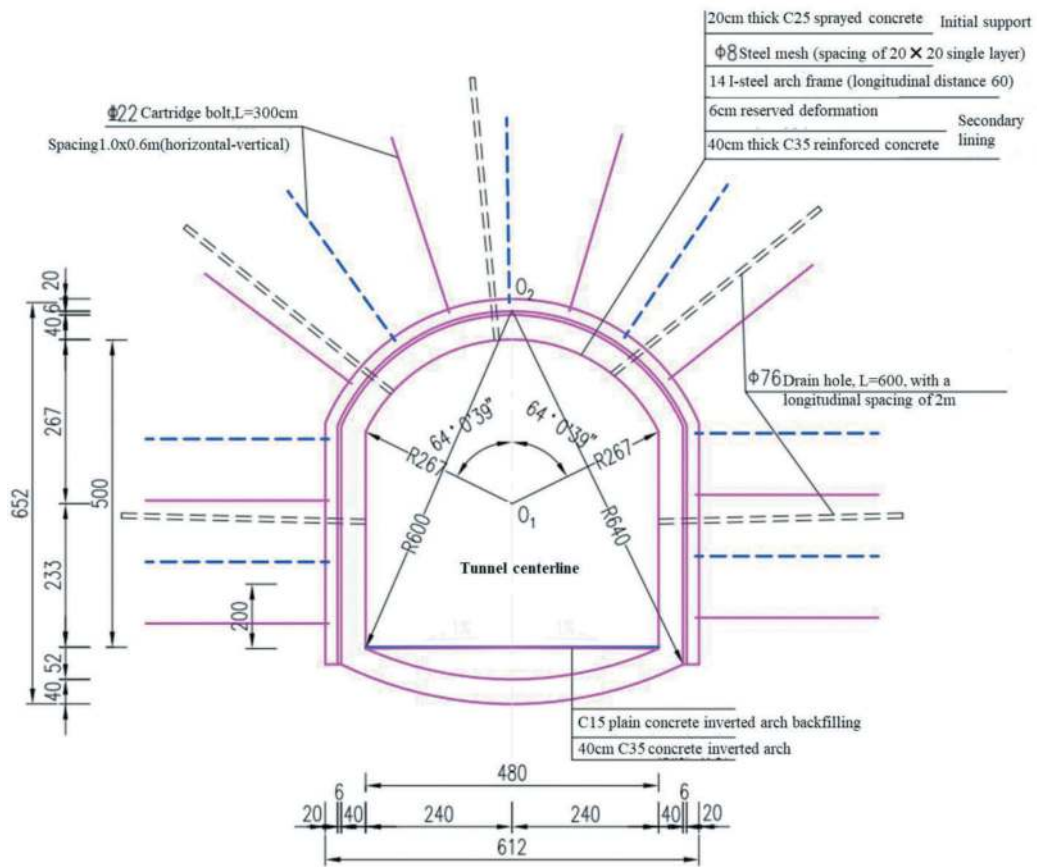

Figure 10. Cross-section of the drainage hole.

Figure 11. Cross-section of drainage branch hole (unit: cm).

According to the geological survey data, the pre-grouting, post-excavation grouting and supplementary grouting measures are designed for the grouting reinforcement of surrounding rock in the tunnel. In

the actual construction, the grouting scheme and paragraph should be adjusted in time according to the proved water volume, water pressure and dynamic changes.

Figure 12. Advanced curtain grouting (unit: cm).

Figure 13. Radial grouting reinforcement (unit: cm).

3.2 Groundwater backflow treatment in Huangyuxi Reservoir and Baiyangping Village

Huangyuxi Reservoir with local land for irrigation and aquaculture is located 600m to the left of tunnel K15+150-890 section. The reservoir capacity is 547,000 m³, and the height difference between the bottom of the reservoir and the tunnel pavement is 278 m. The reservoir water of Huangyuxi Reservoir is easy to flow backward along the fault zone, forming a major water inrush accident. Because the main groundwater flow direction of this section is located on the left side of the tunnel, the drainage system layout on the left side of the tunnel should be strengthened. The P1 drainage tunnel is set up on the 33 m left side of the Zhangjiajie end of the tunnel, P1K14 + 192 ~ P1K16 + 610, 2418 m long; The karst depression of Baiyangping Village on the right side of the exit section of the tunnel is the main water accumulation area of groundwater. Its ground elevation is above 600 m, and the terrain is relatively gentle. There is a risk that groundwater in the Baiyangping Depression pours into the tunnel along the karst channel and joint fissures, forming a huge water gushing in the tunnel. The drainage setting on the right side of the tunnel should be strengthened. A P2 drainage tunnel is set up at 33 m on the right side of the Guanzhuang end, P2K16 + 500 ~ P2K19 + 325, 2825 m long, as shown in Figure 14. The key measures of transverse branch tunnel, anti-water pressure lining and grouting water plugging are adopted at the core of the syncline and fault fracture zone. The transverse branch tunnel of water discharge is set at a spacing of 500m.

Figure 14. Floor plan of the drainage hole.

3.3 Disaster prevention and smoke exhaust

The length of the Yuanguping Tunnel is 5151 m. According to the provisions of Article 10.2.7 of the “Guidelines for Design of Ventilation of Highway Tunnels,” the maximum travel length of fire smoke in the tunnel should not be greater than 5000 m. Therefore, a smoke exhaust duct was set up at the Zhangjiajie end of the tunnel.

The left hole of the tunnel is set at ZK14 + 680, and the right hole is set at K14 + 700. The connecting air duct is perpendicular to the main hole, as shown in Figures 15 and 16. According to the calculation, the air volume required for tunnel exhaust is 244m³/s, and the wind speed in the exhaust duct should not be greater than 13 ~ 20m/s, so the clearance area of the exhaust duct should not be less than 18m². From the perspective of construction space and structural safety, the proposed section of the exhaust flue is a 4.8m×4.6m (width × height) straight wall arch section, with a section area of 22.1m². In order to reduce the scale of the project, the combined construction of the smoke exhaust duct and the water discharge tunnel is adopted. In the P1K14 + 192 ~ P1K14 + 715 section of the water discharge tunnel, the water discharge tunnel structure and the smoke exhaust duct structure are combined and set as the smoke discharge tunnel. The upper layer is the smoke discharge area, and the lower layer is the

Figure 15. Smoke exhaust channel.

Figure 16. The relationship between the smoke drainage hole and the main cave.

Figure 17. Section of smoke and drainage hole (unit: cm).

water discharge area, so as to realize the independent function partition, as shown in Figure 17. An axial flow fan is installed at the opening of the smoke exhaust channel to fully exhaust smoke.

4 CONCLUSIONS AND SUGGESTIONS

In order to solve the design problem of the extra-long tunnel in the water-rich karst platform of the compound syncline basin, this paper takes Yuanguping extra-long tunnel with strong karst development as an engineering example. The conclusions are as follows:

- (1) The 'discharge-based, limited discharge' scheme is adopted. The problem of high pressure and rich water in Yuanguping Tunnel is solved by setting parallel discharge tunnel and discharge branch tunnel to reduce the hydrodynamic pressure of groundwater around the tunnel, and grouting and water plugging measures are adopted in the high risk section of water and mud inrush.
- (2) The P1 discharge tunnel (P1K14 + 192 ~ P1K16 + 610) is set up on the left side of the Zhangjiajie end of the tunnel, which is 2418 m long. It solves the problem that the groundwater of the Huangyuxi Reservoir on the left side of the Zhangjiajie section is poured backward along the fault zone to form a major water inrush accident. The P2 drainage tunnel (P2K16 + 500 ~ P2K19 + 325) is set up at 33 m on the right side of the Guanzhuang

end, which is 2825 m long. It solves the problem that the groundwater in the Baiyangping Depression on the right side of the Guanzhuang section pours into the tunnel along the karst channel and joint fissures to form a huge water gushing in the tunnel.

- (3) The P1K14 + 192 ~ P1K14 + 715 section of the discharge tunnel combines the structure of the discharge tunnel with the structure of the smoke exhaust duct. The length of the joint construction section is 523 m. The Zhangjiajie end of the discharge tunnel is set to be double-layer. The upper layer is the smoke exhaust area, and the lower layer is the discharge area, which realizes independent functional zoning. On the basis of reducing the scale of the project, the problem of disaster prevention and smoke exhaust in extra-long tunnels of more than 5 kilometers is fully solved.

Numerical simulation of the mechanism of strain rockburst under true triaxial loading and unloading conditions

Yadong Xue & Hengjiao Tian*

Tongji University, Shanghai, China

Key Laboratory of Geotechnical and Underground Engineering, Ministry of Education, Shanghai, China

ABSTRACT: Rockburst represents a prevalent hazard in the excavation of deep tunnels, posing substantial risks such as severe economic losses, casualties, equipment damage, and schedule delays. Among the various forms of rockburst, strain rockburst is notably common, underscoring the critical importance of investigating the impact of three-direction pressure value variations on its intensity. To delve into this phenomenon, numerical simulations were conducted utilizing 3DEC software to monitor and analyze kinetic energy, joint friction work, total strain energy, and overall energy release across 10 distinct working conditions. Concurrently, a network of 10 monitoring points was established, with a specific focus on scrutinizing velocities and displacements at points 4 and 10. The findings reveal a consistent pattern in the influence of both the maximum compressive stress (σ_{\max}) and the minimum compressive stress (σ_{\min}) on the occurrence of rockburst intensity. As these stresses increase, so does the intensity of rockburst. Conversely, the intermediate compressive stress (σ_{int}) exhibits minimal impact on rockburst intensity. In practical terms, managing and controlling the maximum compressive stress (σ_{\max}) and minimum compressive stress (σ_{\min}) emerges as a pivotal strategy to mitigate rockburst intensity. This research not only sheds light on the governing principles behind rockburst occurrence but also provides valuable guidance for engineering applications in the realm of rockburst control.

1 INTRODUCTION

With the swift advancement of infrastructure development in western China, the prevalence of deep-buried tunnels is on the rise. Among the formidable challenges faced during the construction of these tunnels, rock burst stands out as a particularly severe disaster (Lijie et al., 2021, Dong et al., 2017).

The incidence of rock bursts is typically characterized by its randomness, suddenness, and destructive nature. Rockbursts can result in significant economic losses, casualties, equipment damage, and schedule delays, among other consequences. Categorized by their breeding mechanisms, rockbursts are broadly classified into three types: strain rockbursts, strain structure surface slip rockbursts, and fracture slip rockbursts. Among these, strain rockbursts are most commonly observed in underground engineering, particularly in hard rock tunnels or deep mining operations (Li et al., 2019, Yang et al., 2020, Yinghua and Fei, 2020). The formation process of rockbursts is intricate, lacking a comprehensive theory to fully explain it. Consequently, rockbursts have garnered

considerable attention from scholars due to their complex and unpredictable nature.

In the past three decades, the research on the mechanism of rock explosion has been carried out from various angles, mainly including engineering phenomena (TAN, 1989), indoor tests (He et al., 2019, He et al., 2015, Su et al., 2018), theoretical analyses (LI, 1997, Li, 2019, ChunlinLi, 2021), numerical simulations (Yu et al., 2022, Yi et al., 2021, Zhang et al., 2020) and so on. Early research on rock bursts mainly from the engineering phenomenon. Bingrui et al. (2011) through the microseismic monitoring signal characteristics of the research on rock bursts. Chongyan et al. (2020) through the granite specimens containing round holes under different lateral load rock burst simulation tests, the use of micro-cameras, acoustic emission (AE) system and infrared thermography and other monitoring systems, analyse the rock burst process of acoustic emission timing, frequency, spatial and temporal characteristics and thermal imaging of the temperature transport law. He et al. (2019) studied the effect of stiffness on

*Corresponding author: 2010hjtian@tongji.edu.cn

the strain rupture of laminated sandstone with different inclination angles through indoor tests. ChunlinLi (2021) considered the development process of rockbursts from the energy point of view, and accordingly gave the supporting structure to prevent rockbursts should be designed with high load and displacement bearing capacity at the same time. Engineering phenomena have been of great help in the study of early rockbursts, but it is difficult to explain the intrinsic reasons for the occurrence of rockbursts. Indoor tests have a complex test programme development, test operation is difficult, and can not provide timely guidance to the field. Theoretical analysis to consider the problem can not be too complex, using many approximations and assumptions. In contrast, numerical simulation to consider the problem can be more complex and comprehensive, to obtain more information, with theoretical research and experimental research part of the advantages.

According to the research conducted by scholars in the field, numerical simulation methods primarily include the finite element method and the discrete element method. Given that rock burst involves significant deformation within a short time frame, the discrete element method proves more advantageous compared to the finite element method. PFC stands out as a representative discrete element software; however, the calibration process can be quite intricate to achieve a particle aggregate resembling the macroscopic properties of the rock body in the field. Both 3DEC and PFC are products of Itasca, yet 3DEC software distinguishes itself by not requiring complex calibration. It has the capability to directly utilize the macro-parameters of the rock, streamlining the simulation process. Additionally, the built-in functions of 3DEC software facilitate the easy retrieval of energy data for each component. Given the strong correlation between rock bursts and energy, employing 3DEC software for numerical simulation presents a significant advantage.

In this study, the 3DEC software was employed to explore the impact of variations in the three principal stresses on the severity of rockbursts, considering actual ground stress conditions. This was achieved by simulating the behavior of the rock mass under loading and unloading conditions. Ten distinct working conditions were simulated in the numerical tests, and the observed patterns from these tests contribute valuable insights for a more comprehensive understanding of the mechanisms governing strain rockbursts.

2 3DEC NUMERICAL SIMULATION

3DEC is primarily intended for analysis in rock engineering projects, ranging from studies of the progressive failure of rock slopes to evaluations of the influence of rock joints, faults, bedding planes,

etc. on underground excavations and rock foundations. 3DEC is ideally suited to study potential modes of failure directly related to the presence of discontinuous features. Both manual and automatic joint generators are built into 3DEC to create individual (and sets of) discontinuities that represent jointed structure in a rock mass. A wide variety of joint patterns can be generated in the model. In addition, a discrete fracture network (DFN) generator is included in 3DEC. Rockburst processes are intricately linked to energy dynamics, and the 3DEC software's built-in functions facilitate the straightforward acquisition of energy values. Additionally, the 3DEC software allows for the direct input of macro-mechanical parameters. Consequently, utilizing 3DEC software for rockburst analysis offers distinct advantages.

2.1 Energy relations in 3DEC

The total energy balance can be expressed in terms of the released energy (W_r), which is the difference between the work done at the boundary of the model and the total stored and dissipated strain energies (Salamon, 1984):

$$W_r = W - (U_t + U_b + W_j + W_p) \quad (1)$$

where, W_r denotes released energy, W denotes total boundary loading work supplied to the system, U_c denotes total stored strain energy in material, U_b denotes total change in potential energy of the system, W_j denotes total dissipated energy in joint shear, and W_p denotes total dissipated work in plastic deformation of intact rock.

A second calculation of released energy can be made based on the kinetic energy, mass damping work, the work performed at viscous boundaries, and the strain energy in excavated material:

$$W_r = U_k + W_k + W_v + U_m \quad (2)$$

where, U_k denotes current value of kinetic energy in the system, W_k denotes total work dissipated by mass damping, W_v denotes work done by viscous (non-reflecting) boundaries, and U_m denotes total strain energy in excavated material.

Usually, the second form of the released energy is particularly useful for dynamic problems because the released kinetic energy is easily calculated.

Joint type	Normal stiffness (k_n) / (Pa/m)	Tangential stiffness (k_s) / (Pa/m)	Cohesion (c) /(Pa)	Internal friction angle (φ) / (°)	Tensile strength (σ_t) / (Pa)
virtual joints	3×10^{12}	1.5×10^{12}	4×10^7	33.69	5×10^6
the newborn joints	3×10^{12}	1.5×10^{12}	8.37×10^6	5	0

2.2 Numerical test programme

2.2.1 Numerical modelling

Numerical simulations were carried out using 3DEC software, the software version used was 3DEC 7.0, and the dimensions of the simulated rock samples in terms of length, width and height were $0.05\text{m} \times 0.05\text{m} \times 0.05\text{m}$ as shown in Figure 1.

For numerical simulations, the relevant mechanical parameters of the rock mass (block) in the 3DEC model are shown in Table 1, and the relevant mechanical parameters of the joints in the 3DEC model are shown in Table 2.

In the above simulations, the blocks are modelled using the Mohr-Coulomb constitutive model, and all blocks are assigned the corresponding mechanical parameters. joints are modelled using the default Mohr-Coulomb constitutive model, and all joints are assigned the corresponding mechanical parameters.

2.2.2 Loading and unloading programmes

In the simulation of rockbursts, the cubic rock specimen is initially subjected to loading on all six faces using 3DEC software, and the process extends over 2000 steps. Subsequently, it undergoes unloading from one of the lowest compressive stress values (simulating real-life tunnel excavation conditions), and this phase continues for 4000 steps. The loading and unloading processes are illustrated in Figure 2.

In Figure 2, σ_{\max} represents the maximum compressive stress, σ_{int} represents the intermediate compressive stress, and σ_{\min} represents the minimum

Figure 2. (a) Rock sample loading process (b) Rock sample unloading process.

compressive stress. It is worth noting that here there is a difference between σ_1 , σ_2 , and σ_3 and the maximum principal stress, intermediate principal stress, and minimum principal stress in the stress state of a point in space. The maximum principal stress, intermediate principal stress and minimum principal stress reflect the stress state of a very small point, while the rock specimen has a certain spatial scale, when this scale is relatively small, σ_1 , σ_2 , σ_3 can be approximated as the maximum principal stress, intermediate principal stress and minimum principal stress.

A total of 10 working conditions were simulated for 3DEC numerical simulation. Among them, $\sigma_{\max}=60\text{MPa}$, $\sigma_{\text{int}}=40\text{MPa}$, $\sigma_{\min}=30\text{MPa}$ are used as the most basic working conditions to study the effect on the intensity of rockburst when σ_{\max} , σ_{int} , σ_{\min} are changed. In the process of unloading, it is assumed that the compressive stress at each face after unloading is $\sigma_{\max-u}$, $\sigma_{\text{int-u}}$, $\sigma_{\min-u}$ and in order to simulate the real excavation better, the maximal compressive stress will be increased (assumed to be increased by 15MPa), the intermediate compressive stress will remain basically unchanged, and the minima will be reduced to zero. The 10 working conditions are shown in Table 3.

2.2.3 Layout of monitoring points

For the 3DEC simulation, a total of 10 points were selected as monitoring points on the unloading surface, and the locations of the 10 monitoring points are shown in Figure 3. The detailed coordinates of each point are P1(0.025, 0, 0), P2(0.025,0,0.0125), P3(0.025,0,0.025), P4(0.025,0,-0.0125), P5(0.025,0,-0.025), P6(0.025,0.025,0), P7(0.025,0.025,0.0125), P8(0.025,0.025,0.025), P9(0.025,0.025,-0.0125), P10(0.025,0.025,-0.025).

2.2.4 Monitoring variables

During the numerical simulation, the changes in the values of the following variables after unloading were monitored mainly at 10 monitoring points. It mainly contains kinetic energy, block strain energy, boundary loading work, joint friction work, joint strain energy, shear strain energy on joints, tensile strain energy on joints, total strain energy, total energy released, X displacement and X velocity.

Table 3. Numerically simulated information on 10 working conditions.

Working Condition No.	σ_{max} (MPa)	σ_{int} (MPa)	σ_{min} (MPa)	σ_{max-u} (MPa)	σ_{int-u} (MPa)	σ_{min-u} (MPa)
1	60	40	30	75	40	0
2	70	40	30	85	40	0
3	80	40	30	95	40	0
4	90	40	30	105	40	0
5	60	45	30	75	45	0
6	60	50	30	75	50	0

3 NUMERICAL SIMULATION TEST RESULTS AND ANALYSIS

3.1 Numerical simulation results

After 2000 steps of loading and 4000 steps of unloading considering the most basic condition ($\sigma_{max}=60\text{MPa}$, $\sigma_{int}=40\text{MPa}$, $\sigma_{min}=30\text{MPa}$), the velocity vector of the rock specimen is shown in Figure 4, and the displacement cloud of the rock specimen in the X-direction is shown in Figure 5.

Figure 4. The velocity vector of the rock specimen ($\sigma_{max}=60\text{MPa}$, $\sigma_{int}=40\text{MPa}$, $\sigma_{min}=30\text{MPa}$).

In Figure 4, due to the existence of joints, the whole model is not symmetric when generating blocks, so the velocity vector diagram is not symmetric either. In the model, the velocity vector inside the red frame line points to the direction of the outer normal of the unloading surface, indicating that the block has a tendency to move outward, i.e., the rock burst phenomenon. In Figure 5, the displacement of

Figure 5. The displacement cloud of the rock specimen in the X-direction ($\sigma_{max}=60\text{MPa}$, $\sigma_{int}=40\text{MPa}$, $\sigma_{min}=30\text{MPa}$).

each block on the unloading surface after the end of unloading is also visualised.

3.2 σ_{max} Laws of influence on rockburst

The initial combination of compressive stresses when considering the law of maximum compressive stress σ_{max} on rockburst is ($\sigma_{max}=60\text{MPa}$, $\sigma_{int}=40\text{MPa}$, $\sigma_{min}=30\text{MPa}$), ($\sigma_{max}=70\text{MPa}$, $\sigma_{int}=40\text{MPa}$, $\sigma_{min}=30\text{MPa}$), ($\sigma_{max}=80\text{MPa}$, $\sigma_{int}=40\text{MPa}$, $\sigma_{min}=30\text{MPa}$), and ($\sigma_{max}=90\text{MPa}$, $\sigma_{int}=40\text{MPa}$, $\sigma_{min}=30\text{MPa}$).

3.2.1 The effect of σ_{max} on energy

The effect of maximum compressive stress σ_{max} on kinetic energy, joint friction work, total strain energy, and total energy released is shown in Figure 6.

As can be seen from Figure 6, with the increase of σ_{max} , all kinds of energy overall show a more obvious trend of increase. The increase in energy to a certain extent can increase the intensity of rock bursts, so from the energy point of view shows that the increase in σ_{max} will increase the intensity of rock bursts.

3.2.2 The effect of σ_{max} on velocity

When researching the X-velocity, point 4 and point 10 in the red box line of Figure 4 are mainly selected as the focus of attention. The effect of the maximum compressive stress σ_{max} on the X-velocity of point 4 and point 10 is shown in Figure 7.

As can be seen from Figure 7, with the increase of σ_{max} , the velocity of point 4 and point 10 shows a more obvious trend of increase. The magnitude of the velocity can also reflect the intensity of the rock burst to a certain extent, so from the point of view of the velocity indicates that the increase of σ_{max} will increase the intensity of the rock burst.

3.2.3 The effect of σ_{max} on displacement

The effect of the maximum compressive stress σ_{max} on the X-displacement at point 4 and point 10 is shown in Figure 8.

As can be seen in Figure 8, the displacement of point 4 and point 10 shows an increasing trend with the increase of σ_{max} . The magnitude of the displacement can also reflect the intensity of the rock burst to a certain extent, so from the point of view of the displacement indicates that the increase of σ_{max} will increase the intensity of the rock burst.

Figure 6. The influence by σ_{\max} on energy (a) kinetic energy, (b) joint friction work, (c) total strain energy, and (d) total energy released.

Figure 7. The influence by σ_{\max} on X-velocity (a) at point 4, (b) at point 10.

Figure 8. The influence by σ_{\max} on X- displacement (a) at point 4, (b) at point 10.

3.3 σ_{int} Laws of influence on rockburst

Considering the law of intermediate compressive stress σ_{int} on rockburst, its initial compressive stress combination is ($\sigma_{\max}=60\text{MPa}$, $\sigma_{int}=40\text{MPa}$, $\sigma_{\min}=30\text{MPa}$), ($\sigma_{\max}=60\text{MPa}$, $\sigma_{int}=45\text{MPa}$, $\sigma_{\min}=30\text{MPa}$),

($\sigma_{\max}=60\text{MPa}$, $\sigma_{int}=50\text{MPa}$, $\sigma_{\min}=30\text{MPa}$), ($\sigma_{\max}=60\text{MPa}$, $\sigma_{int}=55\text{MPa}$, $\sigma_{\min}=30\text{MPa}$).

3.3.1 The effect of σ_{int} on energy

The effect of intermediate compressive stress σ_{int} on kinetic energy, joint friction work, total strain

energy, and total energy released is shown in Figure 9.

As can be seen from Figure 9, with the increase of σ_{int} , all kinds of energy overall show a more obvious trend of increase except kinetic energy. There is very little change in kinetic energy in the Figure. Compared with other types of energy, kinetic energy is more directly reflect the intensity of rock bursts. Therefore, from the energy point of view shows that the increase of σ_{int} has little effect on the intensity of rock bursts.

3.3.2 The effect of σ_{int} on velocity

The effect of the intermediate compressive stress σ_{int} on the X-velocity of point 4 and point 10 is shown in Figure 10.

As can be seen from Figure 10, with the increase of σ_{int} , the velocity of point 4 and point 10 does not change significantly. The magnitude of the velocity can also reflect the intensity of the rock burst to a certain extent, so from the point of view of the velocity shows that the increase of σ_{int} has little effect on the intensity of the rock burst.

3.3.3 The effect of σ_{int} on displacement

The effect of the intermediate compressive stress σ_{int} on the X-displacement at point 4 and point 10 is shown in Figure 11.

As can be seen from Figure 11, with the increase of σ_{int} , the displacement of point 4 and point 10 increases insignificantly. The magnitude of the displacement can also reflect the intensity of the rock burst to a certain extent, so from the point of view of the displacement shows that the increase of σ_{int} has little effect on the intensity of the rock burst.

3.4 σ_{min} Laws of influence on rockburst

When considering the minimum compressive stress σ_{min} on rock bursting law, its initial compressive stress combination is ($\sigma_{max}=60\text{MPa}$, $\sigma_{int}=40\text{MPa}$, $\sigma_{min}=30\text{MPa}$), ($\sigma_{max}=60\text{MPa}$, $\sigma_{int}=40\text{MPa}$, $\sigma_{min}=25\text{MPa}$), ($\sigma_{max}=60\text{MPa}$, $\sigma_{int}=40\text{MPa}$, $\sigma_{min}=20\text{MPa}$), and ($\sigma_{max}=60\text{MPa}$, $\sigma_{int}=40\text{MPa}$, $\sigma_{min}=15\text{MPa}$).

Figure 9. The influence by σ_{int} on energy (a) kinetic energy, (b) joint friction work, (c) total strain energy, and (d) total energy released.

Figure 10. The influence by σ_{int} on X-velocity (a) at point 4, (b) at point 10.

Figure 11. The influence by σ_{int} on X- displacement (a) at point 4, (b) at point 10.

According to the processing and analysis of the relevant data, it is found that the influence of σ_{min} on the intensity of rock bursts is similar to the rule of σ_{max} , i.e., with the increase of σ_{min} , the intensity of rock bursts will also increase accordingly.

4 CONCLUSIONS

Rockburst is one of the common disasters encountered during deep tunnel excavation, and the main conclusions obtained from numerical modelling of the rockburst process using 3DEC discrete element software are as follows:

- (1) Considering 10 different compressive stress combinations under the conditions of 3DEC numerical modelling. The kinetic energy, joint friction work, total strain energy, and total energy released were monitored and analysed. A total of 10 monitoring points were set up and the analyses were focused on the relevant velocities and displacements of point 4 and point 10 among them.
- (2) The effects of the maximum compressive stress σ_{max} and the minimum compressive stress σ_{min} on the intensity of the rockburst show the same pattern. As the value increases, the intensity of the rockburst increases accordingly.
- (3) The intensity of rockbursts is not sensitive to changes in the intermediate compressive stress σ_{int} . That is, with the increase in the value of the intermediate principal stress σ_{int} , the intensity of rock bursts does not change significantly.
- (4) The practical engineering can be achieved through certain means mainly to reduce the maximum compressive stress σ_{max} and minimum compressive stress σ_{min} method to control the intensity of rock explosion.

ABSTRACT: Social demands, such as improving productivity, reforming work styles, and ensuring workplace safety, are prevalent during mountain tunnel construction projects. Therefore, it is necessary to undertake an advanced information-based approach to mountain tunnel construction to address these social demands. Here we address an aspect of this advanced information-based approach by developing a new three-dimensional (3D) modeling system, SG-ReGrid®, which updates 3D geological models using exploration data, such as advanced boring and seismic surveys that are conducted during construction, and requires minimal time and effort compared with conventional software. The 3D modeling system has the ability to identify potential geological risks that may be present ahead of the tunnel face, thereby making it possible to propose design changes in a timely manner and contribute to worksite safety. Furthermore, we are also considering improving the efficiency and generalization of the system to better address the above-mentioned social demands. We demonstrate the effectiveness of the modeling system by first presenting the system configuration and then providing an example application at the Shitara Dam Seto Shitara Line tunnel construction site in Japan.

Keywords: 3D geological model, Sequential update, Visualization, Exploration data, Mountain tunnel

1 INTRODUCTION

The early prediction of geological hazard risks, such as fault zones, significant rock cracks, and groundwater inrush, is required to ensure workplace safety and effective construction schedule management during the construction of mountain tunnels. Therefore, a number of efficient technologies have been developed to explore the state of the rock mass ahead of the tunnel face. For example, the S-BEAT® seismic exploration system is a fast, low-cost surveying method that is undertaken during construction, whereby the sound source is generated by a hydraulic rock-breaker at the tunnel face (Nishi and Wakabayashi, 2016; Yoshikawa et al., 2021). The seismic system has a negligible impact on construction cycle times because it uses existing rock bolts and common rock-breakers during survey.

There are various types of forward exploration ahead of the tunnel face, such as seismic reflection

survey and advanced boring. Geological expertise is often required to spatially visualize and interpret the geological conditions ahead of the tunnel face using these various datasets. However, if rapid integration and three-dimensional (3D) modeling of these seismic, boring, logging, and other datasets can be undertaken, then the geological conditions ahead of the tunnel face will be easier to understand and assess. Furthermore, from a social perspective in Japan, it is necessary to deal with labor-saving costs that are related to construction work, shortage of engineers, and productivity improvements, including BIM/CIM (building/construction information modeling), which are mainly promoted by the Ministry of Land, Infrastructure, Transport and Tourism.

We address the above-mentioned issue by developing a new 3D modeling system, SG-ReGrid®, whereby the initial voxel model is re-gridded using exploration data acquired during tunnel construction. We also present an example application of the system at a tunnel

*Corresponding author: s-yoshikawa@shimz.co.jp

construction site to demonstrate its effectiveness in identifying geological hazards ahead of the tunnel face.

2 NEW 3D MODELING SYSTEM

An overview of the proposed 3D modeling system is shown in Figure 1. The initial model is first created using pre-construction geological surveys that are incorporated into commercially available software packages and mainly interpreted by geological specialists. The target volume where the updates to the geological model are sequentially performed then has to be determined. This initial model (solid model) of the target volume is converted into a voxel model and then input to the model update section (the 3D modeling system). The mode of the voxel model, such as the geological classification of the rock, can be changed according to the purpose of the exploration surveys in this section. Therefore, the elastic-wave (P-wave) velocity structure that is obtained from the pre-construction survey, the rock classification corresponding to the initially designed support pattern, and the lithological classification are used as attribute values for each voxel in the initial voxel model. Sequential updates to the voxel attribute values may include the P-wave velocity structure obtained by advanced boring (hereinafter Br) and active-source P-wave exploration, lithology classification by Br, and strength tests using Br specimens. The physical properties derived from these results and the S-BEAT®-derived reflection surfaces are also classified and included in the updates.

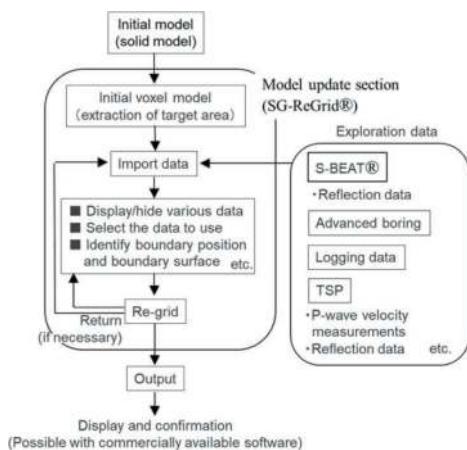

Figure 1. Overview of the 3D modeling system.

The updated geological model can then be output, together with the coordinate and attribute information from the voxel model, and reflected in an analytical model using commercially available software. Furthermore, we can set guidelines on how to input, select, and use various exploration results, with the ultimate goal of enabling non-geological engineers to quickly and easily update the geological models during tunnel construction.

3 SEISMIC EXPLORATION SYSTEM

An example diagram of the unique seismic survey design and exploration process is shown in Figure 2. The system consists of two single-component acceleration sensors (X: longitudinal direction of the tunnel axis), two three-component acceleration sensors (longitudinal (X), transverse (Y), vertical (Z) directions of the tunnel axis), a trigger switch to synchronize the four sensors, and a tablet PC to view and record the sensor data (Figure 3). Each sensor is attached via a jig to the nut of a rock bolt located 10–20 m from the tunnel face.

Figure 2. Cartoon of the S-BEAT® seismic survey design for exploring ahead of the tunnel face.

Figure 3. Photographs of the (A) seismic system and (B) on-site surveying.

If the vibration (oscillation) and sensor (receiver) locations in the system, ground P-wave velocity, and reflected-wave arrival times are all known, then the reflected wave is assumed to have originated from a certain point on the isotravel ellipsoid (Ashida et al., 2001). The ellipsoid is created using the vibration and receiving points, which serve as focal points (Figure 4). The installation of multiple sensors means that a point will be formed where the travel-time ellipses overlap if the observed waves reflect from the same point. This overlapping point is a common reflection point and indicates a rock density and/or P-wave velocity boundary. The position and slope of the reflecting surface can be estimated from this overlapping point and the tangent to the point with high reflection intensity, respectively (Figure 4).

The data analysis consists of setting the geometry, performing bandpass filtering, identifying the initial motion of the direct waves (P waves), calculating the rock P-wave velocity, and deconvolution. A single-component sensor is used to calculate the P-wave

Figure 4. Concept of estimating the reflection point.

velocity. If there is no reference P-wave velocity, then it is assumed to be the P-wave velocity in front of the tunnel face; this value is used in the subsequent reflective surface distribution analysis. A 3D analysis is then performed using the data from the two three-component sensors, whereby the amplitude values (reflection intensity) are weighted according to the directions of reflected wave arrivals in the X, Y, and Z directions. Finally, a 3D map of the imaged reflective surfaces is created. The analysis volume extends 100 m ahead of the tunnel face and ± 50 m in both the vertical and transverse directions of the tunnel, with the origin located at the intersection of SL (spring line) and CL (center line) of the tunnel face. Although the penetration depth of the seismic waves depends on the hardness/softness of the rock at the tunnel face, breaker striking produces a weaker vibration than blasting, such that the exploration range is generally up to ~ 70 m ahead of the tunnel face.

4 AN EXAMPLE ON-SITE APPLICATION

4.1 Site geology

An on-site application of the 3D modeling system has been conducted at the Shitara Dam Seto Shitara Line mountain tunnel construction site in Japan. The mountain consists mainly of sandy and siliceous gneiss (and metachert) of the Ryoke metamorphic rock group and diorite intrusions. The key geological concerns before construction included the local distribution of diorite intrusions (due to the difference in strength from the country rocks), weathering of gneiss layers, and the presence of weak layers such as faults. Tunnel construction was initiated with a primary focus on the effects of weathered tunnel faces and partial clay formation; corresponding measures to prevent/mitigate any associated tunnel face collapse were also undertaken. It was therefore necessary to conduct a re-modeling process from the initial model using the exploration results during construction in a timely and accurate manner.

4.2 Visualization of the exploration data and update of the geological model

First, we had to determine the update range in the model from the solid model, which was created

using general-purpose software (Figure 5A). It is best to limit the update range to the minimum necessary size to shorten the processing time of the model update; the range covered the main and diagonal tunnels at the construction site in the present study (Figure 5B). The initial solid model that was within this range was then converted to a voxel model, which served as the input model for the 3D modeling system.

Figure 5. (A) Initial model (solid model) and (B) initial voxel model for SG-ReGrid®.

An example of the modeling system operation is as follows. Br data were obtained along the diagonal tunnel (Figure 6). Fractured strata were recognized 60–65 m from the tunnel entrance in the Br data, thereby prompting the seismic survey to be conducted ~ 25 m before this weak layer was excavated (Figure 6). The survey results identified five surfaces that were drawn in descending order of reflection intensity (Figure 7). These surfaces are constructed as follows. First, a normal line is drawn from the point at which the reflection intensity is strongest on the radial front of the reflected waves. A surface with an angle that is perpendicular to the normal line is then drawn. This surface is interpreted to represent a rock density and/or P-wave velocity boundary. Incorporating the seismic survey and Br results into the 3D modeling system indicated that the reflection surfaces intersected the weak (fractured) layer (Figure 7). Furthermore, the slope of this reflection surface, which is inclined in the opposite direction of tunnel excavation (i.e., dip slope), highlighted the need to be aware of potential tunnel-face collapse caused by destabilization of this weak layer during excavation.

Figure 6. Advanced boring data, and locations of the weak layer (blue) and the seismic survey (star).

Figure 7. Seismic reflection survey results, which are based on the positions of the boring data and reflective surface.

We then updated the geological model based on these exploration results. We determined that the reflection surface was oriented in the predominant direction of the density and/or P-wave velocity boundary in this area based on past exploration results at multiple sites and added a surface with the same strike and dip (Figure 8A). After moving the boundary surfaces that were parallel to the start and end positions of the weak layer section in the Br data, we defined a newly modeled weak layer in this section (Figure 8B, blue layer). The tunnel face did collapse in this section during excavation (Figure 9). However, construction was safely completed because informed warnings were given well before this weak layer was excavated. The width of the blue layer (weak layer) was increased by ~7 m in the direction of travel based on tunnel-face observations and length of area where tunnel subsidence occurred. We effectively made the necessary design changes because we were able to consider auxiliary construction methods in advance.

Figure 8. (A) Creating and moving the boundary surfaces (B) subsequent modeling of the weak layer.

Figure 9. Collapse occurred to ~2.0 m depth within the weak layer in the diagonal tunnel.

A similar effect was expected on the tunnel face of the main tunnel owing to the weak layer and its proximity to the diagonal tunnel (20–25 m). The range of this weak layer was initially identified in the main tunnel by creating a plan view and longitudinal section (Figure 10). We then conducted the seismic survey to examine the locations of the weak layers in detail and determine the dominant direction of the boundaries and cracks during the excavation of the main tunnel. The reflected surfaces possessed dip and reverse dip slopes (Figure 10). A V-shaped collapse occurred at the actual tunnel face, as predicted from the reflective surfaces (Figure 11). However, the excavation was completed without any delays owing to the preliminary consideration of face bolting and the long-forepiling method based on the re-modeling results.

Figure 10. Examining the location of the weak layer in the main tunnel using information in the diagonal tunnel and additional seismic data.

Figure 11. An example of the weak layer in the main tunnel. White lines denote the geological interpretation, indicating fault, Aplite dyke, and major cracks.

5 CONCLUSIONS

We developed a 3D geological model sequential update system, SG-ReGrid®, to predict the geological conditions ahead of the tunnel face and take the necessary precautions during construction. We presented an example application of this update system the Shitara Dam Seto Shitara Line tunnel construction site in Japan, whereby we acquired exploration data along both the diagonal and main tunnels to quickly visualize and re-model the geological conditions during construction. This rapid re-modeling approach allowed us to assess and highlight potential geological hazards lying ahead of the tunnel faces. Furthermore, the 3D imaging of these weak layers provided the ability to smoothly propose design changes to the client, such as the addition of auxiliary construction methods.

We will continue to improve the 3D modeling system through future field applications, whereby we

will add additional functions as needed to address the requirements at other tunnel construction environments. We are also working on developing guidelines that will allow non-geologists to update the model information. Furthermore, we are considering improving the software to automate the process based on user-defined thresholds of the input data.

The 3D modeling system is a fundamental technology that improves the accuracy of predictive analysis during tunnel construction. We plan to use this model update technology to predict groundwater flow and associated rock displacement during excavation (e.g., Fukuda et al., 2023).

ABSTRACT: The super-large diameter pipe-jacking is widely used in the municipal and rail transit works, which has strict technical requirements for real-time and accurate detection or prediction of geological conditions in front of the working face. In view of this, an advanced geological prediction technology based on the HSP method is proposed for the super-large diameter pipe-jacking project for the first time. In this method, the acoustic wave generated in rock breaking by pipe-jacking machine is taken as the main transmission signal, and the signal acquisition is completed at the same time of rock-breaking, so as to reduce the influence of geological prediction work on the pipe-jacking construction. In order to verify the geological prediction accuracy of the proposed method, the prediction results are compared with the geological survey data, tunneling parameters and actual excavation conditions, and the results show that the method can effectively distinguish the lithological change area and effectively guide the construction. Based on the prediction results of the HSP method, the fuzzy mathematical theory is used to pre-control the tunneling parameters, and the statistical analysis of the parameters in the abnormal area is carried out to obtain the empirical function, so that it can divide the huge amount of excavation parameters generated in the overall construction process into the characteristic spaces of excavation parameters. And the most realistic results are selected from the ten characteristic spaces of tunneling parameters, so as to analyze the tunneling parameters in different characteristic spaces. Finally, it can provide a reasonable reference range for the actual tunneling parameters and effectively avoid construction risks.

Keywords: Advanced geological prediction, HSP method, Pipe-jacking, Fuzzy mathematical theory

1 INTRODUCTION

With the continuous development of the national economy, the tunnel works in China have a scale ranking first in the world, and municipal pipeline works and underground passage works also keep increasing. The pipe-jacking method can significantly reduce the construction's impact on the surrounding environment and road traffic and has wide application prospects. The super-large diameter pipe-jacking construction involves risks affected by complex geological conditions, and tunnel safety accidents in such construction cause immeasurable losses every year. Therefore, advanced geological prediction for tunnels plays a vital role in judging the geological conditions ahead of the tunnel face. In the rapid emergence of mechanized construction, traditional geological

prediction technologies are also being upgraded and improved to adapt to mechanized construction scenarios. For example, onboard HSPs, induced polarization device, and other advanced geological prediction equipment mounted on TBMs have been widely used in various regions of China^[1-3].

To avoid tunnel safety risks in pipe-jacking, TBM, and other mechanized construction, this paper will adopt the HSP method-based advanced geological prediction system for guidance of construction. In 2008, Li Cangsong et al.^[4] first proposed the passive source HSP (horizontal sonic/seismic profiling) detection technology that uses the vibration signal generated in TBM cutterhead's rock-shearing as the excited seismic source. In 2019, Lu Song, Wang Xu, et al.^[5-8] further improved the HSP method to make it more suitable for TBM construction and summarized

detailed treatment process flow and design concepts. For the technology, the elastic waves generated in the TBM cutterhead's strata-shearing are taken as an excitation signal to realize the quick and efficient acquisition of data. However, the modules for site environmental noise processing have still not been studied systematically. In 2021, Zhao Ziyue, et al.^[9] started with the study of site environmental noise and improved the detection process flow of the existing HSP method based on the characteristics of TBM construction on the site.

In this paper, Yanziji New Town Comprehensive Pipe Gallery Project in Qixia District, Nanjing City is taken as a case, and the HSP method is adopted for advanced geological prediction detection. The inversion results obtained are compared with the actual geological survey data, and massive tunneling parameters are simultaneously collected for analysis and processing. Finally, the accuracy of the HSP method is verified based on the actual tunneling conditions. In 2009, Song Kezhi, et al.^[10] used fuzzy mathematical theory to identify the conditions of tunnel surrounding rock during TBM tunneling, and discussed and revealed the relation between the specific thrust and specific torque of the cutterhead, the correlation of the cutterhead thrust, torque, and cutting depth with geological conditions, as well as the corresponding relation between different surrounding rock conditions and TBM tunneling states. In this paper, based on the test results of the HSP method, the fuzzy mathematical theory is used for tunneling parameter pre-control, and statistical analysis is performed on the abnormal area parameters to obtain an empirical function. The tunneling parameter characteristic spaces generated by massive tunneling parameters throughout the construction process are divided into multiple zones, and the most realistic results are selected from ten tunneling parameter characteristic spaces for the analysis and description of tunneling parameter points in different characteristic spaces. Finally, this paper provides a reasonable reference range for actual construction to avoid construction risks.

2 HSP METHOD-BASED ADVANCED GEOLOGICAL PREDICTION TECHNOLOGY FOR DRILL JUMBO ROCK-BREAKING SEISMIC SOURCE

The HSP method is based on the Huygens–Fresnel principle and Fermat's principle and requires the difference in wave impedance of stratum media as a premise. The strata ahead of the tunnel face are identified according to the propagation characteristics of the elastic wave field, including velocity, amplitude, etc. According to the characterization attributes of different components, densities, and elastic moduli in the underground media, a detailed analysis is conducted based on the characteristics of the underground structure. Based on the observation

of the actual tunnel face, the conditions of exposed surrounding rocks are compared. The difference in results is finally summarized for a reasonable adjustment of the inversion parameters, and a result profile reflecting the adverse geological conditions is obtained. Common adverse geological conditions include faults, weathered fracture zones, karst caves, groundwater-enriched zones, etc. The core formula of reflection and transmission characteristics of wave field propagation is as follows:

$$R_{12} = \frac{\rho_2 v_2 - \rho_1 v_1}{\rho_2 v_2 + \rho_1 v_1} \quad (1)$$

Where, R_{12} is the reflection coefficient, ρ_1 is the density of the surrounding rock ahead of the tunnel face; ρ_2 is the density of adverse geological (body); v_1 is the longitudinal wave velocity of the surrounding rock ahead of the tunnel face; v_2 is the longitudinal wave velocity of the adverse geological (body).

2.1 Advanced geological prediction scheme design for super-large diameter pipe-jacking

Currently, the passive source HSP method-based prediction technologies for TBM construction have been applied in many projects, realizing a breakthrough in prediction method without shutting down a TBM or affecting construction. Among them, the mounted and portable HSP method-based prediction technologies have been widely used in many projects at home and abroad. They support continuous data collection and can form a TBM data database. The rich case experience has allowed the HSP technology to be improved.

Based on the existing HSP technology for TBM construction, the overall scheme design for advanced geological prediction for super-large diameter pipe-jacking is realized, the collection and processing of rock-breaking signals of pipe jacking equipment is improved, the technical process is optimized, and a complete prediction flow chart is developed, as shown in Figure 1.

According to the actual construction environment on the site and the tunneling situation of the pipe jacking machine, the installation position of the HSP

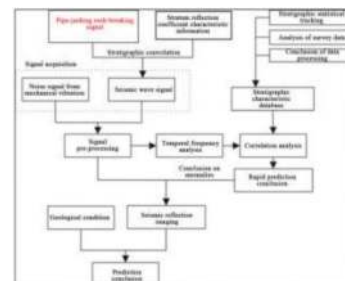

Figure 1. Flow chart of prediction for mechanized construction with drill jumbo.

equipment is reasonably allocated. The onboard equipment is installed on a stable platform to avoid equipment failure due to mud gushing, as shown in Figure 2.

Figure 2. Schematic diagram of onboard HSP equipment.

2.2 Field testing

Yanziji New Town Comprehensive Pipe Gallery is located in Qixia District, Nanjing City. It is an important part of Jiangnan Ring Trunk Pipe Gallery of Najing. In the Project, the pipe diameter is 5.4 m (OD). With respect to the geological conditions of the pipe-jacking section, the upper part is clay soil, and the middle and lower parts are harder rock, i.e., the strata are soft at the upper part and hard at the lower part. The strengths of the upper and lower strata are quite different. This is very likely to cause the deflection of the pipe jacking machine's head toward the weaker strata and the continuous ascending of the pipe jacking machine's head. Under severe conditions, this may even cause land upheaval, sharp increase of jacking force, and jacking failure.

The chainage of the tunnel face under test is K0+658. The original waveform curves collected on the site are subject to data processing and analysis. The inversion analysis results are shown in Figure 3 and Figure 4, the analysis results are shown in Table 1, and the three-dimensional results of the inversion analysis are shown in Figure 5.

Figure 3. Results of inversion analysis on detection at Chainage K0+658 (0 m position of XOY slice – horizontal tunnel axis slice).

Figure 4. Results of inversion analysis on detection at Chainage K0+658 (0 m position of ZOY slice – vertical tunnel axis slice).

Figure 5. Three-dimensional results of inverse analysis on detection at Chainage K0+658.

Table 1. Test and analysis results.

Detection range ^①	Length (m) ^②	Test result ^③
K0+658~K0+716 ^①	58 ^②	The detection results show that the local parts in this section have weak reflection anomalies. Analysis suggests that the rock mass in this section is relatively fragmented as a whole, and lithological changes may exist in local areas. In the detection range, chainage sections: K0+672~K0+678 and K0+710~K0+716 have weak reflection anomalies, indicating that differences in wave impedance exist in these chainage sections. Comprehensive analysis shows that the detection range is an area of lithological changes and the surrounding rock is of poor stability. ^③
K0+716~K0+758 ^①	42 ^②	The detection results show that strong reflection anomalies exist in the local parts of the detection range. Analysis suggests that strong reflection anomalies in the section (K0+753~K0+758) may be caused by the difference in wave impedance between the lithological change area and the break-out free face. The rock mass in the detection range is still relatively broken. ^③

Figure 6. Field testing.

According to the comparison of the geological survey data in Figure 7, the HSP detection results of the lithological change area show the existence of anomalies, which is basically consistent with the geological survey results. Strong reflection anomalies exist at the break-out free face, which is consistent with the actual situation. This proves that the HSP method is feasible and effective for pipe-jacking projects.

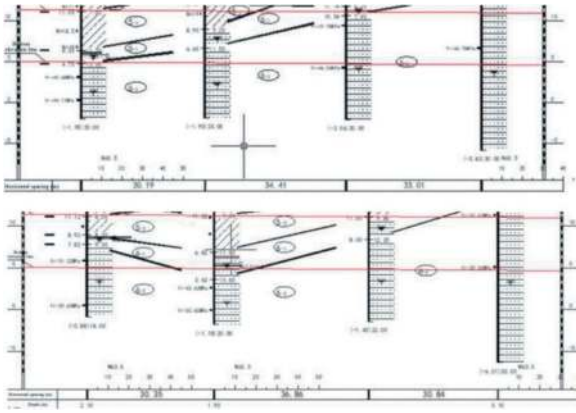

Figure 7. Geological survey data.

3 RESEARCH ON JACKING PARAMETER PRE-CONTROL BASED ON FUZZY MATHEMATICAL THEORY

3.1 Fuzzy mathematical theory analysis

During pipe jacking, the observation of the geological characteristics of the surrounding rock is greatly restricted by the construction conditions. The surrounding rock condition can only be judged based on the observation through the geological observation window and the slag discharge situation. The judgment often involves a certain degree of subjectivity and error. Therefore, the data obtained by various means must be fully utilized for the timely judgment of the surrounding rock conditions. Research shows that the analysis of tunneling parameters is conducive to the effective judgment of the geological conditions of the surrounding rock and the objective reflection of changes in the surrounding rock encountered. Therefore, the cutterhead speed, cutterhead torque, total thrust, flow rate in the slurry inlet pipeline, and flow rate in the slurry discharge pipeline are selected as parameters for judging surrounding rock conditions during pipe jacking. These five parameters are grouped in pairs and subject to analysis based on the fuzzy mathematical method, and the most representative parameter models are summarized.

To ensure the accuracy and universality of statistical data, the existing data of each link are expanded in detail to increase the overall data volume. Tunneling time is introduced into the new data, and data is collected at a rate of one data point every 1-3 minutes to ensure data authenticity and effectiveness and reduce the impact of errors caused by the artificial selection of data. Finally, 9968 data sampling points are obtained. Based on this, correlation analysis of various parameters is carried out and the comparison is shown in Figure 8.

It can be clearly seen from the figure that throughout the entire construction stage, strong correlations exist between four pairs of data: the cutterhead torque and the total thrust, the total thrust and the

4	-0.0356	-0.0703	0.3562	1	0.5146
5	0.0150	-0.0602	0.3273	0.5146	1

Figure 8. Comparison of correlation between parameters.

flow rate in the slurry inlet pipeline, the total thrust and the flow rate in the slurry discharge pipeline, as well as the flow rate in the slurry inlet pipeline and the flow rate in the slurry discharge pipeline. The cutterhead torque and total thrust are commonly used in tunneling parameter research and are very representative parameters. This can reflect the problem of low correlation between the cutterhead torque and total thrust due to human statistical influence in the previous section. With the support of massive data, the interference of human factors is eliminated, and the result generally conforms to the research law of tunneling parameters.

3.2 Analysis of actual jacking parameters

During the pipe-jacking process under certain output thrust and torque conditions, the thrust and torque parameters are obtained through the data acquisition system. They collectively constitute a tunneling characteristic space Ω , and the tunneling parameters of each tunneling test constitute a subspace Ω_i of space Ω . By plotting the tunneling parameter point (x_i, y_i) obtained in a test on the plane Ω , the subspace Ω_i can be obtained, as shown in Figure 9. In the subspace Ω_i , regression analysis on the tunneling parameter point (x_i, y_i) is carried out to obtain the regression curve $y=kx$. By controlling the accuracy of the regression analysis, the boundary curves $y_1=kx-b$ and $y_2=kx+b$ of the prediction interval are obtained. Then, a curve $y_3=k_3x+c$ is made to intersect the curve $y=kx$ at the boundary between the typical mudstone parameters and the typical sandstone

Figure 10. Corresponding relation between tunneling parameters and Their positions in Subspace.

parameters and divide the curve $y=kx$ into two parts. So far, three sets have been established in Space Ω_i , namely A: $y_1=kx-b$, B: $y_2=kx+b$, and C: $y_3=k_3x+c$. They divide Space Ω into four zones, as shown in Figure 9.

Based on the establishment of this relation model and 9968 data, 5 parameters are grouped in pairs and the position of the corresponding relation of each pair is plotted in the subspace. The results are shown in Figure 10 below.

It can be seen from the figure that only Figure 10-(5) and (10) fit the regression model. Since the flow rate in the slurry inlet pipeline and the flow rate in the slurry discharge pipeline are not the parameters of the pipe jacking machine itself, the torque and the thrust are more representative, and the selection of these two parameters is more convincing and consistent with the parameter selection results analyzed by scholars in the industry.

3.3 Torque-thrust research model

Taking the torque and thrust corresponding relation as the main research model, the tunneling status of pipe-jacking under different surrounding rock conditions has a certain corresponding relation with the zones in Figure 9. When pipe jacking is carried out in a relatively complete and homogeneous stratum, the cutterhead torque and cutterhead thrust change basically in proportion. Therefore, when the

tunneling parameter point (x_i, y_i) falls in Zone 1, the torque and thrust are both relatively high, indicating that the pipe jacking is carried out normally in a hard stratum. When the tunneling parameter point (x_i, y_i) falls in Zone 2, the torque and thrust are both low, indicating that the pipe jacking is carried out normally in a soft stratum. When the tunneling parameter point (x_i, y_i) falls in Zone 3, the cutterhead thrust increases abnormally, but the cutterhead torque is very low, indicating that the pipe-jacking cutterhead is held by compressive rocks or is stuck and unable to adjust its displacement normally, or it encounters strong obstacles. When the tunneling parameter point (x_i, y_i) falls in Zone 4, the cutterhead torque increases abnormally, but the thrust is not large, indicating that the surrounding rock is abnormally broken, the tunneling face collapses seriously, and the cutterhead slag outlet is stuck and unable to discharge slag normally, causing the torque to increase abnormally.

Euclidean distance is used for fuzzy discriminant calculation, and the distances (as per the distance from a point to a straight line) between the tunneling parameter point (x_i, y_i) and the points in fuzzy sets (A, B, C) are respectively

$$d_{1i} = \frac{|kx_i - y_i - \hat{\sigma}_e u_{1-\frac{\alpha}{2}}|}{\sqrt{k^2 + 1}}, y_i < y_1(x_i) \quad (2)$$

$$d_{2i} = \frac{|kx_i - y_i - \hat{\sigma}_e u_{1-\frac{\alpha}{2}}|}{\sqrt{k^2 + 1}}, y_i \geq y_2(x_i) \quad (3)$$

$$d_{3i} = \frac{|k_3x_i - y_i + c|}{\sqrt{k_3^2 + 1}}, y_1(x_i) \leq y_i \leq y_2(x_i) \quad (4)$$

Then, each distance is normalized to obtain d_{01i} , d_{02i} , d_{03i} . According to the relation between the normalized distance and the membership degree, the membership degree of the parameter point (x_i, y_i) to fuzzy sets (A, B, C) can be obtained, as shown below

$$\mu_A = \exp\left(\frac{-d_{01i}}{(1 - d_{01i})}\right) \quad (5)$$

$$\mu_B = \exp\left(\frac{-d_{02i}}{(1 - d_{02i})}\right) \quad (6)$$

$$\mu_C = \exp\left(\frac{-d_{03i}}{(1 - d_{03i})}\right) \quad (7)$$

The greater the distance between the parameter point (x_i, y_i) and a fuzzy set, the smaller the membership degree.

- (1) When $y_1(x_i) \leq y_2(x_i)$, the shield tunneling is considered to be in a normal state. At this time, if $y_i \geq y_3(x_i)$, the smaller the membership degree μ_C , the harder the rock; if $y_i < y_3(x_i)$, the smaller the membership degree μ_C , the softer the rock.
- (2) When $y_i \geq y_2(x_i)$, if the membership degree μ_B is close to 1.0, it means that the shield tunneling is basically normal, and the smaller the μ_B is, the greater the possibility that the thrust is higher than that in the normal state.
- (3) When $y_i < y_1(x_i)$, if the membership degree μ_A is close to 1.0, it means that the shield tunneling is basically normal, and the smaller the μ_A is, the greater the possibility that the torque is higher than that in the normal state.

The actual parameter data are substituted into the above equations, and sets A and B are obtained as follows:

$$y = 20.28x + 1325.4 \quad (8)$$

$$y = 20.28x - 9807.28 \quad (9)$$

According to the actual parameters on the site, strata 5-3 dense medium sand and 6-2 moderately dense coarse sand of different lithological properties in the geological survey data are distinguished. Combining the field data and empirical parameters, the following equation is obtained:

$$y = -0.04931x + 5885.597 \quad (10)$$

Figure 11. Corresponding relation between actual tunneling parameters and surrounding rock conditions and their positions in subspace.

Based on the corresponding relation in the above figure, when any data falls in Zone 4, it can be identified there is a large abnormal area such as a free face. Such data in subsequent construction requires more attention. When such data continuously falls in

Zone 4, the TBM needs to be shut down for processing and analysis of causes.

3.4 Pre-control analysis

Based on the above content and overall analysis, the existing parameter patterns are summarized, and the main parameter ranges are divided, as shown in Table 2 below. The mathematical fuzzy method and the clustering analysis method are adopted to establish a torque-thrust model. When the parameter point falls into Zone 1, it is considered that the surrounding rock is hard or the pipe jacking is in the launching stage. When the parameter point falls into Zone 2, the pipe jacking machine is considered to be in a section with the surrounding rock being relatively broken and of poor stability. When the parameter point falls into Zone 3, the pipe jacking machine is considered to be in a normal tunneling stratum. When the parameter point falls into Zone 4, it is considered that the surrounding rock is overall of poor stability and there may exist underground anomalies such as hazardous areas and solution cavities, or free face before break-out. The conditions need to be comprehensively judged based on the geological survey data and other information. The construction contractor needs to pay more attention, strictly monitor the tunneling parameters and slag discharge situation, and be prepared for emergencies.

4 CONCLUSIONS AND SUGGESTIONS

- (1) For the advanced geological prediction scheme design for super-large diameter pipe-jacking, the HSP method-based advanced geological prediction technology is applied for the first time in super-large diameter pipe-jacking. The accuracy of the prediction technology is verified based on the geological survey data, tunneling parameters, and actual tunneling conditions, and it is proved that this technology can be used to identify lithological change areas and guide construction.
- (2) Based on the identification results of the HSP method, the fuzzy mathematical theory is used for tunneling parameter pre-control, and statistical analysis is performed on the abnormal area parameters to obtain an empirical function. The

tunneling parameter characteristic spaces generated by tens of thousands of tunneling parameters are divided into multiple zones. Finally, it is determined that the parameter characteristic space established with torque and thrust is the most realistic result.

- (3) Based on the parameter analysis results, a parameter characteristic space is established with torque and thrust, providing a reasonable reference range for actual construction to avoid construction risks.

Excavation induced settlement in Sydney area

Giovanny Alvarado, Somaye Sadeghian & Yang Dong
 AECOM Australia, Sydney, Australia

ABSTRACT: Excavations affect the state of in-situ stress in the ground, leading to displacements in adjacent buildings and structures. In Hawkesbury Sandstone in Sydney, horizontal stresses are higher than vertical stresses, posing a risk of excavation-induced displacement even in good quality rock. This paper continues the research of other authors and aims to introduce a simplified approach to estimating excavation-induced stress in Hawkesbury Sandstone without numerical modeling. In the authors’ previous study (to be published in the Australian Geomechanics Journal in 2024), a comprehensive investigation using three-dimensional finite element analysis was conducted to determine the displacement trough at the excavation edge. Ground type, excavation depth, and width were considered as variables in these analyses. In this paper, orientations of the principal in-situ stress and length/width ratio are adopted as variables, and correlations are provided to relate the maximum lateral displacement to the orientation of the locked-in stress as well as the length/width ratio of the excavation. The outcomes of this study offer valuable insights for assessing potential damage to buildings during excavations in Sydney and can be used in preliminary design stages before detailed planning.

Keywords: 3D modelling – FLAC3D – PLAXIS3D

1 INTRODUCTION

Excavations lead to changes in the stress distribution within the surrounding ground, resulting in excavation-induced lateral displacement. Such changes in stress are particularly evident in open excavations in the Sydney region, where the horizontal stress resulting from tectonic activities at shallow depths exceeds the vertical stress. As a result, the existing stress conditions are commonly characterized using established relationships that outline in-situ stress as a function of depth (Pells (2004), Bertuzzi (2014), Oliveira and Parker (2014), Hewitt and Kitson (2022), and Lochaden et al. (2019)). In the previous study by the authors, a simplified process for estimating lateral excavation-induced displacement was proposed. The simple correlations provided to estimate (1) the maximum lateral displacement at the edge of the excavation and (2) the displacement trough along the excavation. Initially, a dataset (as shown in Figure 1) was generated by analyzing 60 finite element models of open excavations conducted in Plaxis3D (V22). Various classifications of Sandstone, depths of excavation, and widths were incorporated into the Plaxis3D models, enabling the computation of displacements at the excavation boundary. The independent variables considered were depth, width, and the class of Hawkesbury Sandstone, and the approach of Least Squares Linear Regression was employed to

establish the relationship between excavation-induced lateral displacement and the independent variables. For the sake of simplification, the following assumptions were made: 1) the major and minor locked-in stresses were assumed to be perpendicular to the excavation; and 2) the excavation has a box shape. Figure 2 illustrates these assumptions. Herein, the effect of major and minor locked-in horizontal stress orientation on the lateral excavation-induced displacement is studied. Next, the effect of Length over Width ratio on the estimated lateral displacement is assessed. The paper focused on Hawkesbury Sandstone Class II, III, and IV, with excavation depths

Figure 1. Dataset was created from 60 open-excavation models.

Figure 2. Plaxis3D model.

ranging from 5m to 20m and widths from 10m to 50m. The paper acknowledges certain limitations. It specifies the applicability of the proposed equations to specific conditions, such as the range of sandstone classes, excavation depths, and widths considered in the study. It also emphasizes that the findings pertain to lateral displacement at ground level and do not account for the influence of adjacent excavations on in-situ stress. Despite these limitations, the paper provides a comprehensive and practical approach for assessing excavation-induced lateral displacement in the Sydney region.

1.1 Maximum displacements

The paper defined the maximum excavation-induced lateral displacement (δ_{Max}) at the direction of major principal stress as a function of excavation width (W), and excavation depth (D) for different rock class. Equation 1 and 2 were proposed for Sandstone Class III, and II, respectively.

$$\delta_{Max-III}(mm) = 5.94 - 1.16D(m) - 0.51W(m) + 3.01\sqrt{D(m) * W(m)} \quad (1)$$

$$\delta_{Max-II}(mm) = -4.63 - 1.13D(m) - 0.43W(m) + 2.75\sqrt{D(m) * W(m)} \quad (2)$$

Maximum lateral displacement at the direction of minor principal stress can be estimated from Equation 3.

$$\frac{\delta_{Max(Y-min)}(mm)}{W(m)} = 0.64 * \left(\frac{\delta_{Max(X-max)}(mm)}{W(m)} \right)^2 \quad (3)$$

Where: $\delta_{Max(Y-min)}$: maximum excavation-induced lateral displacement in the direction of the minimum horizontal locked-in stress (mm), see Figure 2

$\delta_{Max(X-max)}$: maximum excavation-induced lateral displacement in the direction of the maximum horizontal locked-in stress (mm)

W : Width of the excavation (m), see Figure 2

1.2 Displacement trough

The paper also suggests Equation 4 for X and Y displacement trough (refer to Figure 2). Equation 4 is defined based on δ_{Max} values in section 2.1.

$$\frac{\delta}{\delta_{Max}} = \exp\left(\frac{-4.685 X^2}{W^2}\right) \quad (4)$$

Where, δ : excavation-induced lateral displacement along the edge of the excavation. δ_{Max} : maximum excavation-induced lateral displacement along the edge of the excavation. W : excavation width in meter. X : distance from the centre of the excavation in meter.

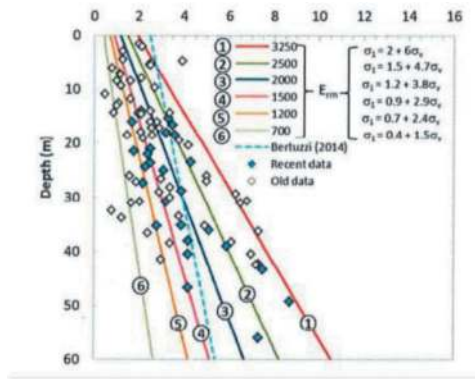

2 FLAC3D MODELS –TO GENERATE DATABASE

In this study and as a continuation of the previous paper, a dataset was generated by analyzing 220 finite difference models of open excavations in FLAC3D 9.00 (Itasca, 2023).

The cases analyzed are depicted in Figure 3. The excavation width was maintained at a constant value of 20 meters, while the excavation length varied within the range of 20 meters to 60 meters in increments of 4 meters (20m, 24m, 28m, 32m, 36m, 40m, 44m, 48m, 52m, 56m, 60m). The analyses were conducted in both Sandstone Class II and III, incorporating different orientations of the major principal stress as an additional variable. The orientations

III	$\sigma_{H-Minor}$ (MPa)	σ_V (MPa)

Figure 5. Model geometry.

were varied at angles of $\alpha=0, 10, 20, 30, 40, 45, 50, 60, 70, 80,$ and 90 degrees.

An equivalent continuum approach was adopted for the geomechanical behavior of Hawkesbury Sandstone II and III. The horizontally bedded Hawkesbury Sandstone was modeled with a transversely isotropic elastic model. Table 1 provides the equivalent continuum design parameters adopted in the study. The values in Table 1 were selected based on previous experience in this area.

Regarding Figure 4a and 4b (Oliveira and Parker, 2014), the locked-in stress reported in Table 2 was adopted

The orientation of Major locked-in horizontal stress has defined as a variable with respect to the excavation as shown in Figure 5.

3 LATERAL DISPLACEMENT VERSUS MAJOR PRINCIPAL STRESS ORIENTATION

This section examines the effect of the orientation of the major lock-in stresses (α). Figure 5 illustrates the geometry of the models. Points A and B are designated at the edge of the excavation, positioned at $Y=0$ and $X=0$, respectively. α is defined as the angle formed between the major horizontal locked-in stress vector and the X-direction (as depicted in Figure 5).

The orientation of the major locked-in stress varied at angles of $\alpha=0, 10, 20, 30, 40, 45, 50, 60, 70, 80,$ and 90 degrees, and the displacements at points A and B (as indicated in Figure 5) were calculated using FLAC3D.

The excavation width remains constant at 20m in all analyzed cases, while the excavation length varies from 20m to 60m. Figures 6 and 7 present the results from the analyzed cases. Figure 6 showcases the impact of the major locked-in stress orientation on excavation-induced lateral displacements.

Graphs in Figures 6a and 6b display the maximum lateral displacement along the width of the excavation (lateral displacement in the X-direction at point A in Figure 5) for Sandstone Class II and III.

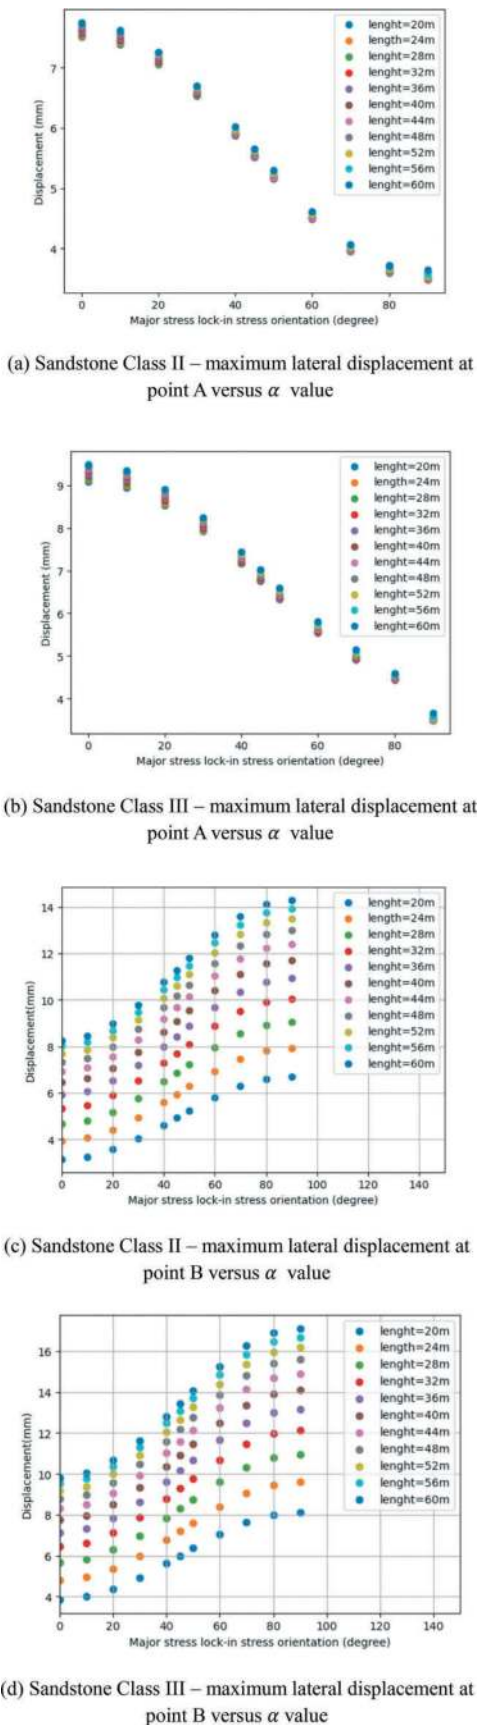

Figure 6. Maximum lateral displacement along the excavation length and width versus α value.

Figure 6a demonstrates that the maximum X-displacement at point A occurs when the major locked-in stress aligns with the X-direction, decreasing as α increases from 0 to 90. A similar trend is observed in both Sandstone Class II and III, although lateral displacements are higher in Class III (Figure 6b) compared to Class II.

Figures 6c and 6d depict the maximum lateral displacement along the length of the excavation in the Y-direction (Y-displacement at point B, as seen in Figure 5). Figure 6c indicates that the maximum Y-displacement at point B occurs when the major locked-in stress aligns with the Y-direction, decreasing as α decreases from 90 to 0. Similar trends are observed in both Sandstone Class II and III, with higher lateral displacements in Class III (Figure 6d) compared to Class II.

3.1 Normalised lateral displacements

Figure 6 shows that the occurrence of maximum lateral displacements at points A and B is observed at orientations $\alpha=0$ degrees and $\alpha=90$ degrees, respectively.

Figure 7 illustrates normalized lateral displacements versus α values. In Figures 7a and 7b, the lateral displacement at point A has been normalized with respect to its maximum value (which occurs at $\alpha=0$, i.e., when the major horizontal locked-in stress is perpendicular to the excavation width). Figures 7a and 7b show the normalized displacement for excavations in Sandstone Class II and III, respectively.

In Figures 7c and 7d, the lateral displacement at point B has been normalized relative to its maximum value, occurring at $\alpha=90$ degrees, where the major horizontal locked-in stress is perpendicular to the excavation length (see Figure 5). Figure 7c illustrates the normalized displacement for excavations in Sandstone Class II, while Figure 7d depicts the corresponding values for Sandstone Class III. The normalized graphs have then been used for curve fitting.

3.2 Curve fitting

The curve fitting function in Python, utilizing the NumPy library, has been employed to derive the following equations (Equations 5) describing the relationship between the major locked-in stress and the X and Y displacements at points A and B, respectively. Figure 8a illustrates the correlation that can be employed to estimate lateral excavation-induced displacement at point A.

$$x_{disp}(\alpha) = (0.45\sin(\alpha)^2 + \cos^2(\alpha)) \cdot x_{disp}(\alpha=0) \quad (5)$$

Where, α is the angle between major locked-in stress and X-direction; x-disp is the lateral displacement at point A (see Figure 5); $x_{disp}(\alpha=0)$ is the displacement at point A when the major locked-in stress is in X-direction. $x_{disp}(\alpha=0)$ can be computed using equation 1 and 2 for Sandstone Class II and III, respectively.

(a) Sandstone Class II – normalised lateral X-displacement at point A versus α

(b) Sandstone Class III – normalised lateral X-displacement at point A versus α

(c) Sandstone Class II – normalised lateral Y-displacement at point B versus α

(d) Sandstone Class III – normalised lateral Y-displacement at point B versus α

Figure 7. Normalised maximum lateral displacement along the excavation length and width versus α .

(a) Curve Fitting: Sandstone Class II and III – normalised X-displacement at point A versus α

(b) Curve Fitting: Sandstone Class II and III – normalised Y-displacement at point B versus α

Figure 8. Curve fitting.

Equation 6 estimates the lateral excavation-induced displacement at point B as a function of α . In which, α is the angle between major locked-in stress and X-direction; y-disp is the lateral displacement at point B (refer to Figure 5); $y_{disp}(\alpha = 90)$ is the lateral displacement at point B if the major locked-in stress is in Y-direction. $y_{disp}(\alpha = 90)$ can also be calculated using equation 1 and 2 for Sandstone Class II and III, respectively. Figure 8b shows the curve versus the database used to drive this curve.

$$y_{disp}(\alpha) = (0.45 \sin(\alpha))^2 + \cos^2(\alpha) \cdot y_{disp}(\alpha = 90) \quad (6)$$

4 LATERAL DISPLACEMENT IN NON-SQUARED SHAPE BOX VERSUS SQUARED SHAPE EXCAVATIONS

In this section, the influence of the Length-to-Width ratio is evaluated in a non-square-shaped excavation. As described in Section 2, the database was created by maintaining excavation width and depth as constant values, both equal to 20 meters. The length of the excavation was initially set at 20 meters (forming a square shape) and progressively increased in

4-meter intervals to reach lengths of 24 meters, 28 meters, and so forth, up to 60 meters. The excavation with dimensions 20 meters by 20 meters is considered the reference case, and the analysis focuses on examining the rise in lateral displacement as the excavation length increases.

The orientation of the major horizontal locked-in stress is assumed to remain constant and perpendicular to the length of the excavation ($\alpha=90$).

Figure 9 presents the outcomes for Sandstone Class II and Class III. The horizontal axis in Figure 10 represents the excavation length divided by 20 meters, which is equivalent to the excavation length in the square-shaped reference excavation. The vertical axis then depicts the maximum lateral displacement along the length of the excavation (Point B in Figure 5), normalized by the lateral displacement in the square-shaped excavation (2 meters wide by 2 meters long, which serves as the reference excavation).

The blue line in Figure 9 was generated using a curve fitting method in Python and the NumPy library. The derived correlation is expressed by the equation:

$$y_{disp} = y_{disp.ref} \cdot 0.91 \exp(3.2L/20m) \quad (7)$$

In which B represents the length and width of the reference square-shaped excavation. L is the length of the B(m) x L(m) dimension excavation. This correlation has been established and is suggested for examination in future studies, particularly for other values of B.

Figure 9. Lateral displacement in a rectangle shape excavation (B(m)-wide x L(m)-long with reference to the square shape excavation of B(m) x B(m).

5 CONCLUSION AND RECOMMENDATION

The suggested approach is summarised as below:

For square shape excavation:

- Calculate the maximum excavation-induced lateral displacement in the direction of the

maximum horizontal locked-in stress based on width, depth, and Hawkesbury Sandstone class using Equations 1 to 2

- Calculate the maximum excavation-induced lateral displacement in the direction of the minimum horizontal lock-in stress using Equation 3.
- Modify the calculated value based on the α value using Equation 5 and 6;

For rectangle shape excavation B(m)-wide x L(m)-long:

- Calculate the maximum lateral displacement for B(m) x B(m) square shape excavation using Equation 1 and 2,
- Modify the calculated values for L(m) long excavation, using Equation (7)

The reader should be mindful of the limitations associated with the proposed equations, outlined below:

- Applicability to Specific Rock Classes:

This approach has been formulated for Hawkesbury Sandstone Class II and III. Its generalization to other rock classes may require further investigation.

- Depth and Width Range:

Equations (1), (2), and (3) are valid for excavation depths ranging from 5m to 20m.

Equations (1), (2), and (3) are applicable to excavation widths within the range of 10m to 50m.

- Depth Limitation for Equations (5) and (6):

Equations (5) and (6) were derived based on 20m-wide x 20m-long excavation. Additional studies are needed to assess their suitability for deeper and wider excavations.

- Limited Applicability of Equation 7:

Equation 7 has been developed based on a 20m-wide and 20m-deep excavation. Further evaluation is necessary to determine its applicability to excavations with different dimensions.

- Bedding Plane and Discontinuity Effects:

The proposed equations do not account for the impact of bedding planes and discontinuities. The models in Plaxis3D and Flac3D assume a continuum media.

The equations presented in this paper estimate lateral displacement at the ground level. Consideration of other factors or locations may necessitate additional analysis.

These limitations highlight the need for careful consideration and validation in applying the proposed equations in various geological and geometric contexts.

A modified approach to assess tunnel excavation stability

Sajjad Anwar*

AECOM New Zealand, Auckland, New Zealand

Geoff Charlesworth

AECOM Australia, Brisbane, Australia

ABSTRACT: This paper discusses and proposes modifications to an earlier simplified approach for the preliminary assessment of excavation behaviour in rock tunnelling by Russe (2008). Modifications are proposed so that new graphs can be used for different rock types considering any tunnel shape and in situ stress state. These graphs can be constructed in computer software MS Excel adopting different rock mass conditions, tunnel shapes and in situ stresses. A discussion is presented with example illustration. The new graphs are arranged in the same logical sequence, of rock mass quality based on Hoek et al (2013) method (1); rock mass strength considering material constant, m_i and blast disturbance factor, D (2); Stability Factor considers the non-circular tunnel profile and anisotropic stress state (3); and Tunnel Excavation Stability (4) of a rock mass using NGI Q system. Based on these new graphs, the excavation behaviour and effective performance of the tunnel support system can be assessed in relation to spalling, rock bursting and squeezing occurrences.

Keywords: Spalling, squeezing

1 INTRODUCTION

The Russo (2008) simplified approach for the preliminary assessment of the excavation behaviour in rock tunnelling and selection of the support system at the tunnel face based on pre-defined design criteria is a useful tool. However, due to its simplifications, it confined its applications to circular cross section and isotropic stress field ($k = 1.0$). The assessment of the rock mass strength does not consider the overall behaviour of a rock mass but rather uniaxial compressive strength of the rock mass at the boundary of an excavation. The squeezing and spalling excavation behaviour in rock tunnelling can be attributed to overall behaviour of a rock mass rather than failure propagation at the excavation surface.

To overcome these limitations, modifications are suggested to the Russo (2008) “multiple graph” approach. These modifications create a new “multiple graph” approach to be used for different rock types considering noncircular cross sections and anisotropic stress state. The new graphs are arranged in the same logical sequence as Russo (2008). The sequence and comparison are provided below in Table 1.

Like Russo (2008) the new “multiple graph” approach can be used to assess excavation behaviour and effective performance of the tunnel support

system in relation to spalling, rock bursting and squeezing occurrences. These graphs can be constructed in computer software MS Excel adopting different rock mass conditions, tunnel shapes and in situ stress conditions. A discussion is presented with examples illustrated below.

2 NEW MULTIPLE GRAPH APPROACH

The new “multiple graph” approach proposes the use of 4 sub-graphs as shown in Figure 1, each graph is arranged to quantify the corresponding properties presented in Table 1. The first graph is in the lower right quadrant and progress is clockwise through system.

2.1 *Graph 1: Estimation of geological strength index*

Graph I is located at the lower right quadrant in Figure 1. It is used to estimate Rock Mass Fabric (GSI) based on Rock Quality Designation (RQD) and Joint Conditions using NGI (2022) Q system joint surface roughness (J_r) and alteration (J_a) number.

The GSI chart published by Hoek and Marinos (2000) was developed on the assumption that GSI would be estimated based on visual exposure

Table 1. Comparison of logical sequence in development of multiple graph approach.

Graph	Russo (2008)	Modification
1	Rock block volume + Joint Conditions = Rock mass fabric (GSI)	RQD + Joint Conditions Rock mass fabric (GSI)
2	Rock mass fabric (GSI) + Strength of intact rock = Rock mass strength	Rock mass fabric (GSI) + Strength of intact rock + material constant (mi) + Blast Disturbance factor (D) = Rock mass global strength
3	Rock mass strength + Isotropic circular profile in situ stress = Competency	Rock mass global strength + Anisotropic noncircular profile in situ stress = Stability Factor
4	Competency + Self-supporting capacity (RMR) = Excavation behaviour	Stability Factor + Rock Quality (Q) = Excavation behaviour and Tunnel Stability

observations of the rock mass in the field. It was envisaged that the estimation of the GSI using GSI (2000) chart would be made by qualified and experienced geologists or engineering geologists. When such individuals are available, the use of the GSI charts based on the descriptive categories of rock mass structure and discontinuity surface conditions have been found to work well. However, there are many situations where engineering staff rather than geological staff are assigned to collect data, which means that the mapping of rock masses or core is carried out by persons who are perhaps less comfortable with these qualitative descriptions. Therefore, attempts were made by many researchers to quantify the estimation of the GSI. Hoek et al (2013), Cai et al (2004) Somnez and Ulusay (1999) and Russo (2008) have published quantified GSI charts which incorporate joint surface and rock structure scales.

The authors of this paper have adopted the quantification of GSI method by Hoek et al (2013) due to its user friendly quantification of the GSI based on readily available RQD data from boreholes and observed joint surface condition parameters Jr and Ja from commonly used Q rock mass classification system for tunnelling applications. The correlation relationship is shown below and is graphically represented in Graph I (located at the lower right quadrant in Figure 1):

$$GSI = \frac{52J_r/J_a}{(1 + J_r/J_a)} + RQD/2$$

It should be noted here that the approach to estimate GSI is not recommended in complex and heterogeneous rock masses, such as a flysch, where the specific charts proposed by Marinov and Hoek (2001) should be used for estimating the GSI.

MULTIPLE-GRAPH TO ASSESS EXCAVATION BEHAVIOUR AND TUNNEL STABILITY

Figure 1. New multiple-graph approach for the preliminary assessment of the excavation behaviour and tunnel support system performance in relation to spalling, rock bursting and squeezing.

2.2 Graph 2: Estimation of rock mass global strength

Graph 2 is located in the lower left quadrant in Figure 1. It is used to estimate the rock mass global strength (σ_{cm}) based on GSI, rock intact strength (σ_{ci}), material constant (m_i) and blast disturbance factor (D). The estimation of the rock mass global strength is based on the equation of Hoek et al (2002).

Most numerical models can follow the process of fracture propagation and this level of detailed analysis is very important when considering the stability of excavations in rock and when designing support systems. However, to assess the performance of the excavation and tunnel stability it is useful to consider the overall behaviour of a rock mass rather than the detailed failure propagation process. For example, when considering squeezing potential of a tunnel excavation, it is useful to have an estimate of the overall strength of the rock mass rather than a detailed knowledge of the extent of fracture propagation at the excavation surface. The estimation of rock mass global strength using Hoek et al (2002) is provided in Figure 2.

A graphic representation of the rock mass global strength using the above equation is presented in Graph 2, which is located at the lower left quadrant in Figure 1. A value of rock mass global strength is graphically obtained by the intersection of the estimated GSI and intact rock strength curves. An average value of m_i of 25 with $D = 0.5$ is used to

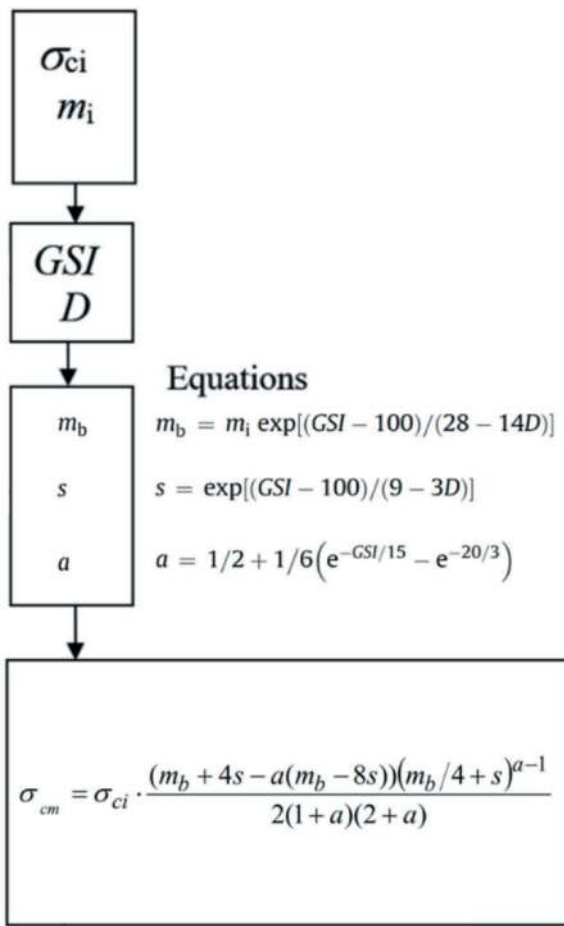

Figure 2. Flow chart for the estimation of rock mass global strength using Hoek et al (2002).

construct the rock strength curves in Figure 1. The curves for a value of m_i other than 25 and D other than 0 can be constructed easily using MS Excel worksheets. The reliability of the rock mass global strength estimation is primarily related to both the effective applicability of the Hoek-Brown failure criterion and the occurrence of shear type failure. The guidance for estimating material constant, m_i value for rock types and blast distance factor, D , is provided in Figures 3 and 4.

2.3 Graph 3: Estimation of rock mass stability factor

Graph 3 is located in the upper left quadrant in Figure 1. It estimates the rock mass Stability Factor based on rock mass global strength (σ_{cm}) and maximum excavation induced tangential stress (σ_{θ}). The Stability Factor is simply defined as the ratio between the maximum excavation induced tangential stress (σ_{θ}) and rock mass global strength (σ_{cm}).

$$\text{Stability Factor} = \sigma_{\theta} / \sigma_{cm}$$

It is important to note here that the simplified assumption made by Russo (2008) about the circular

Rock Type	Class	Group	Texture

Pyroclastic			Agglomerate (19 ± 3)	Breccia (19 ± 5)	Tuff (13 ± 5)	

Values in parenthesis are estimates.
*Conglomerates and breccias may present a wide range of m_i values depending on the nature of the cementing material and the degree of cementation, so they may range from values similar to sandstone to values used for fine grained sediments.
**These values are for intact rock specimens tested normal to bedding or foliation. The value of m_i will be significantly different if failure occurs along a weakness plane.

Figure 3. Guidelines for estimating material constant, m_i for various rock types when laboratory tests are not possible (From Hoek, 2018).

tunnel in isotropic stress field using in-situ stress ratio $k = 1$ is not adopted to estimate σ_{θ} . Instead, an assumed value of $k = 1.5$ is considered along with horse-shoe shaped tunnel profiles with curved side walls, to estimate tangential stress (σ_{θ}) in Figure 1. The tangential stresses, around the horse-shoe shaped tunnel with curved side walls, are estimated using the following relationship developed by Hoek and Brown (1980).

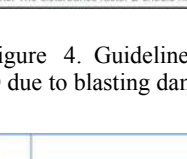

$$\text{The tangential stress } (\sigma_{\theta}) = (A \times k - 1) P_v$$

Where A is tunnel shape constant as provided in Figure 5, k is the ratio horizontal/vertical stresses and P_v is overburden stress = γH , with γ = rock mass density (assumed value = 0.027 MN/m^3) and H = overburden.

The value of Stability Factor = 1 in the graph separates the deformation response of the excavation into the elastic (below) and plastic (above) domains. The iso-overburden curves for any in situ stress ratio (k), rock mass density (γ) and tunnel shape using shape constant (A), can be constructed easily using MS Excel worksheets.

2.4 Graph 4: Estimation of excavation behaviour and tunnel stability

Graph 4 is located upper right quadrant in Figure 1. This shows the relationship between rock mass strength, in situ stress and rock behaviours in tunnels with rock mass quality (Q).

Appearance of rock mass	Description of rock mass	Suggested value of D
	Excellent quality-controlled blasting or excavation by a road-header or tunnel boring machine results in minimal disturbance to the confined rock mass surrounding a tunnel.	D = 0
	Mechanical or manual excavation in poor quality rock masses gives minimal disturbance to the surrounding rock mass.	D = 0
	Where squeezing problems result in significant floor heave, disturbance can be severe unless a temporary invert, as shown in the photograph, is placed.	D = 0.5 with no invert
	Poor control of drilling alignment, charge design and detonation sequencing results in very poor blasting in a hard rock tunnel with severe damage, extending 2 or 3 m, in the surrounding rock mass.	D = 1.0 at surface with a linear decrease to D = 0 at ± 2m into the surrounding rock mass

Note: The disturbance factor D should never be applied to the entire rock mass surrounding an excavation

Figure 4. Guidelines for estimating disturbance factor D due to blasting damage (From Hoek et al, 2018).

Shape Constant	Tunnel shape								
A	5.0	4.0	3.9	3.2	3.1	3.0	2.0	1.9	1.8

Figure 5. Shape Factors for Various Tunnel Shapes (From Hoek and Brown, 1980).

The rock behaviour during tunnelling is controlled by rock bursting, wedge failure and squeezing ground pressures. Rock bursting is a sudden fracturing of rock in conjunction with an audible sound. Rock burst can occur as a violent detachment of rock slabs from the face, sidewalls and crown of a tunnel or it may occur as gradual spalling where the rock slabs progressively. In all cases, the failure phenomenon occurs due to overstressing where the rock surrounding the excavation is brittle and massive. For a preliminary estimation of the possibility of stress-driven instabilities of brittle rocks, the region susceptible to spalling/rockburst is marked with $Q > 1$. With respect to the classification proposed by Diederichs et al. (2010) and Cai and Kaiser (2014) the onset for the spalling and rock bursting failure is taken at Stability Factor $(\sigma/\sigma_{cm}) > 0.8$.

The mobilisation of pressure due to failure of the rock mass around a tunnel opening under the influence of in situ stresses can be expressed as squeezing. Squeezing involves pronounced time-dependent deformations and is generally associated with rocks of low strength and high deformability such as, for example, phyllites, schists, serpentines, mudstones, tuffs, certain kinds of flysch, and chemically weathered igneous rocks. For a preliminary estimation of the possibility of squeezing ground, the method proposed by Singh et al., (1992) and Bhasin and Grimstad

(1996) is considered. A similar approach is recommended by NGI (2022). In this respect the region on the plot with $Q < 1$ is marked, where squeezing ground pressures may be generated. The stable ground onset is taken at Stability Factor of 0.2 to 1 indicating rock mass strength is 5 to 1 times of the tangential stresses around the opening with increasing Q values.

As the overburden depth increases, the tangential stresses around the opening are also increase, resulting in aggravated squeezing problems. E.g., Singh et al. (1992) have developed an empirical criterion based upon the rock mass quality Q and the height of overburden H for predicting squeezing conditions, i.e., when squeezing occurs:

$$H > 350Q^{1/3}(\text{m})$$

Using this method, at $Q = 1$, the onset overburden depth to cause squeezing ground pressures is 350m compared to $Q = 0.01$, where the onset overburden depth to cause squeezing ground pressures is 75m. With this consideration the stable ground line is drawn starting at $Q = 0.001$ at Stability Factor of 0.2 and terminating at $Q = 100$ at Stability Factor of 1.0. Using the same analogy, the lines for mild to moderate and heavy squeezing ground pressures lines are drawn. The onset for mild to moderate squeezing ground pressures is taken at Stability Factor of 1 to 5 indicating tangential stresses around the opening are 1 to 5 of the rockmass strength with increasing Q values. Heavy squeezing ground pressures onset is taken at Stability Factor of more than 5. The unstable wedges or potential of rock wedge failure zone on the plot is mainly associated with poor to good rock mass quality class with Q value in the range of 1 to 100. The potential of rock wedge failure is subject to relatively low stress condition, i.e., when the failure mechanism at the excavation boundary is dominated by the shear strength of discontinuities rather than material shear strength itself. The region between squeezing ground pressures and spalling and rock bursting is marked as the “Unstable wedges” zone.

3 Q VALUE ASSESSMENT

In the case that the Q values are not available for the application of the multiple graphs, it may be useful to consider the procedure described in the following. The Q-value gives a description of the rock mass stability of an underground opening in jointed rock masses. High Q-values indicates good stability and low values means poor stability. Based on 6 parameters the Q-value is calculated using the following equation:

$$Q = \frac{RQD}{J_n} \times \frac{J_r}{J_a} \times \frac{J_w}{SRF}$$

The six parameters are:

RQD = Degree of jointing (Rock Quality Designation)

- J_n = Joint set number
- J_r = Joint roughness number.
- J_a = Joint alteration number
- J_w = Joint water reduction factor
- SRF = Stress Reduction Factor

In accordance with Hoek et al (1993), the parameters RQD, J_n , J_r and J_a represent the rock mass blockiness and joint surface condition (Q'), conceptually equivalent to the GSI. Consequently, given that the possible ranges of variability the following mean value equation can be used to assess Q' value from GSI.

$$Q' = \text{EXP}(\text{GSI} - 44)/9$$

Where in Q system $Q' = \text{RQD}/J_n \times J_r / J_a$

Finally, to get Q value the active stress (J_w/SRF) value shall be added. In case of dry rock mass condition or drained tunnelling conditions the $J_w = 1$ is considered. Other values of J_w such as 0.66 for medium inflow to 0.1 for exceptionally high inflow can be used. The SRF values can be approximated from the Stability Factor ($\sigma\theta/\sigma_{cm}$) value as provided in Table 2.

Table 2. SRF estimation.

Stability Factor $\sigma\theta/\sigma_{cm}$	SRF
< 1.0	1
1.0 to 2.0	2.5
2.0 to 3.0	5
3.0 to 5	10
> 5	20

Once the Q' is determined from the GSI, the Q values can reasonably be estimated by combining remaining active stress parameters i.e., J_w and SRF.

3.1 Practical application of the NEW multiple graph

The new 'multiple graph' has two main applications:

- 1) During the preliminary design stages to assess the expected excavation behaviour and tunnel stability issues, in order to devise a plan for detailed analysis.
- 2) During construction stage, select advance length and support type from Q chart of the NGI (2022) in response to the encountered ground conditions and tunnel face mapped Q values.

Examples 1 and 2 (below in this section) illustrate the application of the new 'multiple graph' approach with reference to the above two main applications.

Example 1: A 10m span horseshoe shaped tunnel (assumed Effective Span Ratio = 1 for the purposes of this example, and the following example) with curved side-wall is located at 160m depth, where

in situ stress ratio is determined as 1.5. The site investigation data has shown the ground conditions at tunnel depth and zone within 2 to 3 times of the tunnel span is moderately strong igneous rock with an average intact strength of 40MPa. The rock unit weight, $\gamma = 0.027\text{MN}/\text{m}^3$. The RQD within the tunnel zone is averaged at 65% with joint surface conditions characterised as smooth, undulating with sandy particles, clay-free thin infillings. Tunnel excavation will be undertaken using drill and blast method.

Solution 1 using Graph 1 lower right quadrant in Figure 1:

- Using NGI (2022) the joint roughness number (J_r) for smooth, undulating surface = 2
- Using NGI (2022) the joint alternation number (J_a) for sandy particles, clay-free thin infillings = 4
- The RQD = 65%

Using Graph 1 which is located lower right quadrant in Figure 1, the GSI is assessed as 50. This indicates rock mass is blocky with poor joint surface quality. The solution 1 illustration is marked in Figure 6.

Solution 2 using Graph 2 lower left quadrant in Figure 1:

- Moderately strong igneous rock with an average intact strength, $\sigma_{ci} = 40\text{MPa}$
- Using Figure 3, the material constant (m_i) for volcanic rocks = 25
- A blast disturbance factor, D is considered as = 0.5

The intercept of GSI = 50 with $\sigma_{ci} = 40\text{MPa}$, read along x-axis given the rock mass (global) strength, $\sigma_{cm} = 8\text{MPa}$. The solution 2 illustration is marked in Figure 6.

Solution 3 using Graph 3 upper left quadrant in Figure 1:

- Tunnel depth, $H = 160\text{m}$
- In situ Stress Ratio, $k = 1.5$
- Shape factor for a horseshoe shaped tunnel with circular wall using Figure 5 = 3.1
- The rock unit weight, $\gamma = 0.027\text{MN}/\text{m}^3$

The intercept of $\sigma_{cm} = 8\text{MPa}$ with tunnel depth, $H = 160\text{m}$, read along y-axis given the Stability Factor, SF ($\sigma\theta/\sigma_{cm}$) = 2.0. The solution 3 illustration is marked in Figure 6.

Solution 4 using Graph 4 upper right quadrant in Figure 1:

- Using GSI = 50, Q' is estimated in accordance with Hoek et al (1993) = 1.9
- The Stability Factor is 2.0, therefore using Table 2, SRF = 2.5.
- Considering drained conditions, with $J_w = 1.0$, the Q value is assessed as $1.9 \times 1/2.5 = 0.76$

The intercept of Stability Factor = 2.0 and $Q = 0.76$, landed in non-squeezing rock pressure zone, potential for unstable wedge failure. The solution 4 illustration is marked in Figure 6.

Figure 6. Example 1 – Graphical solution.

In summary, Graph I [Jr = 2, Ja = 4 and RQD = 65% → GSI≈50 (blocky rock mass with poor joint surface condition)]; Graph 2 [GSI≈50 & σ_{ci} = 40MPa → σ_{cm} ≈8MPa]; Graph III [σ_{cm} ≈8MPa & H = 160m → SF ≈2.0]; Graph IV [SF ≈ 2.0 & Q ≈ 0.8 → (prevalent hazard: wedge instability) → Application of Support Type 5 (i.e., 3.0m long rock bolts with 90mm Fibre reinforced shotcrete) in accordance with Q support chart as shown in Figure 7.

Figure 7. Estimation of support type for example 1.

Example 2: Similar shape of tunnel of Example 1, but located at 500m depth, where in situ stress ratio is assumed 1.5. The site investigation data has shown the ground conditions at tunnel depth and zone within 2 to 3 times of the tunnel span is weak volcanic rock with an average intact strength of 20MPa. The assumed rock unit weight, $g = 0.027\text{MN}/\text{m}^3$ and RQD within the tunnel zone is assumed averaged at

10% with joint surface conditions characterised as rough or irregular, undulating with unaltered joint walls, surface staining only. Tunnel excavation will be undertaken using drill and blast method.

Solution 1 using Graph 1 lower right quadrant in Figure 1:

- Using NGI (2022) the joint roughness number (Jr) for rough or irregular, undulating = 3
- Using NGI (2022) the joint alternation number (Ja) for unaltered joint walls, surface staining only = 1
- The RQD = 10%

Using Graph 1, which is located lower right quadrant in Figure 1, the GSI is assessed as 44. This indicates rock mass is disintegrated with very good joint surface quality. The solution 1 illustration is marked in Figure 8.

Solution 2 using Graph 2 lower left quadrant in Figure 1:

- Weak volcanic rock with an average intact strength, $\sigma_{ci} = 20\text{MPa}$
- Using Figure 3, the material constant (m_i) for volcanic rocks = 25
- A blast disturbance factor, D is considered as = 0.5

The intercept of GSI = 44 with $\sigma_{ci} = 20\text{MPa}$, read along x-axis given the rock mass (global) strength, $\sigma_{cm} = 3\text{MPa}$. The solution 2 illustration is marked in Figure 8.

Solution 3 using Graph 3 upper left quadrant in Figure 1:

- Tunnel depth, H = 500m
- In situ Stress Ratio, $k = 1.5$
- Shape factor for a horseshoe shaped tunnel with circular wall using Figure 5 = 3.1
- The rock unit weight, $g = 0.027\text{MN}/\text{m}^3$

The intercept of $\sigma_{cm} = 3\text{MPa}$ with tunnel depth, H = 500m, read along y-axis given the Stability Factor, SF (sq/scm) = 14.4. The solution 3 illustration is marked in Figure 8.

Solution 4 using Graph 4 upper right quadrant in Figure 1:

- Using GSI = 44, Q' is estimated in accordance with Hoek et al (1993) = 1.0
- The Stability Factor is 14.4, i.e., > 5, therefore using Table 2, SRF = 20.
- Considering drained conditions, with $J_w = 1.0$, the Q value is assessed as $1.0 \times 1/20 = 0.05$

The intercept of Stability Factor = 14.4 and Q = 0.05, indicated heavy squeezing rock pressure zone conditions. The solution 4 illustration is marked in Figure 8.

In summary, Graph I [Jr = 3, Ja = 1 and RQD = 10% → GSI≈44 (disintegrated rock mass with very good joint surface condition)]; Graph 2 [GSI≈44 & $\sigma_{ci} = 20\text{MPa}$ → σ_{cm} ≈3MPa]; Graph III [σ_{cm} ≈3MPa & H = 500m → SF ≈14.4]; Graph IV [SF ≈ 14.4 & Q ≈ 0.05 → (prevalent hazard: heavy squeezing rock

MULTIPLE-GRAPH TO ASSESS EXCAVATION BEHAVIOUR AND TUNNEL STABILITY

Figure 8. Example 2 – Graphical solution.

pressure) → Application of the Support Type 7 (i.e., 3.0m long rock bolts with 200mm fibre reinforced shotcrete + reinforced ribs of sprayed concrete at 2.9m centres) in accordance with Q support chart as shown in Figure 9.

Figure 9. Estimation of support type for example 2.

4 CONCLUSIONS

A modified “multiple graph” approach for the preliminary estimate of the rock mass excavation behaviour and tunnel stability, and consequently, assessment of support type for the probable hazards for tunnelling has been illustrated.

The new modified “multiple graph” approach utilizes simplified assumptions similar to those made under Russo (2008) “multiple graph” approach, i.e., circular tunnel in homogeneous/isotropic rock mass, equivalent continuum modelling, $k=1$.

Examples are presented to show the application of the new ‘multigraph’ to predict the stability problems in tunnels in both competent and less competent rocks. The new multigraph approach involves the estimation of stress-strength parameters through simple empirical criteria. The method is based on previous case studies involving rock stress problems and squeezing rock. For the assessed probable hazards, the support system is estimated from the NGI (2022) Q-Chart, which can then be further analysed.

Study on crosslink-induced Xanthan Gum biopolymer treated soil as a subsea tunnel backfill grout for saline condition permeability control

Jeonguk Bang*, Dong-Yeup Park, Jin Kim, Sanghon Im & Gye-Chun Cho

Department of Civil and Environmental Engineering, Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Korea

ABSTRACT: Subsea tunnels have become indispensable for navigating challenging terrains, but geological and hydro-mechanical challenges mar their construction. Inadequate subsurface exploration can result in accidents like cave-ins, face collapses, and water intrusions. Water intrusions can be particularly devastating due to their high sea levels. While traditional lime-based or cement-based grout materials have been used to tackle the water inflow, environmental drawbacks were inevitable. Biopolymer-based grouts, specifically xanthan gum, have gained attention for their eco-friendliness and durability. This study focuses on the application of cross-linked XG in reducing hydraulic conductivity in marine clay in seawater conditions. Through the consolidation test, the cation cross-linkage induced xanthan gum-treated marine clay showed a significant drop in permeability compared to the untreated sample. The results suggest the possible application of cross-linked xanthan gum as an eco-friendly subsea tunnel grouting for permeability control in saline environments.

Keywords: Water inflow, Hydraulic conductivity, Consolidation test, Permeability

1 INTRODUCTION

Ever since the construction of the Thames Tunnel in London in 1825 to 1843, extensive numbers of subsea tunnels have been constructed and operated to pass through challenging areas. Despite its advantages of not being affected by severe weather above the surface, subsea tunnels encountered drawbacks due to their geological and hydro-mechanical conditions. Insufficient and inaccurate subsurface exploration caused severe accidents such as cave-ins, face collapses, and water intrusions (Guo et al., 2021). In the case of water inrush subsea tunnel, it can lead to significant and catastrophic effects owing to the high water levels of the sea (Xue et al., 2019). For example, the Seikan Tunnel in Japan experienced four disastrous water inflows during its construction, causing casualties, financial losses, and construction delays (Anderson et al., 1994). Therefore, proper exploration before construction and sufficient grouting during construction are needed to prevent water inflow of subsea tunnels.

Grouting is applied to stabilize and reinforce the strata to mitigate unfavourable conditions in subsea tunnelling. A conceptual model of subsea tunnel grouting consists of five stages: backfill grouting and permeation grouting, compaction grouting, primary fracture grouting, secondary compaction grouting, and secondary fracture grouting (Zhang et al., 2014). While conventional grout materials are categorized as lime-based or cement-based grout materials, they can cause pollution due to their high pH characteristics. Other low-pollution grout materials or recycled material-based grouts, such as bulk solid waste (Wu et al., 2022), epoxy resin-modified grout (Wang et al., 2021), or slag-based grout (Perez-Garcia et al., 2019), have been introduced as an alternative.

Recently, biopolymer-based grout materials have been proposed as a pollution-free, environmentally friendly, and durable solution. Biopolymers are biological organism-derived polymers that are eco-friendly and carbon-neutral. Extensive research has suggested biopolymer applications for grout materials, considering its practical effect on hydraulic

conductivity reduction for infiltration prevention (Momeni et al., 1999; Khatami et al., 2018; Lee et al., 2021; Ryou et al., 2023). Xanthan gum (XG) biopolymer, a bacteria-originated ionic polysaccharide, interacts by attributing the formation of an interconnecting network between clay particles (Kwon et al., 2023). Moreover, XG biopolymers undergo a hardening process in the presence of cations to induce cross-linkage between xanthan gum polymers. This cross-linkage promotes the gelation of XG to form a rigid and bulk-size system (Lee et al., 2023). However, most biopolymer applications are limited to fabricated soil samples in the laboratory and distilled water conditions. This study examined the permeability drop of cation cross-linkage induced XG-treated marine clay's permeability reduction in seawater conditions.

2 MATERIALS AND METHODS

2.1 Materials

2.1.1 Soil: Marine clay

This study utilized marine clay samples that were bored and sampled near the Ulsan seabed (35° 33'N, 129° 32'E). The sampling depth of 23.0 ~ 23.8 m was used, and its mean grain size (D_{50}) is 19.22 mm. In-situ water contents (w) is 58.55 % with a liquid limit (LL) and plastic limit (PL) of 65.4 % and 23.3 %, respectively, with a specific gravity of 2.71. Figure 1 shows the particle size distribution, and this marine clay can be classified as fat clay with sand (CH) according to the unified soil classification system (USCS). The X-ray diffraction analysis (XRD) quantified the compositing minerals of the marine clay, as shown in Table 1. The soil samples were oven-dried at 130 ± 1 °C for at least 24 h to evaporate the pore water and sieved using no. 40 sieve before use.

2.1.2 Biopolymer: Cross-linkage induced xanthan gum

The negatively charged carboxyl group of XG hydrogel forms a bind when it encounters an aqueous solution containing cation. This process is the cross-linkage-induced gelation of xanthan gum with cations such as Na^+ , Ca^{2+} , and Cr^{3+} . This study utilized trivalent chromium (Cr^{3+}) as a cross-linkage agent since Cr^{3+} is an essential mineral for humans and less toxic than the heavy metal ion hexavalent chromium (Cr^{6+}) (Baruthio et al., 1992). Moreover, a trace amount of sodium chloride (NaCl) was used as a surface-active agent to minimize individual repulsive force and to promote binding between XG and Cr^{3+} (Nolte et al.,

1992). A rigid system due to the gelation of Cr^{3+} cross-linked XG (CrXG) is shown in Figure 2.

Figure 1. Particle size distribution of marine clay.

Figure 2. Gelation process of XG and Cr^{3+} .

2.2 Methods

2.2.1 Specimen preparation

The experimental specimens were prepared using CrXG treated the dried marine clay sample. Dry XG powder (CAS: 11138-66-2; Sigma-Aldrich) with a mass ratio of 1% to the dried marine clay and chromium nitrate nonahydrate (Daejung Chemical Co.) with a mass ratio of 30% to the XG powder was prepared. Research-graded NaCl

Table 1. Composition of minerals in marine clay.

Quartz	Muscovite/Illite	Calcite	Albite	Orthoclase	Kaolin	Chlorite	Pyrite	Halite	Hornblende	Montmorillonite
28.9	24.2	18.7	11.9	7.5	3.4	2.2	1.9	1.3	-	-

with a mass ratio of 10 % to the XG powder was mixed with XG, Cr^{3+} with an initial water content of 58.55 %, corresponding to the in-situ water content. The CrXG hydrogel was thoroughly mixed using a laboratory hand-blender for 1 min before use. Finally, dried marine clay was hand-mixed with the CrXG to reach the desired water content and XG ratio.

2.2.2 Consolidation test

The permeability of the CrXG-treated marine clay was measured through a 1D consolidation test according to ASTM D2435-11 (ASTM, 2020). An automatic computerized consolidation test apparatus (Wykeham Farrance; 26-WF3120) with an oedometric cell of diameter and height of 63.5 mm and 20 mm, respectively. A saturated porous plate and wet filter paper (Whatman; Grade 42 filter paper) were placed on the specimen's top and bottom for drainage and equilibrium between seawater. Before testing, the prepared CrXG-treated marine clay specimen was placed and compacted by tamping in 3 layers inside the oedometric cell. The oedometric cell was placed in the consolidation apparatus, and laboratory substitute seawater was poured according to ASTM D1141-98 (ASTM, 2021). Before the test, the initial void ratio was calculated using the specific gravity, initial height, and cell area.

The consolidation was performed with six incremental steps of 12 kPa, 25 kPa, 50 kPa, 100 kPa, 200 kPa, and 400 kPa and three unloading steps of 200 kPa, 100 kPa, 25 kPa. The loading duration was 24 hours for each loading and unloading, and the displacement was measured using a top-mounted linear variable displacement transducer (LVDT). The coefficient of consolidation (c_v) at each loading was analyzed by the log time method (Casagrande et al., 1940). The hydraulic conductivity (k) was computed at each loading step, and the final compressibility index (C_c) and swelling index (C_s) were derived using the void ratio-pressure relation (Terzaghi et al., 1996).

3 RESULTS AND DISCUSSIONS

3.1 Consolidation behavior of CrXG treatment

Figure 3 shows the time-displacement curve at 200 kPa loading step for untreated and CrXG-treated marine clay. The final compression of the two cases is almost identical with or without the CrXG treatment. However, the time-displacement curve shape of the CrXG-treated sample depicts a delayed shift. When compared, each case's 50 % compression point at 200 kPa is 123 sec of the untreated sample and 1608 sec of the CrXG-treated sample.

Figure 4 depicts the void ratio-pressure curve for untreated and CrXG-treated marine clay. The compressibility index (C_c) is 0.313 and 0.329 for untreated and CrXG-treated samples. It can be assumed that the compressibility is smaller due to CrXG treatment but almost identical, as it was seen for each loading step. However, the swelling index

(C_s) is 0.071 and 0.046 for untreated and CrXG-treated samples, respectively. The difference in the swelling index is due to the hydrophilic XG biopolymer absorbing the seawater in the unloading process. This behavior can be desirable as the XG-treated soil swells to fill the fractures when pressure dissipates.

Figure 3. Time-displacement curve at 200 kPa loading.

Figure 4. Compression curve.

3.2 Permeability behavior of CrXG treatment

As the coefficient of consolidation (c_v) is in inverse proportion to the 50 % compression point at the log-time method (i.e., $c_v = T_v H^2 / t_{50}$), the coefficient of consolidation (c_v) is smaller for the CrXG-treated marine clay. Permeability k at each void ratio was computed using the coefficient of volume change (m_v) and coefficient of consolidation (c_v) relationship (i.e., $k = c_v m_v / \gamma_w$). Figure 5. illustrates the computed permeability at each void ratio (e_p). CrXG-treated marine clay depicts a significant permeability drop from the initial treatment, lower than 10^{-7} cm/s. The requirement for a hydraulic barrier is 10^{-7} cm/s (US EPA, 1998; Benson et al., 1999). The treated sample meets the criteria, while the untreated sample was above the limit. The

decrease in the permeability k was caused by the gelation of CrXG hydrogel in the pore space in the marine clay.

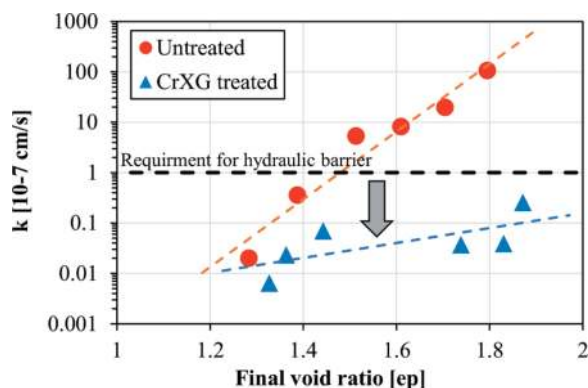

Figure 5. Permeability with a variation in the void ratio.

4 CONCLUSIONS

This study examined the utilization of cation cross-linkage induced xanthan gum biopolymer on the hydraulic conductivity of the marine clay. CrXG demonstrated its potential use as a grout material for subsea tunnels owing to its permeability reduction when the marine clay was treated. The gelation of CrXG hydrogel and its binding characteristic with the clay particles by the attraction of electric forces contributed to the drop in permeability. However, the undrained shear strength and microscopic analysis of CrXG treatment needs to be considered to fully comprehend the CrXG and clay particle interactions.

Fixing of unstable water-saturated soils by artificial freezing for construction of inter-tunnel joints during metro construction

E.A. Deplagni*, V.P. Kivliuk & D.S. Konyukhov*
Mosinzhproekt JSC, Moscow, Russia

ABSTRACT: Different variants of freezing of soils around the inter-tunnel assemblies under construction in unstable water-saturated soils are shown and analysed on the basis of the experience gained at various underground construction sites in Moscow. The peculiarities and disadvantages of each variation of freezing methods are considered. In order to minimise the risks of emergencies during mining operations and complications during the creation of ice-loading fence, recommendations have been developed. When freezing soils, granulated solid carbon dioxide ('dry ice') was used as a cold carrier along with aqueous calcium chloride solution. Freezing of soils by 'dry ice' is based on heat extraction from the surrounding ground body by means of solid cryo-agent (carbon dioxide), which is periodically loaded into the freezing column until an ice-loaded enclosure of the required dimensions is created. This method of ground freezing due to low sublimation temperature (-78 °C) allows reducing considerably the duration of the active freezing period and was successfully applied both independently and in addition to the traditional brine method. Examples of practical implementation of the described method are given.

Keywords: ground freezing, underground space development, tunnelling, metro construction, 'dry ice', water-saturated ground

1 INTRODUCTION

Soil stabilization for the construction of inter-tunnel joints in complex engineering and geological conditions is becoming more and more important, as tunnels are driven by TBMs, and the depth of tunnels under construction in Moscow tends to decrease. The geological structure of the city is such that during the construction of deep subways, interconnections were located, as a rule, in clay or limestone, i.e. in soils that did not require special methods of preliminary stabilization. Now, more and more often, the joints are located at a depth of 20 to 35 m, and these depths are mainly water-saturated sands and sandy loam, i.e. running sands (Konyukhov, 2022).

It should be recalled that in the event of a blowout into a mine, the mine must be flooded immediately to avoid subsidence and the associated catastrophic consequences (Kulikova, Balovtsev, Skopintseva, 2023; Kulikova, Konyukhov, 2022). Interconnections are located, as a rule, between tunnels that have been tunnelled, as well as between a tunnel and a tunnelling structure, such as a dewatering plant

under construction or a tunnel ventilation plant, which are full enclosing structures of a shaft or an excavation. Flooding of such excavations is problematic and sometimes even impossible due to the huge size of the excavations or the presence of an existing shaft or interconnections nearby.

That is why the construction of interconnections in drift sand under the rock pressure of 0.2-0.35 MPa is a dangerous type of tunnelling work.

For safe mining operations it is necessary to create a closed strong fence around the dikes to prevent the breakthrough of running sands into the excavation.

Artificial freezing of soils is used as a method of temporary stabilization of unstable water saturated soils during construction of underground structures in complex engineering and geological conditions.

Compared to chemical stabilization, cementation, etc., artificial ground freezing is the only controllable method of ground stabilization: the continuity and thickness of the created ice-soil barrier is controlled by hydrogeological and thermometric measurements in specially drilled boreholes.

*Corresponding author: deplani.ea@mosinzhproekt.ru; konyukhovds@mosinzhproekt.ru

Nowadays, both the traditional brine freezing method (concentrated aqueous solution of calcium chloride cooled to $-20\text{ }^{\circ}\text{C}$... $-25\text{ }^{\circ}\text{C}$ is used as a cold carrier) and zonal freezing with granulated 'dry ice' (granulated solid carbon dioxide) are widely used.

The purpose of this paper is to consider examples of selection of the most reliable and optimal method of freezing of soils around the piles on the basis of analysis of the existing experience at various underground construction objects.

2 OBJECTS INVESTIGATED

2.1 Object No. 1. Serebryanoborsky tunnels junction

Tunnel construction at the crossing of the Serebryanoborsky forestry zone and the specially protected recreation area was carried out by a trenchless method – by the Herrenknecht pressurized face EPB TBM.

The left and right transport tunnels with an outer diameter of 13.75 m are double-decked. The upper tier of each of the tunnels is designed for motor transport in one direction and has three traffic lanes, while the lower tier is designed for one metro track. Between the transport tunnels there is a service tunnel with an outer diameter of 6 m for maintenance and processing purposes, also constructed in a trenchless way.

It was also necessary to pretreat/stabilize the soils in a trenchless method at great depth without causing any damage to the environment and landscape.

The interconnection between transport tunnels has a cross-section of $5.5(\text{b}) \times 6.9(\text{h})$ metres (Figure 1).

Figure 1. Soil freezing elements on the stage 1: 1 – freezing station (two refrigeration units); 2 – freezing columns; 3 – brine pipeline with a diameter of 140 mm; 4 – conditional boundary of the ice-soil fence; 5 – thermometric well T2; 6 – contour of the tunnelling interconnection; 7 – left transport tunnel; 8 – service tunnel.

The construction plan was to build the interconnection in two phases:

- 1) from the left transport tunnel to the service tunnel;
- 2) from the service tunnel to the right transport tunnel.

In the first phase, the interconnection was constructed between the 13.75 m diameter left transport tunnel and the 6 m diameter service tunnel. To freeze the soils around the interconnection, boreholes from the transport tunnel and short counter boreholes from the service tunnel were drilled horizontally using pre-venters (Figure 2), with the freezing station located in the left transport tunnel directly at the interconnection location.

Figure 2. Graph of ground temperature change during freezing of the interconnection between the left transport and service Serebryanoborsky tunnels.

The issue of cold carrier circulation in the columns drilled in the two tunnels was solved in the following way: two horizontal boreholes of 140 mm diameter were drilled from the left tunnel at the level of the interconnection axis for brine pipes, with their entrance into the service tunnel lining. Since the soil at this level is hard loam, the drilling was carried out without any additional reinforcement measures. In this way, a unified spreading network was created for freezing the soils from the two tunnels simultaneously.

Earlier this problem was considered (Taranenko, et al., 2008), but we were forced to return to the Serebryanoborsky tunnels interconnection by a condition that always occurs when soils are frozen between excavations. The issue is, that in the constructed tunnels and excavations, when ventilation is operating, a constant heat influx is created, which complicates the freezing process. (Figure 3).

The thermometric borehole was drilled horizontally from the left transport tunnel and passed in close proximity above the service tunnel. The diagram in Figure 3 shows that at the distance of the borehole above the service tunnel, despite the presence of counter freezing boreholes drilled from the tunnel, as well as near the lining of the transport tunnel, temperature anomalies caused by ventilation were observed. At the same time, the rings of both the service and transport tunnels in the area of works were lined with heat insulation made of 100 mm thick URSA mineral wool mats with a layer of polyethylene film.

An important conclusion follows from this: the contour of the closed ice-ground enclosure around the interconnections under conditions of heat inflow

Figure 3. Scheme of ground freezing around the interconnection by the combined method: 1 – axis of the track I; 2 – ice and soil barriers; 3 – installation of tunnel ventilation; 4 – axis of the passage; 5 – axis of the track II; 6 – columns for brine freezing; 7 – thermometric columns; 8 – hydraulic observation wells; 9 – columns for freezing with ‘dry ice’.

coming from the ventilation of the constructed tunnels cannot be formed only by vertical, inclined or horizontal freezing boreholes drilled before the lining or tangentially to the tunnel. To create such a contour it is necessary to drill counter boreholes from the constructed tunnels, overlapping the heat flow zone.

2.2 Object No. 2. Freezing of sidings on the adjacent to the tunnel ventilation installation on the crossing from Karacharovo station to Tekstilshchiki station of the Big Circle Line of the Moscow Metro

The tunnel ventilation installation consisted of a - 73.25 m long excavation between the constructed tunnels. Four tie-backs had to be constructed from the excavation to the tunnels in frozen ground (Figure 4).

To solve the problem, a two-stage combined method of soil freezing was used, i.e. artificial freezing of soils was carried out both by the traditional brine method and by using granulated ‘dry ice’. Drilling of brine freezing wells was carried out both from the surface and with the help of freeze pipes (preventers) drilled from the constructed tunnels (Figure 5).

To optimise the freezing and sinking processes, the work area was divided into compartments corresponding to each interconnection. Soil freezing could be carried out either sequentially in each bay or in parallel, depending on the sequence of mining operations.

The purpose of brine freezing was to create continuous ice-soil contours of the compartments, excluding communication with external water-

Brine network for simultaneous maintenance of freezing columns drilled both from the surface and from the constructed tunnel: 1 – freezing station; 2 – brine network; 3 – ‘dry ice’ filling columns; 4 – ground massif frozen with ‘dry ice’; 5 – traditional contour freezing with brine; 6 – columns drilled from the tunnel; 7 – water table; 8 – constructed tunnel; 9 – waterlogged ground; 10 – groundwater level.

saturated soils. The contours of the compartments were frozen to the full depth, up to 2 m into the water-retaining clays.

The purpose of freezing the soils with ‘dry ice’ was to create a sealed ‘slab’ above the vault part of each compartment inside the brine contour of the fixed soils 3 m thick in unstable water-saturated soils.

‘Dry ice’ freezing on each bay was carried out in parallel with the brine method so that the active periods of freezing by both methods ended simultaneously.

Construction of horizontal interconnection at the described object was carried out by trenchless method at a depth of 20-25 m in unstable water-saturated

sands. To exclude the possibility of floatation under pressure of 0.2 MPa into the excavation, it was necessary to create a hermetically sealed ice-load fence around it.

The method of artificial freezing of soils provides the only method of controlling the ice-loading enclosure continuity – water lifting in the intra-circuit hydraulic monitoring well. Therefore, the second stage of freezing, i.e. creation of the ice-loaded slab above the junction, could be started only after the water rise in the in-circuit monitoring well had been recorded. Otherwise, at the second stage, the water in the observation well would have frozen and the control of ice-loading contour continuity would have been lost.

If to exclude freezing of the array by ‘dry ice’ and to freeze the second stage by brine, then, firstly, it would increase the total freezing period in 1.5-2 times; secondly, as a result of increase of the ground volume due to frozen water, the pressure on the walls of the pit and tunnel lining would increase, as it is practically impossible to perform zone-by-zone freezing by brine; thirdly, it would lead to increase of the number of working refrigeration units.

The use of ‘dry ice’ as a colder carrier allows reducing considerably the terms of active freezing (4-5 times) in comparison with the traditional brine method, which allows avoiding the general increase of freezing terms. Soil freezing is carried out zonally, which eliminates soil swelling and reduces pressure on the constructed structures.

Besides, in case of accidental damage to the freezing column, which got into the sinking zone, the column is cut off, the bottom of the column is welded to it and freezing continues, while in the case of brine method there is a threat of release of brine circulating in the system into the ground (up to 20 m³), which is fraught with defrosting of the latter. Further use of the damaged column is excluded. In connection with the above, the necessity of two-stage freezing is justified: first, contour freezing (until water rise is detected in the observation well due to the increase in its volume during crystallisation during freezing and, consequently, pressure increase inside the interconnection), and then the creation of a fixed array above the excavation by ‘dry ice’.

For the purpose of simultaneous brine freezing both from the surface and from the tunnel, two brine net-works were installed to serve the upper and lower columns for each tunnel, with freezing stations located on the surface (Figure 6).

Two main boreholes were drilled through each tunnel to run the forward and return brine lines underground. Drilling through the tunnels is fraught with the risk of releasing flow earth into the tunnel, so the work was carried out in the following order:

- the interval from the surface to the contact with the tunnel lining was drilled with a D395 bit with the

Figure 6. Freezing of soils around the junction by an array in the absence of a water table: 1 – ice-soil array frozen by ‘dry ice’; 2 – columns for ‘dry ice’ backfilling; 3 – battered tunnel sections; 4 – shoring of excavation; 5 – inlet ventilation; 6 – exhaust ventilation.

- subsequent insertion of a 325 mm diameter pipe; subbasic cementation was performed in the pipe;
- diamond drilling with a diameter of 250 mm was performed with drilling of cement stone in the 325 mm diameter pipe and reinforced concrete tunnel lining;
- 219 mm diameter pipe from the tunnel was lowered into the borehole, it was fixed with a clamping plate; then grouting was performed between the 325 mm and 219 mm diameter pipes;
- a 120 mm diameter hole was cut in the pressure plate; then a 114 mm diameter pipe was lowered into the borehole, welded to the pressure plate and grouted between the 219 mm and 114 mm diameter pipes.

For the convenience of construction of walkways in the tunnel sections, cast iron rings were laid in the interconnection. In order to exclude the possibility of deformation of the lining, all reinforced concrete and cast-iron tunnel rings located near the excavation were braced with temporary wooden beams.

Despite the favourable performance of the freezing works at the site, the described system has a number of disadvantages:

- the difficulty and danger of main boreholes drilling through the tunnel lining;
- complexity of installation of the brine network in the tunnel due to the presence of numerous wooden beams;
- complexity of maintenance of freezing boreholes in the tunnels, as the descent into the tunnels was located at a distance of about 500 m from the freezing area.

Finally, the main disadvantage of the considered freezing system is the fact that often the enclosing structures of excavations are not airtight, as it was the case at the considered object. In order to stop water entering the excavation, vertical drainage pipes were installed in the flume of the excavation at a height up to the ground surface so that the water would be set at the water table. In addition, it was necessary to caulk the joints between the cast iron tubes in the tunnels to eliminate water dripping. Without these measures, an artificial movement of water in the ground would have been created, preventing the freezing process.

There is one more interesting peculiarity: as it is known, water rise in the intra-circuit monitoring well occurs because water pressure in the contour increases when the ice-ground enclosure is closed. However, if the inter-tubing joints in the tunnel rings located under the freezing contour are not well sealed, the water may completely or partially unload into the tunnel when the pressure increases. And then, instead of the water level rising in the hydro-monitoring well, it is possible to fix a drop in the level, or, even worse, the level will not change.

So, we draw conclusions from the experience gained at the two sites considered:

1. To cover the tunnel zone of heat and heat inflow, it is necessary to drill freezing boreholes, inevitably breaking the tunnel lining.
2. It is necessary to exclude the danger of soil flow into the tunnel when drilling through its lining, and in this case do without a 'telescope' of pipes.
3. It is necessary to exclude artificially created groundwater movement in the freezing zone.
4. It is undesirable to have a brine network in the tunnel because of the difficulty of its maintenance.
5. Finally, it is necessary to minimise the pressure of the frozen massif on the tunnel rings.

It was possible to find an optimal variant of soil freezing for the construction of interconnections, satisfying all the above requirements, at the following object.

2.3 Freezing of interconnections on the abutment to the drainage unit on the section from Kakhovskaya station to Prospekt Vernadskogo station of the Big Circle Line of the Moscow Metro

The dewatering installation at this site was a shaft driven using a specialised Herrenknecht VSM 7800/5600 shaft boring system. From the shaft to the tunnels penetrated, it was necessary to construct two tie-backs in water-saturated sands. The task was complicated by the absence of water-retaining clays beneath the tunnels. In such cases it is impossible to create an ice-loaded contour by vertical freezing boreholes. To ensure safe mining operations, an array of frozen ground is usually created.

It was decided to perform zonal freezing of the soil mass by vertical boreholes using granulated 'dry ice' (Figure 7) with drilling through the tunnelled sections that fall within the zone of sidewall construction.

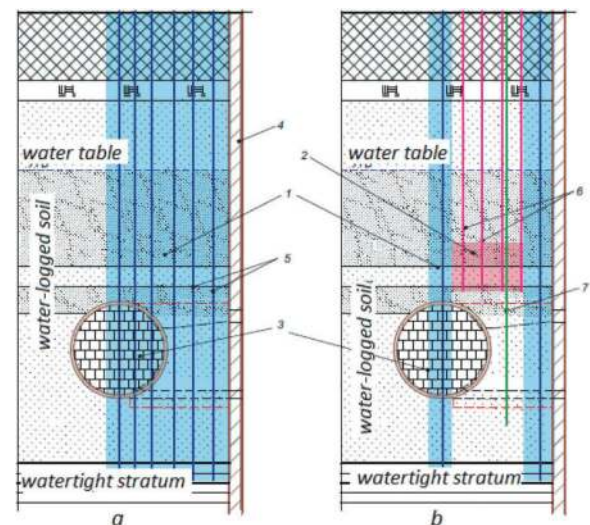

Figure 7. Recommended variant of freezing: *a* – cut along the brine contour; *b* – cut along the junction axis; 1 – ice-load fence from brine columns; 2 – ice-load mass frozen with 'dry ice'; 3 – rubbled tunnel section; 4 – excavation fencing structure; 5 – columns for brine freezing; 6 – columns for freezing with 'dry ice'; 7 – hydro-observation well.

The key idea was to pre-bottom the tunnel sections located in the zone of ice-loaded mass? prior to drilling operations.

First, it allows drilling freezing boreholes from the ground surface through the tunnel with a single bit diameter and not to be afraid of floatation into the tunnel. Second, it reduced the influence of intra-tunnel ventilation on the process of soil freezing, as well as eliminated the 'dripping' of water in the tunnel in the freezing zone. Third, the shoring played the role of a temporary support for the freezing period.

It should be emphasised that 'plugging' does not mean filling the tunnel sections with sandbags. Before drilling, the tunnel sections were densely filled with foam blocks fixed with cement mortar. It was important that no air cavities were left for the possibility of drifting out of the tunnel. Iron-concrete partitions 1 m thick were built at the ends. The sections of the backfill had to be 2 m wider on each side of the bore-hole drilling zone so that the latter would not go beyond the limits of the backfill as a result of possible deviations during drilling.

The choice of the 'dry ice' freezing method is conditioned by the fact that during soil development in a solid ice-loaded massif, the columns falling into the mining zone are inevitably cut off. Maintaining the array in the frozen state is not difficult for this method of freezing. The fragment of the column, interfering with the junction construction, is cut out,

at the same time, a bottom is welded to the upper part of the column and the ice filling into the above vaulting zone of the interconnection continues, while the ice is poured into the lower part of the column directly from the excavation. In the case of brine freezing, an additional brine network would have to be installed to maintain the ice mass in the under drain zone of the store.

In all freezing columns, 'dry ice' was poured from the bottom of the borehole 3 m deeper than the trough in the development to a depth of 5 m above the vault, with 2 m considered the 'evaporation zone'. Every hour, as evaporation progressed, the 'dry ice' was backfilled to the specified level.

Attention should be paid to the safety of works during freezing with 'dry ice'. During this work, it is strictly forbidden to let people down into unventilated excavations located below the ground surface and within 50 m from the freezing site.

Descent of people is possible provided that there is supply and exhaust ventilation in the excavation with air velocity of at least 0.5 m/s, taking into account that carbon dioxide, formed in the process of sublimation of solid carbon dioxide, is heavier than air and accumulates in low points of the excavation. The ventilation should be continuous, with a backup fan in case of an emergency shutdown.

As the shaft was driven by a mechanised system and represented an additional source of heat flow, freezing boreholes were drilled around the perimeter of the shaft to prevent groundwater movement along the shaft lining. In the future, excavations that involve the construction of tie-ins should also be pre-frozen where possible.

With this type of work technology, there is no need to install cast iron rings in the tunnels in the areas where the interconnections are to be constructed. It is advisable to leave the reinforced concrete tubes with pre-assembled metal insulation.

3 CONCLUSIONS

On the basis of the acquired experience in freezing of soils around inter-tunnelling in unstable water-saturated soils, the following algorithm of these works is recommended:

1. Shore up the tunnel sections falling into the zone of ice-loaded contour or massif above the interconnections with densely laid foam blocks.
2. A combined method of freezing is optimal: first, an ice-load fence should be created around the development contour, controlled by an intra-contour hydraulic observation well, and then a 3-4 m thick array (slab) should be frozen above the junction vault. It is recommended to use the method of creating ice-loaded massif only in conditions when there is no water table under the tunnels for more than 10 m, because when freezing the ground massif the control of its continuity is lost, as there is no possibility to fix the water rise in the hydraulic observation well.
3. The brine contour should be located around the development contour of the disruption at a distance of at least 1 m. In this case, in each ring of the tunnel to avoid the loss of its bearing capacity should be located no more than 1 row of wells with a spacing of at least 1 m.
4. All boreholes should be drilled from the ground surface through the tunnels.
5. In case of ground freezing with dry ice, install ventilation in the excavation. During the works on the joint construction, the tunnel lining should be gradually dismantled.
6. Upon completion of the work, cut off the columns forming the brine contour; weld the bottoms to the upper ones, fill all the columns with cement mortar; the gaps between the columns and the tunnel lining should be injected with cement mortar through the plates welded to the tunnel lining.

Factors impacting thawing-refreezing around tunnels in permafrost soils

Sachin Gavhane*

Research Scholar, MIT World Peace University, Pune, India

Sandeep Potnis*

Professor, MIT World Peace University, Pune, India

ABSTRACT: Permafrost system is a fragile state of equilibrium, conditioned by the heat transfer between the ground and atmosphere. Construction and operation of Tunnels in such environment poses unique sustainability challenges and inevitably relies on the comprehensive sensitivity analysis involving thermal, hydraulic and mechanical (THM) behaviours. Freeze-thaw (FT) cycles in permafrost, are characterised by the dynamic thermal loads and stress reversals. This study examines the refreezing of thawed zone around a tunnel in permafrost, using Thermal Module of Rocscience software RS2. The key results indicate that while tunnel causes thawing of permafrost radially around it, conversely, in winters, the tunnel acts as a heat sink, absorbing heat from the surrounding, trying to refreeze the thawed zone. The maximum zone of thawing is reached in July of first year and generally refreezes in 8 FT cycles. However, some cases also prohibit the refreezing. Areas with higher N_{thaw} (1.29) values or higher FT cycles(60/year), or higher amplitudes (19.5) exhibit slower refreezing rates and more extensive thawed zone that do not refreeze by 8th FT cycle. The study discusses that the effects of the soil thermal properties can be balanced by modulating those of tunnel liner. The study also brings out reduced thawed zone from 4.4m (at 35m) to just 2.1m in crown (at 65m), concluding that confining pressures affect the thermal regime, melting point and soil thermal conductivity. The results indicate that presence of water table actually assists refreezing and reduces the thawing zone (3.3m at crown) compared to the one without (4.4m at crown). The findings on the extent and behaviour of thawing zone could have significant implications on the planning for permafrost tunnels, particularly in India, where recently the Bilaspur-Leh railway line is announced. Given the unique geo-cryology of the region, substantial alignment of the project is likely to face the permafrost conditions.

Keywords: Permafrost, Freeze-Thaw, Finite Element Analysis, Rocscience, N-Factor, Thermal Conductivity, Specific Heat Capacity, Unfrozen Water Content

1 INTRODUCTION

The Indian government recently announced the construction of the Bhanupali- Bilaspur -Leh railway line. Given the unique environment and geo-cryology of the region, a substantial portion of the alignment is likely to face the permafrost conditions. Though Permafrost is no new to the international fraternity, this term is relatively less frequent in Indian context.

S. Nawaz Ali et al (2017) quoted that though Permafrost is an integral component of the Indian Himalayas, but has hardly been ever studied and thus lacks scientific data on its degradation. Gruber, (2012); Gruber et al., (2017) reiterated that the Hindu Kush Himalaya has a wide belt of permafrost visualized by a global model. These authors along with Gautam et al., (2016) and Wu et al., 2017 have further gone on record stating that the permafrost in the Indian Himalayas remains largely unaddressed.

As per Muller (1940), Permafrost is a ‘ground’ beneath where temperature below freezing has existed continuously for at least two consecutive years”. ‘Temperature’ and ‘Time’, and not the material characterises the permafrost and hence soil mechanics in these cases is a function of Thermal state. A change in thermal regime causes a phase change in pore fluid state thereby triggering a ‘hydraulic’ regime in the ground which in turn manifests into ‘Mechanical’ outcome.

Underground infrastructure development in such regions presents significant yet unique challenges as is seen from the recent spate of floods and landslides in the Manali region. Tunnels, in particular, are affected by the freeze-thaw (FT) cycles that occur in permafrost regions. Taking cue from the studies carried out in China during the construction of the Qinghai-Tibet Railway (that connects Tibet with the rest of China), where more than 550 kilometers of the railway was built on permafrost, it is

*Corresponding author: sandeep.potnis@mitwpu.edu.in; 1032210004@mitwpu.edu.in

high time the scientific and academic community in India take cognisance of this very aspect of the geocryology. While thawing causes the tunnel to settle, refreezing may also cause frost heaving pressure on the tunnel liner which if not factored may cause serious damages to the Tunnel. In this context, the report on Qinghai Highway Line 227 in 2007 by Liu et al., (2011) stated that, the lining structure of the Daban Mountain tunnel is seriously damaged by intrusions; serious transverse/ longitudinal lining cracks, and serious large-scale dislocations at the crown springing levels. Despite these challenges, the construction of tunnels, remains crucial for connecting communities in permafrost regions to the mainland.

2 THE STUDY

Thus, a parametric study was undertaken in 2D plane strain, THM (thermal, hydraulic, and mechanical) coupled analysis, of tunnel constructed in permafrost, using the versatile RS2 Rocscience software. **This paper addresses** the important but hardly studied aspect of influence of varied factors on the refreezing process and the **extent** of thawing zone around the tunnels in Permafrost. In absence of any known Permafrost tunnel in India, this Prelim Research was completed on the what-if location in Ladakh, India. A study site with known soil parameters was chosen at an altitude of 4500 m, Ladakh, India.

Figure 1. Trumpet curve.

3 STUDY SECTOR AND ENVIRONMENTAL DATA

3.1 Meteorological data

The parameters driving the simulations were obtained from the meteorological stations, experimental research station and the literatures published to date and comprised of data from Jan 2008 to Jan 2021. The input data as found at the site represented graphically in Figure 2.

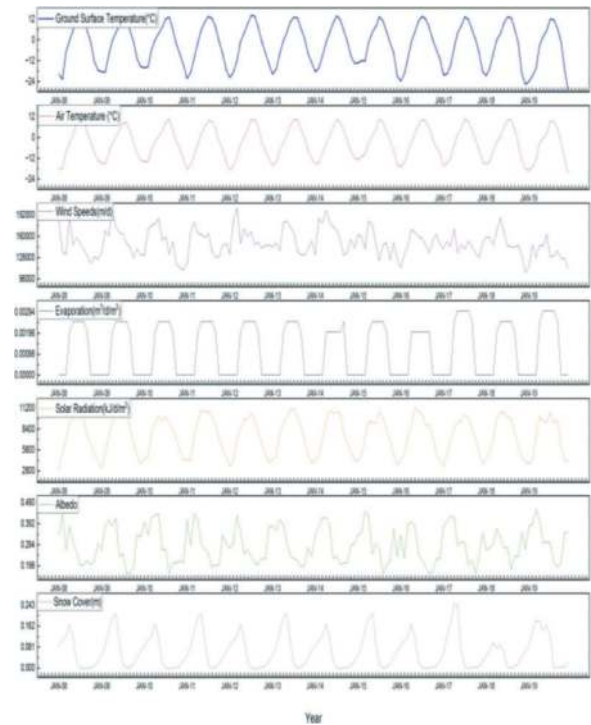

Figure 2. Meteorological input data.

3.2 Ground surface data

The ground temperatures in Ladakh are colder than the air temperatures due to the ground albedo as studied by John Wani et al., (2019) published in The Cryosphere. The MAGT at site area varied from -18 to +12 °C. Rocscience software provides to obtain realistic conditions of the permafrost, in form of the Initial Temperature grid. Given the geothermal gradient; a bottom flux of 2.44 kJ/day/m² was applied. The surface skin temperature obtained at site was then compared to the Initial grid so obtained and the results are close to those of site. Refer Figure 1(b).

3.3 Freezing and thawing indices of surface and air

The Freezing and Thawing Indices of Surface and Air were calculated and the presence of permafrost was reconfirmed by the Carlson's Approximation Criteria (1952) for existence of permafrost in the area by using, $\frac{I_{st}}{I_{sf}} < \frac{\lambda_f}{\lambda_{th}}; 0.48 < 1.25$

4 METHOD

4.1 Description of model

Refer Figure 3. The models are 100x 100 m with four soil layers (BHUKOSH site and well logs). Side boundaries are modelled as adiabatic ones. Top boundary is Free with climatic flux. A Km long, curved horseshoe shape tunnel, with invert to crown 9.21m; composite liner with shotcrete 300 mm thick and Secondary lining of 550mm with 50 cm geotextile and

water proofing membrane was used in numerical model. Piezo line is as per the water table in the area. The 2D section analysed is at 100m chainage from the portal. Mesh of fine graded six noded triangular mesh with gradation factor of 0.1 refined around the tunnel perimeter and in regions of high thermal gradients, is used.

Figure 3. Soil stratigraphy and boundary conditions.

4.2 Assumptions incorporated in the study

The permafrost soil is assumed to be Homogenous, isotropic and non-saline. Thermal diffusivity assumed as unity. The climatic conditions/trend generally stays same in a period of 30 years. The tunnel

These are as enumerated in Tables 1 to 3. Based on the Parameter to be studied and the objective of the modelling suitable boundary conditions close to actual site conditions were applied.

5 RESULTS AND DISCUSSION

Overall, the maximum extent of the thawing zone was generally reached in the Jul/ Aug month in first year from the tunnel commissioning year. The refreezing commenced from the tunnel perimeter extending radially outwards before the outer fringe started to refreeze and converge. The refreezing fringe is normally non-uniform as the formation of ice crystals during phase change is influenced by the permeability of the soil and its underlying layers. The radial ground around the perimeter up to a distance of 3-4m generally freezes and re-establishes quasi equilibrium state in the 8th F-T cycle under the given conditions in the study area.

Related results are graphically depicted as below and presented/ discussed in succeeding paragraphs. The Graphs are segregated into Uncontrollable (Refer Figure 4) and Controllable Parameters (Refer Figure 5) and indicate the measurements at crown and invert.

5.1 Effect of N Factor indices on thawing-refreezing of permafrost.

A Base model ($N_{thaw} = 1.29$; $N_{freeze} = 1.09$) was used along with Model-A2 having ($N_{thaw} = 1.29$;

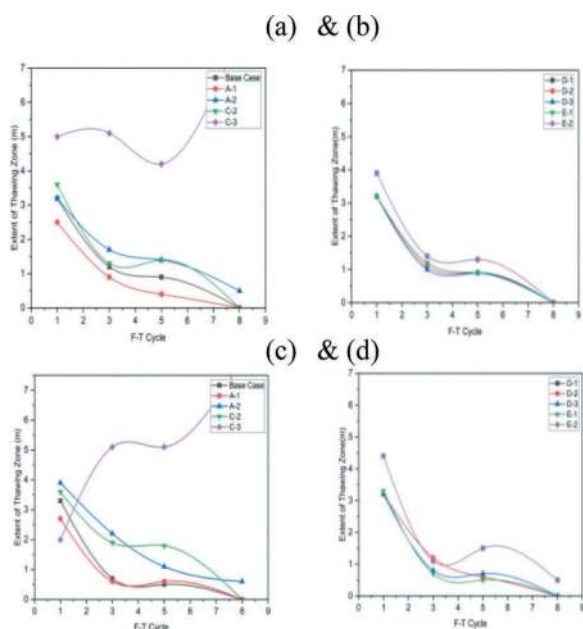

Figure 4. Extent and behaviour of maximum thawing zone due to the effect of uncontrollable parameters.

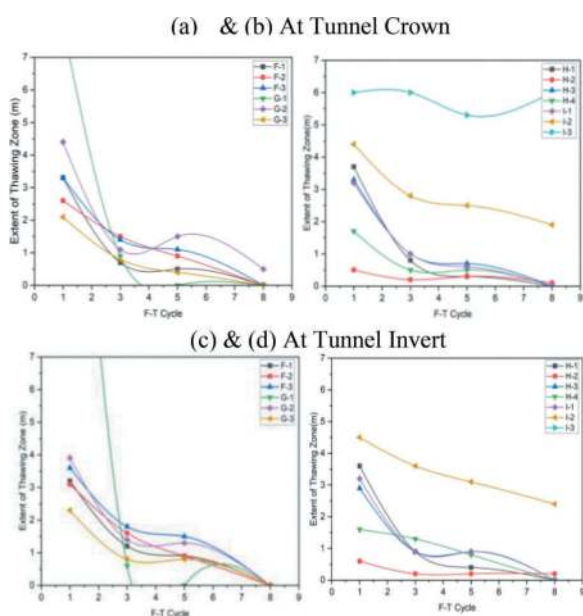

Figure 5. Extent and behaviour of maximum thawing zone due to the effect of controllable parameters.

$N_{freeze}=0.8$) and a Model-A3 having ($N_{thaw}=0.8$; $N_{freeze}=1.29$) to analyse the ibid parameter.

The Results & Discussion are summarised below.

5.2 Effect of frequency of freeze thaw cycle

Two models with 60 F-T cycles and 15 F-T cycles each were examined to analyse the extent and the time taken to attain maximum thaw and entire refreezing respectively.

Table 4. Effect of N factor indices.

Results	Discussion
The thawing zone extent observed was,	A higher N-thaw value indicates a greater thawing, resulting in a more extensive thawed zone. A lower N-freeze value indicates a slower rate of refreezing of the thawed zone and longer duration of thawed conditions and thus more prominent impact on the stability of the ground.
(i) 3.3m (crown) for $N_{thaw}=1.09$;	On the other hand, a lower N-thaw value and a higher N-freeze value indicate a lesser degree of thawing and a faster refreezing rate, which can result in a shallower and less extensive thawed zone and a lower impact on ground stability.
(ii) 2.7m (crown) for $N_{thaw}=0.8$;	
(iii) 3.9m (crown) for $N_{thaw}=1.29$.	
<u>Rate of Refreezing.</u> The radial width of thawed zone from 1 st to 3 rd FT cycle respectively reduces from:	
-(i) 2.3 m at crown in 1 st FT cycle to 0.7m in 3 rd FT cycle for $N_{freeze}=1.09$ compared to;	
(ii) 0.9m to 0.6m for $N_{freeze}=1.29$ and	
(iii) 3.3m to 2.2m for $N_{freeze}=0.8$;	
In Base Case and Case, A-2; the entire thawed zone refreezes in 8 th FT cycle.	
With highest N_{thaw} and lowest N_{freeze} i.e., Case A3; the thawed zone formed around the tunnel persists.	

The results are discussed in Table 5 as following:

5.3 Effect of amplitude and ambient air temperatures

This parameter depicts the effect of global warming in permafrost soils. Three cases with increasing amplitude and corresponding increase of T max from the initial 12° C to 14° C and 22° C.

Results & Discussion are summarily enumerated as below in Table 6 along with results of numerical modelling in Figure 6.

5.4 Effect of soil thermal properties

Thermal Conductivity (varied through Quartz content(Q); prominent in soils of Ladakh) and Thermal Heat Capacity are studied through three variations.

Results and Discussion. The thawing and refreezing rate in the model D-1 is been compared with the other cases. The important results and related discussion points are as below in Table 7.

5.5 Effect of presence of Water Table (WT) on thawing- refreezing of permafrost

Two models– base model with water table and base model without water table were examined.

Table 5. Effect of frequency of freeze thaw cycle.

Results	Discussion
<p>Model with 60 F-T cycles/year experiences an unusually larger thawed zone in the first year (6.1m at Invert). The extent of thawing zone increases with every passing F-T cycles.</p> <p>Refreezing time increases as the number of FT cycles increase.</p>	<p>With a high number of FT cycles, the thawed zone around the tunnel shall be deeper and larger, which takes longer to refreeze.</p> <p>In general, each FT cycle causes additional thawing and refreezing. However, as the number of cycles increases, the thermal regime around the tunnel reaches a quasi-equilibrium state, where the rate of thawing balances the refreezing and thawed zone stabilizes. The specific number of cycles required to reach this state will depend on the properties of the soil and the tunnel, as well as the duration and frequency of the freeze-thaw cycles.</p>
<p>Model with 15 F-T cycles/year exhibits consistent and smaller thawed zone. (4.4m at Invert).</p>	<p>From the results of the N factor and the FT cycles the following thumb rule for predicting the freezing/thawing time for the Nth cycle can be derived.</p> <p><i>Predicted freezing/thawing time for Nth cycle = Freeze/thaw time taken in the first cycle * N factor (N-1)</i></p>

Table 6. Effect of amplitude and ambient air temperatures.

Results	Discussion
<p>The maximum thawing zone occurs in July of first year, with maximum extent around the crown and invert of the tunnel.</p> <p>All other conditions remaining same, the extent of the thawing zone was expected to increase with the increasing amplitude and T_{max} and the results are in conformity.</p> <p>When amplitude magnitude is 15.5 and $T_{max} = 12^{\circ}C$, the entire ground refreezes and re-establishes quasi-equilibrium state in the 8th F-T cycle.</p> <p>In Case-C2, only the crown and invert are refrozen in 8th FT cycle, while pockets of unfrozen water 0.6 to 1m wide persists around the sidewall.</p>	<p>A larger amplitude and greater T_{max} indicate more extensive thawed zone and vice versa. However, a lower T_{min} also means shorter duration of thawed conditions, which means less impact on the ground stability and is thus favourable for tunnels in permafrost.</p> <p>With subsidiary iterations (excluded from the results) this study also found that refreezing occurs faster at locations with amplitude of up to magnitude 8 and T_{max} upto 10°</p>

Figure 6. Numerical modelling results of effect of amplitude & ambient temperature.

The important results and related discussion points are as below in Table 8.

5.6 Effect of shape of tunnel in permafrost

Three models were considered; one each of horseshoe (base model), circular and rectangular tunnels with WT.

5.6.1 Results & discussion

The important results and related discussion points are as below in Table 9 and Figure 7.

5.7 Effect of depth of tunnel in permafrost

Three cases of tunnels with horseshoe shape at the depth of 20m, 35m and 65m respectively were considered and numerically modelled. The findings of this study shows that shallow tunnels in permafrost soil may not be feasible unless preconstruction measures such as thermosyphons and ground freezing methods

Table 7. Effect of soil thermal properties.

Results	Discussion
<p>The maximum thawed zone (July of first year) has extent up to</p> <ul style="list-style-type: none"> - 4.4m at crown, 3.9m each at sidewalls and invert in MODEL D-1(Q:0.47 & C:886 kJ/kt/C); - 3.2m at crown/ invert and 2.9m at sidewalls in MODEL D-2 (Q:0.1 & C:886 kJ/kt/C). <p>Refreezing is achieved</p> <ul style="list-style-type: none"> - only at the invert by 8th FT cycle in MODEL D-1, whereas - in MODEL D-2- the thawed fringe around the entire tunnel perimeter refreezes by 8th FT cycles. <p>In MODEL D-3(Q:0.47 & C:1772 kJ/kt/C): wherein, the specific heat capacities of soil layers are doubled, NO MAJOR CHANGE IS OBSERVED.</p>	<p>Thermal conductivity, reflects the ease with which thermal energy is transferred from one point to another. Specific heat capacity, on the other hand, reflects the capability to store thermal energy.</p> <p>Quartz has a relatively high thermal conductivity hence soils with a higher quartz content conduct heat more easily than soils with lower quartz content. Also, due to lower coefficient of thermal expansion compared to ice, it can lead to differential stresses and cracking with temperature fluctuations. This can cause further destabilization of the soil around the tunnel and increase the potential for thawing and degradation.</p> <p>Results indicate that the soils with higher specific heat capacities have similar effects to those with lower thermal conductivity/quartz content.</p> <p>Thus, in permafrost regions, the Soil thermal properties effects need to be balanced by optimum choice of other parameters such as liner properties/depth and shape of tunnels.</p>

Table 8. Effect of presence of water table (WT).

Results	Discussion
<p>The thawed zone</p> <ul style="list-style-type: none"> -around crown is 4.4m without WT v/s 3.3m with WT; -around the sidewalls it is 3.9m v/s 3m and for inverts it is 3.9m v/s 3.2m respectively <p>In Model w/o WT the ice layer growth is limited and even in 8th FT cycle the thawed zone around crown and side walls persists with only the Invert refreezing</p> <p>For the model with water table the frozen fringe grows continuously and the entire thawed zone is refrozen in 8 FT cycles.</p>	<p>The Thawing zone is prominently larger for the model without water table. In absence of water table or when the tunnel is above the water table, the thawed zone can persist for longer periods as it leads to a closed system, which allows water to move freely through the soil, promoting further thawing. The lack of ice lenses means that the soil remains unfrozen, leading to extended period of thawing. Only the Invert refreezing is probably due to the capillary rise of water to the freezing front from the Clay in the lower layer.</p> <p>A water table above the permafrost tunnel leads to an open system, which promotes the formation of ice crystals, trapping the water and further preventing its free flow through the soil (decreased permeability). Since the water that migrates is replenished continuously by the water table, ice crystals multiply during the freezing period and helps refreezing of the entire thawed zone by eight FT cycles.</p>

are rigorously applied prior to construction and that the excavation is restricted to freezing winter days.

Results. The important results and related discussion points are as below in Table 10.

5.8 Effect of thermal properties of tunnel liner on thawing- refreezing of permafrost

The model with average thermal conductivity (λ) and Specific heat capacity(C) was compared with two different models one where conductivity was modulated using insulation and another without insulation but increased Specific heat capacity.

A special case was also considered with a Gravel lining of granitic aggregates of well graded composition

12mm and 20mm densely packed in Gabion baskets of 0.3m width placed around the tunnel lining perimeter prior to secondary lining. *The Thermal properties of the liner can be carefully modulated to control the extent of thawing and rate of refreezing as per this study.*

Results are briefly touched upon and discussed in the succeeding Table 11 and depicted in Figure 8.

5.9 Effect of inside tunnel temperatures on the extent of thawing

To study this effect three models with internal tunnel temperatures of 12 °C, 16 °C and 22 °C were modelled to depict the temperatures due to the traffic conditions inside.

Table 9. Effect of shape of tunnel in permafrost.

Results	Discussion
<p>The circular tunnel in Model F-2 has the least maximum thawing zone in crown and invert amongst the three. With just 2.6m in crown and invert the thawing zone is smaller as compared to the rectangular tunnel with 3.6m in crown/invert and 3.5m in sidewalls.</p> <p>While the Model F-1(Horseshoe) and Model F-2(Circular tunnel) is refrozen in the 8th FT cycle, the rectangular tunnel persists with thawing zones (very few unfrozen pockets) along the perimeter.</p> <p>The refreezing around circular tunnel is more uniform as compared to other cases.</p>	<p>Circular shapes are more suited in permafrost environment. One of the likely reasons for this is that circular shape has least surface area and hydraulic perimeter resulting into minimum heat exchange coefficient and least exchange of heat with the surroundings.</p> <p>The non-circular shapes can create stress concentrations at corners or edges, potentially increasing the risk of damage or failure.</p> <p>A tunnel with a larger diameter or a flatter profile result in a larger thawed zone and slower refreezing and vice versa</p> <p>The anomaly in a horseshoe-shaped tunnel of larger thawed zone at inverts compared to the crown, is due to the difference in the curvature of radius of invert vis a vis the crown.</p> <p>Smaller and steeper radius of curvature leads to larger thawing zones.</p>

Table 10. Effect of depth of tunnel in permafrost.

Results	Discussion
<p>Though the tunnel at the depth of 20m indicates refreezing of the thawing zone in 4th FT cycle. However, the thawing zone as a result of construction shall merge with the active layer during maximum temperature months of July/August.</p> <p>The model at depth 35m, records the extent of thawing zone as 4.4m at crown and 3.9m at sidewalls and invert respectively. The refreezing of the thawing zone occurs only at invert after 8 FT cycles.</p> <p>The model at depth of 65m has the least extent of maximum thawing zone with just 2.1m at crown, 2.6m at sidewalls and 2.3m at invert.</p>	<p>At shallow depth i.e., 20m overburden, the confining pressure is very low, which causes the surrounding soils to thaw more easily due to the heat generated by the tunnel. The thawing also results in increased Pore water Pressure thereby reducing the effective stresses to minimum.</p> <p>In general, an increase in confining pressure causes the melting point of ice to decrease, meaning that ice can melt at a lower temperature than it would at standard atmospheric pressure and well explains the thawed zone.</p> <p>The high confining pressures also increases the thermal conductivity of permafrost soils by causing the ice particles in the soil to come into closer contact.</p> <p>However, the confining pressure also have a shielding effect by maintaining the structural integrity of the soil, which prevents further melting making them more thaw resistant. This in turn restricts the pore water pressure increasing the overall effective stresses.</p> <p>The test results for deep tunnels, are in good agreement with the findings of Liang Tang et al., (2018) who observed a strain hardening behaviour in expansive soils(clay) with the increase in the confining pressure.</p>

5.9.1 Results & discussions

The discussions on the results are as tabulated below in Table 12.

6 CONCLUSION

The conclusions drawn can be summarised as below: -

Permafrost is a four-phase particulate system in a fragile state of equilibrium conditioned by the 'Heat Exchange'. Any change above or disturbance underneath is going to affect its Thermal equilibrium.

The re-establishment of quasi equilibrium by refreezing process around a tunnel in permafrost can be affected by several factors many beyond our control while others could be controlled by an informed choice.

Certain factors beyond control viz the 'Soil Thermal properties' and 'Presence of water table' largely influence not only the extent and behaviour of thawing, but the rate of refreezing and the quantum of differential stresses/ cracking too.

The study on controllable parameter brings out deeper, smaller diameter circular tunnels with modulated thermal conductivity of liner material alongside

Table 11. Effect of thermal properties of tunnel liner.

Results	Discussion
<p><u>Base Case H1 $\lambda_{concrete}=1.95 \text{ W/m}^2\text{C}$; $C=1000 \text{ kJ/kT/C}$:</u> This case exhibits a larger extent of thawing reaching up to 3.7m at the crown, 3.8m at sidewalls and 3.6m at invert.. <i>A higher rate of refreezing was observed and the thawed zone entirely refreezes in the 8th FT cycle.</i></p> <p><u>H2 $\lambda_{combined}=0.2636 \text{ W/m}^2\text{C}$; $C=1000 \text{ kJ/kT/C}$:</u> The maximum extent of thawing zone is drastically reduced to 0.5m-0.8m only. However, a low rate of refreezing was observed and thin <i>unfrozen fringe continues to remain around the perimeter</i> even after the 8th FT cycle.</p> <p><u>H3 $\lambda=1.95 \text{ W/m}^2\text{C}$; $C=1916 \text{ kJ/kT/C}$</u> Compared to base case <i>the maximum extent of thawing zone reduced from 3.7m to an average 3.1m.</i> The entire thawed zone was refrozen by 8th FT cycle.</p> <p><u>H 4 $\lambda=1.95 \text{ W/m}^2 \text{ C}$; $C=1000 \text{ kJ/kT/C}$ plus Gravel Separator:</u> <i>A substantial reduction in the extent of maximum thawing zone was observed.</i> The maximum extent of thawing zone was restricted to 1.7m from the earlier 3.7 at the crown; 2.1 m from the earlier 3.8m at sidewalls and only 1.6m from the earlier 3.6m at invert, respectively. Gravel Separator also resulted in a <i>stable rate of refreezing with uniform frozen fringe and refreezing the entire thawed zone by the 8th FT cycle.</i></p>	<p>The Model H-1 results stated indicate- that with higher thermal conductivity the tunnel shall act as a heat sink in winters promoting heat loss from the surrounding soil and refreezing of thawed zone.</p> <p>Model H-2 indicate that putting an insulation liner along with the concrete tunnel liner restricts the extent of thawing zone, albeit also slows down the refreezing rate.</p> <p>The thermal conductivity, specific heat capacity and the coefficient of heat exchange of the tunnel lining significantly controls the heat exchange between the tunnel and the surrounding soil, which affects the size and depth of the thawed zone around the tunnel.</p> <p><i>Model H-4 indicate that the use of Gravel separator lining with the concrete liner can be an effective method in controlling the thawed zone.</i></p> <p>The gravel layer due to high porosity yet strong intra granular arrangement not only reduces the thermal conductivity but also helps segregate the water and ice crystals thereby reducing the thawing around the tunnel. <i>Gravel use also prevents heaving force from directly acting on the composite liner.</i></p>

Figure 7. Numerical modelling results of effect of shape of tunnel.

closely monitored and controlled internal Tunnel temperatures are more apt for such environment.

The findings of the study will help the Permafrost Tunnel engineers in planning tunnels at right depth, to design incorporating correct geometry and shape, in selecting appropriate materials/insulation and implementation of right thermal management & instrumentation scheme. Sometimes simple solutions like a ‘Gravel Separator Layer prior to the secondary

Figure 8. Numerical modelling results of effect of thermal properties of liner.

lining and help separate the particulate phases and prove effective as discussed in the study.

Generalisations on the refreezing of the thawed zone in any particular FT cycles would be ambitious and would differ from case to case depending on the site conditions and above-mentioned causative factors.

Table 12. Effect of inside tunnel temperatures.

Results	Discussion
The extent of the thawing zone was expected to increase with the increasing tunnel temperatures and the results are in conformity.	During operation of the tunnel, the heat generated by the equipment and ventilation systems inside the tunnel lead to a higher heat exchange coefficient between the tunnel and the surrounding environment, resulting in thawing of the permafrost around the tunnel.
The thawing zone ceases to refreeze when the internal tunnel temperature of the tunnel exceeds 12° C.	During the cold winters, the tunnel is supposed to act as a heat sink and absorb heat stored in the surrounding permafrost, leading to refreezing of the permafrost around the tunnel. But this can only happen when Tmax of the ground surrounding the tunnel absorbed during the summers is more than the Tunnel inside temperatures which are generally colder due to the outside cold air suctioned through portals. Hence as seen from the second case the Tunnel can only act as a sink till the inside tunnel temperatures are maintained below the maximum annual average temperature of the ground through artificial cooling. As the inside tunnel temperature increases beyond the annual average, the heat exchange is only one way- from tunnel to the surrounding throughout the year. As a result, the thawing zone only keeps increasing with every passing year as is seen in cases T2(Tunnel temperature 16° C) and T3(Tunnel temperature 22°C) findings.

Finally, while the construction of tunnels remains crucial for connecting communities in permafrost regions to the main land, the results of disturbing the permafrost equilibrium without the ability to anticipate and ensue correctly the changes and their impacts can be catastrophic.

7 LIMITATIONS AND SCOPE FOR FURTHER STUDIES

This study was attempted on the what-if location in Ladakh, India and assumes permafrost soil as isotropic and homogenous. Thermal diffusivity and Salinity in soils excluded can form part of the future studies.

School of Civil Engineering, Southeast University

ABSTRACT: Based on a long and narrow deep foundation pit in Nanjing Jiangbei New Area, a three-dimensional finite element model was established to analyze the effect of setting partition walls on the deformation of a long and narrow foundation pit. The results show that the length of the foundation pit is reduced by setting the partition wall to carry out the partition excavation, which has a good control effect on the overall deformation of the long and narrow foundation pit and can also significantly reduce the horizontal displacement and surface settlement in the long side direction of the foundation pit, especially in the middle area of the long side.

Keywords: Long and narrow deep foundation, Partition wall, Deformation characteristic, Horizontal displacement, Surface settlement

1 INTRODUCTION

The rapid pace of urbanization has led to extensive development of urban underground spaces. There is an increasing construction of complex underground projects, including underground shopping malls, parking lots, and basements of high-rise buildings. As a result, the number of deep foundation pits, particularly long and narrow ones, is increasing due to spatial constraints in urban areas. These long and narrow deep foundation pits are characterized by a large length-to-width ratio and considerable depth, presenting new challenges.

Elongated deep excavations can lead to excessive horizontal displacement and ground settlement, potentially causing damage to nearby structures. Remedial measures must be taken to mitigate these risks. Strengthening the ground and reinforcing support structures are common measures to reduce displacement and surface settlement (Gaba, 1990; Parashar et al., 2007). Additionally, some scholars (Ou et al., 2011) have investigated the effectiveness of installing partition walls connected to diaphragm walls. Research results indicate that partition walls can effectively reduce wall deflection and surface settlement. In a study on deep foundation excavation by Lin et al. (2012), it was found that the horizontal deflection of diaphragm walls is influenced by factors such as construction sequence, spacing of partition walls, and the height of partition walls below the excavation surface.

Hsieh et al. (2012) employed a two-dimensional plane strain analysis method to analyze the deformation characteristics of excavations with partition walls. They derived an equivalent beam model based on the deflection behavior of continuous beams and the principle of superposition. However, excavation is a three-dimensional (3D) spatial problem. Therefore, to gain a better understanding of the deformation characteristics of elongated deep excavations with partition walls, it is necessary to conduct 3D numerical analysis (Wu et al., 2019).

This study utilized numerical simulations conducted with Plaxis 3D software to analyze the impact of partition walls on the horizontal displacement of diaphragm walls and the surface settlement surrounding a long and narrow deep foundation pit in the second phase of the Jiangbei Underground Space Project in Nanjing. The findings of this study can offer valuable insights for the design of future elongated deep excavations.

2 ENGINEERING SITUATIONS AND NUMERICAL MODEL

2.1 *Engineering situations*

The long and narrow deep foundation pit studied in this paper is the H1 ramp foundation pit of the second phase project of Jiangbei Underground Space in

*Corresponding author: daigl@seu.edu.cn

Nanjing, Jiangsu Province, China. The width of this foundation pit is about 31.5 m, the length is 180.3 m, and the excavation depth is about 16 m. The layout of the foundation pit is shown in Figure 1. The shorter side of this foundation pit is reinforced with a diaphragm wall measuring 0.8 m in thickness, featuring a concrete grade of C30. On the other hand, the longer side is fortified with a diaphragm wall that has a thickness of 1.0 m, matching the concrete grade of C30. The diaphragm wall extends to a depth of 37.5 meters. The foundation pit is vertically equipped with three concrete internal supports. The cross-sectional dimensions are 0.8 m \times 0.8 mm, and the support depths are 1.4 m, 7.46 m, and 12.46 m, respectively. The horizontal spacing between them is 6 m. The primary form of support is a combination of struts and diagonal braces.

Figure 1. H1 foundation pit plane diagram.

Within the excavation range of this foundation pit, there are a total of 7 soil layers. The basic physical and mechanical parameters of these soil layers are listed in Table 1.

2.2 Numerical model

Plaxis 3D software is used for numerical simulation. To mitigate the impact of boundary conditions on the simulation results, the horizontal boundary is set to 5 times the excavation depth, resulting in a model size of 192 m \times 241 m. The vertical boundary extends 3 times the excavation depth, equating to 80 m. The surface is unconstrained, serving as a free boundary, while the bottom of the model is entirely fixed. The side boundary of the soil is fixed in the normal direction.

The constitutive model of the soil adopts the HSS model, with specific parameter values listed in Table 1. The basic parameters for the diaphragm wall and concrete support can be found in Table 2.

Table 2. Basic parameters of the diaphragm wall and concrete support.

Type	Size (mm)	γ (kN/m ³)	E (Gpa)
Diaphragm wall	800	25	30
Angle brace	1000 \times 1000	25	32.5
Internal supports	800 \times 800	25	32.5
Tie beam	600 \times 600	25	32.5

The excavation of the foundation pit is divided into three stages. In stage 1, the excavation reaches a depth of -1.7 m, and the first support is constructed. Stage 2 involves excavating to a depth of -7.76 m and installing the second support. Finally, in stage 3, the excavation reaches a depth of -12.76 m, and the third support is constructed.

3 RESULT ANALYSIS (WITHOUT PARTITION WALLS)

3.1 Horizontal displacement (without partition walls)

The horizontal displacement contour maps of the diaphragm walls after each excavation stage are shown in Figure 2. From these contour maps, it can be observed that the excavation-induced unloading results in horizontal displacement of the diaphragm wall towards the pit direction. Furthermore, the horizontal displacement increases with the increasing depth of excavation.

Figure 3 presents the horizontal displacement of the ground diaphragm wall at the midpoints of the long side, short side, and corner of the H1 foundation pit as a function of excavation depth. These figures demonstrate that the horizontal deformation patterns of the ground diaphragm wall at these three positions consistently follow similar trends throughout different stages. In the first and second stages, the maximum horizontal displacements are both below 5 mm, with the peak displacement located at the top of the diaphragm wall. During the third stage, a substantial increase in horizontal displacement is observed

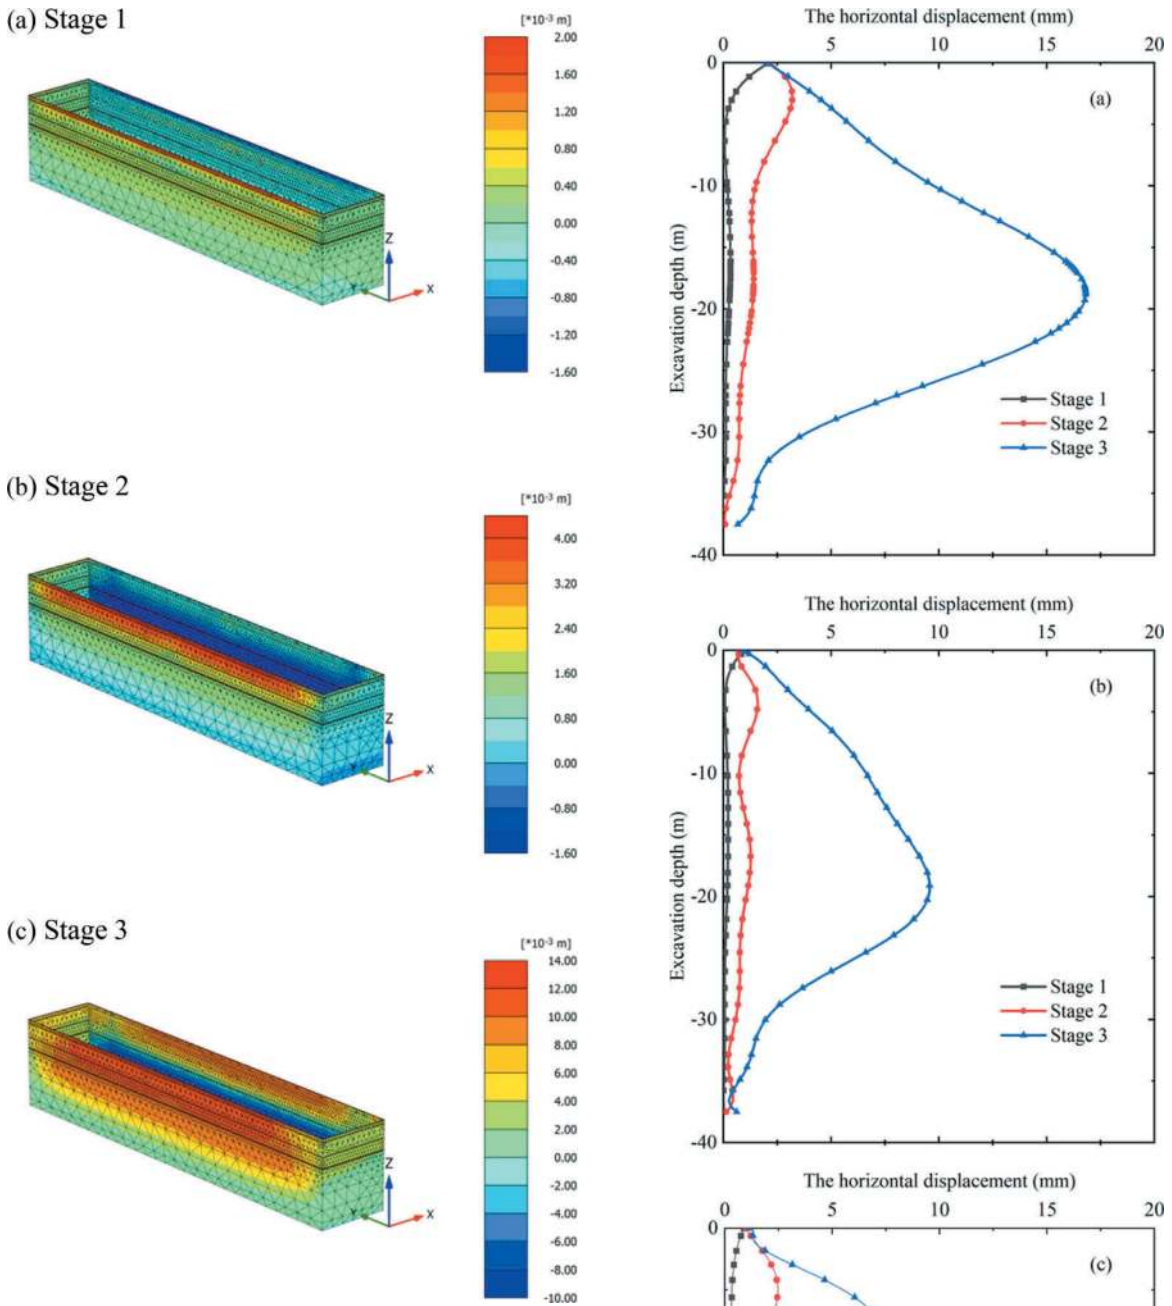

Figure 2. Horizontal displacement contour maps of diaphragm walls at different stages.

compared to the preceding two stages, with the maximum displacement occurring in the middle of the diaphragm wall at a depth of approximately 19 m.

Several studies have investigated the relationship between horizontal displacement (ϵ) and excavation depth (H) in deep foundation pits. Peck (1969) proposed a control line of $\epsilon = 1\% H$, and Clough (1990) proposed a control line ranging from $0.22\% H$ to $0.5\% H$. Figure 4 illustrates the relationship between the maximum horizontal displacement (ϵ) and excavation depth (H) for the H1 ramp foundation pit studied herein. The figure reveals that the maximum horizontal displacement is generally constrained below 0.22% of the excavation depth in each stage.

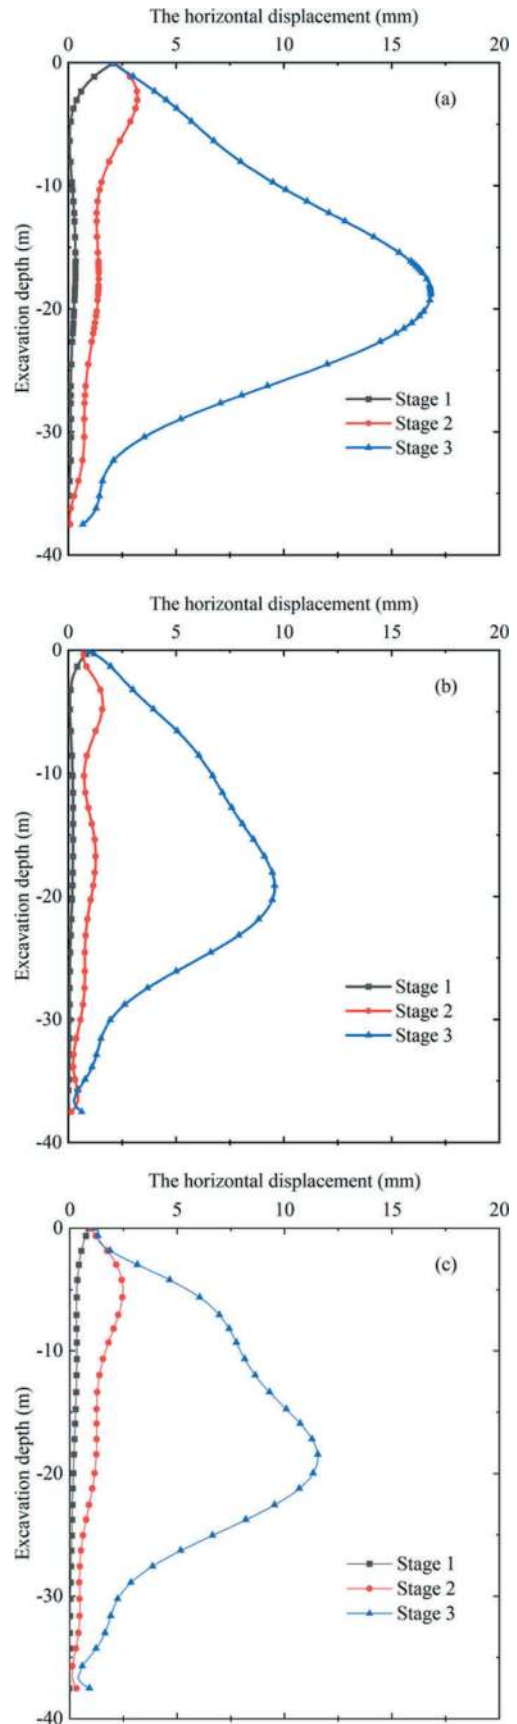

Figure 3. Horizontal displacement with depth at different positions of h1 foundation pit: (a) the long side, (b) the short side, (c) the corner.

Figure 4. Relationship between maximum horizontal displacement and excavation depth.

3.2 Surface settlement analysis (without partition walls)

Figure 5 shows the surface settlement at the midpoint of the long side (a), the midpoint of the short side (b), and the corner (c) of the foundation pit. From these figures, it can be observed that the surface settlement deformation outside the foundation pit mainly concentrates within a range of twice the excavation depth, with the maximum settlement occurring within a range of one excavation depth. The trend of surface settlement exhibits a pattern of initially increasing and then decreasing.

Figure 6 illustrates the correlation between the maximum surface settlement around the foundation pit and the excavation depth across various excavation stages. Clough (1990) and O'Rourke (1993) proposed settlement control lines ranging from $\epsilon = 0.15\% H$ to $\epsilon = 0.5\% H$. The figure shows that the settlement points at the corners are distributed below $\epsilon = 0.15\% H$, whereas those in the central area are distributed below $\epsilon = 0.24\% H$.

4 RESEARCH ON EXCAVATION OF PARTITION WALLS

Based on the aforementioned analysis, it can be concluded that the deformation of elongated deep excavations is closely related to the aspect ratio of the excavation, particularly the dimensions of the long side. Therefore, effectively utilizing the spatial effect can achieve efficient control over the deformation of elongated deep excavations and the surrounding environment. One of the most direct measures is to reduce the length of the excavation. Implementing partition walls to reduce the actual length of the excavation can bring about structural changes to the excavation. This point has also been confirmed by Ou et al. (2006).

In order to analyze the influence of partition walls on the deformation characteristics of elongated deep excavations, three additional partition walls were introduced based on the finite element model described in the previous section. The partition walls

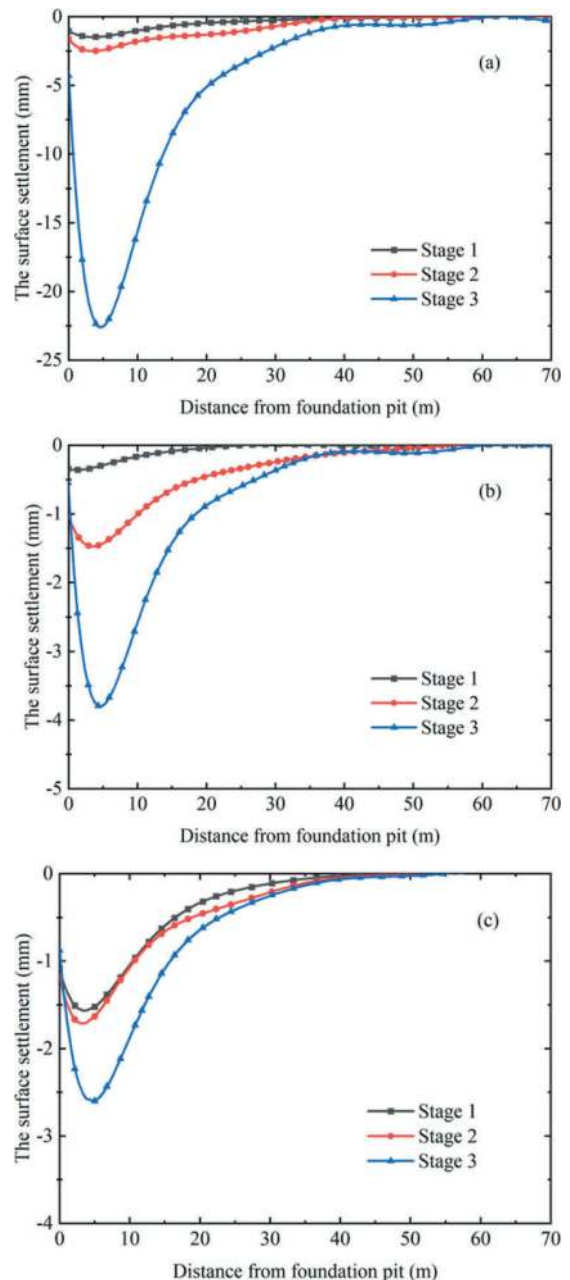

Figure 5. Surface settlement at different positions outside the foundation pit: (a) the midpoint of the long side, (b) the midpoint of the short side, (c) and corner.

consist of diaphragm walls with a thickness of 0.8 m, and their depths at the bottom are consistent with the existing diaphragm wall. Thus, the H1 foundation pit is divided into three regions, namely, A, B, and C, as illustrated in Figure 7. The synchronous excavation method is employed for all the three regions.

4.1 Comparative analysis of horizontal displacement

Figure 8 illustrates the horizontal displacement of the diaphragm wall at three excavation stages, comparing the scenarios with and without partition walls. The figure demonstrates that despite the presence of partition walls, the horizontal deformation of

Figure 6. Relationship between the maximum surface settlement and excavation depth.

Figure 7. Numerical model with partition walls.

Figure 8. Comparison of horizontal displacement between partition wall and no partition wall.

the diaphragm wall maintains a concave shape, which aligns with the deformation trend proposed by Hsieh et al (2012). The horizontal displacements in regions A, B, and C increase gradually with the depth of excavation, with the maximum

deformations occurring near the excavation face. During stage 3, the diaphragm wall exhibits a maximum horizontal displacement of approximately 8 mm with the partition wall.

Figure 9 illustrates a comparative diagram of the maximum horizontal displacements in regions A, B, and C. The figure shows that region B exhibits the largest horizontal displacement regardless of the presence of partition walls. The partition walls result in a maximum horizontal displacement of 9.47 mm for the connected wall in region B, compared to 16.81 mm without partition walls. The partition wall also leads to a significant decrease in the maximum horizontal displacements for regions A and C at each excavation stage, effectively controlling the deformation of the excavation. This suggests that the partition walls, which reduce the length of the excavation, are highly effective in controlling deformation during excavation. Partition walls offer support in the longitudinal direction of the connected wall, effectively restricting horizontal displacement.

Figure 9. The maximum horizontal displacement of each area.

4.2 Comparative analysis of surface settlement

Figure 10 reveals that the ground surface settlement pattern outside the excavation, after the installation of partition walls, resembles that observed when partition walls were present. In both instances, the maximum settlement occurs 5-10 m away from the pit's edge. During Stage 3, the maximum settlement value reaches 22.59 mm without partition walls, whereas with partition walls, the ground surface settlement outside the excavation is only 2.53 mm (11.2% of the former). In the remaining two stages, the ground surface settlement outside the excavation experiences a certain degree of reduction following the installation of partition walls. This suggests that the installation of partition walls effectively controls the ground surface settlement outside the excavation and mitigates its impact on the surrounding environment.

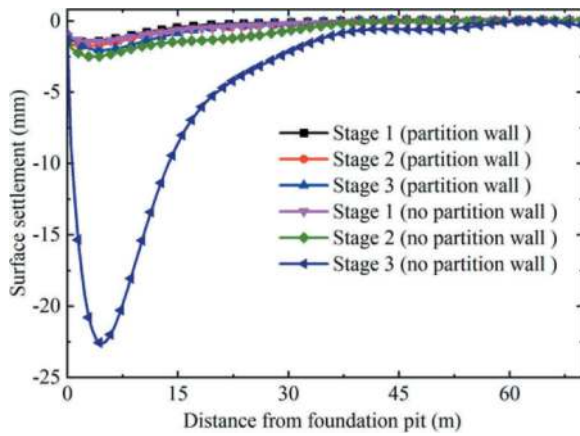

Figure 10. Comparison of surface settlement between the partition wall and no partition wall.

In order to further analyze the influence of partition walls on the surface settlement of the surrounding area in the excavation, the maximum surface settlement values in regions A, B, and C were compared. From Figure 11, it can be observed that after the installation of partition walls, the maximum surface settlement values in regions A, B, and C are all around 2.5 mm. Compared to the case without partition walls, they have reduced by 2.16 mm, 20.17 mm, and 2.14 mm, with reduction rates of 45.45%, 88.85%, and 46.72% respectively. In region B (the central area along the long side of the excavation), there is a significant reduction in the maximum surface settlement, indicating that the partition walls has a noticeable inhibitory effect on the surface settlement in the central area along the long side of the foundation pit.

Figure 11. The maximum surface settlement of each area.

5 CONCLUSIONS

- (1) The maximum horizontal displacement of the diaphragm wall in each excavation stage of the

long and narrow deep foundation pit is generally controlled below 0.22% H, and the maximum surface settlement outside the foundation pit is controlled below 0.24% H. Both the maximum horizontal displacement and the maximum surface settlement occur in the central area along the long side of the diaphragm wall.

- (2) The utilization of partition walls to shorten the length of the long and narrow deep foundation pit enables an effective reduction in the horizontal displacement of the diaphragm wall and the surface settlement outside the foundation pit. The central area along the long side exhibits the most substantial decrease, with a 43.66% reduction in the maximum horizontal displacement of the diaphragm wall.
- (3) This study focuses solely on examining the impact of installing two partition walls on the deformation characteristics of the long and narrow deep foundation pit. Future research should aim to explore the optimal configuration of partition walls to achieve the most effective deformation control.

Disturbance effect and surrounding rock pressure characteristics of loess shield tunnels

Xingbo Han, Peiyuan Wang, Ziming Chen, Haolan Feng, Hao Cui & Fei Ye*
Chang'an University, Xi'an, China

ABSTRACT: Subjected to the unique mechanical properties of loess strata, the disturbance from shield tunneling and subsequent stress relocation within this stratum show their own features. In this study, by developing a UMAT subroutine that can characterize the constitutive properties of the loess strata, a FEM method is proposed to simulate the loess behavior during the shield tunneling and validated by experiments, using the user programming of ABAQUS. With this method, the soil behavior and redistribution of stress fields are investigated with varying water contents. Results show that the increase in water content of loess results in the displacement development of the loess stratum being gradual at the beginning, and the displacement increases rapidly after reaching 15% water content. In terms of soil pressure, the built-up pressure at the tunnel shoulder shows a unimodal distribution with the increase in water content. In addition, the pressure differential between the two tunnel shoulders becomes apparent at 20.2% water content. At 25.5% water content of loess, the soil pressure at the tunnel invert reaches its maximum. The pressure built-up at the crown drops with the increase in water content.

Keywords: shield tunnel, loess stratum, secondary development, water content, surrounding rock pressure

1 INTRODUCTION

The safety of tunnel structures is directly influenced by the load or pressure from the disturbed surrounding soil. Therefore, understanding the influence mechanism of construction disturbance on stratum stability, as well as the disturbance caused by soil load, is crucial for guiding safe construction and optimal design of tunnels. A large number of scholars have conducted extensive research through numerical simulations such as the finite element method.

Atkinson and Cairncross (1973) used the finite element method to calculate the ground stability of shallow tunnels. In 1983, Clough et al (1983), who proposed the Finite Element Method, analyzed the soil response of EPB shield tunnel. These early studies mostly adopted linear elastic constitutive, which is still widely used in a large number of recent research. Subsequently, Yang et al (1985) gave a nonlinear finite element calculation process for the plane strain problem of cavern excavation. Lyamin and Sloan (2000), as well as Yamamoto et al (2011), used the M-C nonlinear constitutive model to obtain a more accurate stress solution of surrounding rock in tunnel excavation. The ideal elastic-plastic

constitutive was applied by Zheng et al (2008) in the Strength reduction method to calculate the slope safety factor. Then, the three-dimensional models with complex Geometry (Zhang et al., 2022), modified elastic-plastic and viscoelastic-plastic constitutive (Pan et al., 2019; Luo et al., 2018) were applied in the recent research. At the same time, new methods such as node-based finite element method (NS-FEM) (Vo-Minh et al., 2018; Vo-Minh and Nguyen-Son., 2021a; Nguyen and Vo-Minh., 2022) and smooth finite element method based on stable nodes (SNS-FEM) (Vo-Minh and Nguyen-Son., 2021b) have been applied. These methods further consolidate the important position of finite element numerical simulation in tunnel engineering mechanics analysis.

Several studies have been conducted to simulate the stress and deformation characteristics of loess surrounding soil for tunnels. For instance, Hu et al, (2011) used ABAQUS to simulate the stress and deformation characteristics of loess surrounding soil for tunnel Humaling. Song et al. (2018) used the Drucker-Prager model through ANSYS to simulate the mechanical behavior of surrounding soil under immersion by changing material parameters. Lai

et al (2018) used the Duncan-Chang model to study the effect from loess surrounding soil to the structure underwater immersion through secondary development. Pan et al (2019) used FLAC3D to simulate the pressure arch of an unsupported loess tunnel based on the Mohr-Coulomb constitutive model. In these studies, the elastic constitutive model was mostly applied in simulating the tunnel surrounding soil, and only limited conclusions of regularity can be conducted from these simulation works. To address this issue, it is necessary to realize the simulation of reasonable mechanical behavior of loess through secondary development. Therefore, this study intends to use the elastic nonlinear constitutive model which can reflect the characteristics of loess to describe the stress-strain relationship of loess stratum. Then, it is proposed to realize the reasonable simulation of the construction behavior of the loess shield tunnel through the secondary development of ABAQUS. Finally, based on the proposed reasonable numerical simulation method, this study investigates the influence of excavation and water content on the mechanical behavior of tunnel and stratum. The research conclusions are expected to provide support for designing loess shield tunnels.

2 ELASTIC NONLINEAR CONSTITUTIVE OF LOESS AND ITS SECONDARY DEVELOPMENT

The reasonable stress-strain relationship of soil is the key to accurately analyzing geotechnical tunnel engineering problems. The stress-strain relationship of general rock or soil can be expressed as:

$$\{\sigma\} = [D]\{\varepsilon\} \quad (1)$$

Where $[D]$ is the stiffness matrix, which can be expressed as a function of modulus and Poisson's ratio:

$$[D] = f(E, \nu) \quad (2)$$

Where E is the modulus, ν is the Poisson's ratio.

As early as 1963, Kondner obtained the stress-strain relationship of soil by using a hyperbolic curve through a large number of triaxial tests:

$$\sigma_1 - \sigma_3 = \frac{\varepsilon_a}{a + b\varepsilon_a} \quad (3)$$

Where the elastic modulus $E = a + b\varepsilon_a$, a , b are constants. This formula can directly reflect the stress-strain relationship of soil by linear elastic relationship.

Subsequently, Duncan and Chang proposed the incremental elasticity model- Duncan—Chang Model. The elastic coefficient in the elastic matrix

can change with the change of stress state, which can more reasonably reflect the nonlinear relationship of soil stress and strain:

$$[D] = \frac{E_t}{(1 + \nu_t)(1 - 2\nu_t)} \begin{bmatrix} (1 - \nu_t) & \nu_t & \nu_t & 0 & 0 & 0 \\ \nu_t & (1 - \nu_t) & \nu_t & 0 & 0 & 0 \\ \nu_t & \nu_t & (1 - \nu_t) & 0 & 0 & 0 \\ 0 & 0 & 0 & (1 - 2\nu_t)/2 & 0 & 0 \\ 0 & 0 & 0 & 0 & (1 - 2\nu_t)/2 & 0 \\ 0 & 0 & 0 & 0 & 0 & (1 - 2\nu_t)/2 \end{bmatrix} \quad (2)$$

Where E_t is the tangent modulus of the soil, ν_t is the tangent Poisson's ratio.

However, for loess strata, Xie and Xing (2014) pointed out that the stiffness matrix is different from that of general soil, which can be expressed as:

$$[D] = \frac{E}{(1 + \nu)(1 - 2\nu)} \begin{bmatrix} 1 - \nu & \nu & \nu & 0 & 0 & 0 \\ \nu & 1 - \nu & 0 & 0 & 0 & 0 \\ \nu & 0 & 1 - \nu & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 - 2\nu & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 - 2\nu & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 - 2\nu \end{bmatrix} \quad (5)$$

Where the elastic modulus E can be expressed as:

$$\begin{aligned} E &= E_t = (1 - R_f s)^2 E_i \\ &= \left[1 - R_f \frac{(1 - \sin \varphi)(\sigma_1 - \sigma_3)}{2c \cos \varphi + 2\sigma_3 \sin \varphi} \right]^2 K p_a \left(\frac{\sigma_3}{p_a} \right)^n \end{aligned} \quad (6)$$

Poisson ratio ν_t can be expressed as:

$$\nu_t = \frac{G - F \lg(\sigma_3/p_a)}{\left\{ 1 - \frac{D(\sigma_1 - \sigma_3)}{K p_a \left(\frac{\sigma_3}{p_a} \right)^n \left\{ 1 - \frac{R_f(\sigma_1 - \sigma_3)(1 - \sin \varphi)}{2c \cos \varphi + 2\sigma_3 \sin \varphi} \right\}} \right\}^2} \quad (7)$$

In Eq.(6) and (7), E_i is the initial modulus, R_f is the failure ratio, c is the cohesion, φ is the angle of internal friction, p_a is the atmospheric pressure, K is intercept of straight lines, n is the slope of straight lines, D , G and F are experimental constant.

Therefore, to describe the mechanical behavior of loess strata under the influence of shield construction more reasonably, the stiffness matrix is constructed in ABAQUS through secondary development.

3 RATIONALITY VERIFICATION OF THE SELF-DEVELOPED CONSTITUTIVE

In this section, the simulated triaxial test results are compared with the indoor triaxial test experiment results to verify the rationality of the self-developed elastic nonlinear constitutive model.

A three-dimensional standard soil sample finite element model with the same size as the indoor sample is established to simulate the conventional

indoor triaxial compression test. Calculations are performed here for two soil samples. One is from reference Gao and Li (2006) (No.1 in Table 1), and the other is from the project site of Xi'an Metro Line 8 with the moisture content of 15.1% (No.2 in Table 1). The height of the specimen is 80mm and the diameter is 39.1mm showing in Figure 1. The numerical model is divided into 25341 elements, and the soil is simulated by C3D8 elements. The relevant parameters of the model are listed as Table 1.

Table 1. Elastic nonlinear constitutive relation of loess stratum.

No.	K	n	R_f	c/kPa	$\varphi/^\circ$	G	D	F
1	376	0.35	0.84	38	30	0.466	1.18	0.184
2	216	0.41	0.86	35.95	24.39	0.192	3.41	0.073

Figure 1. Three-dimensional standard soil sample finite element model.

In the numerical simulation, the displacement of the side ($U_2 = 0$) and the bottom ($U_3 = 0$) of the model is 0, and the top is the free surface. The confining pressures with 100 kPa, 200 kPa, 300 kPa, σ and 400 kPa were applied during the test. After the stress was balanced, a 12 mm displacement load was applied along the Z-axis direction at the top free surface. The comparison between numerical simulation and indoor triaxial test results are shown in Figure 2. It can be seen from both Figure 2 (a) and (b) that the results of the numerical simulation of the loess triaxial test based on the elastic nonlinear constitutive model obtained by secondary development are consistent with the results of the laboratory test. The constitutive bilinear characteristics of loess can be well reflected in numerical simulations. The UMAT subroutine in this study is feasible in simulating loess mechanical problems.

4 SOIL DISTURBANCE CHARACTERISTICS OF LOESS SHIELD TUNNEL CONSTRUCTION

4.1 Modelling

Based on the elastic nonlinear constitutive model UMAT subroutine, this section studies the soil deformation and surrounding rock pressure of loess strata under shield construction. One section of Xi'an Metro Line 8 was taken as an engineering case. The outer diameter of the segment is 6.2 m with the thickness of 0.35 m. This section of the tunnel is buried in the loess stratum. The buried depth is 15 m. The numerical model adopts the C3D8 element, and the mesh division is shown in Figure 3. The parameters of the loess stratum are listed in Table 1. The parameters of the segment shield shell are listed in Table 2.

The elastic nonlinear constitutive model UMAT subroutine established in Section 2 is used to describe the constitutive relationships of loess. The

Table 2. Model material parameter table.

Materials	Density/(t/m ³)	Young's modulus/Pa	Poisson ratio
Segments	2.6	24 500 000	0.2
Shield shell	7.85	245 000 000	0.2

construction process containing excavation, shield shell supporting and segment assembly are simulated by using life-and-death element method. The soil and the segment are set with binding constraints, and the segment is in contact with the soil. In the model, a fixed constraint is set at the bottom of the soil, and the displacement perpendicular to the plane is 0. A support pressure with the amount of 200kPa was applied on the tunnel front face during the drilling.

Figure 3. Model grid diagram.

4.2 Disturbance characteristics of soil and comparison with model test results

The vertical displacement of soil caused by tunnel excavation is the most significant. According to the calculation of this model, the three-dimensional equivalent surface of vertical displacement of soil after excavation is shown in Figure 4. It is found from Figure 4 that there is a certain range of collapse area above the tunnel face. The soil is displaced towards the direction of the tunnel face. And the closer to the tunnel face, the greater the soil displacement. The boundary of the collapse area is platform-shaped. Then a 1:50 scale indoor experiment was carried out to verify the numerical result. The experiment equipment is shown in Figure 5. The detailed parameters of the experiment have been reported by Han et al. (2023). The macroscopic morphology and digital image analysis results of the collapse surface obtained by the test are shown in Figure 6. The collapse area is also obviously characterized by a platform distribution. This also shows that the proposed self-developed constitutive model has applicability.

Figure 4. Numerical simulation results of vertical displacement of soil.

Figure 5. Model test settings.

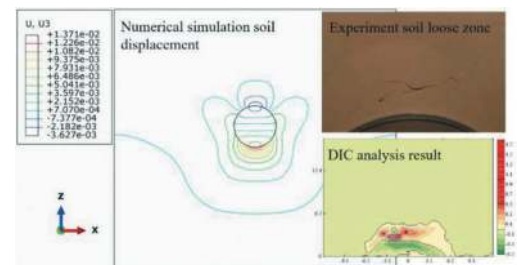

Figure 6. Numerical simulation and model test soil loose area comparison.

4.3 Surrounding rock pressure characteristics

In this section, the shield excavation process in the loess stratum is simulated based on the elastic non-linear constitutive model UMAT subroutine. The surrounding rock pressure corresponding to different excavation steps under the action of self-weight stress is extracted showing in Figure 7. It is found that the surrounding rock pressure under the action of self-weight stress in the vault is the largest, followed by the arch bottom. And the surrounding rock pressure both side wall is the smallest. With the excavation of the tunnel, the distribution law of surrounding rock pressure has changed, and the surrounding rock pressure of the arch shoulder exceeds the vault. In addition, the surrounding rock pressure

of the arch waist also gradually increases. The surrounding rock pressure of the vault measured by the experiment (black stars in Figure 7) is close to the numerical simulation results.

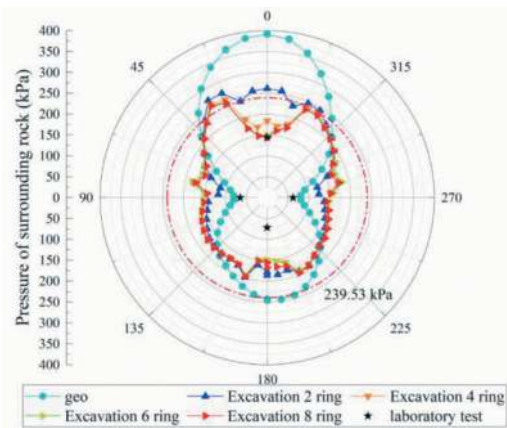

Figure 7. Surrounding rock pressure corresponding to different excavation steps.

5 CHARACTERISTICS OF SURROUNDING ROCK PRESSURE OF LOESS SHIELD TUNNEL WITH DIFFERENT WATER CONTENT

Based on the triaxial test for the loess from the shield tunnel site of Xi'an Metro Line 8, the Duncan-Chang parameters under different moisture contents of the engineering loess strata are measured as shown in Table 3. Subsequently, the above parameters are input into the numerical calculation model. The surrounding rock disturbance and surrounding rock load of loess shield tunnel construction under different water content are analyzed.

Table 3. Parameters of the elastic nonlinear constitutive model of loess with different water content.

Moisture content (%)	K	n	R_f	$c/$ kPa	$\varphi/^\circ$	G	D	F
11.8	318	0.5	0.94	45.00	27.91	0.223	3.73	0.087
15.1	216	0.41	0.86	35.95	24.39	0.192	3.41	0.073
16.8	153	0.32	0.81	36.55	23.91	0.169	3.02	0.065
20.2	127	0.26	0.75	30.32	22.45	0.133	2.77	0.046
25.4	92	0.16	0.71	33.96	15.93	0.123	2.65	0.033

5.1 The overall displacement of soil

The overall deformations of the soil after tunnel excavation and support under different water contents are shown in Figure 8. It can be seen from Figure 8 that the maximum value of the overall displacement of the soil gradually increases with the increase of the stratum water content. During the shield excavation process, the soil displacement at the tunnel face is the largest. In addition, when the water content increases

to 25.4 %, the area with large disturbance has developed to the surface. When the water content exceeds 15 %, the soil displacement develops rapidly. The maximum displacement of the 25.4 % water content formation is about 10 times that of the 11.8 % water content formation (Figure 9).

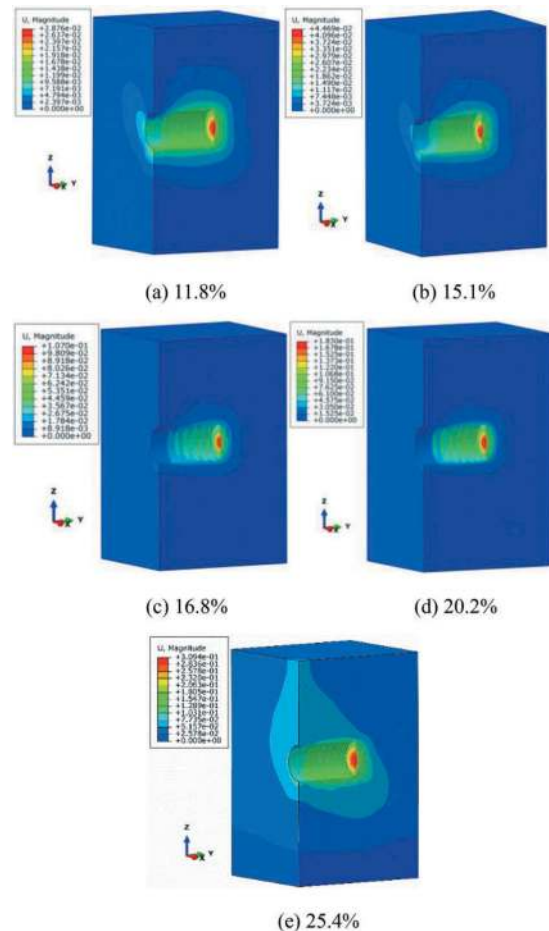

Figure 8. The overall deformation diagram of soil during shield tunneling under different water content loess strata (unit:m).

Figure 9. The maximum value of the overall and vertical displacement of the soil during shield tunneling in loess strata with different water contents.

5.2 Pressure of surrounding rock

The surrounding rock pressure during shield tunneling in loess stratum with different water contents is extracted and compared, as shown in Figure 10. The formation water contents are 11.8 %, 15.1 %, 16.8 %, 20.2 %, and 25.4 %, respectively.

It can be seen from Figure 10 that the law of surrounding rock pressure distribution during shield tunneling at different water contents situations is similar. With the increase in water content, the surrounding rock pressure gradually increases (the closer the whole is to 239.53 kPa).

The changes of surrounding rock pressure in different directions after the completion of shield tunneling under different water content are compared in Figure 10 (f). It can be seen that, with the increase of water content, the surrounding soil pressure at the arch waist increases first and then decreases. When the water content is 20.2 %, the surrounding rock pressure on both sides of the arch waist increases most significantly. The surrounding rock pressure at the arch bottom increases gradually, and the surrounding rock pressure at the arch bottom is the largest when the water content is 25.4 %. The surrounding

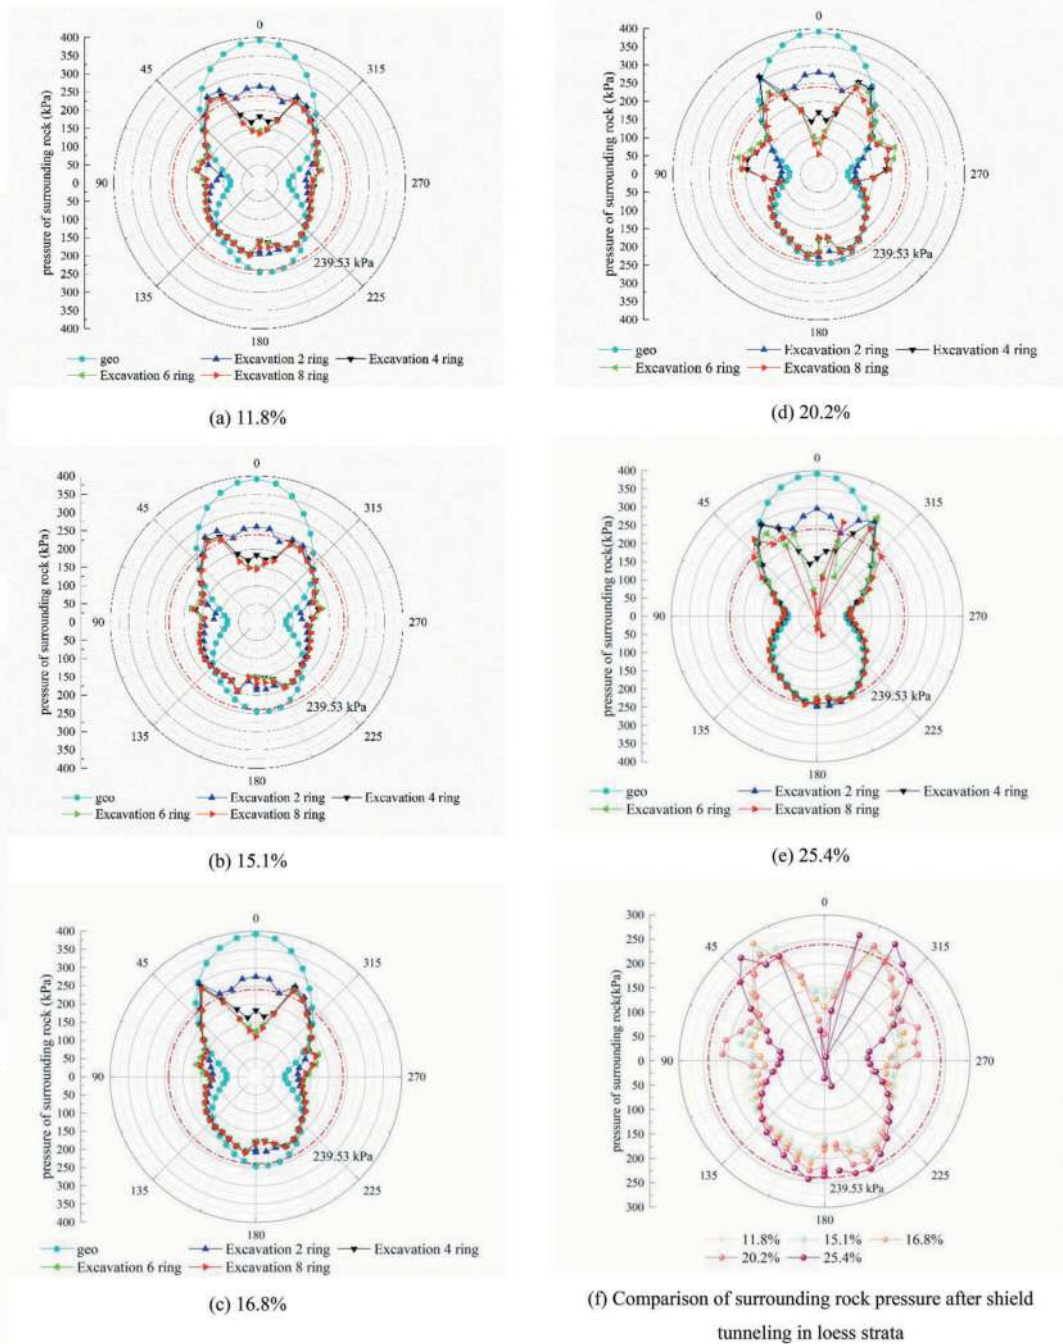

Figure 10. Surrounding rock pressure during shield tunneling in loess strata with different water contents.

rock pressure of the vault decreases from large to small, and from positive to negative. This shows that, with the increase in water content, compressive stress gradually appears in the vault. When the water content is 25.4%, the variation range of surrounding rock pressure of the vault is the largest.

6 CONCLUSION

In this research, we first established an elastic nonlinear constitutive model to reflect the characteristics of loess stratum. Then, we proposed a numerical simulation method for loess tunnel engineering by applying the elastic nonlinear constitutive into the software ABAQUS. The accuracy of the numerical method was verified by comparing it with the triaxial test and the indoor scale experiment. Finally, we studied the influence of excavation and water content on the mechanical behavior of tunnel and stratum in loess area. Detailed conclusions are follows:

- (1) The elastic nonlinear constitutive model proposed in this work can reasonably simulate the disturbance law of loess shield tunnel construction to the stratum. With an increase in water content, the maximum value of overall displacement of the loess stratum gradually increases. When water content exceeds 15%, soil displacement develops rapidly.
- (2) With an increase in water content, surrounding rock pressure at arch waist increases first and then decreases.
- (3) When water content is 20.2%, surrounding rock pressure on both sides of arch waist increases most significantly. When water content is 25.4%, surrounding rock pressure of arch bottom is largest. Surrounding rock pressure of vault decreases from large to small, and vault gradually appears under compressive stress. When water content is 25.4%, surrounding rock pressure of vault changes most.

ABSTRACT: The grout propagation plays a crucial role in the design of polyurethane grouting for reinforcing and sealing fractured rock. Understanding the influence of isocyanate index on the diffusion process is essential for selection and material modification to improve the grouting effectiveness. In this study, a numerical method was developed to simulate the grout propagation of polyurethane, considering the coupled of reaction kinetics and fluid flow. Furthermore, the influence of the isocyanate index on pressure, diffusion distance, component conversion and density were analyzed. These findings contribute to the preparation and selection of polyurethane grout for practical engineering applications.

Keywords: Polyurethane, Fracture grouting, Isocyanate index, Grout propagation, Numerical simulation

1 INTRODUCTION

In recent years, the increasing use of two-component polyurethane grouting material with self-expanding characteristics has gained great attention, driven by advancements in the modern polymer industry. Unlike traditional grouting materials such as cement and sodium silicate entirely rely on static pressure, the two components of polymer grout, black material (isocyanate) and white material (polyol, blowing agent, catalyst, foam stabilizer, and other additives) chemically react rapidly after mixing, leading to the volume expansion as the primary driving force of polymer grout. With the advantages of rapid reaction, high expansion rate, excellent impermeability, safety and environmental protection over traditional alternatives, the polymer material has been widely

used in the repairing of uneven settlement of high-speed railway subgrade, treatment of voids under airport pavements, non-excavation maintenance of highways, quick tunnel repairment, and dam anti-seepage reinforcement (Fang et al., 2019; Guo et al., 2020; Guo and Wang, 2009; Wang et al., 2022; Zhang et al., 2021). Understanding and regulating the diffusion and evolution of polymer grout in rock fractures are of great importance in grouting design.

As a chemical grouting material, the isocyanate index of polyurethane grout significantly impacts on the process of chemical reactions, manifested as an increase in volume and temperature macroscopically. For the grout propagation of polymer material, the molar ratio of NCO to OH, known as the isocyanate index greatly influences the increase in cross-link of

*Corresponding author: haomm1213@outlook.com

polyurethane, hard segment content and unreacted NCO functional groups (Eun and Lee, 2020). Tu et al. (2007) examined the influence of isocyanate index on the density, compressive strength, and thermal conductivity of polyurethane foam, but the presence of physical blowing agent was not considered in their works. Kim et al. (2008) synthesized various types of rigid polyurethane foams with HFC-365mfc as the physical blowing agent, and the effect of isocyanate index on the foam properties such as reactivity, cell morphology, mechanical and dynamic mechanical properties, and thermal properties had been analyzed. For the diffusion patterns of polymer grout in rock fractures, Hao et al. (2018) simulated the diffusion process of polymer grout in rock fractures, and obtained the time-varying characteristics of pressure field and diffusion distance. Li et al. (2019) presented an analytical solution to model the radial transient flow of polymer grout with variable density in a planar fracture and the analytical expressions of the diffusion radius, radial velocity and pressure distribution over time between the fracture walls in self-expanding phase were derived. Liang et al. (2021) established a single radial diffusion model of fracture grouting and analyzed the influence of grouting amount, expansion ratio and aperture on the diffusion patterns of polymer grout in rock fractures. These studies treated the polymer grout as a homogeneous fluid with known density and viscosity variations over time, without considering the intrinsic driving mechanism of chemical reactions. Jia et al. (2022) incorporated chemical reaction kinetic equations into the numerical simulation of the diffusion process of polymer grout in a planar fracture under adiabatic conditions, analyzing the time-varying laws of grout component conversions, temperature, diffusion range, density, pressure and other variables, but did not investigate the influence of isocyanate index of polymer grout material on the grout propagation.

In summary, existing studies mainly focus on the mold filling or free rising process of polyurethane, with simplistic consideration of the external environment and surrounding media conditions compared to the expansion process in the fractures; these studies primarily investigate the influence of operating parameters and external environment on the expansion and diffusion of polymer grout, while paying less attention to the influence of isocyanate index. In our study, coupling the chemical kinetics and grout flow, a numerical model for the spread and expansion of polymer grout in a rock fracture was established. Based on the lubrication theory, the governing equation combining chemical kinetic equation were solved to investigate the propagation of polymer grout in a fracture. Furthermore, the influence of isocyanate indexes on the spread, pressure, conversion and density were analyzed. The results are able to improve the comprehensive understanding of the diffusion process of polymer grout in rock fractures and provides valuable references for

choosing material proportions as needed in practical engineering applications.

2 CHEMICAL KINETICS

2.1 Gelling reaction

Gelling reaction is the process of isocyanate react with polyol to form polyurethane, as can be seen in formula (1).

The chemical reaction kinetic equation for this reaction, i.e., the rate equation, is:

$$\frac{dX_{\text{OH}}}{dt} = A_{\text{OH}} \cdot \exp\left(-\frac{E_{\text{OH}}}{RT}\right) \cdot c_{\text{OH}}^0 \cdot (1 - X_{\text{OH}}) \cdot \left(\frac{c_{\text{NCO}}^0}{c_{\text{OH}}^0} - 2 \frac{c_{\text{W}}^0}{c_{\text{OH}}^0} X_{\text{W}} - X_{\text{OH}}\right) \quad (2)$$

2.2 Blowing reaction

The blowing reaction refers to the process of reaction between isocyanate and water to produce carbon dioxide, which is a process of rapid expansion of the volume of polymer grout. The chemical reaction equation is as follows:

The chemical reaction kinetic equation is:

$$\frac{dX_{\text{W}}}{dt} = A_{\text{W}} \cdot \exp\left(-\frac{E_{\text{W}}}{RT}\right) \cdot c_{\text{OH}}^0 \cdot (1 - X_{\text{W}}) \cdot \left(\frac{c_{\text{NCO}}^0}{c_{\text{OH}}^0} - 2 \frac{c_{\text{W}}^0}{c_{\text{OH}}^0} X_{\text{W}} - X_{\text{OH}}\right) \quad (4)$$

Where, c_i^0 and X_i denote the initial concentration and conversion of component i respectively, and i takes W, OH and NCO when denoting water, polyol and isocyanate, respectively. A_{OH} and A_{W} are the pre-exponential factors for the gelling and blowing reactions, respectively. E_{OH} and E_{W} are the activation energies for the two reactions, respectively. R is the ideal gas constant, and T is the grout temperature.

3 MATERIAL MODELS

3.1 Density model

During the reaction process, the polymer grout is considered as a homogeneous mixture of two gases and three liquids. In this case, the gas part consists of the gaseous physical blowing agent produced by vaporization of the liquid physical blowing agent and the carbon dioxide generated by the blowing reaction. The liquid part is formed by water, the polyurethane mixture and the liquid physical blowing agent dissolved in the grout. Thus, the calculated expression for the density of the polymer grout at any moment is:

$$\rho = \frac{1 + r_W^0 + r_{BL}^0}{\frac{r_{CO_2}RT}{PM_{CO_2}} + \frac{r_{BG}RT}{PM_B} + \frac{(1-X_W)r_W^0}{\rho_W} + \frac{r_{BL}^0 - r_{BG}}{\rho_{BL}} + \frac{1}{\rho_p}} \quad (5)$$

Where, r_W^0 and r_{BL}^0 are the initial mass fraction of water component and liquid physical blowing agent, respectively. r_{BG} and r_{CO_2} are the mass fraction of gaseous physical blowing agent and carbon dioxide, respectively. M_{CO_2} and M_B are the molar mass of carbon dioxide and physical blowing agent, respectively. ρ_{BL} and ρ_p are the density of liquid physical blowing agent and polyurethane, respectively. P is the pressure of the grout.

3.2 Solubility of physical blowing agent

The solubility of the physical blowing agent in the polymer grout varying with the grout temperature obtained from experiments is as follows:

$$r_{BL} = 0.03518 + \frac{0.04341}{1 + \exp\left(\frac{T-430.8294}{19.2898}\right)} \quad (6)$$

$$r_{BG} = r_{BL}^0 - r_{BL} \quad (7)$$

4 FLOW CONTROL EQUATIONS

Considering the characteristics of polyurethane material, the following assumptions and simplifications are made: a) The polymer grout is regarded as a viscous fluid. b) The expansion process takes place in an adiabatic environment, where there is no heat exchange with the external surroundings. c) The polymer grout is fully reacted, and all the gases generated during the reaction are incorporated into the mixture. d) The polymer grout is an isotropic homogeneous continuous fluid, and the flow process is considered as laminar flow. e) The reaction process in the fracture is a two-phase flow with grout and air.

4.1 Governing equations

A quasi-3D model developed by Li et al. (2019) was used in this paper, and set the scales of z direction much smaller than those of x and y directions (with order of magnitude differences). The model takes the geometric characteristic of the fracture into account and introduces the assumptions of the Hele-Shaw model to deduce the partial derivatives of the velocity with respect to z at fracture walls and the derived equation is a function of the aperture and the average velocity. The conventional difference scheme for the diffusive term is partly replaced by the derived analytical expression, thus the three-dimensional problem of grout flow in parallel fracture can be transformed into a two-dimensional problem.

The flow of the polymer grout satisfies the following equations:

(1) Mass conservation equation

The flow of the polymer grout satisfies the mass conservation equations:

$$\frac{\partial \rho}{\partial t} + \text{div}(\rho \mathbf{u}) = 0 \quad (8)$$

Where, ρ is the density, t is the time, \mathbf{u} is the velocity vector, and div is the scatter.

(2) Momentum conservation equations The flow of the polymer grout satisfies the momentum conservation equations:

$$\begin{aligned} \frac{\partial(\rho u)}{\partial t} + \text{div}(\rho u \mathbf{u}) &= \text{div}(\mu \text{grad} u) - \frac{\partial}{\partial z} \left(\mu \frac{\partial u}{\partial z} \right) + S_u \\ \frac{\partial(\rho v)}{\partial t} + \text{div}(\rho v \mathbf{u}) &= \text{div}(\mu \text{grad} v) - \frac{\partial}{\partial z} \left(\mu \frac{\partial v}{\partial z} \right) + S_v \end{aligned} \quad (9)$$

Where, u and v are the flow velocities in the x and y directions, respectively; S_u and S_v are the source terms in the x and y directions, respectively; μ is the velocity.

(3) Energy conservation equation

Under adiabatic conditions, the energy conservation equation of the polymer grout is:

$$\begin{aligned} &(C_p + r_{CO_2} C_{CO_2} + r_W C_W + r_{BG} C_{BG} + r_{BL} C_{BL}) \frac{dT}{dt} \\ &= \left(\frac{-\Delta H_{OH} c_{OH}^0}{\rho_p} \right) \frac{dX_{OH}}{dt} \\ &+ \left(\frac{-\Delta H_W c_W^0}{\rho_p} \right) \frac{dX_W}{dt} - \lambda \left(-\frac{dr_{BL}}{dt} \right) \end{aligned} \quad (10)$$

Where, C_i and r_i is the specific heat capacity and mass fraction of component i , and i takes p, CO₂, W,

BG and BL when denoting polyurethane, carbon dioxide, water, gaseous physical blowing agent and liquid physical blowing agent, respectively. ΔH_{OH} and ΔH_W are the heats of gelling reaction and blowing reaction, respectively. λ is the heat of evaporation of physical blowing agent.

(4) Scalar-transport equations

The component mass conservation equations for the hydroxyl and water components (ignoring the diffusion terms) are as follows:

$$\frac{\partial}{\partial t}(\rho\alpha_F X_{OH}) + \text{div}(\rho\alpha_F X_{OH}\mathbf{u}) = \rho\alpha_F Q_{Kin,OH} \quad (11)$$

$$\frac{\partial}{\partial t}(\rho\alpha_F X_W) + \text{div}(\rho\alpha_F X_W\mathbf{u}) = \rho\alpha_F Q_{Kin,W} \quad (12)$$

Where α_F represents the volume fraction of grout in a cell, $Q_{Kin,OH}$ and $Q_{Kin,W}$ represent the rate of change of hydroxyl fraction conversion and water fraction conversion, respectively:

$$Q_{Kin,W} = A_{OH} \cdot \exp\left(\frac{-E_{OH}}{RT}\right) \cdot c_{OH}^0 \cdot (1 - X_{OH}) \cdot \left(\frac{c_{NCO}^0}{c_{OH}^0} - 2\frac{c_W^0}{c_{OH}^0} X_W - X_{OH}\right) \quad (13)$$

$$Q_{Kin,W} = A_W \cdot \exp\left(\frac{-E_W}{RT}\right) \cdot c_{OH}^0 \cdot (1 - X_W) \cdot \left(\frac{c_{NCO}^0}{c_{OH}^0} - 2\frac{c_W^0}{c_{OH}^0} X_W - X_{OH}\right) \quad (14)$$

(5) VOF model

The volume of fluid (VOF) method is employed to accurately track the interface between the grout and air phases. The sum of the volume fractions of the grout phase and air phase of each cell is 1 in the computational domain. Therefore, there are three values representing the volume fraction of the grout phase: $\alpha_F = 1$ means that the cell exclusively contains polymer grout, $0 < \alpha_F < 1$ means that the cell contains both polymer grout and air, and $\alpha_F = 0$ means that the cell only contains air without grout present. The volume fraction of the polymer grout satisfies:

$$\frac{\partial\alpha_F}{\partial t} + \mathbf{u}\text{div}\alpha_F = 0 \quad (15)$$

4.2 Solving process

- Dissect the solution area, divide the grid cells, and generate information of the number, center and interface coordinates of each cell;

- Set the boundary types and location information of the solution area;
- Initialize the VOF functions, initial pressure, velocity vectors, initial temperature, initial reactant concentrations and initial conversions of each cell;
- Assign material properties such as density and viscosity based on current volume fraction, temperature, pressure and reactant conversions of each cell;
- Calculate and discrete scalar-transport equations based on current temperature, conversions, density, and velocity vectors to obtain current reactant conversions;
- Calculate the energy equation and obtain the temperature field distributions;
- Solve the continuous and momentum discrete equations according to the PISO algorithm to obtain the converged velocity vectors;
- Solve the volume functions of the fluid cells based on the current flow velocity values in each direction;
- Update and output the current fluid volume function values and the values of parameters such as pressure, velocity, density, temperature, and conversion;
- Update the time, and start a new round of solving.

5 NUMERICAL CALCULATION

5.1 Settings of operating conditions

The foaming polyurethane grouting material mainly relies on the self-expanding characteristics to achieve the purpose of filling voids, compacting rock, and controlling seepage. During the grouting process, isocyanate reacts with polyol to generate a large amount of polyurethane. Additionally, the reaction between isocyanate and water produces urea and carbon dioxide, which serves as a source of bubbles for foam expansion. Therefore, this paper mainly investigates the influence of isocyanate index on the grout propagation.

The numerical simulation program was developed in Fortran language to accurately solve the expansion process of polymer grout in the fracture. The model size is set as 0.8 m × 0.8 m (the dimension in the z direction has a large order of magnitude difference from those in the x and y directions), with the cell size of 0.01 m × 0.01 m. The bottom, left and right sides of the model are wall boundaries, while the upper side is free surface boundary as shown in Figure 1. Water is chosen as the chemical blowing agent while HCFC-141b serves as the physical blowing agent. The initial pressure is set as 0.75 MPa and initial temperature is 313.15 K. Since the viscosity of the grout does not change much before curing, the constant value of 1 Pa·s is taken here. Furthermore, the initial radius of the grout is set as 0.19 m. Then a series of simulation calculations are carried out.

According to the composition ratio range of polymer grouting material (Li et al., 2021), the isocyanate index varies from 1.12 to 3.62 and the detailed settings are shown in Table 1. The parameters of chemical reaction kinetic models and material properties related are listed in Table 2 and Table 3, respectively (Jia et al., 2021).

5.2 Results and discussion

The pressure of polymer grout contributes to filling cracks and pores, enhancing the bond with surrounding soil or rock, and providing lateral support and restraint. Studies have shown that it exhibits a three-stage variation of slow increase, sharp increase and gradual decrease in the plane fracture grouting under adiabatic conditions (Jia et al., 2022), indicating the existence of a peak value. Hence, the maximum pressure of the polymer grout deserves further attention. At the same time, component conversion is an important parameter to indicate the degree of reaction. Besides, the density of self-expanding grouting material plays a significant role in its mechanical properties (Li et al., 2022), and the mechanical properties of self-expanding grouting material with different densities are essential in evaluating the repairing effect on underground structures. The decrease in density corresponds to the expansion of the volume, which is crucial for achieving proper filling range and fracture integrity. For the reasons above, to achieve the comprehensive evaluation and optimization of self-expanding grouting materials, it is necessary to take the pressure, diffusion distance, component conversion and density into consideration.

1) Pressure

Figure 2. The influence of isocyanate index on pressure at grouting hole.

Figure 2 shows the time-variation curves of pressure at grouting hole for different isocyanate indexes. The pressure of grout increases rapidly and then decreases. And the larger the isocyanate index, the slower the rate of pressure increases and decreases. Besides, it can be seen obviously that the maximum pressure of the polymer grout diminishes as the isocyanate index increases. It may be attributed to the excess isocyanate groups react with polyurethane generated by the gelling

reaction, and at the same time, self-polymerization reaction occurs (Xu et al., 2017), to a certain extent, inhibit the occurrence of the gelling reaction and blowing reaction, which reduce the contribution of carbon dioxide gas generation, i.e., bubble growth to pressure. Therefore, the maximum pressure decrease.

2) Diffusion distance

Figure 3. The influence of isocyanate index on diffusion distance from the grouting hole.

Figure 3 illustrates the time-variation curves of diffusion distance from the grouting hole under different isocyanate indexes. The diffusion rate decreases with the increasing isocyanate index due to the inhibitory effect mentioned in (1). However, the final diffusion distance exhibits a pattern of initially increasing and then decreasing as the isocyanate index increases. When it is less than 2.12, as the isocyanate index increases, the increased formation of carbon dioxide gas from the isocyanate-water reaction results in the increase in the final diffusion distance of the grout. For larger values, complete reaction of isocyanate with hydroxyl group and water occurs, and the isocyanate further reacts with polyurethane generated through the gelling reaction, forming allophanate containing urea groups which are much more polar compared to urethano in polyurethane (Sami et al., 2014). Thus, the isocyanate-polyurethane reaction greatly promoted the formation of hydrogen bonds between molecular chains, and then increased the physical cross-linking degree and interaction forces among molecular chains, leading to the molecular chain more difficult to slip. As a result, the final diffusion distance decrease.

3) Component conversion

Figure 4 shows the time-variation curves of component conversion of water and hydroxyl group

(a) Conversion of water component

(b) Conversion of hydroxyl component

Figure 4. The influence of isocyanate index on component conversion of water and hydroxyl group.

for different isocyanate indexes. It can be seen from the figure that the component conversion gradually increases over time, and finally tends to be stable. The final component conversion of water and hydroxyl group increases with isocyanate index increasing. When the isocyanate index reaches 2.12, the final conversion of the water and hydroxyl components can be almost up to 100%, at this point continue to increase the isocyanate index, the final component conversion is not changing much.

Under the same isocyanate index, the increase rate of component conversion of water is greater than that of component conversion of hydroxyl group, which is mainly because one isocyanate molecule can react with two water molecules, but can only react with one hydroxyl molecule.

4) Density

Figure 5 shows the time-variation curves of density for different isocyanate indexes. The density of grout gradually decreases with the

Figure 5. The influence of isocyanate index on the density of polymer grout.

reaction time and the decreasing rate decreases with the increase of the isocyanate index. For the final density, when the isocyanate index is less than 2.12, the increasing of isocyanate index, i.e., the higher proportion of isocyanate, means the more generation of carbon dioxide. The significant volume of gases causes more expansion of the polymer grout, resulting in an increase in volume and then a decrease in final density. However, when the isocyanate index is larger, the hydroxyl group and water molecule are reacted completely by the isocyanate as shown in Figure 4. Excessive isocyanate further reacts with polyurethane to produce allophanate, while self-polymerization occurs to form dimer, trimer and other compounds. Additionally, a large amount of free isocyanate groups with higher density remains uninvolved in the chemical reactions, increasing the final density of the polymer grout.

6 CONCLUSION

In this paper, based on the coupled of reaction kinetics and fluid flow, a simulation model of the flow diffusion of polymer grout in rock fractures was established. The grout propagation of polymer grout under different isocyanate indexes of polymer grout were numerically calculated. The results show that:

As the isocyanate index increases, the maximum pressure of the grout gradually decreases with the increase of isocyanate index. Besides, there is an inflection point in the effect of isocyanate index on spread and curing density. Thus, to obtain a higher expansion performance of polyurethane grout, while considering the reaction rate, it is recommended that the isocyanate index is between 1-2.

Notations

A_{OH}	Preexponential factor for gelling reaction ($m^3/mol/s$)
A_W	Preexponential factor for blowing reaction ($m^3/mol/s$)
E_{OH}	Activation energy for gelling reaction(J/mol/K)
E_W	Activation energy for blowing reaction(J/mol/K)
ΔH	Heat of reaction (J/mol)
λ	Heat of evaporation (J/kg)
C	Heat capacity (J/kg/K)
c	Concentration (mol/m^3)
r	Mass fraction
X	Conversion
M	Molecular weight (kg/mol)
P	Pressure (Pa)
R	Universal gas constant
t	Time (s)
T	Grout temperature (K)
u	Velocity vector (m/s)
S	General source term for conversion equation
μ	Viscosity ($Pa \cdot s$)
ρ	Density(kg/m^3)

Indices

0	Initial
BL	Liquid phase of physical blowing agent
BG	Gas phase of physical blowing agent
NCO	Cyanate group
OH	Hydroxyl group
W	Water
P	Polyurethane

Dynamic soil response around a shallow rectangular tunnel and adjacent building

Zhengyao He* & S.P. Gopal Madabhushi

Department of Engineering, University of Cambridge, Cambridge, UK

ABSTRACT: Recent earthquake events indicated that shallow buried structures are susceptible to be damaged during a strong cyclic loading. This is even further critical when considering the adjacent surface building in a congested urban area. With the requirement to minimize the tunnel uplift and building rotation, it is firstly important to understand the dynamic soil behaviour around these structures during the earthquake. In this paper, the main research aim is to investigate the seismic soil response around a shallow, rectangular tunnel that is adjacent to a nearby building founded on loose, saturated sand. The results from two separate dynamic centrifuge tests will be presented. The soil deformations around the tunnel-building system will be obtained by adopting Geo-PIV_RG software based on the Particle Image Velocimetry (PIV) technique. Dynamic effects on the soil stiffness due to the earthquake loading will be studied by using the cone penetrometer test (CPT). Finally, the conclusions will be drawn on the effect of the relative building-tunnel lateral distance with the same tunnel buried depth.

Keywords: Cut & cover tunnel, Soil-structure interaction (SSI), Centrifuge modelling, Earthquake engineering

1 INTRODUCTION

Shallow cut-and-cover tunnel has been widely used in congested urban areas. Designing these underground structures is critical and the interaction of the surface building should be accounted for. Recently earthquakes have caused substantially irreparable property and personal losses in the urban city such as 2023 Turkey–Syria earthquake, 2023 Morocco earthquake and 2008 China Wenchuan earthquake.

Most recently, there are many researchers focus on the dynamic underground structure behaviour subject to seismic loading. Hashash et al. (2001) conducted a state-of-the-art review of the currently understanding of the seismic underground design, and the demand for additional work. This work has been extended by Tsinidis et al. (2020), and Chen et al. (2023) particular for the shield tunnelling. It was observed that the tunnel uplift due to the earthquake-induced soil liquefaction is one of the major concerns for the shallow cut-and-cover tunnel. Early study of the tunnel floatation due to excess pore pressure started by Chou et al. (2008a, 2008b, 2011) as part of the BART project in California. Dynamic centrifuge testing is adopted to study the dynamic soil and tunnel responses. Chian and Madabhushi

(2012) studied the effects of the tunnel buried depth on the floatation resistance.

Considering the increasing complexity of the surface structures in the urban area as shown in Figure 1. It is important to consider the dynamic building interaction when analysing the seismic behaviour of the adjacent tunnels. Dashti et al. (2016) and Hashash et al. (2018) adopted centrifuge testing and 3D numerical modelling to study the dynamic interaction between the multi-story structures and the adjacent underground braced excavations subjected to cyclic loading through a series of centrifuge tests and 3D numerical modelling. Miranda et al. (2023) conducted similar work but adopting PIV technique to capture the soil deformation during the cyclic loading.

This research aims to investigate the influence of the lateral building-tunnel distance with fixed tunnel buried depth the dynamic tunnel and soil behaviour subjected to earthquake loading through two dynamic centrifuge tests. Soil shear resistance and surface soil deformations are studied by adopting a high-speed imaging based PIV technique and cone penetrometer test (CPT). The observations from experiments form the basis of understanding the tunnel-building dynamic interaction under liquefied soil.

2 CENTRIFUGE MODELLING

Centrifuge modelling has been widely adopted to study the seismic structural behaviour under liquefied soil strata. It simulate the prototype non-linear soil stress and strain with a scaled down model by centrifugal accelerating the model in N g-level. Scaling laws for centrifuge testing following Madabhushi (2014) are selected in this study as given in Table 1. Two dynamic centrifuge models were conducted by using the Turner beam centrifuge with a rotational radius of 4.125 m at the Schofield Centre, Cambridge University. Testing g-level is 60 g for both tests. Most recent generalized scaling laws derived by lai et al. (2005) stated that the soil behaviour is highly depended on the confining pressure after reaching the peak deviatoric stress based on 1 g testing. However, this modified scaling law is not suitable to be applied in the dynamic centrifuge tests as the stress and strain are scaled differently.

Table 1. Scaling laws for centrifuge tests.

Parameters	Model/prototype	Dimensions
Length	N^{-1}	L
Mass	N^{-3}	M
Stress	1	$ML^{-1} T^{-2}$
Strain	1	1
Force	N^{-2}	MLT^{-2}
Seepage velocity	N	LT^{-1}
Time (seepage)	N^{-2}	T
Frequency	N	LT^{-1}
Acceleration	N	LT^{-2}
Velocity	1	LT^{-1}

Note: N, scaling factor

2.1 Structural design

The scaled down aluminium tunnel model is designed to represent a two-lane 12 m \times 6 m rectangular cut-and-cover motorway tunnel at the prototype scale.

The axial stiffness and flexural stiffness of the aluminium tunnel is equivalent to the concrete tunnel with 300 mm wall thickness at the prototype scale. The surface building is simulated as a rigid aluminium block with 6 m span at the prototype scale. This block simulates the dead load of a two-storey residential building and gives approximately 50 kPa contact pressure on the soil strata beneath at the testing g-level. Both transverse edge of the tunnel and building model are attached with polytetrafluoroethylene (PTFE) plates to minimize the in-plane direction friction between the model and the container as this is a 2D cross-section model. Figure 2 shows the installation of the tunnel and building model in test ZA03

Figure 2. Completed model of test ZA03 before spinning.

2.2 Test preparation

Both two tests are prepared in a rigid aluminium container with a Perspex observing window panel. This type of container has been commonly adopted by the previous researchers to study the dynamic buried structural behaviour (Chian and Madabhushi, 2012; Chian et al., 2014; Cilingir and Madabhushi (2011a, 2011b, 2011c)). Hostun HN31 sand (Mitrani, 2006; Haigh et al., 2012) is selected and poured by an automatic sand pouring machine following by Madabhushi et al. (2006). Details of the sand property are given in Table 2. A servo-hydraulic centrifuge shaker designed by Madabhushi et al. (2012) is implemented to apply the scheduled input motion to the centrifuge model.

Table 2. Hostun sand material properties.

Parameters	Value
f (degrees)	33 ^a
D_{10} (mm)	0.209
D_{50} (mm)	0.335
e_{min}	0.555 ^a
e_{max}	1.01 ^a
G_s	2.65 ^a
K (m/s)	1×10^{-3b}

a Data from Mitrani (2006).

b Data from Haigh et al. (2012)

Both centrifuge model ZA03 and ZA04 are saturated with premixed high viscous methyl cellulose fluid at the designed viscosity. Prior to seismic analysis, it is important to conduct a preliminary static factor of safety (FoS) analysis to ensure the reasonable tunnel buried depth and the tunnel stationary before applying any cyclic loading. This simplified FoS calculation against the vertical floatation shown in Equation (1) does not consider the complex contribution from the adjacent building contact pressure and friction along the soil slip surface, where is the tunnel buoyancy, F_T is the tunnel structural self-weight, F_{Soil} is the effective soil overburden pressure. As the result the tunnel FoS against floatation is calculated as 1.17 for ZA03 and 1.12 for ZA04.

$$FoS = \frac{F_{Soil} + F_T}{F_B} > 1 \quad (1)$$

Table 3. Centrifuge tests configurations.

Test ID	Earthquake			Lateral distance (m)
	Type	Frequency (Hz)	PGA (g)	
ZA03_RD=43%	Sinsweep	100 - 1	0.04	6
	Sinusoidal	1	0.23	
	Sinusoidal	1	0.35	
	Sinusoidal	1	0.06	
ZA04_RD=42%	Sinsweep	100 - 1	0.08	3
	Sinusoidal	1	0.21	
	Sinusoidal	1	0.33	
	Sinusoidal	1	0.05	

Note: Lateral distance, tunnel edge to building edge

The test configurations for both centrifuge tests are summarized in Table 3. The loose Houstun sand are prepared with similar relative density and been fully saturated. Same earthquake sequence is applied to both tests to investigate the effect of the lateral tunnel-building distance on the dynamic soil and structural behaviour.

3 DYNAMIC SOIL RESPONSE

3.1 Cone penetration test

Saturated soil shear resistance is particularly critical subjected to cyclic loading. During a rapid cyclic loading such as a strong earthquake, the hypothesis of soil liquefaction being considered as partially drained event that the drainage condition is highly depended on the confining pressure. Earthquake-induced excess pore pressure can significantly damage the interparticle friction and caused substantial loss of soil shear strength. Soil shear resistance will then be recovered with time due to the drain of excess pore pressure.

Figure 3. CPT system adopted in test ZA04.

Two cone penetration test (CPT) is performed at the free-field in test ZA04 to measure the soil shear resistance before and after the earthquakes. This model scale CPT system contains a load cell with capacity of 500 N and maximum testing depth of 200 mm as shown in Figure 3. The measured penetration resistance q_c is determined as the measured tip load over the CPT cross-section area. As the results, the CPT measured penetration resistance adjacent to tunnel is shown in Figure 4 at the prototype scale. The load cell output has been processed with an 8th order Butterworth filter under the low pass frequency of 80 Hz to minimize the centrifuge power noise. The measured depth covers the range from the surface to the base of the tunnel.

Soil at the sub-surface has low penetration resistance due to the low confining pressure before the earthquake. This has increased proportionally with the increasing of depth, confirming the uniformity of the soil layer. This CPT penetration resistance profile can be further investigated to determine the soil slip surface frictional resistance against tunnel floatation. Most recently, there are many researchers investigate the orientation of the soil slip surface adjacent to the tunnel (Chian and Madabhushi, 2012). It should be noted that the existence of the building can significantly affect the orientation of the soil slip surface, as well as the soil shear strength due to building's contact pressure.

During the earthquake, saturated soil lost most of the shear capacity due to the excess pore pressure generation, and the frictional resistance along the slip surface significantly reduced. Tunnel is observed to float upward due to the soil shear strength reduction and the excess pore pressure generated along the tunnel lining. It will be interesting to analyse the soil slip surface shear resistance on the building side, as the building contact pressure can minimize the liquefaction ratio beneath the building.

Figure 4. CPT penetration resistance profile for test ZA04.

After the earthquake, excess pore pressure existed in the soil porous media drain by the time and the soil shear strength recovered. The horizontal cyclic loading caused densification to the soil layer, this is supported by the additional CPT penetration resistance profile shown in Figure 4. Tunnel uplift caused circular loop shaped soil movement adjacent to the tunnel side wall. This leads to a reduction of the soil unfactored penetration resistance around tunnel's base depth due to the suction beneath the tunnel during the tunnel uplift. Soil densification also leads to the increasing of the shear strength at the sub-surface. It should be noted that the tunnel has been pushed away from the building during the earthquake. This can cause additional lateral pressure to the soil layer and thereby, increase the CPT measured shear resistance.

3.2 Soil surface deformation

Earthquake-induced soil deformation is a primary concern in the congested urban area. Most recent research on the dynamic building behaviour with the shallow foundation in liquefied soil has conducted by Dashti et al. (2010a, 2010b), Dashti and Bray (2013) and Adamidis and Madabhushi (2018) through a series of dynamic centrifuge tests. Significant building settlements have been widely observed due to the shear strength reduction beneath the foundation. Buried structure

floatation during the earthquake has been investigated by Chian and Madabhushi (2012) and Chian et al. (2014) for the circular tunnel, Watanabe et al. (2016) and Miranda et al. (2023) for the rectangular tunnel. It is critical to analyse the soil surface deformation within a buried structure and an adjacent building.

The soil surface deformation within the tunnel-building system is obtained by adopting the Particle Image Velocimetry (PIV) technique. A high-speed imaging-based code GeoPIV_RG designed by Stainer et al. (2016) is implemented to analyse the soil movements during the cyclic loading.

The soil surface profile before the earthquake, after 2 and 4 cycles of shaking as well as the post-earthquake profile for both tests are shown in Figure 5a and 5b at the prototype scale. Soil heave within the tunnel range and the soil settlement within the building range are observed in both tests. It can be seen that the soil deformations are cumulatively built up as more cyclic loading applied to the soil profile. The maximum soil deformations are determined as the difference of the soil final vertical position and the initial position before the earthquake. Maximum soil heave within the tunnel axis is captured as 0.21 m for the test ZA03 and 0.17 m for the test ZA04. Maximum soil settlement within the building axis is captured as 0.6 m for the test ZA03 and 0.54 m for the test ZA04. This present the surface soil profile within the tunnel-building system is more stable when then tunnel-building distance is decreased.

In addition, More uniform soil settlement distribution is observed beneath the building range for the test ZA04 than ZA03. This indicates the building perform less rotation when the tunnel-building distance is reduced. A possible hypothesis is that as the tunnel-building distance is increased, there are less interaction effect to the building from the adjacent tunnel. As the tunnel-building distance is reduced, there are more contribution of the tunnel interaction to the building behaviour during the earthquake as the tunnel lining stiffness is significantly higher than the liquefied soil stiffness. This is a particularly critical phenomenon for the SSI problem, because more interaction between the structures generally caused more susceptible damage during the cyclic loading.

Figure 5a. Surface deformation during the earthquake for test ZA03_EQ2 (Prototype scale)

Figure 5b. Surface deformation during the earthquake for test ZA04_EQ2 (Prototype scale)

4 CONCLUSIONS

This paper presents the current research to investigate the effect of the tunnel-building distance under the liquefied soil subjected to earthquake loading. Two dynamic centrifuge tests are conducted to analyse the dynamic soil response within a tunnel-building system by reducing half of the tunnel-building distance. A exemplified 1 Hz 10 cycles sinusoidal input motion with similar PGA is selected from the earthquake sequence for both tests. Soil stiffness and the soil surface deformations during the earthquake are observed in the centrifuge test using a miniature CPT test and a fast imaging based PIV technique respectively.

It can be seen that the frictional resistance along the surface slip surface contribute significantly to the tunnel FoS against floatation at the rest. During the earthquake, this frictional resistance is reduced due to the soil liquefaction and recovered after the earthquake with the drainage of the excess pore pressure. Soil profile is more stable when less tunnel-building distance during and after the earthquake. This is proved by the less soil heave along the tunnel axis and less soil settlement below the building and with less building rotation.

This research gives a further understanding of the dynamic tunnel and building behaviour under the liquefied soil. Additional centrifuge outputs such as the excess pore pressure generation along the tunnel lining, the comprehensive soil deformation profile within the tunnel-building system, and the tunnel movements are currently under process and will be presented in the future publications.

ACKNOWLEDGMENTS

The authors would like to appreciate to the technicians at the Schofield Centre for their contribution during the preparation and operation of the centrifuge tests.

Chemical-combined jet grouting for mass treatment of break-in area in Vietnamese urban underground construction

Hanh Quang Le*

FECON RAITO Underground construction JSC, Vietnam

ABSTRACT: Pipe Jacking method has been applying in Vietnam for urban drainage system since the 2000s, typically the wastewater sewer project along Nhieu Loc - Thi Nghe canal started in 2005; wastewater sewer project along Tau Hu - Ben Nghe canal in Ho Chi Minh City. Construction of the wastewater sewer in Ho Chi Minh City started in 2016 and the Yen Xa sewage system project in Hanoi started in 2020.

In the world, the traditional method of soil reinforcement for Pipe jacking is grouting with chemicals to reinforce the break-in and break-out areas. The main material composition is sodium silicate. This method is very effective in sandy soils but shows weakness when it is not effective enough in improving clayey soils and organic soils at locations with pipe jacking diameters larger than 1m (one meter). The geological characteristics of Hanoi and Ho Chi Minh City are sedimentary geology with many layers of soft clay soil. Therefore, after reinforcing with chemical grouting practically, this could not reach the necessary required strength for waterproof objective. Consequently, during the opening of the tunnel eyes, it caused many problems such as: The collapse of the tunnel eye causes the roadbed, the embankment to collapse at the shaft sides, or the sinking of the drilling robot head, contractor must construct a new shaft to rescue. All incidents have a direct impact on urban traffic flow, delaying progress and increasing construction costs.

This paper proposes the solution of combining Chemical grouting and Jet grouting JSG for mass treatment of break-in area. This method was successfully applied in Hanoi and Ho Chi Minh underground drainage system projects, and it has brought remarkable results when it is almost completely overcome the entire collapse incident when cutting the tunnel eye for the pipe jacking construction.

1 INTRODUCTION

The tunnel eye is considered to apply Chemical grouting method to stabilize and waterproof technical shaft when cutting tunnel eye. In fact, Chemical grouting method is very useful in sandy soil, but it shows the weakness in clayey soil, especially in soft clay with organic. During the application and construction process, water leakage and landslides at the tunnel eye occur more frequently at the location of the tunnel located in the soft clayey soil layer. In statistic, these incidents are often occurred on the tunnel eye diameter is $> 1.0\text{m}$. Some main causes can be listed as follows:

- Chemical materials do not penetrate evenly in soft clay and difficulty forming gel in soils

containing organic material, so the effect of stabilizing the soil mass does not increase significantly, sometimes even causing the soil mass to lose its original state and become weaker.

- The jacking machine causes a front force to cause cracking on improved block, water seeps into the shaft through tunnel eye, causing erosion and instability of soil mass.
- The process of excavation inside the shaft causes displacement, causing cracks in the improved soil block, reducing stability, and creating water seepage paths.

To overcome the main causes of the above problems, the soil mass at tunnel eye must be reinforced with enough strength to avoid overburden pressure and machine pressure when it drives to enter the

shaft. The combination of Jet grouting and Chemical grouting was chosen to research. Jet grouting is added 01 row at least beside shaft wall then chemical grouting. Column diameter Jet grouting is small enough to create a soil-cement wall that is stable enough for the jack drill head to be safely installed and ready to drill. Therefore, the 2-phase jet grouting method jumbo jet special grout (JSG) was chosen with a column diameter ranging from 1.0m (one meter) to 1.2m (one point two meter). The rest of the soil block in front of the tunnel entrance is grouted and improved with chemical grouting.

2 INTRODUCING THE APPLICATION METHOD

2.1 Chemical grouting method (CG)

Chemical grouting method uses the main material which is sodium silicate combined with gel-forming additives pumped at low pressure, pumping flow is about 8-16 liters/minute, the material is pumped into the soil. through the drilling rod to the designed location and penetrates the cracks and pores of the soil and then solidifies to create a more stable soil mass and prevent water from seeping through. Figure 1 describe chemical grouting sequency and Figure 2 explains how grout material penetrate into soil.

Figure 1. Sequence of chemical grouting.

At the initial stage of injection, outside surface of the rod is shielded and initial penetration area ① is formed. Then within ①, solution flow paths are created radially. (Flow paths create vertical plane).

Along the flow paths plane ① other paths are created in the area ②. Solution further penetrates around these flow paths and solidified will be formed and grow in area ②.

Further injection shall grow the flow paths plane to the area ③ and penetration area will expand outward.

With the method of using Sodium silicate material, the volume of grout pumped can usually be applied according to the void coefficient of sandy soils of 35% or more, clayey soils of 24% or more. Designing the amount of grout to be pumped according to geology according to Japan Grouting association (reference [1]) in Table 1. Details need to

Figure 2. Describes the principle of penetration of chemical liquid into the soil.

carefully consider the characteristics of the soil layers within the treatment area to adjust.

Table 1. Standard table for chemical grouting design.

Soil condition	N value	Void ratio %	Filling rate %	Injection ratio %
Sand & gravel	0 ~ 50	40	90	36.0
	50 <	35	90	31.5
Sand	0 ~ 30	45	90	40.5
	30 <	35	90	31.5
Cohesive soil	0 ~ 4	70	40	28.0
	4 ~ 8	60	40	24.0

2.2 Jet grouting method (JSG)

The 2-phase jet grouting method JSG uses cement slurry pumped at a high pressure of about 20 Mpa, with a pump flow of about 60 liters/minute. The air phase provides additional support to the slurry fluid to cut the soil to the desired diameter and mix the soil more evenly. Principle of the JSG method is described in Figure 3 (reference [2]).

The application method is most effective in sandy soils and can also be applied to cohesive soils. However, the characteristics of cohesive soils need to be carefully considered, especially soils containing organic humus. Although the method also has limitations when applied to organic clays, in general, with using cement slurry mixing, it can still create a treated soil mass with much better properties than the Chemical grout method.

According to JJGA (reference [2]), selecting design parameters for Jet grouting construction in cohesive soil is refer to Table 2. Standard design strength for improvement structure can be selected from Table 3.

The values in this table were set in accordance with experimental results of the sampled core. (4-week strength). In general, strength suppressing hardening agent is applied to the sandy soil. Standard design strength of an improvement structure in the case such hardening agent is applied to a five layered cohesive soil, or the like is considered to decreases as follows:

$$\begin{aligned} \text{JG-2} &= \text{JG-1} \times 70\%; \\ \text{JG-3} &= \text{JG-1} \times 50\%. \end{aligned}$$

Figure 3. Principle of JSG 2-phase Jet grouting method (JJGA).

Unit weight for an improvement structure is equal to that of original ground. Sand and pebbles are equivalent to the sandy soil. 1-week strength is equal to 30 ~ 40% of 4-week strength.

Coefficient of permeability is approximately the following value, in accordance with lab tests results for sampled core. $k = 1 \times 10^{-6} \text{ m/s}$ to $1 \times 10^{-7} \text{ m/s}$.

Properties of hardening agent are as follows:

- JG-1: strength development type (standard type)
- JG-2: strength suppressing type (moderate strength type)
- JG-3: strength suppressing type (low strength type)
- JG-4: for humic soil
- JG-5: for cohesive soil

3 APPLICATION OF CHEMICAL-COMBINED JET GROUTING

Based on geological conditions and underground sewer system design, the sewer system stretches over

Figure 4. Map of Shaft 13.0.

Table 2. Standard table for Jet grouting design.

Criteria	Cohesive soil					Humic soil *
	N < 1	N = 1	N = 2	N = 3	N = 4	
Effective diameter (m) with depth ($0\text{m} < Z \leq 25\text{m}$)	2.0	1.8	1.6	1.4	1.2	-
Withdraw time (min/m)	30.0	2.0	23.0	20.0	16.0	-
Discharge rate (m^3/min)	0.06					

* Need to be studied in case

Table 3. Selecting design strength parameters.

Hardening agent	Soil	Uniaxial compressive strength (MN/m ²)	Adhesive strength c (MN/m ²)	Adhesion f (MN/m ²)	Bending tension force (MN/m ²)	Deformation coefficient E50 (MN/m ²)
JG-1	Sandy soil	3	0.5			300
	Cohesive soil	1	0.3			100
JG-2	Sandy soil	2	0.4			200
JG-3	Sandy soil	1	0.2	$c \times 1/3$	$c \times 2/3$	100
JG-4	Humic soil	0.3	0.1			30
JG-5	Cohesive soil	1	0.3			100

Table 4. Geological parameters table.

Soil layer	Layer thickness t (m)	Unit volume weight γ_t (kN/m ³)	Void ratio e	Internal friction angle ϕ (°)	Adhesive strength C (kN/m ²)
1- Road bed	1.40	18.0	-	30.0	0
2- Stiff clay	0.60	18.5	0.841	12.5	28.635
7- Soft clay	4.80	19.8	0.673	17.5	19.417
8- Soft clay, organic	10.20	17.8	1.153	7.5	11.571

a large area, some sewer pipe locations are not located in the geological layer most suitable for the Chemical grouting method. Most of instability problems occur with the location of the tunnel in a layer of loose, flexible clay mud, sometimes mixed with organic matter.

The chemical-combined Jet grouting method was applied in Yen Xa 2 project. This paper analyses requirement of reinforcement on a typical case of Shaft 13.0 (Figure 4) before and after the soil is grouted by chemical to verify the necessary of Chemical-combined Jet grouting method.

3.1 Typical geological condition at the project

Result of the study and assessment of geological conditions of the area survey showed the ground structure to a depth of 30m is divided into 21 soil layers. According to geological data, borehole AD-6. Shaft 13.0 is located in stratigraphy including 4 layers, soil characters are shown in the Table 4.

Layer 1: Made ground: beton, brick, sand, sandy clay, roots, organic matter, ect.

Layer 2: . Clay, darkish brown, yellowish brown. Soft to firm.

Layer 7: . Clayey Sand, brown, brownish grey, blackish grey. Soft.

Layer 8: Sandy Clay, brownish grey, blackish grey, greyish; mixed with organic matter. Very soft.

3.2 Check the thickness of the soil improvement at the tunnel eye reinforced only with chemicals

3.2.1 Calculation condition

Calculation parameter table of the tunnel eye:

Ground elevation:	GL = 0.00 m
Tunnel eye centre depth	H = 11.78 m
Groundwater level	$h^* = 2.50$ m
Water unit volume weight	$\gamma_w = 10.00$ kN/m ³
Heavy load on top	$q = 10.00$ kN/m ²
Tunnel eye diameter	D = 1.30 m
Safety ratio	Fs = 1.20
Improved adhesive strength	$c' = 0.012$ MN/m ²

Figure 5. Calculation diagram.

Table 5. Geological parameters table.

Soil layer	Layer thickness t (m)	Unit volume weight γ_t (kN/m ³)	Underwater weight γ_t' (kN/m ³)	Internal friction angle ϕ (°)	Adhesive strength C (kN/m ²)	Adhesive after improvement C' (kN/m ²)
1- Road layer	1.40	18.0	8.0	30.0	0.00	0.00
2- Stiff clay	0.60	18.5	8.5	12.5	28.64	28.64
7- Soft clay	4.80	19.8	9.8	17.5	19.42	19.42
8- Soft clay, organic	10.20	17.8	7.8	7.5	11.57	11.57

3.2.2 Calculation formula for earth pressure and water pressure

$$K_A = \tan^2\left(45^\circ - \frac{\varphi}{2}\right) \quad (pa > 0)$$

$$p_A = K_A \cdot \left\{ \left(\sum \gamma_i \cdot H \right) + q \right\} - 2 \cdot C \cdot \sqrt{K_A}$$

$$w = p_A + p_w$$

$$F_s = F/W$$

$$F = l \times C' \times L$$

$$W = S \times w$$

$$L = (F_s \times S \times w) / (l \times c') = 6.02 \text{ m}$$

Where, P_A is earth pressure (kN); P_1 is above the release part (kN); P_2 below the release part (kN); P_w is water pressure (kN).

Using the formula above, earth pressure P_A is calculated as P_1 above the release part and P_2 below the release part, and water pressure P_w is added to calculate the resultant force P

Upper side	$P_1 = 167.73 \text{ kN}$
Lower side	$P_2 = 188.54 \text{ kN}$
Outside force:	$w = P_A + P_w = 178.13 \text{ kN/m}^2$
Open radius:	$r = 0.65 \text{ m}$
Adhesive strength after improvement	$c' = 11.57 \text{ kN/m}^2$
Perimeter:	$l = 4.08 \text{ m}$
Open area:	$S = 1.33 \text{ m}^2$
Required improved thickness	$t = 6.10 \text{ m}$

The thickness required to process is quite large, the hole to open the tunnel eye is within the weak organic clay layer, it is not possible to ensure stability when cutting to open the tunnel eye when the jack drill enters the shaft. Therefore, it is necessary to add a layer of jet grouting close to the tunnel eye to ensure stability. Additional Jet grouting to combine with Chemical grouting is considered at shaft location 13.0.

Calculation parameter table of the tunnel:

Figure 6. Calculation diagram.

Ground elevation	GL = 0.00 m
Centre depth of tunnel eye	H = 11.78 m
Groundwater level	$h^* = 2.50 \text{ m}$
Unit volume weight of water	$\gamma_w = 10.00 \text{ kN/m}^3$
Top load	$q = 10.00 \text{ kN/m}^2$
Tunnel eye diameter:	$D = OD + (0.15 \text{ m} \times 2) = 1.30 \text{ m}$
Safety factor	$F_s = 1.70$
Design strength	$q_u = 1.00 \text{ MN/m}^2$
Adhesive strength after improvement	$c' = 0.30 \text{ MN/m}^2$

Calculation formula for moment

$$M_{D1} = \left(\sum_{i=1}^i (\gamma_{ii} \cdot H_i) + q \right) \cdot D \cdot \frac{D}{2}$$

$$M_{D2} = \gamma_t \cdot \frac{\pi}{4} D^2 \cdot \frac{4}{3\pi} \cdot D = \frac{\gamma_t \cdot D^3}{3}$$

$$M_R = \frac{c_0 \cdot \pi \cdot D^2}{2}$$

$$F_s \cdot M_D - M_R = \Delta M_R$$

$$\Delta M_R = \Delta c \cdot \theta \cdot D^2 = > \theta = \frac{F_s \cdot M_D - M_R}{\Delta c \cdot D^2} = > \theta$$

$$= \sin^{-1}\left(\frac{t}{D}\right) = > t = D \sin \theta$$

Table 6. Geological parameters table.

Soil layer	Layer thickness t (m)	Unit volume weight γ_t (kN/m ³)	Weight in water γ_t' (kNm ³)	Internal friction angle φ (°)	Adhesive strength C (kN/m ²)	Adhesive after improvement C' (kN/m ²)
1-Road bed	1.40	18.0	8.0	30.0	0.00	0.00
2-Stiff clay	0.60	18.5	8.5	12.5	28.64	28.64
7-Soft clay	4.80	19.8	9.8	17.5	19.42	19.42
8-Soft clay, organic	10.20	17.8	7.8	7.5	11.57	300.0

Starting moment	MD1 = 185 kNm
	MD2 = 13 kNm
Resistance moment	MR = 31 kNm
Increasing moment	$\Delta MR = 305 \text{ kN/m}^2$
From the above	$\theta = 0.602 \text{ rad}$

Required improved thickness by Jet grouting
 $t = 0.80 \text{ m}$

When the jacking machine reaches the tunnel eye, the gap between the machine body and the borehole is created as a path for water from the outside to enter the tunnel eye. In addition, the machine pressure may cause damage to soil improvement soil block. Therefore, it is necessary to add a Jet grouting block to ensure the safety of machine arriving.

Figure 7. Calculation diagram.

Calculation parameter table of the tunnel:

Ground elevation	GL = 0.000 m
Centre depth of tunnel eye	H = 11.780 m
Groundwater level	$h' = 2.500 \text{ m}$
Unit volume weight of water	$\gamma_w = 10.0 \text{ kN/m}^3$
Top load	$q = 10 \text{ kN/m}^2$
tunnel eye diameter	D = 1.300 m
Safety factor	$F_s = 1.70$
Design strength	$q_u = 0.16 \text{ MN/m}^2$
Adhesive strength after improvement	$c' = 0.08 \text{ MN/m}^2$
Required thickness of excavator length	$1 + \alpha, 1 = 1.5 \text{ m}$

Calculation formula for earth pressure and water pressure

$$K_A = \tan^2(45^\circ - \frac{\varphi}{2}) \quad (pa > 0)$$

$$p_A = K_A \cdot \{(\sum \gamma_i \cdot H) + q\} - 2 \cdot C \cdot \sqrt{K_A}$$

$$w = p_A + p_w$$

Required thickness: α is

$$t = F_s \sqrt{\frac{1.2 \cdot w \cdot r^2}{\sigma_t}}$$

$$t = 1.7 \cdot \sqrt{\frac{1.2 \cdot 178.13 \cdot 0.65^2}{53}} = 2.3 \text{ m}$$

$$w = w - p_w = p_A + p_w - p_w = p_A$$

$$\alpha = 1.7 \cdot \sqrt{\frac{1.2 \cdot 85.33 \cdot 0.65^2}{53}} = 1.6 \text{ m}$$

Lateral pressure acting on the shield centre.

Earth pressure P_A ; above the release part P_1 and below the release part P_2 .

Upper side	$P_1 = 167.73 \text{ kN}$
Lower side	$P_2 = 188.54 \text{ kN}$
Outside force	$w = P_A + P_w = 178.13 \text{ kN/m}^2$
Open radius	$r = 0.65 \text{ m}$
Shear strength	$\sigma_t = 53.00 \text{ kN/m}^2$
Outside force	$P_A = 85.33 \text{ kN/m}^2$
Required section length:	$t = 2.30 \text{ m}$
Length of machine	$+ \alpha = 1.5 + 1.6 = 3.10 \text{ m}$
So, necessary improvement section	$= 3.10 \text{ m}$

The larger of the required section and excavator length $+ \alpha$

On arriving side, the design pipe diameter is 1.0m, the tunnel eye is larger with diameter of 1.3m for pipe jacking machine passing. With a larger pipe diameter, 02 rows of jet grouting could be applied according to stability. Layout Chemical grouting combined Jet grouting on arriving side with designed pipe diameter of 1.0m as Figure 8 and Figure 9 follow.

Figure 8. Layout of Chemical grouting and Jet grouting.

Figure 9. Section of Chemical grouting and Jet grouting (A-A).

According to the layout, quantity of Chemical grout combined jet grout is summarised in table 7.

3.2.3 Result of construction

Before applying Chemical grouting and Jet grouting method, field permeability test was conducted to verify coefficient of permeability of chemical grouting (Figure 10). Trial jet grouting was also conducted at project to ensure quality of Jet grouting column, target values were archived, $q_u \geq 1.0$ Mpa, $k \leq 1.10^{-7}$ m/s (Figure 11 and Figure 12).

The results of test are shown in Figure 11 and Figure 12.

According to project quality control policy. After soil improvement by Chemical grouting combined Jet grouting 14 days, small holes were cut on soft eye to check water leakage condition and improved soil

Figure 10. Field permeability test on Chemical grouting and Core sampling on Jet grouting.

Figure 11. Result of UCS test on Jet grouting sample.

Figure 12. Result of field permeability test.

Figure 13. Check water leakage and cut tunnel eye.

Table 7. Quantity of Chemical combined Jet grouting.

Method	Number of holes	Drilling length (m/hole)	Grouting length (m/hole)	Total grouting length (m)	Grouting ratio (%)	Total grout (m ³)
Chemical grouting	10	13.38	4.5	45	37	13.4
Jet grouting	4	13.38	4.5	45	100	21.6

condition (Figure 13). If there were no water leakage, tunnel eye will be cut partly. After tunnel eye was cut fully, seal ring will be installed to prevent mud and water increase during machine passing. When machine passed the tunnel eye safely, it will be move to the next jacking span.

4 CONCLUSION AND RECOMMENDATION

Lessons learned from jacking shaft locations where water leakage and subsidence occurred when cutting tunnels eye in Ho Chi Minh City. The technical solution combining Chemical grouting and Jet grouting at the tunnel location was researched and applied from the beginning for the project in Hanoi City, and the quality test results met the requirements. During the process of cutting and opening the tunnel eye for the pipe jacking machine to operate, there was no problem of water leakage causing subsidence from then on. Construction work in deep shaft is guaranteed to be safe.

With a long sewer system over a large area must ensure the slope and design flow, so it is inevitable that the sewer elevation will be within

the weak soil layer such as organic clays. Jet grouting method solves the strength of tunnel eye blocks, Chemical grouting method solves the problem of seepage, this combination is completely suitable and can be applied to projects with similar properties.

ACKNOWLEDGMENTS

We would like to sincerely thank the contribution and support of FECON-RAITO underground construction JSC Company during the survey, visit construction, data collection and results analysis process.

ABSTRACT: The deep excavation or tunnel construction adjacent to an existing metro station will cause additional stress and displacement in the as-built structures, which might affect its functionality and/or even threaten the structural integrity. A systematic deformation control methodology for underground space construction is discussed in this paper, taking the Huangmugang Transportation Hub Project in Shenzhen as an engineering case study. This project is in close proximity to the existing metro line 7 station, which continues under normal operations during the entire course of extensive underground construction activities. For maintaining construction safety at different construction stages, systematic and stringent control of ground and structural deformations become critical, in view of the engineering risk challenges in complex ground and built environments. Staging construction approaches by zones with protective measures and monitoring are discussed. The rationality and effectiveness of the deformation control by ground reinforcement, construction disturbance control and monitoring among other engineering measures are verified. The principle, methodology and relevant experience are of relevance for similar projects.

Keywords: Existing station, Mined tunnel, Deep excavation, Metro protection, Risk assessment

1 INTRODUCTION

With the rapid development of urban construction, the demand for utilization efficiency of traffic resources in urban areas has been increasing. For urban rail transit projects, the expansion and extension of existing metro lines is the main content of development. In this process, new rail transit projects often need to be constructed near various existing structures (such as tunnels and metro stations), resulting in a large number of complicated conditions involving adjacent structures (Zhang et al., 2011). Due to the existence of as-built underground structures, the soil stress of adjacent strata was redistributed during construction activities, which inevitably affected the displacement and stress response of the as-built underground structure (Li, 2009). Therefore, the approach to optimize design and construction sequences of a newly-built underground structure to effectively control the deformation of existing structures have become a key issue.

In recent years, a series of calculation and analysis methods had been applied to deformation control and safety risk assessment of adjacent structures caused by underground space construction (Guo et al., 2015). Theoretical calculation, FEM simulation and monitoring data analysis were adopted to quantify the stress and deformation caused by underground construction, then design optimization and corresponding protective measures have been taken according to the analysis results (Guo, 2015 and Wang et al., 2018). Zhao (2019), Sun (2013) and Feng (2018) analysed the spatial relationship and characteristics between new projects and existing structures, and specified construction methods to be applied to mitigate the risks of close proximity construction on existing structures. Tao et al. (2010) and Liu et al. (2010) studied the pre-construction stage risk assessment, and mitigation of the construction risk in advance through safety rating and systematic risk management.

The previous research mainly studied the deformation mechanism and key construction

*Corresponding author: Maxim.Li@aecom.com

technology of the adjacent existing rail transit structure under common construction conditions (the newly-built underground structure crossing sideways or downwards). However, research on the structural design and in-situ monitoring of new projects under complex construction conditions (the newly-built underground structure crossing both sideways and downwards) is still insufficient. Based on the Huangmugang (HMG) transportation hub project, this paper studies the comprehensive safety impact of a mined tunnel under short distance and deep excavation in close proximity to the existing Shenzhen Metro Line 7 station, and systematic deformation control measures that were applied during construction. According to the in-situ monitoring results, the deformation experienced by the existing station is small and well controlled within a safe range.

2 PROJECT OVERVIEW

2.1 Project background

The HMG Transportation Hub Project is located in the northeast of Futian District, Shenzhen, at the intersection of Sungang West Road, Ningang West Road, Huaifu Road and Huaqiang North Road. It is a three-line subway interchange hub for the existing Line 7, planned Line 14 and planned Line 24. The existing Line 7 station is laid underground along Huaqiang North Road and Ningang West Road, which is a three-storey underground structure with side stacked platforms. The Line 14 station is laid underground along Huaifu Road and Ningang West Road, which was planned to be a three-storey underground one-platform interchange station (with existing Line 7 station). The Line 24 station is laid underground along Sungang West Road and was planned to be a four-storey underground station. The site location of the HMG transportation hub is shown in Figure 1.

Figure 1. Site location of HMG transportation hub.

The existing Line 7 station has a length of 232m, and a width of 21.85m at both ends and 11.7m in the middle. The structure base slab depth of Line 7 station is around 27.6m~28.35m. The Line 14 station is a newly-built station, close to the west side of the existing Line 7 station, with a length of 262m, a width of about 44.6m~81.3m and a base slab depth of about 28.35m~29.1m. This was connected with the Line 7 station after completion. Another newly-built station, for Line 24, has a 70-degree cross relationship with the existing Line 7 station, with a length of 235.2m, a width of 28.2m and a maximum buried depth of 40m. In addition, two metro tunnels for Line 24 passed through the bottom of the Line 7 station. See Figure 2 for the plan-view relationship of the three metro stations at the HMG hub.

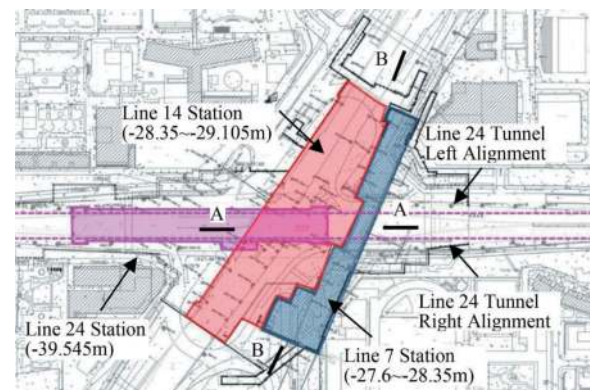

Figure 2. Layout plan of HMG transport hub.

2.2 Geological conditions

The project site is located in the Pearl River Delta, with a relatively flat terrain and a ground surface elevation of about 18.5m~25.50m. The geological profile of the station area was identified as: (1) Fill (partially rubble); (2) Soft Clay (SC); (3) Clayey Soil (CS); (4) medium to coarse Sand; (5) Eluvial Soil (ES) on Granite; and (6) Granite with different weathering degrees. The base slab of the newly-built station is mainly located on strongly weathered Granite (SWG) and moderately weathered Granite (MWG), and show characteristics of differential

Figure 3. Typical geological profile (B-B).

weathering along the station profile. There are two main sources of groundwater in the stratum: in the Quaternary loose strata and in bedrock fissures, which occur in the Quaternary Sand layer and Granite bedrock, respectively. The relationship between the typical geological profile and the newly-built station structure is shown in Figure 3.

2.3 Spatial relationship of station structures

There are two key construction works in the project that obviously affected the existing Line 7 station. One is the construction of the new Line 14 station, which is in close proximity to the existing Line 7 station. The other is the new metro tunnels of Line 24, where both tracks passed through the foundation of the Line 7 station, and the shortest distance between the top of the tunnel and the base slab of the existing station is only 1.9m (Figure 4).

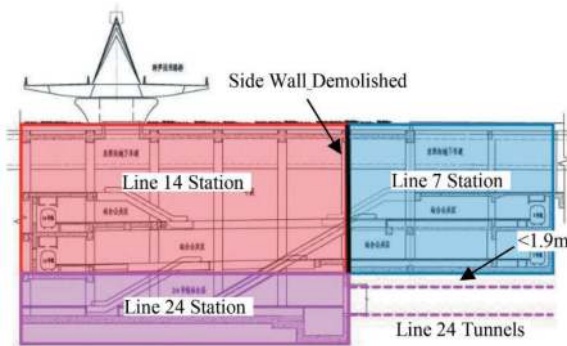

Figure 4. Elevation relationship among 3 stations (A-A).

3 ENGINEERING RISK ASSESSMENT

3.1 Quantitative risk assessment system

Since multiple engineering works of the project need to be commenced in complex and challenging conditions, a quantitative risk assessment system was proposed at pre-construction to synthetically identify risks at a high level and to investigate the corresponding risk factors.

The system used is the Analytical Hierarchical Process (AHP) technique, which was developed by Saaty (1977, 1980), and contains a multitude of uncertain variables and multi-level decision making and management mechanisms. The Alternatives and Criteria are chosen according to a Work Breakdown Structures (WBS) and Risk Breakdown Structures (RBS), respectively. Once the calculation is finished, Fuzzy Comprehensive Evaluation (FCE) is used to revise the AHP so that the assessment results could be represented mathematically.

Based on the assessment result, 3 major high level risks are identified:

- (1) Deep excavation of new stations
- (2) Demolition of Line 7 station side walls
- (3) Tunnelling under-crossing Line 7 station

3.2 Deep excavation of new stations

In the process of deep excavation, the stress state of the stratum within a certain range is redistributed due to unloading effect, and deformation or ground movement occurs. The change of stress state in the stratum indirectly affected the stress balance system of the existing underground structure itself, which is reflected in the increase of additional internal stress and additional deformation of permanent structures. When deformation or internal force exceeds a certain limit, it may lead to structural damage of the station structure, thus affecting structural safety and serviceability of the rail transit system.

3.3 Demolition of Line 7 station side walls

During construction of the Line 14 station, the structural side walls of the existing Line 7 station needed to be demolished to form an open passage between the old and new stations. See Figure 5 for the demolition scope of the side walls, ranging from the first to third floors of the existing Line 7 station.

Figure 5. Demolition of side walls of Line 7 station (B-B).

According to previous research on the construction technology and structural behaviour of slab walls opening into an underground metro station, the wide opening of reinforced concrete side walls not only changes the original structural boundary conditions, but also changes its stress distribution (An et al., 2020). The key structural portion of the existing station, as the main loading-bearing component, is working together with the new station structure component to accommodate loading and internal stress transmitted through the structural system. The internal stress transformation of the spatial structure at the station opening interface is quite complicated. Commonly, internal stress around the structural opening is concentrated, which is the weakest portion of the entire structure system. The newly-built structure combined with the opening portion have a significant impact on the spatial stress redistribution (Xie et al., 2012).

3.4 Tunnelling under-crossing Line 7 station

After the fourth storey underground excavation work of Line 24 station was completed, two tunnels with diameter of 7.5m passed through and under the base slab of the existing Line 7 station. The purpose of

under-crossing the 7.5m tunnel is to provide launching space for further TBM boring of the Line 24 metro tunnels. Both tunnels were planned to be constructed by conventional mining, with excavation lengths of 48.8m and 39m respectively, as shown in Figure 6.

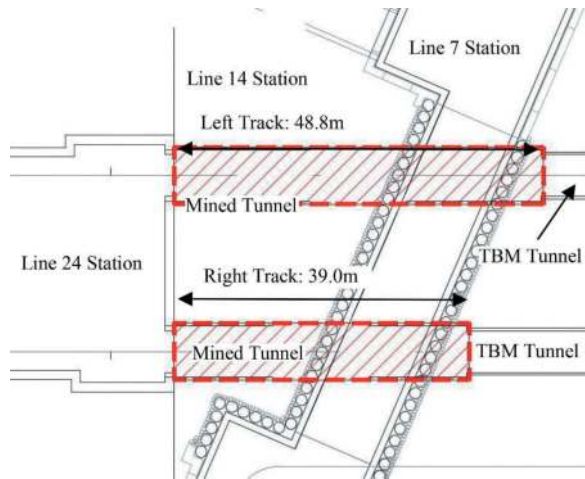

Figure 6. Layout of mined tunnels.

The lower portion of the two mined tunnels will encounter moderately to slightly weathered Granite, while the upper portion of tunnel and Line 7 station foundation are located in strongly weathered Granite. The space between the tunnel and Line 7 station is quite narrow, less than 2m thin. If drilling and blasting is adopted, the vibration generated by blasting will greatly disturb the existing station and strongly weathered Granite stratum. After being disturbed by construction vibration, the strongly weathered Granite stratum will become extremely unstable, gradually softening and disintegrating under the added effect of groundwater. Finally, the strength of the stratum might decline greatly, inducing collapse or excessive deformation in a short time (Zhu, 2013). The collapse of a softened stratum will have a significant influence on the stability of the existing Line 7 station, seriously affecting safety and further operations.

4 SYSTEMATIC DEFORMATION CONTROLS

According to the results of the pre-construction quantitative risk assessment, several key risk factors emerge. As the daily operation of the existing Line 7 station cannot be interrupted during construction, to minimize the impact of construction on the existing stations, based on ALARP principles (Yang et al., 2015), a whole-process risk management system was applied to the project. Scientific and systematic risk management processes and technologies were organized for the engineering design stage, construction stage and in-situ monitoring, so as to control and lower engineering risks into an allowable range.

4.1 Deep excavation work

Before the permanent structures of the Line 14 and Line 24 stations are constructed, an ELS system needs to be set up first for deep excavation.

In this project, the deformation of the existing Line 7 station is one of the key controlling factors. Based on engineering practices and related research, the top-down construction method has obvious advantages in controlling ground deformations during excavation (Xie et al., 2014). Compared with other construction methods, the top-down method uses the structural slab as a supporting component, which has high stiffness and relatively small deformation. For this reason, the top-down method was finally adopted and commenced as shown in Figure 7.

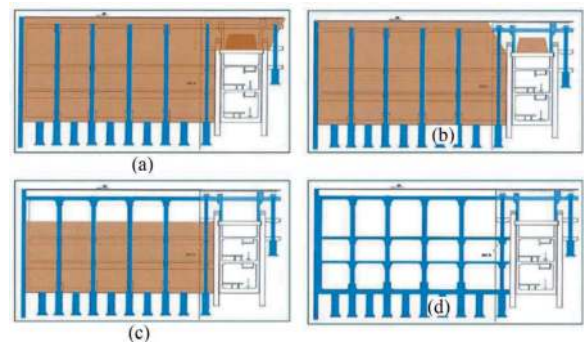

Figure 7. Construction sequences of top-down excavation: (a) Construction of diaphragm wall and structural columns; (b) Excavation of soil overlaying Line 7 station; (c) Excavation of new station area in layers and construction of structural slab; (d) Top-down excavation to base level.

Due to huge volume of excavation work and differential excavation levels, in order to further control the deformation induced by excavation, on the basis of the top-down method, the whole area was excavated by stages and zones, as shown in Figure 8. According to the different depth and risk level, the construction sequence is listed as follows:

- (1) Excavation of A portion (excavation depth between 20m~30m);
- (2) After completion of A portion, B portion was excavated (excavation depth between 30m~40m);
- (3) Finally, two affiliated areas were excavated (excavation depth did not exceed 20m).

4.2 Side walls demolition

The demolition of the side walls was commenced after completion of the deep excavation work, to ensure operational and structural safety of the existing Line 7 station. Under the principle of “reinforcing before demolishing, transforming structural system by stages and zones”, the demolition and reconstruction of the side walls were divided into stages. Detailed construction procedures are shown in Figure 9.

Figure 8. Deep excavation by stages and zones.

Figure 9. Side wall demolition by stages and zones: (a) Demolition of the first sequence side walls and construction of new RC beams and columns; (b) Demolition of the second sequence side walls and construction of remaining RC beams.

The first stage was mainly commenced inside the existing Line 7 station. After the construction area was completely enclosed, temporary steel columns were erected near the side walls to be demolished in the station. In the second stage, side walls in the first sequence were demolished from top to bottom by the layered and sequential method, and new RC beams and columns were constructed from bottom to top afterwards. In the third stage, the side walls from the second sequence were demolished by the same method, and then the remaining new RC beams were constructed.

4.3 Tunnelling work

After demolition and reconstruction of the side walls were completed, the mined tunnels under-crossing the Line 7 station were commenced. As previously noted, the distance between the top of the tunnel and Line 7 station base slab is quite small, and the strongly weathered Granite stratum is easy to soften and collapse during tunnelling. It is crucial to ensure the stratum stability at the top of the tunnel for deformation control of the existing Line 7 station.

Based on a comprehensive comparison of the risk levels of various tunnel supporting methods, use of a large-diameter pipe umbrella combined with small-diameter duct grouting was adopted. The support was arranged across a 120° interval above the tunnel vault. The pipe umbrella is comprised of steel pipes of 108×5 mm, with circumferential spacing between pipes of 30cm. Each 6m long steel pipe was pushed into the front of the cave roof at an elevation angle of $1^\circ \sim 2^\circ$. The small duct for grouting has a diameter of 42mm and a wall thickness of 3.5mm. Each 3m long duct was arranged at a circumferential spacing of 30cm. The typical section of forepoling support is shown in Figure 10.

Figure 10. Typical section of forepoling support.

The primary lining of the tunnels also requires strengthening according to the stratum lithology and risk characteristics. Twenty-two grid steel frames with a spacing of 0.5m was fully arranged, and double-layer steel mesh was arranged inside and outside the steel frame, as well as C25P6 shotcrete with a thickness of 350mm.

In addition, the tunnelling parameters have also been strictly controlled and mainly listed as follows:

- (1) Before tunnelling, unfavourable geological bodies were detected and forecasted by

comprehensive means of advanced geological drilling and geological radar.

- (2) During tunnelling, a benching method was adopted, and the length of the upper and lower benches was strictly controlled.
- (3) Tunnel blasting was controlled precisely, with blasting vibration velocities not exceeding 2.5cm/s.

5 DEFORMATION MONITORING RESULTS

The deformation monitoring of the existing Line 7 station was carried out by combining automated and manual monitoring. According to the risk level of construction engineering and surrounding environment, the monitoring level was classified as Grade I. The main monitoring items include vertical and horizontal deformation of the station structure, differential settlement of deformation joints and axial force of temporary steel columns. Within the influence range of transportation hub construction, the monitoring points were set to 5m~10m spacing within one monitoring section.

Monitoring ran through the whole construction process, including the top-down deep excavation, demolition of the Line 7 station side walls and the Line 24 tunnelling by conventional mining. Some monitoring results of each stage are shown in Table 1.

Table 1. Deformation results of Line 7 station (in mm).

Monitoring Portion	Measured Value/mm			Allowable Value/mm
	Excavation Work Completion	Side Wall Demolition Completion	Tunnelling Work Completion	
Side wall (horizontal)	-5.30	-5.45	-7.13	±10.0
Top slab (vertical)	-2.71	-3.22	-6.07	±10.0
Base slab (vertical)	-2.11	-6.32	-7.71	±10.0
Differential settlement	1.52	2.31	3.06	±4.0

As can be seen from the table, although the monitoring data of Line 7 station show an increasing trend with the development of different construction stages, the deformation values of structure portions are still within the allowable safety range.

6 CONCLUDING REMARKS

The construction conditions of the HMG transportation hub project is complicated and encounters engineering challenges with safety concerns of the existing Line 7 station. With application of

quantitative risk assessment process, a systematic deformation control method aimed at deep excavation, structure demolition and tunnelling was proposed, and the deformation of the existing stations has been effectively controlled during construction. Thereby, several remarks are derived as follows:

- (1) For a complex underground space development project in close proximity to an existing station structure, a top -down excavation method can effectively control the deformation of the nearby stratum and structures. For development projects with complex processes, an appropriate construction method is a crucial factor to mitigate engineering risks.
- (2) In similar projects, it is necessary to adhere to the principles of constructing in stages and with benches, and supporting ahead of the face to minimize disturbance induced by construction activities to the pre-existing structures.
- (3) For complex underground engineering, it is necessary to comprehensively consider all key risk factors, and consider the relationship between each factor and the construction sequences. This allows for an effective systematic deformation control method to be proposed to reduce engineering risks to a reasonable level.
- (4) Dynamic monitoring plays an important role in underground construction engineering, including advanced geological prediction and automatic monitoring, which can timely reflect unexpected geological conditions and risks.

ABSTRACT: Backfill grouting is one of the important components of the shield construction method. The grout diffusion is very complicated under the influence of the physical and mechanical properties of the soil and the properties of the grout itself. In order to understand the diffusion mechanism of grout behind the tunnel segments, a visual grout diffusion model test device is used for indoor test. Two typical soils, sand and clay, are selected and a pure cement grout with a water - cement ratio of 1:1 is prepared. During the grouting process, the grout diffusion distance, seepage pressure and soil pressure are monitored in real time. After 24 hours of grout solidification, the soil in the model cylinder is excavated in layers. Combined with the theory of grout injectability, the injectability of grout in sand and clay is determined. The main conclusions are as follows: the grout mainly undergoes penetration and infiltration diffusion in sand. Due to the adsorption and deposition of cement particles, different extents of filter mud and filter cake appear in each layered sand. The grout mainly undergoes screening and splitting diffusion in clay, and different extents of splitting grout veins appear in each layered clay. Due to the large permeability coefficient of sand, cement grout or fine particle cement grout can be used in practical engineering grouting. The permeability coefficient of clay is small, and chemical grout or grout with good filling property can be used.

Keywords: Backfill grouting, Sand, Clay, Diffusion mode, Indoor test

1 INTRODUCTION

In the 21st century, all countries in the world are promoting and developing shield construction methods and gradually moving toward a new era of longer, larger, deeper, wider and more intelligent shield tunnels of a higher level. As an important component of the shield construction method, the backfill grouting, the adaptability of the grout to the formation (Shirlaw et al 2004; Oreste et al 2021), the reinforcement effect of the grout, and the interplay of the formation-grout layer-segment have also become the focus of research (Katebi et al 2015; Liang et al 2020).

The formation is identified as a porous medium due to its internal pore structure, and the grout is composed

of solid particles and water. Due to the different physical and mechanical properties of different strata, the grout diffusion mechanism in the strata is different. Existing related studies have mainly focused on sand and clay formations. Sandy soil (particle size 1-0.05 mm) content greater than 50 % is sand (Li et al 2016; He et al 2016). Sand has good ventilation and water permeability, strong capillary action and fast water operation (Cai et al 2018; Chen et al 2019). China's sand strata are mainly concentrated in the northwestern regions, such as Gansu, Ningxia, Inner Mongolia and Xinjiang (Sun et al 2020). Unlike sand, clay contains very few sand particles, and the main constituents are silica and alumina (Lamber 1958a; Lamber 1958b). The permeability of clay is low, and

*Corresponding author: sihan.Li@chd.edu.cn

water does not pass easily through it. The pores of clay with too small pores are mostly occupied by bound water, and the capillary action is weak(Seed et al 1959; Levoueil et al 1990). China's clay strata are mainly concentrated in the southeastern regions, such as Jiangsu, Zhejiang, Hubei and Guangdong(Weng et al 2011). The diffusion modes of backfill grouting of shield tunnels are divided into four types, namely, filling diffusion, penetration diffusion, compaction diffusion and splitting diffusion(Akbulut et al 2002; Ye et al 2013; Ye et al 2016; Ye et al 2020). However, due to the influence of surrounding strata, grout characteristics, grouting parameters and other factors, the diffusion modes are transformed and doped with each other and there is no obvious boundary(Ye et al 2022). In order to study the grout diffusion characteristics of backfill grouting, it is necessary to observe the diffusion process and the grouting effect(Ying et al 2022). However, because the grouting behind the shield tunnel segment is a concealed project, this process is performed behind the ring segment. Only the in-situ test at the negative ring segment of the shield tunnel shows the diffusion process better, but the in-situ test at the negative ring segment does not simulate the true formation. Therefore, the indoor model tests with strong pertinence and high flexibility have been used by many researchers to study the construction process of backfill grouting. The overall model test can better show the stress situation, and strain, grout diffusion properties and grout effects of the segment by simulating the whole section of the whole grout section. The local model test studies the grout diffusion in some dimensions and then selects the characteristic points to be injected using some segments, soil and grout.

In this paper, we focus on the grout diffusion mechanism in different formations. In the case of sand and clay, a visual grout diffusion model test device was used to perform backfill grouting in sand stratum and clay strata, respectively, and to monitored the change in grout diffusion distance, seepage pressure and soil pressure during the grouting process. The permeability coefficient was measured and analyzed for each layer of soil in the model tube. It is concluded that the penetration and infiltration diffusion modes mainly occur in sand strata, while the screening and splitting diffusion modes mainly occur in clay strata. Combined with the permeability coefficients of sand and clay, the groutability criteria for backfill grouting were determined.

2 MODEL TEST

2.1 Test device and materials

2.1.1 Test device

The visual grout diffusion model test device consists of an injection device, a model device, a pressure regulator device and a data acquisition device. Due to the high permeability coefficient of sand, the diameter of the model tube is set to 100 mm and the height to 2000 mm. The diameter of the model

cylinder used for clay grouting is set to 300 mm and the height to 700 mm to reduce the effect of boundary conditions. The specific test device is shown in Figure 1. The injection device consists of a grout storage bucket, a grout pump and a buffer. The pressure regulator device consists mainly of a three-way interface, a pipeline pressure gauge and a pipeline flow meter. The model device consists mainly of a plexiglass cylinder, frame structure, a shield-tail voiding device and sealing device. The data acquisition device consists mainly of soil pressure gauge and seepage pressure gauge.

Figure 1. The visual grout diffusion model test device.

2.1.2 Test material

The sand is mixed coarse sand with particle size of 0.5 - 1 mm. The clay is made from the soil of the shield foundation pit of the D8KC - 1 section of Xi'an Metro Line 8, and the undisturbed soil is dried and the water content is adjusted by the method of remolding the soil. The relevant parameters of the test soil are shown in Table 1. The grout is pure cement grout with a 1:1 water-cement ratio. The grouting pressure is controlled at 0.2 MPa - 0.4 MPa.

Table 1. Test soil related parameters.

	Moisture content/ %	Specific gravity	Gravity/ $\text{kN}\cdot\text{m}^{-3}$	Dry unit weight/ $\text{kN}\cdot\text{m}^{-3}$	Void ratio	Saturation/ %
Sand	20	3.47	19.5	14.4	0.984	62
Clay	20	2.70	15.8	13.1	1.037	55

The cement is selected from a cement plant in Xianyang City, Shaanxi Province, of Hailuo ordinary Portland cement P.O 42.5 grade. The technical indicators are listed in Table 2.

2.2 Test procedures

- (1) The expansion rubber band is pasted on the lower splint groove of the frame kit and on the

Table 2. P.O 42.5 grade cement technical indicators.

Stability	Setting time/min		Flexural strength/MPa		Compressive strength/MPa	
	pre-hardening	final gel	3d	28d	3d	28d
Qualification	198	240	5.6	7.5	26.4	45.2

Figure 2. Particle size distribution of cement.

Figure 3. Test soil preparation process.

outer surface of the shield-tail voiding device. Install the waterproof connector and water stop rubber plug for the plexiglass tube, and affix the scale. After the preparation work is completed, the frame structure and the plexiglass tube are assembled sequentially.

- (2) The shield tail gap simulation is set to 10 cm. After the shield tail disengagement device is supported by the lower screw, the test soil is filled in every 10 cm layer. Keep the same amount of soil filled each time, and use the same impact strength and compaction times to consolidate the soil.
- (3) When the soil is filled to the place where the monitoring element is buried, the soil pressure gauge and the seepage pressure gauge are connected and the waterproof joint is tightened. After the filling is completed, the upper pressure plate is tightened, and the upper and lower nuts of the fastening screw are tightened, and the moisture content monitoring element is inserted from the water stop rubber plug.
- (4) The inert iron oxide is chosen as the grout indicator, with a dosage of 5 % of the cement dose.

The mixed grout is poured into the grout storage cylinder.

- (5) To ensure the initial grout pressure and grout flow rate, the grout pump should be turned on first and the valve at the grout port should be closed. The pressure of the storage grout is not less than 0.2 MPa and then the grout pump is turned off.
- (6) Pull down the shield tail disengagement device and turn on all monitoring elements. The grout pump is turned on and the grout pressure is controlled to 0.2 - 0.4 MPa.
- (7) After the grouting is completed, the valve at the bottom of the model cylinder is closed to avoid backflow from the grout. After the grout solidifies, the test device is removed and the soil is excavated to find out the diffusion of the grout inside the soil.

The grouting stopping time is controlled. When the pipeline flow meter value does not increase and remains unchanged for 2 min, it indicates that the grout cannot be injected and the grouting is stopped at this time.

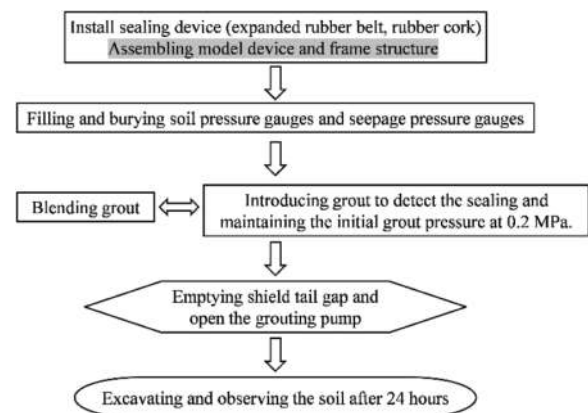

Figure 4. Test procedures.

2.3 Result analysis

2.3.1 Grout diffusion distance

The diffusion process of the grout was observed and recorded by a high-definition camera, as shown in Figure 5. When grouting in sand, the curve of the grout diffusion distance as a function of time is roughly linear, with an inflection point at 10 s. Within 0 - 10 s, the grout diffusion distance increases sharply, and after 10 s, the grout diffusion rate decreases significantly. This is due to the large aperture size of sand. In the initial grouting stage, the grout is easily permeable and diffuses over long distances. During the subsequent grouting process, the cement particles gradually penetrate and blocked the pores of sand, which reduces the permeability of the sand and makes it difficult for grout to continue to diffuse. Subsequently, only a small amount of very fine cement particles and water infiltrated into the sand under grout pressure. The maximum diffusion distance of the

grout is eventually maintained at 68 cm. When grouting in clay, the time - dependent curve of the grout diffusion distance shows irregular fluctuations. In 0 - 150 s, the grout diffusion rate fluctuates, and after 150 s, the grout diffusion rate is almost 0 and the diffusion distance remains constant. This is due to the small pore size of the clay, which makes it difficult for the grout to penetrate into the clay during the initial grouting stage. Under continuous grout pressure, the grout may be compacted and diffused, which causes the grout diffusion distance increase slowly. It is worth noting that for some time periods, the grout diffusion distance is almost constant. The maximum diffusion distance of the grout is eventually maintained at 55 cm. After waiting for the grout to solidify for 24 hours, the soil in the model tube is excavated in layers to further observe the specific grout diffusion.

Figure 5. The grout diffusion distance.

Figure 6. Grout diffusion in sand.

Figure 6 and 7 show the grout diffusion in sand and clay, respectively. The sand in the model cylinder was cut in layers, and it was found that the color of the sand gradually faded away from the grouting hole. 6 - 8 cm is pure cement block and 8 - 10 cm is a mixture of grout and sand. A thick dense filter mud appears at 18 - 20 cm, indicating that the pores of the soil at this location are completely blocked by cement particles, and that the grout has been unable to penetrate into the soil. Filter mud also appears at 26 -

Figure 7. Grout diffusion in clay.

28 cm, but is thin in thickness, indicating that the grout has spread to the site, but at a small value. 54 - 100 cm sand is lighter in color and the position of the grout diffusion cannot be directly observed with the naked eye. Combined with the curves of the grout diffusion distance in sand, it shows that the grout has a seepage and penetration diffusion mode in sand. Observing the grout diffusion in clay, it can be found that at the bottom of the model cylinder, the grout is almost non-diffusive, and the grout only generates water migration at the interface with the soil. In stratigraphic excavations, however, it was found that there were grout veins of different sizes in the clay. At 40 - 50 cm, the thickness and width of the veins are smaller. At 20 - 30 cm, a large thickness of grout veins is found. Combining the grout diffusion situation with the time - dependent curve of the grout diffusion distance, it shows that the grout has undergone screening and splitting diffusion mode in clay.

2.3.2 Seepage pressure

The seepage pressure in each layer of sand and clay is extracted as shown in Figure 8 and 9. As the grout diffuses in the sand, the seepage pressure is larger at

Figure 8. Seepage pressure in sand.

Figure 9. Seepage pressure in clay.

20 cm, 40 cm and 60 cm. The increase in the seepage pressure in each layer occurs mainly in the first 30 s, and the seepage pressure shows a slow downward trend after 30 s. This is due to the large pore size of the sand, and during the initial grouting stage, the grout penetrates the sand at a large rate. As the cement particles adsorb and clog, the diffusion rate of the grout decreases and the seepage pressure of each layer decreases. Since the grout does not diffuse to 80 cm and 100 cm, the seepage pressure at these two points is always 0. The increase of seepage pressure in sand shows a linear trend, with a maximum seepage pressure of 163 kPa appearing at 20 cm. As the grout diffuses in the clay, the seepage pressure in each layer shows a stepwise fluctuation trend for the first 150 s. After 150 s, the seepage pressure in each layer gradually remains stable. This is due to the small pore size of clay. Under the grouting pressure, the grout first undergoes pressure screening diffusion. When the clay has a certain extent of compaction, the grout splits and diffuses, resulting in fluctuations in the seepage pressure curve. As grout veins are generated, the clay reduces the grout pressure, resulting in a gradual stabilization of the seepage pressure. It is found that when the grout diffuses in clay, the seepage pressure of each layer is significantly lower than that in sand, with a maximum seepage pressure of 29 kPa appearing at 20 cm.

2.3.3 Soil pressure

The soil pressure of each layer in sand and clay is extracted as shown in Figure 10 and 11. As the grout diffuses in the sand, the increase in soil pressure is mainly concentrated in the first 100 s, showing a linear increase trend. After 100 s, the soil pressure in each layer gradually remains stable. The maximum soil pressure in sand is 170 kPa, which occurs at 40 cm. As the grout diffuses in the clay, the soil pressure fluctuates continuously for the first 150 s and decreases after 150 s. This is consistent with the change of seepage pressure in each layer of clay. As the result of the splitting and diffusion of grout, the soil pressure will show a step-like fluctuation as the grout splits the clay and produces grout veins. By comparison, it is found that the soil pressure increases

Figure 10. Soil pressure in sand.

Figure 11. Soil pressure in clay.

linearly due to the penetration and infiltration diffusion of the grout in the sand. Combined with the grout diffusion in sand and clay, the seepage pressure and soil pressure changes of each layered soil, it can be concluded that the penetration and infiltration occur mainly in the sand. The screening and splitting diffusion mode occur mainly in the clay.

Figure 12. Permeability coefficient of sand.

Figure 13. Permeability coefficient of clay.

2.3.4 Permeability coefficient

After waiting for the grout to solidify for 24 hours, the soil in the model cylinder was sampled in layers to determine the permeability coefficient of each layer. Figure 12 shows the permeability coefficient for each layer of sand. It can be found that the permeability coefficient of sand is large, at the level of 10^{-2} cm/s. Sand at 40 cm has the smallest permeability coefficient, 0.001 cm/s. The permeability coefficient of sand at 60 cm increases, which that at 80 cm and 100 cm remains constant. This is because the grout diffusion distance in sand is limited, and the generation of the filter mud leads to a decrease in permeability of the sand. Figure 13 shows the permeability coefficient in each layer clay. It can be found that the permeability coefficient of clay is small, at the level of 10^{-5} cm/s. The permeability coefficient of clay at 10 cm is the smallest, which is 0.2×10^{-5} cm/s. The permeability coefficient of clay began to increase after 10 cm and remained stable at 30 cm, with a stable value of 1.1×10^{-5} cm/s. It can also be inferred that the penetration diffusion, infiltration diffusion and screening diffusion of the grout will affect the permeability of the soil and reflect the diffusion mechanism of the grout in terms of the permeability coefficient.

3 PERMEATION DIFFUSION BASIC TYPES AND GROUTABILITY JUDGEMENT

3.1 The basic types of penetration diffusion

It is considered that the formation structure is a porous medium with internal pores, and the grout is a mixture of viscous solid particles and water. When penetration diffusion occurs, the solid particles in the grout fill the pores of the soil, but when the pore diameter of the soil is smaller than the solid particle size of the grout, the grout particles cannot enter the stratum, and only the free water and the very small particles in the grout can continue to enter. Therefore, the penetration diffusion is classified into screening (pressure filtration) diffusion, infiltration diffusion and penetration diffusion. The main classification is shown in Figure 14.

Figure 14. Main types of penetration diffusion.

The main controlling factor determining the type of permeation and diffusion is whether the grout particles enter the formation, which depends on the particle size of the grout particles and the pore diameter of the formation.

The specific explanation is as follows:

Grout particles do not diffuse: When the grout particle size exceeds $1/3$ of the pore diameter of the formation, the grout particles cannot enter the formation, and only the free water in the grout can penetrate into the formation.

Grout particles diffuse: Based on whether the deposition of grout particles in the process of entering the soil affects the diffusion, it is divided into infiltration diffusion and penetration diffusion. When the grout particles can penetrate into the soil, the pore channels of the soil are gradually filled due to the adsorption and deposition of the grout particles, which hinders the further diffusion of the grout. An obvious filter cake or filter mud is formed at the interface between the grout and the soil. In the penetration diffusion, the pore diameter of the soil is much larger than the diameter of the grout particles. The grout particles can diffuse freely in the soil, and the adsorption and deposition of the grout particles have little effect on the diffusion distance.

3.2 Groutability judgement

In the process of grout penetration diffusion, groutability reflects the difficulty of grout particles to enter soil pores, and also determines the basic types of screening diffusion, infiltration diffusion and penetration diffusion. On the one hand, the injection depends on the characteristics of the porous media, and on the other hand, it depends on the properties of grout. The properties of porous media are dominated by its permeability and seepage structure, and the properties of grout are dominated by the gradation distribution and rheological properties of the grout particles. The determination of injectability in the domestic and foreign proposals is not uniform, according to literature investigation. The gradients of the strata and the pore conditions are mostly used to determine whether the grout particles can enter. Landry's theory is used as follows (Landry et al 2000):

$$k = 116(0.7 + 0.034t)(D_{10})^2 \quad (1)$$

$k > 1 \times 10^{-1}$ cm/s, cement grout can be injected into the formation; 1×10^{-1} cm/s $> k > 5 \times 10^{-3}$ cm/s, fine

cement particles can be injected into the formation; $5 \times 10^{-3} \text{ cm/s} > k > 1 \times 10^{-4} \text{ cm/s}$, chemical grout can be used for grouting.

Combined with the determination of the permeability coefficient for sand and clay in Section 2.3.4, this is determined by Landry's theory of groutability. Since the permeability coefficient of sand is mostly 10^{-1} cm/s , cement grout and fine-grained cement grout can be used. The permeability coefficient of clay is about 10^{-5} cm/s , so cement grout and fine-grained cement grout cannot be injected into the soil. For the backfill grouting of clay shield tunnels, one of the main functions of backfill grouting is to fill the shield tail gap and stabilize the stratum and segment. The groutability of the grout cannot be used as a basis for judging the grouting effect. Therefore, it can be considered to inject chemical grout or find other grout with good filling properties to perform the backfill grouting of the shield tunnel.

4 CONCLUSIONS

In this paper, two typical soils, sand and clay, are chosen to study the diffusion mechanism of grouting grout behind shield tunnel segments. A visual grout diffusion model test device was used to monitor the grout diffusion distance, seepage pressure and soil pressure in real time. After 24 hours of grout solidification, samples were taken to determine the permeability coefficient of each layer of soil, and the groutability of grout in sand and clay was determined by combining the groutability theory. The main conclusions are as follows:

- (1) The grout mainly undergoes penetration and infiltration diffusion modes in sand. In the initial grouting stage, the grout diffusion distance in the sand increases linearly. When the cement particles adsorb and plug the pores of the sand, the curve of the diffusion distance with time shows an inflection point, and the increase rate of the diffusion distance decreases. During the grouting process, the seepage pressure in the sand is larger, and the seepage pressure increases faster.
- (2) The screening and splitting diffusion modes mainly occur in the clay. In the initial grouting stage, the seepage pressure and soil pressure in the clay fluctuate step by step. After excavating the layered soil, it is found that there are different extents of grout veins in the clay. With the increase of the height of the model tube, the thickness and width of the grout veins decrease.
- (3) The permeability coefficient of sand and clay in the model tube was measured by stratified sampling. Combined with the theory of grout injectability, it is found that cement grout or fine-grained cement grout is suitable for backfill grouting in sand. The backfill grouting in clay stratum is suitable for chemical grout or grout with good filling property.

ABSTRACT: Ground response curves (GRCs) serve as an important intermediary during tunnelling, as it provides an effective way to evaluate the response of surrounding rock and installation of support structure. The choice of stress-dilatancy rule might cause different description on the behavior of surrounding rock and thus, have strong influence on the resulting GRCs. In order to find out such influences, GRCs based on different stress-dilatancies are calculated under the framework of cavity contraction solution, where the finite strain (Hencky strain) is also assumed. In this study, a bounding surface plasticity model is used as the elasto-plastic driver with a cohesion weakening Mohr-Coulomb bounding surface being introduced. In terms of the stress-dilatancy rule, the stress-dilatancy rule used in the Cam-clay model, Rowe's stress-dilatancy rule and a modified Rowe stress-dilatancy rule are introduced in this paper. Stress distributions and GRCs under different in-suit stresses are calculated by deriving semi-analytical solutions. The resulting stress distributions and GRC are validated by comparison with previous works in the literature. Moreover, GRCs under different in-suit pressures are also derived and investigated to fully evaluate influences of stress-dilatancy selection on GRCs. Results show that: The proposed solution in this paper captures the response of the surrounding rock of deep-buried tunnel reasonably. The GRC calculated in this paper is in good agreement with classical results in the literature and can be used in tunnelling. An inappropriate stress-dilatancy rule may provide inappropriate suggestions for support installation of deep-buried tunnels.

Keywords: Ground response curve, Stress-dilatancy, Bounding surface, Deep-buried tunnel

1 INTRODUCTION

Nowadays, with the rapid development of underground facility constructions and deep mining engineering, more and more deep-buried tunnels (Ou et al., 2021; Yang et al., 2023) are being constructed. The excavation, support and maintenance of deep-buried tunnels rely on the accurate investigation and evaluation on the response of surrounding the rock in depth. And the control of negative effects during tunnelling requires a reasonable description of the behavior of deep-buried rocks.

Cavity contraction solutions are widely used to investigate the repose of surrounding rock after excavation. In particular, solutions based on elasto-plastic models are used very frequently, such as solutions based on the GZZ model (Su et al., 2022), Mohr-Coulomb model (Mo et al., 2020; Pan & Brown, 1996; Vrakas & Anagnostou, 2014), CASM (Yu et al., 2019), Hoek-Brown model (Lee & Pietruszczak, 2008; Pan & Brown, 1996), etc. However, the results of these solutions are highly dependent on the definition of the elastic limit or yield surface (Dafalias, 1986). The bounding surface theory

*Corresponding author: liangjg5@mail2.sysu.edu.cn

calculates the plastic strain increment by exploiting the distance between the current bounding and loading surface (Huang et al., 2022; Kang et al., 2020; Masoumi et al., 2016), and there is no need to define the value of elastic limit. The application of bounding surface theory to the response analysis of deep-buried tunnel could avoid the negative effects of uncertainties of the value of elastic limit. However, the stress-dilatancy rule used in a bounding surface constitutive model has a strong influence on the deformation prediction of rocks under high stress ratios when stress level is low. It has been pointed out that the dilatant response of the surrounding rock affects the stress distribution and displacement of a tunnel (Pan & Brown, 1996). Thus, the choice of stress-dilatancy can affect the effectiveness of the resulting ground response curve (GRC), which is used to design the support structure (Yu et al., 2019). It is necessary to evaluate the influence of stress-dilatancy on the GRCs of deep-buried tunnels.

To this end, cavity contraction solution and GRCs are investigated in this paper. In section 2, a cohesion weakening bounding surface model is introduced to model the surrounding rock of deep-buried tunnels, and the resulting cavity contraction solution is derived to obtain the GRC. The proposed solution and resulting GRC are then validated in section 3. Finally, comparisons are conducted on GRCs obtained from different stress-dilatancy rules, and discussions focus on the influences of stress-dilatancy on GRCs for deep-buried tunnel.

2 METHODOLOGY

This section presents the cohesion weakening bounding surface model, stress-dilatancy rules being used, the derivation of controlling equations, and the boundary conditions.

2.1 Bounding surface model and stress-dilatancy rules

The bounding surface model and stress paths during cavity expansion and contraction are presented in Figure 1. The Mohr-Coulomb type bounding surface (Wood, 2003) is written as Equation (1). The movement of the bounding surface is attributed to the cohesion weakening mechanism, as written in Equation (2).

$$\bar{F} = \bar{q} - M(\theta)\bar{p} - M(\theta) \cdot \cot \phi \cdot c(\gamma^p) = 0 \quad (1)$$

$$c(\gamma^p) = c_r + (c_i - c_r) \exp[-k(\gamma^p/\Upsilon)] \quad (2)$$

Where, \bar{p} and \bar{q} are image stress on current bounding surface, $M(\theta)$ is the slope of the bounding surface considering the Lode angle, θ . ϕ is the frictional angle and γ^p is the accumulative plastic shear strain. c_i and c_r are the initial and final cohesion. k and Υ are model parameters that controlling the cohesion weakening.

Figure 1. Cohesion weakening bounding surface and stress paths.

In this bounding surface model, a simple but effective mapping rule is introduced to link the image stress and current stress on loading surface (Huang et al., 2022; Kang et al., 2020; Masoumi et al., 2016). Besides, the total plastic modulus, h could be calculated by summarizing two components (Huang et al., 2022; Kang et al., 2020; Masoumi et al., 2016). One component h_b is derived by using consistency on Equation (1), while the other one h_f describes the distance between the current bounding and loading surface. By combining Hoek's law, the incremental elasto-plastic stress-strain matrix around a circular opening could be written as Equation (3),

$$\begin{Bmatrix} \delta \varepsilon_v \\ \delta \gamma \end{Bmatrix} = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix} \begin{Bmatrix} \delta p \\ \delta q \end{Bmatrix} \quad (3)$$

Where, $a_{11} = n_p m_p / h + 1/K$, $a_{12} = n_q m_p$, $a_{21} = n_p m_p$ and $a_{22} = n_q m_q / h + 1/2G$. $\delta \varepsilon_v$, $\delta \gamma$, δp and δq are total volumetric, deviatoric strain increment and increments of both mean and deviatoric stress. n_p and n_q are components of the unit normal vector of the bounding surface. $m_p = d/\sqrt{1+d^2}$ and $m_q = d/\sqrt{1+d^2}$ are components of the unit plastic flow vector, while is the stress-dilatancy $d = \delta \varepsilon_v^p / \delta \gamma^p$. K and G are both elastic bulk and shear modulus and could be calculated by using the Young's modulus and Poisson's ratio. Stress-dilatancy rules considered in this paper are listed in Table 1.

Table 1. Stress-dilatancy rules being considered.

Rowe	$d = \frac{9(M-\eta)}{9+3M-2M\eta}$
Cam-clay	$d = M - \eta$
Modified Rowe (MR)	$d = \frac{9(M(\gamma^p, \theta) - \eta) - B}{9+3M(\gamma^p, \theta) - 2M(\gamma^p, \theta)\eta - B}$

Notes: $M(\gamma^p, \theta) = [1 + A \exp(-m\gamma^p)]M(\theta)$ and $B = \alpha\sigma_0/(\alpha + \beta\sigma_0)$ in Table 1. A , m , α and β are model parameters for the modified Rowe stress-dilatancy. σ_0 is the in-suit stress around the circular opening.

When considering the simplified cavity contraction problem (Yu et al., 2019; Mo et al., 2020) as in this paper, the definition of mean, deviatoric stress and the volumetric, deviatoric strain are listed in Equations (4)-(7),

$$p = (\sigma_r + \sigma_\theta)/2 \quad (4)$$

$$q = \sigma_\theta - \sigma_r \quad (5)$$

$$d\varepsilon_v = d\varepsilon_r + d\varepsilon_\theta \quad (6)$$

$$d\gamma = d\varepsilon_\theta - d\varepsilon_r \quad (7)$$

Where, σ_r , σ_θ , ε_r and ε_θ are radial hoop stress and strain components.

2.2 Controlling equations

As shown in Figure 2, distributions of both radial and hoop stress varying with the distance r around the circular opening could be written as follows (Yu et al., 2019; Mo et al., 2020),

$$\frac{rd\sigma_r}{dr} + \sigma_r - \sigma_\theta = 0 \quad (8)$$

By combing Equation (3) and Equations (4)-(8), the controlling equations of the mean, deviatoric stress and the volumetric strain around the circular tunnel could be derived as Equations (9)-(11), while an auxiliary variable $\zeta = (r - r_0)/r$ being introduced along with Hencky strain ($\varepsilon_r = -\ln(dr/dr_0)$, $\varepsilon_\theta = -\ln(r/r_0)$, $\varepsilon_v = \ln(v/v_0)$) (Chen & Abousleiman, 2013; Yu et al., 2019; Mo et al., 2020).

Figure 2. A contracting cavity and its GRCs.

$$\frac{Dq}{D\zeta} = \frac{-1}{\left[\frac{(a_{22}+a_{12})}{(a_{21}+a_{11})} + 0.5\right]} \left[\frac{q}{1-\zeta - \frac{e^{\zeta v}}{1-\zeta}} + \frac{2}{(1-\zeta)(a_{21}+a_{11})} \right] \quad (9)$$

$$\frac{Dp}{D\zeta} = -\frac{(a_{22}+a_{12})Dq}{(a_{21}+a_{11})D\zeta} - \frac{2}{(1-\zeta)(a_{21}+a_{11})} \quad (10)$$

$$\frac{D\varepsilon_v}{D\zeta} = -\left[a_{21} \frac{Dp}{D\zeta} + a_{22} \frac{Dq}{D\zeta} + \frac{2}{1-\zeta} \right] \quad (11)$$

By solving Equations (9)-(11) using the Runge-Kutta method, we could also calculate the current position of any rock medium around the tunnel by introducing Equation (11) and integrating as follow,

$$\frac{r}{a} = \frac{\zeta}{\xi(a)} \frac{d\zeta}{1-\zeta - \frac{e^{\zeta v}}{1-\zeta}} \quad (12)$$

2.3 Boundary conditions and the derivation of GRCs

The boundary conditions being introduced in this paper are listed in Table 2. To solve Equations (9)-(11), integration is conducted from the far field to the cavity wall. When support pressure under various combinations of in-suit stress and cavity wall deformation is derived by solving Equations (9)-(11), we could obtain a ground response curve under certain in-suit stress by plotting the radial stress on the cavity wall against the cavity wall deformation, as shown in Figure 2. When all in-suit stresses of our interest are considered, GRCs under various in-suit stresses could be derived and used to design supporting structure of a deep-buried tunnel.

Table 2. Boundary conditions.

	$p_0 = \sigma_0$
	$q_0 = 0$
	$\varepsilon_{v0} = 0$
Far field	$\zeta_0 = 1 - r_{\infty 0}/r_\infty$
Cavity wall	$\zeta(a) = 1 - a_0/a$

3 VALIDATIONS

In this section, the stress distributions calculated by using the proposed solution in section 2 are validated by comparing with other solutions in the literature. In addition, the ground response curve derived by using the proposed solution is also validated in this section.

3.1 Validation on stress distributions

Stress distributions around a circular opening is calculated by using the solution being proposed in section 2, with the modified Rowe stress-dilatancy rule being

used. The resulting distributions of both radial and hoop stress component are presented in Figure 3, which are compared with analytical results provided by Park & Kim (2006) and Lee & Pietruszczak (2008).

Model parameters are the same as in Lee & Pietruszczak (2008) with $\sigma_0=3.0\text{MPa}$, $E=10.0\text{GPa}$, $\mu=0.20$, $\phi=30^\circ$, $c_f=0.5\text{MPa}$ and $c_r=0.3\text{MPa}$. As shown in Figure 3, stress components derived in this paper near the tunnel wall ($r/a \leq 2.4$) is the same as those provided by both Park & Kim (2006) and Lee & Pietruszczak (2008). Moreover, the trend of the distribution of both radial and hoop stress are the same for result in this study and provided by Lee & Pietruszczak (2008), while the slight difference on values of stress components and the position of maximum hoop stress might be due to the definition of elastic limit in Lee & Pietruszczak (2008). Moreover, the resulting cavity wall deformation of the proposed solution is $al/a_0=0.995$, which is very similar to results of $al/a_0=0.998-0.992$ in Park & Kim (2006) and Lee & Pietruszczak (2008). In this word, the solution proposed in this paper have the capability to capture the response of rocks around the tunnel reasonably.

Figure 3. Stress distribution under 3.0MPa in-suit stress.

3.2 Validation on GRC

In this section, a GRC obtained by using the proposed solution in this paper under the modified Rowe stress-dilatancy rule is validated through comparing with results provided by Alonso et al. (2003) and Lee & Pietruszczak (2008), as shown in Figure 4. Model parameters are $\sigma_0=20.0\text{MPa}$, $E=10.0\text{GPa}$, $\mu=0.25$, $\phi=30^\circ$, $c_f=1.0\text{MPa}$ and $c_r=0.8\text{MPa}$. It is clear in Figure 4 that the GRC derived by this paper shows reasonable agreement with other results. Differences between the proposed solution and other results on medium range support pressures might be attributed to the used of the modified Rowe stress-dilatancy rule (i.e. MR in Figure 4), which could predict higher volumetric deformation under high mean stress level comparing with other stress-dilatancy rules.

Figure 4. Comparisons between GRCs derived by different solutions.

(a)

(b)

Figure 5. Resulting GRCs under the in-suit stress of (a) 10MPa and (b) 30MPa.

4 COMPARISONS ON GRCS

In this section, GRCs under the in-suit stress of both 10MPa and 30MPa are derived by using same parameters in section 3.1, with all stress-dilatancy rules in Table 1 used. These 2 selective in-suit stresses model the buried depths of approximately 400m and 1200m (Vrakas & Anagnostou, 2014), respectively. The resulting GRCs are shown in Figure 5.

As shown in Figure 5, when the buried depth is shallow with lower in-suit stress, ground response curves calculated by those stress-dilatancy rules are divergent on lower support stresses and convergent on medium to high stresses. MR provide the smallest deformation prediction under low support pressure. This might be caused by the swift convergence of the MR as the plastic strain is large under 10MPa in-suit stress and small support stresses. When the in-suit stress is higher, MR will predict larger deformation under the middle range of support stress, while the deformation predicted by Rowe and Cam-clay stress-dilatancy rule are smaller, since the d value of those 2 rules are only constrained by stress ratio and becomes smaller under large mean stress level. In addition, the deformation of the tunnel wall becomes convergent as support stress increasing. Since the deformation of the tunnel being restricted under high support stresses. As the choice of stress-dilatancy rule determines the deformation of rocks under certain mean stress level, an inappropriate stress-dilatancy rule might result in an inappropriate choice of support structure installation.

5 CONCLUSIONS

In this paper, a cohesion weakening bounding surface model coupled with 3 stress-dilatancy rules is used in the cavity contraction solution, to investigate influence of choices of stress-dilatancy rule on GRCs for deep-buried tunnels. The solution derived in this paper is validated thorough comparing with existing classical solutions on stress distribution around tunnel and GRC of a tunnel. Then GRCs obtained by three stress-dilatancy rules under 10MPa and 30MPa in-suit stress are compared. The proposed solution in this paper shows good agreement with results in the literature, no matter for the stress-strain distributions or the resulting GRC. Since the deformation of rocks under medium and high mean stress level is sensitive to the choice of stress-dilatancy, using an inappropriate stress-dilatancy rule may provide inappropriate suggestions on support installation of deep-buried tunnels.

Rocksoil S.p.A., Milan, Italy

ABSTRACT: “Jet-grouting” is a jet injection technology that has widely been used in geotechnical works since the 1970s. Nowadays, it is one of the most popular ground improvement techniques due to its applicability in almost all soil types. Its peculiarity is to change drastically ground characteristics, thanks to the effect of very high-speed jets, able to break up the soil and to mix it with cementitious slurry, improving soil’s mechanical parameters and reducing its permeability. In the paper, a general overview of the technology will be given, together with the design criteria for the particular tunnelling applications.

Keywords: jet grouting, vertical, sub-horizontal, portal, excavation face

1 INTRODUCTION

Nowadays, jet-grouting technology is one of the most popular ground improvement techniques due to its applicability in almost all soil types. Its peculiarity is to change drastically ground characteristics, thanks to the effect of very high-speed jets, able to break up the soil and to mix it with cementitious slurry, improving soil’s mechanical parameters and reducing its permeability. Several techniques and construction processes can be used for jet-grouting execution, depending on the types of fluid injections and on working parameters.

Jet-grouting has a fundamental role in the progress that has been achieved over the last thirty years in tunnel construction (Lunardi, 1986). Jet-grouting treatments can be executed by surface, where space is available and overburden is limited, or directly at the tunnel face. Horizontal jet-grouting made possible to overcome all the difficulties connected with excavation in cohesionless soils. Sub horizontal jet-grouting is used to create a series of columns of improved ground, side by side ahead of the face around the profile of the extrados of the tunnel to be excavated. Jet-grouting technology is also applied for the construction of tunnel portals in cohesionless or slightly cohesive soils too. Tunnelling can be performed with a very low overburden, by jet-grouting shell, arch shaped, thus minimizing the risk of slope instability and providing outstanding results from an environmental and landscape point of view.

2 JET-GROUTING

The technology involves the injection of a high-speed fluid (water jet or grout jet) through small-diameter nozzles into the subsoil to erode the surrounding soil, while the nozzles are rotated and lifted towards the ground surface at a constant speed. The eroded soil is simultaneously mixed with the injected grout to form the admixture, and a soil-cement column with a quasi-cylindrical shape would be formed after some days of solidification. It is possible to reach columns with diameters ranging between 500 mm and up to 2,500–3,000 mm, owing to the adopted systems, the working parameters and the soil types. Grout pressure, rate of ascent, angular speed, and number and diameters of nozzles are the main parameters to be controlled to obtain the improved soil of the desired shape and size. Soil investigation and field tests must be carefully planned for each application.

2.1 Classification

Based on the different methods of fluid injection, jet-grouting technology can be conventionally classified into three basic types of systems (Figure 1):

- a) single-fluid system (only grout);
- b) double-fluid system (grout and air);
- c) triple-fluid system (water, grout and air).

*Corresponding author: giovanna.cassani@rocksoil.com

The “single-fluid” system utilizes grout as the cutting jet to achieve cementation of the eroded soil. In the most common case of drilling without casing, a self-drilling monitor will be used, by rotation or roto-percussion system, with the drilling rod equipped both with injection nozzle and with cutting tool. In the “double-fluid” system, a compressed air shroud is introduced around the grout jet to enhance the cutting distance of the grout jet; the construction process is the same of the single-fluid system, adding an additional nozzle for the air. In the “triple-fluid” system, water is used for the cutting jet together with a compressed air shroud, and grout is injected separately through a lower nozzle at a much smaller pressure to mix with the eroded soil. The adoption of a lower viscosity fluid such as water (in comparison with that of grout) allows the cutting distance to be further enhanced, especially in cohesive soils. The three methods are represented in Figure 1 (Cassani et al., 2022).

2.2 Parameters

The key jet-grouting operational parameters governing the jetting performance are as follows:

- Characteristics of jetting fluid, i.e. water-cement ratio of grout (W/C).
- Pressure (MPa) and flow rate of jetting fluid ($Q = \text{m}^3/\text{h}$).
- Jetting time, which is a function of the traverse velocity of nozzle, and hence the withdrawal rate (m/min) and rotation speed (rpm).
- Characteristics of nozzle: nozzle diameter (mm), number of nozzles (N) and nozzle shape.

Figure 1. Jet-grouting systems: (a) single fluid; (b) double fluid; (c) triple fluid.

The injection pressure is controlled by pressure gauges; the jet energy and consequently the radius of action mainly depend on pressure. The upper pressure limit is essentially determined by the capacity of the pump used. The number and diameters of nozzles determine the injection capacity: the volume of grout injected into the ground per unit of time and, consequently, the rate of treatment. High flow rates require high power pumps to maintain high pressure. Larger nozzle diameters make more efficient use of the power employed, while large number of nozzles, with the same rates, decreases performance, due to a greater loss of head, so it is preferable to limit the number of nozzles. The water-cement ratio of the grout is the

most important parameter regarding the mechanical properties of the treated soil and the initial behaviour of the soil-grout mixture; a low water-cement ratio is extremely important where there is groundwater flow, as this could wash away the cement shortly after injection. The injection time depends on the withdrawal rate and the angular velocity of the drill rod; it is controlled by a timer placed on the drill rig (normally, 1 m every 2–6 minutes and 10–20 rpm). Raising is usually performed in 4–5 cm steps, thus allowing the jet to act on the surrounding ground, for set time intervals. The diameter and the mechanical properties of the ground treated, as well as the time required for treatment, are strongly affected by the withdrawal rate. Table 1 shows the range of jet-grouting parameters commonly adopted for the three conventional jet-grouting systems (Lunardi, 1997a). Typical withdrawal rates, expressed in cm/min, and rotation speed, in rpm, are reported in the table. It is possible to link the flow rate of jetting fluid (Q), the volume (V) and the speed of treatment (v), with the formula $V = Q/v$; the flow rate Q depends on jetting area, i.e. the number and diameters of nozzles, and on the jet speed, in turn related to the injection pressure (P). Thus, the knowledge of these working parameters allows to evaluate a global design parameter: the “linear specific energy”, by the

Table 1. Ranges of jet grouting parameters for conventional jet grouting systems.

Parameters	Single fluid system	Double fluid system	Triple fluid system
Water pressure (MPa)	-	-	30~40
Flow rate of water (L/min)	-	-	80~200
Number of nozzle (n°)	-	-	1.5~3.0
Nozzle diameter (mm)	-	-	1~2
Air pressure (MPa)	-	0.7~1.5	0.7~1.5
Flow rate of air (m^3/min)	-	8~30	4~15
Grout pressure, (MPa)	40~70	30~70	7~10
Flow rate of grout (L/min)	100~300	100~600	120~200
Grout density [g/cm^3]	1.25~1.6	1.25~1.8	1.5~2.0
Number of nozzle (n°)	1~6	1~2	1~3
Nozzle diameter (mm)	1.0~4	2~7	5~10
Withdrawal rate (cm/min)	15~100	10~30	6~15
Rotation speed (rpm)	7~20	2~20	7~15
Specific Energy (MJ/m)	10~20	40~80	120~200

formula $E = P Q/v$, expressed in MJ/m of linear jet-grouting, or the “volume specific energy”, by the formula $E = P \cdot Q/(v \cdot V)$, expressed in MJ/m³ (according to Tornaghi, 1993). Using these correlations, it is possible to dispose of a rational approach to compare several combinations of working parameters and find the best technical and economical solutions for each application.

2.3 Context

From the experiences acquired in several geotechnical works, we can state shot jet-grouting can be successfully performed in any type of soil (Figure 2.a), independently of grain size and permeability, with the exception of very hard cohesive soils whose strength cannot be overcome by the jet (such as stiff silts and clays, with undrained cohesion greater than 0.2–0.5 MPa). This technology has the advantage of being able to treat “stratified soils” too (alternating sands, silts, clays, etc.), providing almost uniform levels of cementation and waterproofing. In fine-grained soils, the outer surface of the columns obtained is normally well defined and fairly regular; in coarse-grained and heterogeneous grounds, this surface is irregular and there is the systematic appearance of “root effect”, i.e. grouting through “claquage” outside the radius of action of the jet. The occurrence of still groundwater does not in any way compromise the results of the treatment. When seepage occurs, special precautions, such as the addition of accelerators to the grout, give good results even at the groundwater speed of the order of 0.1 cm/s. The compressive shear strength of jet-grouted soil generally increases from clays to gravels (see Figure 3). Maximum strengths of about 20–30 MPa could be reached in sands and gravels, while in fine-grained peaty soils, it is hard to attain values ten times lower.

Figure 2. a) Jet-grouting applicability; b) Cassia Tunnel - External track: total length 232 m.

Figure 3. Compressive strength of jet-grouted soils.

2.4 Design approach and technical specifications

The design of ground improvement using jet-grouting must involve these main following stages:

- defining soil investigations and preliminary field tests;
- choice of grout type and operating parameters,
- deciding the pattern, shape and size of the grouted volumes,
- identification of the most appropriate numerical model to study the stress-strain distribution in the soil treated
- choice of the monitoring and controlling systems.

The most critical aspect is the ones related to the pattern and dimensions of jet-grouting treatments. It is essential to understand that ground volumes treated by jet-grouting are cemented ground and not real structures; there phase to define thickness and required strength, it is necessary to predict the stresses acting on treatments. The treated ground can take compression and shear, and consequently, the application of other types of stresses, i.e. tension, should be avoided. In this case, the insertion of bars and steel sections into improved ground can be achieved, especially for retaining structures, usually before setting takes place, by gravity or using high-frequency vibrators or re-drilling. It must be remembered that the existence of more rigid volumes in the ground may possibly be used to produce a system channelling stresses along a desired direction and these stresses should be carefully considered in dimensioning. The analysis of such problems implies generally the use of the finite element method, since the types of problems connected with jet-grouted ground are clearly non-linear. In addition to this, it is often necessary to analyse structures whose shape changes over time due to excavation or construction operations. This requires starting with the analysis of the natural untreated conditions and passing through an appropriate sequence of stages realistically approximating the actual development of the work. Once the geometry of the treatment is defined and the required strength is fixed, it is necessary to study

the correct pattern, considering the column diameters easily achieved in the geotechnical context of intervention and an appropriate overlapping to ensure the continuity of treatment. The working parameters will be set, based on database experiences in similar contexts or according to the specific energy approach discussed in Section 2.2, and they will be confirmed or fine-tuned by a field test. Designer must define in detail, in addition to the executive technical specifications, the prescribed requirements in terms of diameter, strength and permeability of the soil treated, to be checked by tests.

3 TUNNELLING APPLICATION

The authors when designing a tunnel always apply ADECO-RS approach (Analysis of the controlled deformations in rocks and soils) which is related to one only parameter common to all the excavations, that is the tenso-deformative

behaviour of the system “front of the excavation advancement core” and to the introduction of the concept of precontainment of the cave and of the “conservative systems” (Figure 4).

Particularly, design has been articulated in:

- An investigation phase, during which the designer, has carried out the categorization of the soil crossed by the tunnel in terms of geotechnical parameters. This step is essential to complete the analysis of the existing natural balance, and to correctly work in the following design phase;
- A diagnosis phase, during which have been prepared theoretical forecasts regarding the deformative answers of the soil to the excavation action. The soil behaviour can be intended in terms of genesis, localization, evolution and entity of the probable reaction which, without intervention of soil improvement, would commence at the excavation face and, as a consequence, in the soil ring at the cavity. From the combined analysis of the deformation behaviour of the system excavation front advancement core and of the cavity, one can infer which will be the homogeneous deformative behaviour in the domain of the three fundamental categories of behaviour (category A: stable front, category B: front stable in short terms, category C: unstable front);
- A phase of therapy, during which, following the predictions made in phase of diagnosis, the designer selects the type of action to be exerted (pre-containment or simple containment) and the necessary interventions, among the three behaviour categories (A, B and C) in order to obtain the complete stabilization of the tunnel, and he perfects the choice in terms of systems, cadence and phases of excavation. Then, he defines the composition of the longitudinal standard sections and the cross sections dimensions, assessing their efficacy by using computation tools.

Figure 4. ADECO-RS approach.

3.1 Portals

The construction of tunnel portals often involves solving problems that are closely connected with the morphology of the slope to be entered, with the existence of nearby constructions, with the geometry of the structures to be constructed and the type of material involved.

The preparation of a portal site and of the wall to be excavated, very frequently requires substantial cuttings which are of no particular concern when working in rock, but are very problematic when working in soft soils, especially if they are loose. If the decompression caused by excavation in ground with little cohesion is not adequately confined, there is a risk that it will easily and rapidly propagate into the medium with serious effects for the whole

slope. The only way the entrance to the portal of a tunnel can be excavated without decompressing the ground is clearly by creating a structure to confine (or better preconfine) the ground in advance ahead of the future excavation which is capable of conserving the existing natural equilibrium.

The systems available for achieving this goal were to place the following structures at the entrance of the bored tunnel:

- large diameter pile walls, anchored if necessary;
- “Berlin” or soldier pile walls;
- Reinforced Concrete diaphragm walls.

The construction of large diameter piles on slopes tending towards instability is, however, often difficult, if not impossible, because, it is often the case that the morphology of the slopes does not allow the use of the heavy operating machinery required. On the other hand

the lability of Berlin type structures themselves, which rely to a large extent on anchors which reach into stable zones of the ground for their effectiveness, mean that these systems are not always sufficiently reliable. Not even r.c. diaphragm walls are sufficient for the most delicate situations: earth removal and the introduction of water have the effect of reducing the shear strength of the ground with consequences for which there is no remedy in some situations.

These problems were then made worse because the lack of adequate techniques to improve the ground in advance and of suitable operating systems, required bored tunnels to be driven with overburdens measurable in terms of tunnel radii. This required huge portions of the ground to be removed with the risk of triggering ground decompression that is very difficult to confine (Figure 5).

Figure 5. a) very deep cut is made into the slope for a tunnel portal in semi-cohesive soils using conventional systems (anchored Berlin wall; overburden: twice the diameter of the tunnel); b) The same portal as the one above, after it had collapsed because of the decompression induced in the slope.

The availability of a jet-grouting systems for improving ground, introduced in Italy around thirty years ago, allowed to invent and experiment an innovative solution to create preconfinement structures in loose or poorly cohesive soils with properties that would overcome the problems that have been described. The idea consists of creating a confinement shell, before excavation for the portal commences, consisting of rows of columns of ground improved by means of jet-grouting, which geometrically enfold the section of artificial tunnel (see Figure 6). The

magnitude and distribution of the treatment are decided on the basis of each specific operating and geotechnical context. A top beam in r.c. joins the tops of the columns to help make it a single rigid structure. Once the earth has been removed for the entrance to the portal, the work is completed with:

- a layer of shotcrete sprayed on the whole surface of the exposed wall;
- drainage pipes placed sub-horizontally through the improved ground to prevent the formation of heads of water behind it.

Figure 6. Tunnel portals with shell of improved ground by means of vertical jet-grouting (Lunardi, 2008).

The structure thus built functions by means of the sub-horizontal arches and is subject mainly to compressive and shear stress. The creation of shells of this type is strictly dependent on the subsequent tunnel being driven using horizontal jet-grouting methods. Thanks to the characteristics of this ground preconfinement technology, which requires only minimum overburdens, bored tunnels can be driven with extremely low cover, with many important advantages, including the way it fits unobtrusively into the environment.

3.2 Sub horizontal jet-grouting columns

The use of sub-horizontal jet-grouting column inside a tunnel could be performed mainly by two way: around the cavity or at the face and together also (see Figure 7).

Truncated cone ‘umbrellas’ realized by sub-horizontal columns of jet-grouting as a conservative protective intervention. It creates ahead of the face around the cavity a protective shell. It channels stresses around the outside of the face performing, as the term says, a protective action which conserves the natural strength and deformation characteristics of the ground.

Sub-horizontal jet-grouting is used to create a series of columns of improved ground, side by side ahead of the face around the profile of the extrados of the tunnel to be excavated. An arch of improved ground with considerable strength is created to provide protection to the ground inside the advance core along the longitudinal direction, lightening the load on it and giving it stability; this arch produces cavity confinement action occurring along the transverse direction, sufficient to prevent the ground around it from decompressing and consequent deformation from occurring. It therefore allows subsequent tunnelling operations to proceed under the protection of an arch effect already operational and therefore in complete safety.

Reinforcement of the core-face by means of sub-horizontal jet grouting column is a conservative reinforcement intervention. It acts directly on the consistency of the advance core, improving its natural strength and deformation characteristics by means of the reinforcement techniques.

Figure 7. Sub-Horizontal jet grouting: intervention map, assessment through 3D analysis and parameters.

4 CASE HISTORY

The solutions described in section 3 have been developed by Prof. Lunardi and his teams more than 30 years ago and from that time applied in a lot of cases. In this section the authors just mention the tunnelling applications of sub-vertical and sub-horizontal jet-grouting columns and they will give more details about one face reinforcement application more recently designed.

The first time that sub-vertical jet-grouting to pre-confine excavation was experimented in 1980 at Sesto San Giovanni (Milan), in an area destined to contain a ventilation chamber 9.80 m deep on a section of the Milan metro line 1 under construction. The first application for the construction of tunnel portals occurred five years later for the T1 portal on the Pontebba side of the S. Leopoldo tunnel on the Pontebba-Tarvisio railway line. This application was suddenly followed by several application (Lunardi, 2008):

- S. Elia Tunnel (Messina-Palermo motorway): portal on the Messina side under construction, 1986 (Figure 8a).
- Pianoro Tunnel (new high speed/capacity railway line between Bologna and Florence), 1996.
- Gran Sasso Tunnel, Assergi side Portal, xxxx.
- Tunnel No. 2 (Sibari-Cosenza railway line): the use of jet-grouting technology enables tunnel portals to be built in difficult grounds with full respect for natural equilibriums and for the landscape, 1992 (Figure 8b).

Figure 8. Examples of portal of tunnels by jet-grouting shells. (a) S.Elia Tunnel, Messina-Palermo Motorway and (b) Tunnel N2, Sibari-Cosenza Railway Line (Lunardi, 2008).

Horizontal jet-grouting made possible to overcome all the difficulties connected with excavation in cohesionless soils. In this case also a statics design that is congruent with the features of the treated ground was fundamental, namely, a design in which the material is mainly subjected to compressive and shear stresses.

This is the famous ‘umbrella’ treatment which, by penetrating beyond the face of a tunnel, develops arching in the ground ahead of the excavation. The first application of this technique, which was developed in 1983, was during the construction of the ‘Campiolo’ tunnel, along the Udine Tarvisio railway line (Figure 9).

The first case was followed by several application:

- Underpass of the Campinas railway yard in Brazil (1987)
- Milan-Chiasso railway line, Monte Olimpino 2 tunnel, (1984)
- The Rome Greater Ring Road: Appia Antica Underpass (Lunardi 2000a), Cassia and Trionfale Tunnels
- Firenzuola tunnel, high speed/high capacity railway line Bologna-Florence (Lunardi, 2000b)
- Road underpass of the Ravone Railway Yard (Bologna, Lunardi & Cassani, 2001)

Figure 9. Campiolo Tunnel, Udine-Tarvisio railway line (Lunardi, 2008).

The most recent and challenging application is the one of the Isarco River Underpass. The southernmost construction lot of the Brenner Base Tunnel is the construction lot know as Isarco River Underpass. This lot links the Brenner Base Tunnel with the existing Brenner line and the railway station in Fortezza. The work has been completed in 2023. Since in this section the tunnel tubes are just a few meters below the surface, a portion of the activities pertaining to this construction lot has been carried out building artificial tunnels. Furthermore, as loose fluvioglacial materials and the groundwater layer crossed, it has been necessary to adopt specific ground consolidation procedures including ground freezing and the so-called jet grouting.

The Isarco River Underpass passes through the alluvial deposit of the valley bottom and through the dejection conoids of the tributary rivers. These loose

deposits, heterogeneous both in composition and in granulometry, consist of gravels and rounded sand, with frequent boulders and thick layers of sandy silt. The flanks of the valley are covered by coarse particle size material, composed by slope debris, alluvial sediments and weather material. Figure 10. Shows the geological profile and Table 2 summarizes the geotechnical parameters.

Excavation section C1 (Figure 11 reported a general scheme) has been applied in case of loose soils of quaternary origin. Particularly in the Northern sector, in correspondence of the Debris Flow with unstable behaviour, to underpass the motorway A22 and the SS12; the overburden is ranging between 25 to 30 m. It is applied in the Southern sector too, in correspondence of the detritus conoids where unstable core-face behaviour is expected. This section type considers pre-consolidation intervention around the cavity (blue mark in Figure 11 and at the core-face (red marks in Figure 11), aimed creating the conditions of stability and waterproofing of the natural soil.

Figure 10. Isarco River Underpass Geological Profile (Lunardi et al. 2018, Lunardi et al. 2019).

Table 2. Soil mass geotechnical parameters.

SOIL TYPE	γ (kN/m ³)	ϕ (°)	c' (kN/m ²)	E_s (MN/m)
Debris Flow	21,0	30	10	60
Slope Debris	21,0	35	0	60
Alluvional sediments	20,5	36	2	60
Weathered material	21	30	0	30

Figure 11. Reinforcements sketch made by jet grouting sub-horizontal columns.

Figure 12. Section C1: Blue marks truncated cone 'umbrellas', red marks core face reinforcements.

The design requires that excavation is performed without reducing the groundwater level, in hydrostatic conditions. For this reason it is necessary to create a grouted arch around the cavity and a plug at the face, so that the advance core is waterproofed. The last requirement has been satisfied thanks to the application of a special jet-grouting technology: Quick set jet grouting - QSJG - based on a "triple-fluid" system. The fluid added to the most common "double-fluid" system is a silicate and its accelerating characteristic was fundamental for "the quick" development of the ground column resistance and waterproofing. Despite to the not ideal conditions for jet grouting application, the adoption of QSJG solve the most critical issues related to this technology (Figure 13). The truncated cone 'umbrellas' realized by sub-horizontal columns create a pre-containment structure in the ground before its excavation, with the creation of "arch effect" which minimizes the deformations. The reinforcement of the

Figure 13. Section C1: detail of sub-horizontal jet-grouting column and detail of the excavated ground.

core-face by means of sub-horizontal jet grouting column acts directly on the consistency of the advance core, improving its natural strength and deformation characteristics.

The performed interventions made the cavity and the advance core waterproofed allowing to perform the excavation in hydrostatic condition with a hydraulic head of 25m on the crown key.

The work phases related to this kind of intervention can be summarize as follow:

- 1) reinforcement of the core-face with sub horizontal columns of ground improved by means of jet-grouting (Figure 14);
- 2) creation of columns of sub-horizontal jet-grouting in advance in the crown;
- 3) creation of sub horizontal columns of improved ground under the tunnel floor (Figure 15);
- 4) full face excavation with steel ribs and shotcrete placed (Figure 16);
- 5) the face is given a concave shape and is sprayed with shotcrete;
- 6) the kickers and the tunnel invert are excavated and cast at a distance from the face of ≤ 1 diameter;
- 7) water-proofing is placed and the final lining is cast at a distance from the face of $\leq 2 \div 3$ diameters.

5 CONCLUSIONS

Jet-grouting has a fundamental role in the progress that has been achieved over the last thirty years in tunnel construction. Jet-grouting treatments can be executed by surface, where space is available and overburden is limited, or directly at the tunnel face. In the paper, the authors rendered a general overview of the technology, together with the design criteria for tunnelling applications such as portals, cavity and excavation face reinforcements.

Figure 14. Reinforcement of the core-face with sub horizontal columns of ground improved by means of jet-grouting.

Tunnelling can be performed with a very low overburden, by jet-grouting shell, arch shaped, thus minimizing the risk of slope instability and providing outstanding results from an environmental and landscape point of view.

Horizontal jet-grouting made possible to overcome all the difficulties connected with excavation in

cohesionless soils. Sub horizontal jet-grouting is used to create a series of columns of improved ground, side by side ahead of the face around the profile of the extrados of the tunnel to be excavated. The authors listed a series of application performed during the latest 30 years and described the most recent and challenging application related to one section of the Isarco River Underpass.

Stability analysis of surrounding rock in a highway tunnel crossing a water-rich fault fracture zone

ABSTRACT: One of the most challenging aspects of tunnel construction is the encounter with unfavourable geological conditions such as fault zones with fractured rock. When crossing fault zones, it is generally necessary to implement advance support to reinforce the fractured rock and block the seepage path, and then use the CD method or CRD method to excavate the tunnel to ensure the stability of the surrounding rock. However, if the CD method is employed for excavation, it would require changing the excavation method and implementing and removing temporary supports during the construction process, which does not align with the requirements of safe and environmentally friendly tunnel construction. The three-bench seven-step excavation method (TSEM) has been widely used in fractured rock excavation as a method that can stabilize the surrounding rock with simple procedures and low cost. Therefore, a comparative study can be conducted on the excavation methods of fault fracture zone surrounding rock. Based on the A Tunnel project in Beibei District, Chongqing, finite element numerical simulation methods were employed to compare the effects of the CD method and the TSEM on the stability of the surrounding rock. The research indicates that the CD method has limited advantages in terms of displacement control, rock stress, and expansion area of the plastic zone. Therefore, it is feasible to replace the CD method with the three-step seven-step excavation method, which has practical implications for similar projects.

Keywords: Fault zones, CD method, Three-bench seven-step excavation method, Numerical simulation

1 INTRODUCTION

In the process of tunnel construction, special geological conditions will be encountered from time to time, and crossing the water-rich fault zone is one of the common ones. Due to the complexity of the mechanical problems involved in tunnelling through a fractured fault zone, traditional mechanical analysis methods are difficult to apply. Therefore, scholars often analyse the stability of highway tunnels crossing fractured fault zones based on numerical computational methods: Wang et al.(2016) utilized numerical simulation methods to investigate the deformation and stress distribution characteristics of surrounding rock in fractured zones with different dip angles and widths of the fault. They combined model experiments to study the tunnel collapse process during construction and found a good agreement between the results of the two

approaches. The study by Zuo et al.(2015) indicated that the time-dependent settlement and deformation of the surrounding rock arch can be effectively transformed into a model of sudden instability. According to the criteria for determining sudden instability of the surrounding rock, the obtained state of surrounding rock instability corresponds well to the actual rock failure conditions. This approach has achieved favourable results in analysing the stability of surrounding rock in fractured fault zones. Peng et al.(2022) simultaneously considered the influences of groundwater and blasting on the stability of the surrounding rock. They established a sharp-point sudden instability model for tunnelling through fault zones with abundant water, which was used for analysing the stability of the surrounding rock in fractured fault zones.

Significant research achievements have been made regarding the influence of tunnel excavation methods

*Corresponding author: 2232527@tongji.edu.cn

on the stability of weak surrounding rock: Li et al. (2020) systematically compared the distribution of deformation and plastic zone of surrounding rocks obtained by two excavation methods, cd method and step method; Li et al.(2015) studied the influence of TSEM on the stability of the surrounding rocks of loess tunnels by taking the displacement characteristics as the main entry point and found that significant subsidence occurred on the arches and surface of loess tunnels. Zhou et al.(2021) compared the influences of the Benching method and the CD method on the stability of surrounding rock when crossing coal seams. They concluded that, under conditions allowing for greater subsidence, using the Benching method for tunnel construction is technically feasible and can achieve favourable technical and economic benefits.

In the face of complex geological conditions, it is often necessary to design a variety of excavation methods to cooperate with each other to complete the tunnel excavation, but the excavation methods should not be changed frequently during the tunnel construction process, and the excavation methods of the same tunnel should be simplified as much as possible. Otherwise, it will induce numerous unsafe factors and increase the construction cost. Based on this, the purpose of this paper is to analyse the feasibility of using the three-bench seven-step excavation method (TSEM) to replace the center diagram method (CD method) to excavate the fault zone by using finite element analysis. In order to simplify the tunnel excavation method and improve the technical and economic benefits of tunnel construction.

2 PROJECT OVERVIEW

2.1 Geological condition

The tunnel crosses the backslope mountain formed by the Wintang Gorge backslope, and only the Jialingjiang. The tunnel crosses the F1 fault, the fault strikes

Figure 1. Geological condition.

north-east, tends to the north-west, dipping angle of $60 \sim 85^\circ$, the left side of the lower plate strata for the T_{1j}^4 (mainly composed of limestone) and a small part of the T_{1j}^3 (mainly composed of limestone), the right side of the upper plate strata for the T_{1j}^3 . According to a thorough borehole survey, the rock formation in the 0-150m interval exhibits a fractured structure, with the rock core being moderately fragmented.

2.2 Fault fracture zone construction scheme

According to Specifications for Design of Highway Tunnels, surrounding rock classification is determined according to rock hardness rock integrity and BQ value comprehensively (Table 1). A total of seven lining schemes and four excavation schemes were designed according to the surrounding rock classification to meet the support and excavation requirements of the emergency stopping zone section from Class III to Class V perimeter rock.

According to Table 2, fault fracture zone corresponds to V surrounding rock (Geologically poor sections), should choose the lining program for the S5a, and its adaptive advanced support programs in the pipe shed or two-layered conduit, excavation methods selected in the CD method. Therefore, it can be determined that the construction program of the fault fracture zone is as follows: firstly, apply pipe shed or two-layered grouting conduit for tunnel arch advanced support, and then use CD method for excavation, lining program selection S5a, of which: two-layered conduit are made of hot-rolled seamless steel pipe, with a single length of 4.5m, a diameter of 42mm, a wall thickness of 4mm, and are arranged within the range of 120° on the top of the arch, with an annular spacing of 40cm, of which the outer insertion angle of 10° is 10° . Among them, the outer insertion of slow inclination angle of 10° to 15° , steep inclination

Excavation Methods	Advanced Support Methods	Surrounding Rock Classification	
		Three-lane Section	Emergency Stop
Three Benching Tunnelling Method	\	III	III
TSEM	Forepoling Bolts	IV, V (Deeply buried and geologically normal sections)	IV
CD Method	One-layered Conduit	V (Geologically poor sections)	\
CD Method/ Double Side Drift Method	Pipe shed, Two-layered Conduit	V (Shallow buried sections)	V

3 THE NEED TO CONDUCT EXCAVATION PROGRAM SELECTION

In the original design, three benching tunnelling method, CD method and double side drift method are adopted for a few III surrounding rocks, fault fracture zones and emergency stopping zones respectively, but the three benching tunnelling method is adopted for most of the IV surrounding rocks and V (Deeply buried and geologically normal sections) excavation. Tunnel left line design statistics are as follows, from the table it can be seen that the use of three TSEM accounted for 73.74% far more than the other two excavation methods (Table 3). Due to the poor physical and mechanical properties of surrounding rocks in V (Shallow buried sections). The resulting surrounding rock pressure is also larger, it is difficult to ensure that after changing the excavation method to guarantee the safety of construction, but for the CD method designed to excavate the V (Deeply buried and geologically

normal sections) surrounding rock geological poor section still exists optimization possibilities, consider using three benching tunnelling method to replace the TSEM in the next door method, specifically for the following reasons:

The three benching tunnelling method is simple, fast and more economical. Compared with the CD method, if the step method is used, the amount of temporary support used per meter of tunnel support structure is reduced, the loss of materials is reduced, resulting in the application of temporary support when the cost of manpower, material resources, time are reduced, so in the surrounding rock conditions allow, it is advisable to try to use the step method of construction, in order to shorten the construction period, reduce the cost of the purpose.

Frequent changes in excavation methods for the same tunnel are not economical and may even cause safety problems. If the CD method is replaced by the TSEM, it will reduce the abandoned temporary work on one hand, and simplify the excavation method on the other hand, which is beneficial to the management and economy of the tunnel construction.

The CD method causes secondary disturbance to the surrounding rock when removing the CD method after excavation, while the step method avoids secondary disturbance to the surrounding rock when removing the temporary support, and the number of stress redistribution is reduced.

4 COMPARISON OF EXCAVATION METHODS FOR FAULT FRACTURE ZONES

4.1 Assumptions and descriptions of the numerical model

As shown in the Figure 2, the three-dimensional numerical simulation was carried out using Midas GTS NX finite element software. Considering the scope of the rock mass affected by the tunnel excavation, the height of the tunnel section span and the length of the F1 fault, the length of the model was determined to be 60 m, width 100 m and height 100 m. The length of the fault zone was taken to be 40 m according to the geotechnical report, and the stratigraphic model was T_{1j}^4 , fault zone and T_{1j}^3 from left to right as shown in the figure. It is

Table 3. List of tunnel construction scheme.

Surrounding Rock Classification	III	IV			V		
Length	355	1040			1433		
Excavation Methods	Three Benching Tunnelling Method	TSEM	TSEM	TSEM	CD Method	TSEM	Double Side Drift Method
Excavation Length Percentage	355 12.00%	230.13 73.74%	650 \	50 \	371.75 12.57%	1251.12 \	50 1.69%

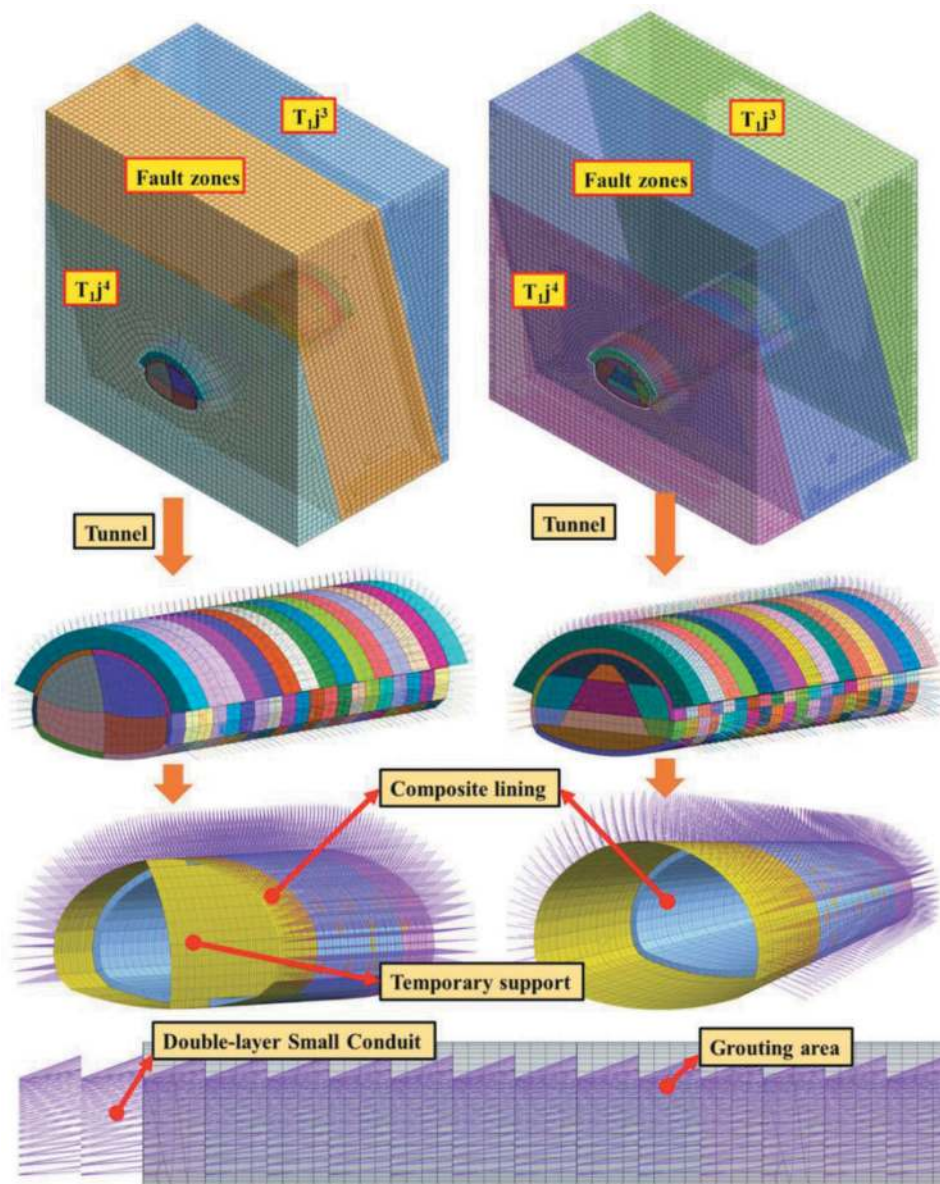

Figure 2. Numerical model.

necessary to select different simulation units and corresponding constitutive models for different simulation objects, the stratum and grouting reinforcement area are simulated by solid units, the constitutive model adopts the Mohr-Coulomb model, the support is simulated by plate units and considered as elastic, and the two-layered conduit are simulated by implanted trusses and considered as elastic. The normal displacements of the left, right, front, back and lower part of the constrained model are used as the displacement boundary conditions.

To simulate the CD method excavation, the arch advanced support (support distance 4m) is constructed first. The excavation was then carried out in the order of drift ① ~④(excavation length 3m). Primary support and temporary support will be applied after each step of excavation is completed. After the primary support was closed, the removal of the

temporary support began (removal length 12m). Pouring of the invert after removal of the first temporary support (pouring distance 12m). To simulate the TSEM excavation, the arch advanced support (support distance 4m) is constructed first. The excavation was then carried out in the order of drift ① ~ ⑦(excavation length 3m). Primary support and temporary support will be applied after each step of excavation is completed. Pouring of the invert after the primary support was closed (pouring distance 12m). (Figure 3)

4.2 Simulation results

4.2.1 Displacement

For both vertical and horizontal displacement values, both excavation method displacements are larger

Figure 3. Construction process simulation.

Table 4. Physical and mechanical properties.

	E/MPa	N	$\gamma/(\text{kN}/\text{m}^3)$	c/MPa	$\varphi/^\circ$
T_{ij}^3, T_{ij}^4	6000	0.35	26.3	0.7	39
Fault Zones	1200	0.35	22.5	0.05	27
Grouting Area	4000	0.35	25	0.2	45
Primary Support	26000	0.2	22	\	\
Lining	30000	0.2	25	\	\
Bolt	200000	0.3	78.5	\	\

within the fault zones and the displacement control of TSEM is weaker than CD method (Figure 4-7). It is noteworthy that sudden changes in displacement were observed for both excavation methods near the stratigraphic junction locations (construction locations 10 and 50) and large displacement differences were observed at both the top and waist of the tunnel. Therefore, when the tunnel crosses the fault zones, the difference in surrounding rock stiffness before and after the fault zones will lead to uneven deformation along the longitudinal direction of the tunnel. Such uneven deformation acting on the

lining structure may cause shear damage. The horizontal displacement difference is larger under both excavation methods, and the settlement is larger in the TSEM but it is uniform and the settlement difference is small, which shows some advantages compared with the CD method.

4.2.2 Stresses

The principal stress nephogram of the two excavation methods are similar and maximum principal stresses are manifested as compressive stresses. The maximum principal stresses in the side wall at the same monitoring location are larger than those at the top and bottom of the tunnel, and the maximum principal stresses in the fault zones of the side wall at different monitoring locations are smaller than those in the strata on both sides. In summary, the maximum principal stress maxima are located at the side wall of the strata on both sides. The minimum principal stress at the same monitoring position is tensile stress at the top and bottom of the tunnel and compressive stress at the side wall the tunnel; the minimum principal stress at the top and bottom of the tunnel at different monitoring positions is tensile stress, and the range of tensile stress has been

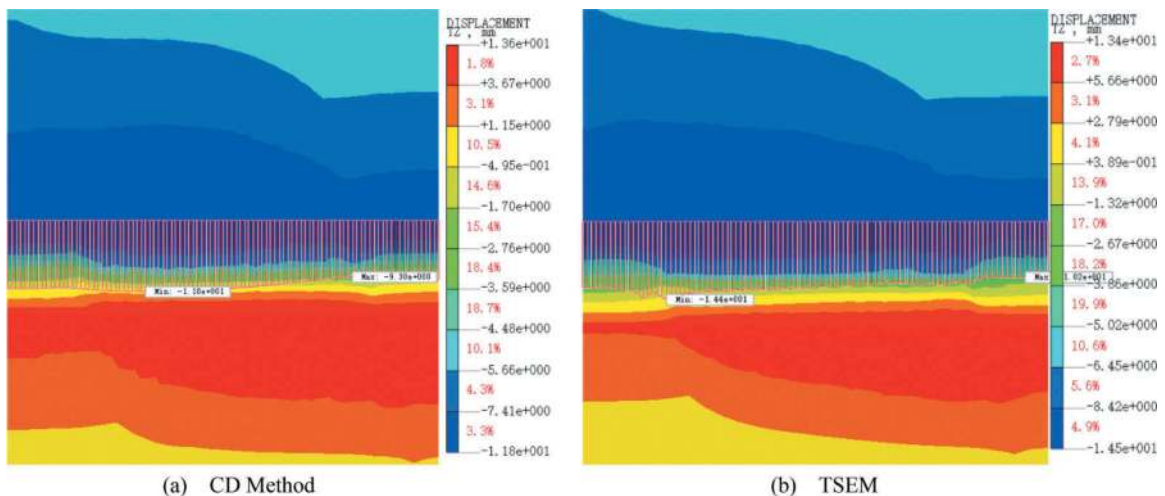

Figure 4. Vertical displacement nephogram.

(a) CD Method

(b) TSEM

Figure 5. Horizontal displacement nephogram.

Figure 6. Vertical displacement.

Figure 7. Horizontal displacement.

expanding with the monitoring position from the left to the right; the minimum principal stress at the side wall of the tunnel at the same monitoring position has been compressive stress, but it has been larger in the two sides of the ground layers and smaller in the fault zones.

The plastic zones are observed in the sidewall of the tunnel within the fault zones and its adjacent region. But it is primarily concentrated within the fault zones. Hence, in the comparison of the two excavation schemes, five sets of data of the sidewall within the range of construction steps from primary support closure to tunnel completion in the fault zones were selected for comparison, and Table 5, 6 was obtained based on Equation (1) Moore-Cullen damage criterion.

$$\varphi_p = \sin^{-1} \frac{\sigma_1 - \sigma_3}{\sigma_1 + \sigma_3 + 2c \cot \varphi} \quad (1)$$

Where, σ_1 is maximum principal stress(pa); σ_3 is minimum principal stress (pa); c is cohesion (pa); φ is friction angle ($^\circ$).

As illustrated in Figure 10, two positions adjacent to the waist and shoulders of the tunnel were chosen as points of comparison. For the comparison position 1, φ_p varies within 3° for both methods after primary support closure, and the surrounding rock at the position 1 is not grouted and reinforced, so $\varphi=27^\circ$ for the position 1 surrounding rock. Comparing the two excavation methods, both $\varphi_p > \varphi$ after primary support closure, indicating that the rock body has been sheared at this time, but the value of φ_p under the

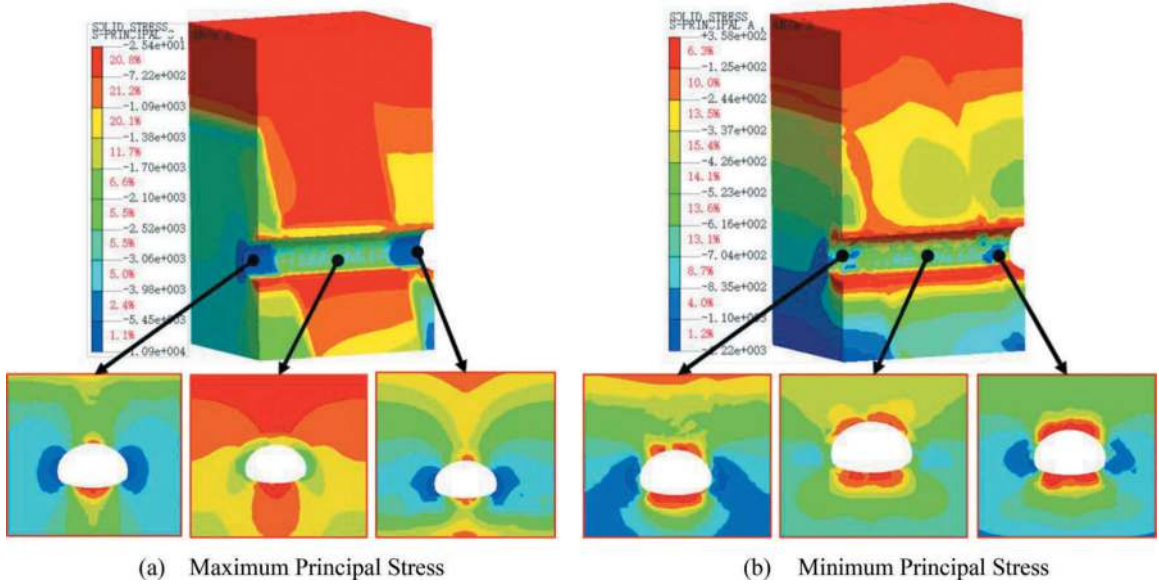

Figure 8. CD method principal stress nephogram.

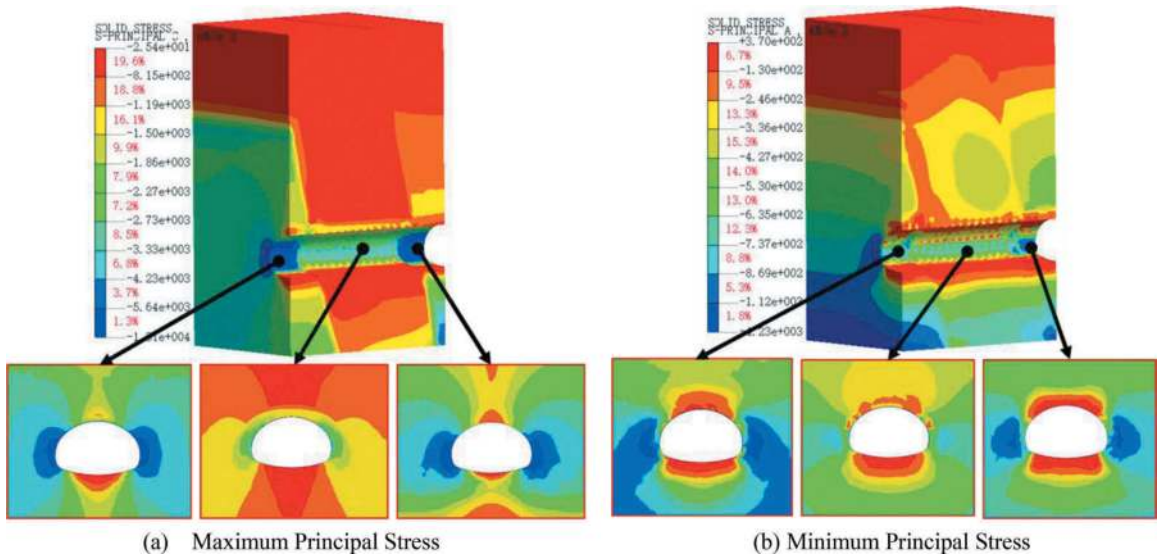

Figure 9. TSEM principal stress nephogram.

three benching tunneling method is greater than that under the CD method, and the surrounding rock is in a more unfavorable state. Therefore, for the excavation of surrounding rock at the position 1, the primary support should be applied earlier for timely control. The rupture angle of the two methods varies within 2° after the primary support is closed, and the surrounding rock at the position 2 is reinforced by grouting, so the surrounding rock $\varphi=27^\circ$. Comparing the two excavation methods, there are results $\varphi_p > \varphi$ at different stages, when the CD method is used for excavation to get φ_p are greater than the same stage of the three benching tunneling method with seven steps, which is in a more unfavorable state. In addition, even though there is advanced support for the

Table 5. Comparison position 1 stress state.

Construction Stage	CD Method			TSEM		
	σ_1 /MPa	σ_3 /MPa	$\varphi_p/^\circ$	σ_1 /MPa	σ_3 /MPa	$\varphi_p/^\circ$

surrounding rock of the position 2, shear damage still occurs, and more reasonable advanced support measures with higher strength should be proposed.

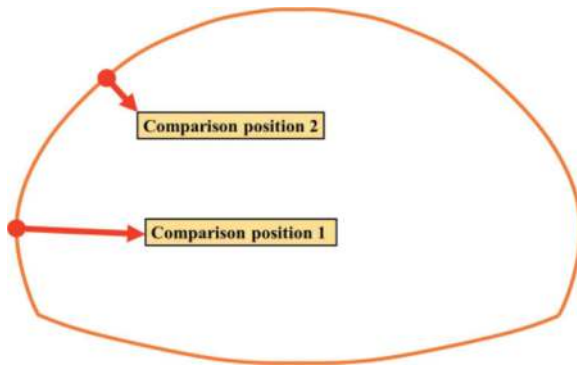

Figure 10. Comparison position.

5 CONCLUSIONS

Summarizing the displacement and stress comparisons, it is considered that TSEM can be used instead of the CD method of excavation. The reasons are as follows:

Displacement convergence value. The CD method has better deformation control ability than TSEM, but for the arch settlement and tunnel peripheral displacement generated under both excavation methods are within the range of the code-recommended

recommendations, the TSEM is applicable to the excavation of fault zones under the same conditions.

Displacement difference. Horizontal displacement difference generated under both excavation methods at the stratum junction is larger, but the tunnel top settlement convergence value is larger using the TSEM but the settlement is uniform and the settlement difference is small, which shows some advantages.

Surrounding rock stress. The surrounding rock at the shoulder and waist of the tunnel within the fault zones of are damaged under both types of excavation, but each has its own advantages and disadvantages, and a comparison of the value of φ_p shows that the stress on the surrounding rock at the waist of the tunnel is worse using the TSEM of CD method, and that the stress on the surrounding rock at the shoulder of the tunnel is worse using the CD method of the middle-septal door excavation. The advantages embodied in the CD method are limited. In summary, replacing the CD excavation method with TSEM can greatly reduce the construction process, shorten the construction period, and save the construction cost while being environmentally friendly.

ABSTRACT: As a typical layered rock mass, Phyllite has significantly anisotropic physical and mechanical properties compared with homogeneous rock mass. In order to further explore the influence of strength anisotropy of Phyllite on the displacement field of surrounding rock, based on the Dashazui Tunnel of Jinning Expressway, the Finite difference method (FDM) is used to study the difference of displacement field of surrounding rock of Phyllite tunnel under the two constitutive models of Mohr Coulomb and Ubiquitous-joint, and it is verified by the field measured displacement. According to the simulation results of different working conditions, compared with the Mohr Coulomb constitutive model, the Ubiquitous-joint model is more suitable for the actual data of the displacement field of the surrounding rock. The selection of the Ubiquitous-joint model better reflects the phenomenon of concentrated failure in Phyllite tunnels during excavation.

Keywords: Tunnel, Phyllite, Ubiquitous-joint model

1 INTRODUCTION

Phyllite, which is widely distributed in southwest China, is one of the low-grade metamorphic rocks, and is formed by metamorphism of claystone or volcanic tuff. Due to the different proportions of its main components, although the structure is similar, there are still great differences in specific physical and mechanical parameters (Li et al., 2014). As a typical stratified rock mass, its anisotropic mechanical properties are often different from the failure forms of conventional tunnels when tunnel diseases occur (Si et al., 2021; Zan et al., 2023; Wu et al., 2022). In view of its anisotropic mechanical properties, scholars around the world used uniaxial/triaxial compression test, uniaxial creep test, X-ray powder diffraction, electron microscope scanning and Brazil disc splitting test to study, and achieved fruitful results (Xu et al., 2018; Ramamurthy et al., 1993; Ozbek et al., 2018; Hu et al., 2017).

Numerical simulation is widely used in the study of the mechanical behavior of layered rock tunnels, and the treatment of joints is usually divided into

explicit and implicit methods. The Ubiquitous-joint model treats the rock as a composite consisting of “matrix” and “joints”, and directly considers the strength criterion and flow law of the matrix and joints separately in the constitutive equations, i.e., the treatment of joints is “implicit” (Deangeli & Omwanghe, 2018). Simulation of nodules by modeling them individually, e.g., by 3DEC software is referred to as the display approach. Tien & Kuo (2001) proposed an ontological model for analyzing laminated rock bodies using two independent sets of criteria namely sliding damage controlled by discontinuous surfaces and non-sliding damage controlled by the rock matrix. Saeidi et al., (2014) A new anisotropic strength criterion was proposed for analyzing the strength of transversely isotropic rock bodies by integrating several metamorphic and sedimentary rock mechanical parameters. Shi et al., (2016) introduced two parameters to represent the direction of minimum strength and the anisotropic effect in a laminated rock mass, and accordingly established a strength criterion for laminated rock masses. Fortsakis et al., (2012) investigated the anisotropic

*Corresponding author: 408996541my.swjtu.edu.cn

mechanical behavior of tunnelling in a laminated rock mass by qualitatively dividing the laminated rock mass into rocks and joints. And the destruction of joints often leads to the further development of the surrounding rock fissures, resulting in the deterioration of the surrounding rock, and then the occurrence of surrounding rock instability triggering a series of tunnel diseases (Meng et al., 2013; Wang et al., 2014). In order to further investigate the influence of the phyllite joints on the deformation of the surrounding rock after tunnel excavation, this paper investigates the mechanical behavior of the phyllite tunnels after excavation by means of SEM electron microscopy, triaxial experiments, numerical simulation combined with on-site measurements. And through the study, we find out an intrinsic model that can be used to simulate the centralized damage in the excavation process of phyllite tunnel, which can provide certain reference for future projects.

2 PROJECT OVERVIEW

The Dashazui Tunnel project of Jinyang to Southern Ningnan section of G4216 expressway is the support project of this paper. The tunnel is located in the northeast margin of Hengduan Mountain system in southwest, between Sichuan Basin and Yunnan-Guizhou Plateau, with high terrain in northwest and low in southeast. The Dashazui Tunnel is a two-way four-lane road tunnel with a design speed of 80km/h. The length of the left line tunnel is 3940m, and the mileage of the tunnel is Z3K189+946 and Z3K193+886 respectively. The length of the right line tunnel is 3974m, and the starting and ending mileage of the tunnel are K189+900 and K193+874 respectively. In this paper, the K1190+463 section of Dashazui Tunnel is taken as the research object, and its surrounding rock is quartz phyllite. According to the field geological survey report, the Angle between K190+463 section and the tunnel axis is 317° , and the dip Angle is 51° .

Figure 1. Section diagram of K1190+463.

3 MECHANICAL PROPERTIES OF PHYLLITE

3.1 Microstructure analysis

The macroscopic failure of rock (tensile, shear) has different manifestations at the microscopic level, on the other hand, the microscopic fracture mode also determines the macroscopic failure behavior of rock. The block of rock sample is taken from the engineering site, processed, and then glued to the sample table with conductive adhesive for SEM scanning. The scanning effect of quartz phyllite under electron microscope when magnified to 20000 times is shown in Figure 3. The surface of the sample debris is smooth, and the details are composed of thin layered structures with uniform thickness. The proportion of the sample bedrock is much larger than that of mineral particles, and no scale blastoblastic structure is found. Quartz phyllite based on this project is a macroscopic anisotropic material composed of transverse isotropic planes superimposed.

Figure 2. 20,000x electron microscope scan.

3.2 Uniaxial triaxial compression experiment

3.2.1 Sample preparation

The rock samples used in this study were all taken from the K193+760 mile palm face of Dashazui Tunnel, and the core drilling machine was fixed with bolts on the palm face for sampling. After the sampling was completed, the samples were taken to the laboratory for cutting and processing, and the samples were prepared according to the engineering rock mass test method standard. Finally, 5 rock samples were formed, as shown in Figure 3.

The density of phyllite samples after water absorption was measured by free water absorption method, and the density parameters obtained were as follows:

3.2.2 Compression experiment

Two groups of samples were selected for uniaxial compression experiment, and the remaining three

Figure 3. Phyllite sample.

Table 1. Phyllite density parameter.

Sample number	1	2	3	4	5
Saturation density (kg/m ³)	2738.34	2712.89	2749.08	2731.68	2737.97
Mean density (kg/m ³)	2733.99				

groups were subjected to conventional triaxial compression experiment. The loading rate was controlled by axial displacement and set at 0.1mm/min until the specimens were completely destroyed. According to the sampling depth and subsequent numerical simulation requirements, the confining pressure conditions of the five samples are set as shown in Table 2. According to the experimental results, quartz phyllite is not an ideal elastic-plastic body, and its stress-strain curve can be divided into a compaction stage, an elastic stage and a strength cliff decline stage when the peak strength is reached.

Table 2. Normal triaxial compression test condition table.

Sample number	1	2	3	4	5
Confining pressure (MPa)	0	0	1	3	5

Poisson's ratio and elastic model quantity of phyllite samples can be obtained by calculating the elastic stage of stress-strain curve. Combining the three groups of triaxial test data, the average Poisson's ratio and elastic modulus of phyllite samples are 0.33 and 5.85GPa. By drawing the molar envelope of phyllite samples under different confining pressures, the internal friction Angle of quartz phyllite is 45° and the cohesion is 2.31MPa.

4 NUMERICAL CALCULATION

4.1 Model building

The length of K190+463 section of the right line of Dashazui Tunnel was selected as the calculation section, and the tunnel buried depth was 100m. In order to avoid the influence of boundary effect, the distance between the tunnel contour and the left and right borders as well as the bottom boundary was selected to be 4 times the hole diameter according to the Saint-Venant theorem, and the model size was 140m×60m×180m (as shown in Figure 4). The excavation method is three-step method, the circulation footage is 1.5m, and the step length is 6m.

Figure 4. Schematic diagram of numerical calculation model.

Considering the coordinated deformation of shotcrete and I-steel frame, and the primary support is mainly shear failure, the elastic modulus of the grille steel frame is converted to C25 shotcrete by using equivalent stiffness as the initial support parameter. In addition, considering that the secondary lining in actual construction is far away from the face of the palm, the force is mainly borne by the initial support of the tunnel, so only the initial support is activated in the calculation process. Cable unit is used to simulate the bolt. The section of Z5b lining adopts 3m long bolt with 1.2m spacing and plum blossom layout. The initial support parameters are shown in Table 3.

Table 3. Initial support parameter table.

Structure	Elasticity (GPa)	Poisson's ratio	Density (kg/m ³)	Thickness
Initial support	3.19	0.2	2614.06	0.24
Cable	210	0.2	7850	-

4.2 Mohr Coulomb model parameters

Considering that the whole surrounding rock is not homogeneous and dense in actual engineering, the surrounding rock parameters obtained by mechanical experiments directly used in numerical simulation will cause large errors. Considering lithology, rock formation occurrence, construction disturbance and other influencing factors, the rock mass strength parameters suitable for numerical calculation should also be reduced by Hoek-Brown strength criterion (E. Hoek et al., 2002). The Hoek-Brown strength criterion is calculated as follows:

$$\sigma_1 = \sigma_3 + \sigma_c \left(\frac{\sigma_3}{\sigma_c} m_b + s \right)^\alpha \quad (1)$$

$$m_b = m_i \exp\left(\frac{GSI - 100}{28 - D}\right) \quad (2)$$

$$s = \exp\left(\frac{GSI - 100}{9 - 3D}\right) \quad (3)$$

$$a = \frac{1}{2} + \frac{1}{6} (e^{-GSI/15} - e^{-20/3}) \quad (4)$$

Where: σ_1 is maximum principal stress of rock mass failure; σ_3 is minimum principal stress of rock mass failure; σ_c is uniaxial compressive strength of rock; m_b and s is H-B criterion empirical parameters; a is Coefficient of determining rock mass characteristics. m_i is Lithology index; D is disturbance factor; GSI is geological strength index of rock mass.

Among them, since the parameters are selected from the laboratory test, the GSI value is 100, $a=0.5$, $m_i=m_b$. The least square method was used to fit the previous uniaxial compression test and triaxial compression test data m_i . The result is that $m_i=23.31$.

Combined with the rock mass structure, weathering degree and structural plane state of the surrounding rock mass on the face of the tunnel construction site, and referring to the quantitative table of GSI index based on the macro-characteristics of rock mass given by Hoek-Brown, the geological strength index of rock mass GSI is determined to be 20. The value of the disturbance factor D is 0.7. Uniaxial compressive strength of rock (σ_c) is 11.04MPa. In addition, a is 0.52 and s is 3.93×10^{-2} . Equation (5) can be used to calculate the deformation modulus of surrounding rock.

$$E_m = \begin{cases} \left(1 - \frac{D}{2}\right) \sqrt{\frac{\sigma_c}{100}} 10^{\frac{(GSI-10)}{40}}, & (\sigma_c \leq 100MPa) \\ \left(1 - \frac{D}{2}\right) 10^{\frac{(GSI-10)}{40}}, & (\sigma_c > 100MPa) \end{cases} \quad (5)$$

Taking the H-B strength envelope as the object, the equivalent description of M-C criterion for rock mass strength is expressed by tangential or secant lines of σ_1 - σ_3 curves. The final solution is: $E_m=0.39GPa$, $\sigma_{cm}=0.92MPa$, $c=0.12MPa$, $\varphi=22.11^\circ$.

4.3 Ubiquitous-joint model parameter

Ubiquitous-joint model is based on the Mohr Coulomb model, and the joint surface is also subject to the Mohr Coulomb yield criterion. The failure of rock mass may occur in rock matrix and joint plane, or both. (Sainsbury et al., 2008) studied the modification of rock mass parameters of four types of rock mass: carbonate rock, phosphate rock, mica pyroxene and dolomite. The elastic modulus of rock mass is 30%~50% of the intact rock measured by triaxial test, the tensile strength is 36%~56% of the cohesive force, and the cohesive force of joint surface is 1%~0.1% of the rock mass. The friction Angle of joint surface is 10° ~ 21° smaller than that of rock. The parameters obtained from phyllite triaxial test of Dashazui Tunnel were selected for rock matrix reduction and joint plane parameters, as shown in Table 4.

4.4 Ubiquitous-joint model parameter

Under the Mohr Coulomb model, the tunnel arch settlement reaches 21.42mm, invert heave reaches 23.83mm, and the longitudinal displacement is large. The position of the side wall of the tunnel arch foot converges horizontally, and the maximum value reaches 15.15mm. Under the Ubiquitous-joint model, the deformation after tunnel excavation shows asymmetry, the maximum vertical settlement occurs at the left arch waist, and the horizontal displacement of the left arch waist is larger than that of the right arch waist. From the perspective of the plastic zone after excavation, under the Mohr Coulomb model, the failure of surrounding rock is mainly shear, and the development of plastic zone is relatively symmetrical (as shown in Figure 5). Under the Ubiquitous-joint model, the failure form of surrounding rock of the tunnel is mainly shear failure of the joint plane, and the most serious direction of failure is basically perpendicular to the dip Angle of the joint plane, that is, the vertical Angle of the dip Angle of the joint plane has serious damage and large deformation influence range, while the parallel joint plane inclination direction has light deformation and small damage range (as shown in

Table 4. Matrix and joint plane parameters of phyllite rock mass.

	Elasticity(GPa)	Angle of internal friction($^\circ$)	Cohesion(MPa)	Poisson's ratio	Tensile strength(MPa)
Rock mass matrix	1.5	45	2.31	0.33	0.92
Joint plane	-	15	0.00154	0.33	0.92

Figure 6). It can be seen that the deformation of phyllite tunnel shows obvious asymmetry under the influence of joint inclination.

Figure 5. Mohr Coulomb model plastic region cloud image.

Figure 6. Ubiquitous-joint model plastic region cloud image.

4.5 On-site measurements

Comparing the on-site monitoring data of Dashazui Tunnel K193+760 with the numerical simulation results of the above two types of models(as shown in Figure 7), it is obvious that the use of Ubiquitous-

joint model is the most suitable for the on-site displacement and deformation characteristics. From the on-site measurement results, the settlement of the left arch waist is larger than that of the right arch waist, the final settlement value of the left arch waist is 22.42mm, and the final settlement value of the right arch waist is 15.18mm. The use of the Ubiquitous-joint model matches the asymmetric deformation of the arch waist of the tunnel on-site. Using the Mohr Coulomb principle model with Hoek-Brown discount parameter, the settlement of the arch top is 21.42mm, which is in good agreement with the on-site monitoring data, but the left and right arch girdle settlements are equal to 19.81mm, and the error of the left arch girdle settlement is more than 40%. In addition, the horizontal convergence of the side wall measured in the field is about 6.81mm, which is relatively close to that calculated by the Ubiquitous-joint model. The horizontal convergence of the side wall calculated by Mohr Coulomb based on the Hoek-Brown reduced parameter is 13.97mm, which is significantly different from the on-site monitoring data. Comprehensive field test data, Ubiquitous-joint model is more suitable for the calculation of phyllite tunnels, and the calculated displacement maps and plastic zones are also in line with the general deformation characteristics of the laminated surrounding rock, the azimuthal displacement in the radial pressure perpendicular to the nodal surface is larger, and the shear damage impact zone is also larger.

Figure 7. Comparison of on-site measurement and numerical simulation.

5 CONCLUSIONS

This chapter relies on the K190+463 section mileage of the right line of the Dashazui Tunnel Project as the calculation section for numerical simulation, and uses the Mohr Coulomb constitutive model and Ubiquitous-joint model to carry out numerical simulation. The numerical simulation results are verified by field measurement data, and the following conclusions are drawn:

- (1) Based on the results of the triaxial compression test, the Hoek-Brown criterion was used to reduce the strength parameters of the rock mass suitable for numerical calculation. The numerical simulation results show that the vertical displacement, horizontal convergence, and the range of plastic zone of the tunnel have certain symmetry.
- (2) The joint plane parameters and rock mass matrix parameters are obtained by reducing the rock mechanics parameters using the Ubiquitous-joint model. The numerical simulation results show that the maximum vertical displacement and horizontal displacement of the tunnel do not appear in the vault and side wall because of the joint dip Angle. The range of plastic zone also shows asymmetry.
- (3) On-site monitoring data show that the settlement of the left arch girdle in K190+463 section is larger than that of the right arch girdle, and the overall deformation shows asymmetry. The asymmetric deformation indicates that the tunnel excavation section shows some concentrated damage due to the anisotropy of the phyllite rock mass. The results of the numerical simulation using the Ubiquitous-joint model are more consistent with the deformation and damage form of the surrounding rock in the field.

ABSTRACT: Planning and accommodation of underground metro stations in available land areas is an important aspect of any metro project. Designer has to adopt the innovative solution for station design due to limited space. To accommodate the station box within the available area, station may have to be constructed with the combined construction approach of NATM and cut and cover. In this approach main station box is constructed with a cut and cover method and platform tunnel is constructed with a NATM method. The sequence of construction can be simultaneous or opening of tunnel is carried out from the cut & cover shaft or TBM tunnel excavation is done before station excavation. Any underground excavation has a major influence on the nearby existing structures. This paper covers the various aspects of ground response to the interaction between strutted excavation and NATM tunnel excavation. Study of integrated excavation is carried out with varying the width of rock column between station excavation and NATM platform tunnel. The variations in the geological stratification and impact of different construction sequences are investigated.

1 INTRODUCTION

India has seen a huge development in the metro rail projects in the last 3 decades. Several Underground Metro projects have been constructed and many are in the under-construction and planning phase. Planning and design of the underground metro station is a challenging job. As most of the underground stations are planned in a densely populated area to gain more public ridership. Underground metro stations are usually planned under roads, empty ground. Planning of underground station under existing road has major issue i.e., protection of buildings adjacent to the metro station. One of the underground metro stations were planned in a densely populated area in Mumbai, on narrow roads, and in the station vicinity, several dilapidated buildings were present. Hence few stations were planned to construct with a mixed method of cut and cover for station box and NATM method for Platform tunnel. Owing to the presence of

buildings in the vicinity of the station footprint the possibility of a complete cut and cover station was not feasible. Hence the innovative idea of integrated NATM platform tunnel and cut & cover station excavation is adopted in many stations. This study inspires by the same case where the station box is being executed by adopting the methodology of cut and cover method and the platform is being constructed by the NATM tunnelling method [1]. Connection with station box and NATM platform is made with the intermediate cross passages at regular intervals. Research study emphasis on the behaviour of integrated cut and cover excavation and excavation of NATM tunnel using predictable element of soil-structure interaction analysis. The results response of ground under different parameters are presented in this paper.

Alignment of the underground metro is generally planned through a heavily built-up urban area. Many times, important Landmarks and Heritage structures are located nearby or directly above the tunnel

*Corresponding author: swarup.bec.civ@gmail.com

alignment. Owing to land availability constraints, cost of private properties, inadequate available road width, and the very important presence of Heritage buildings planning, and design of metro alignment is important part of any underground metro project.

The alignment of an underground metro project is constructed with twin tunnels by Tunnel Boring Machine (TBM) connecting two stations. The underground stations or shaft are generally proposed to be constructed by adopting the cut & cover construction methodology, and NATM method of construction and ground settlements are to be limited to protect existing buildings.

Due presence of a high-water table, high rise building imposes a higher surcharge load which leads to higher settlements; however, the designer has to control it well within the acceptable limit. In high water table areas generally, excavation is done with a water-tight retaining system to prevent ground settlements due to seepage during excavations. To maintain the water table in the non-excavated area proposal of the recharge well may be required.

The purpose of this study is to carry out the assessment of rock column between cut & cover station and NATM tunnels of one Underground Metro project in Mumbai. This paper provides an analysis for safety of rock column.

- ❖ In Preliminary stage, the rock column width was 2.6m based on tender stage GIR.
- ❖ During construction stage, after preparing actual GIR, Geotechnical parameters were revised, and rock quality is considered to be poor w.r.t Tender GIR. Rock column width needed to increase for stability of supporting system during excavation.

Following analyses are performed –

- a) Rock Column width 4m between cut & cover Station and NATM Tunnel
- b) Rock Column width 5m between cut & cover Station and NATM Tunnel

2 LITERATURE REVIEW

The settlement data from TBM tunnelling in varying ground condition which are representative of the Mumbai geology are analysed and presented in this section.

In the year 1958, Martos has examined the settlement trough shape on mining excavations, which was represented by a Gaussian or Normal distribution curve.

On the later stage, Schimdt, and Peck in the year 1969 has shown that surface settlement in the above tunnels were experienced in a similar form. O'Reilly and New has developed the Gaussian mode in the year 1982, by assuming that the ground loss could be represented by a radial flow of material towards the tunnel and that the trough could be related to the ground conditions through an empirical

“trough width parameter” (K). The model was guided by an analysis of case history data.

Due to the above assumptions, it was possible to develop equations for vertical and horizontal ground movements that were also presented in terms of ground strain, slope, and curvature (both at, and below, the ground surface). From there on, the equations are being widely used to access the potential impact of tunnelling works during the design stage. The base equation is as mentioned below.

$$S = S_{\max} \exp\left(\frac{-x^2}{2(kz)^2}\right) = \frac{AV}{(kz)\sqrt{2\pi}} \exp\left(\frac{-x^2}{2(kz)^2}\right)$$

Where S = ground settlement at a point; Smax = maximum ground settlement; A = cross-sectional area of tunnel; V = % of ground loss assuming the ground is incompressible i.e., V = Vs/A, where Vs is the volume loss; k = empirical constant also called as trough width parameter; and Z = depth of tunnel axis.

For an example, to determine /predict the ground movement only the following parameters were adopted /considered.

- ❖ Clough, O'Rourke and Peck adopted the excavation depth to determine ground movement as it is the only parameter.
- ❖ To predict the ground movement wherein the excavation depth is the main parameter in the formula, Bowles considered the area covered by lateral wall movement as a parameter.
- ❖ To predict the concave type and spandrel type of settlement profiles, Hsies and Ou used the excavation depth as the only parameter.
- ❖ Osman and Bolton adopted the plastic zone, which is completely related to the excavation depth and was the only parameter used in the prediction.

3 DESIGN OF TEMPORARY SUPPORT SYSTEM AND GEOLOGY

In combination of cut & cover and NATM underground metro station construction, there is access Tunnel at regular interval for connection between them. During excavation for access tunnel and Platform tunnel high stresses around the opening are to be checked and controlled. Therefore, rock column stability check is very important. This study has been performed using PLAXIS 2-D finite element analysis program.

As per requirement of Employer, all the tunnel sections shall be complied with Schedule of Dimension (SOD). The profile of Tunnel may be circular, D-Shape or horseshoe and it depends on the ground conditions. Here horse-shoe shape tunnel is considered. Cross sectional area of Tunnel is around 90.4 sqm., width is 11.2m and height is 10m. Overburden (soil mixed with rock) of 18m is considered above tunnel crown in this analysis. Actual geotechnical

profile and information is collected from GIR of project. Class IV and V rock are identified at final excavation level which is 28m below ground. For parallel construction and stability of the system, all the secant pile are terminated 4m below the final excavation level.

For stability analysis, following parameters have been considered in the model –

- Co-efficient of lateral earth pressure=0.5
- The soil is modelled by using Mohr-Coulomb material model
- Using Mohr-Coulomb material model, Rock mass is modelled where the strength and deformation properties are derived using Hoek and Brown criterion based on Hoek and Torres (2002).
- Water table at ground level
- Secant pile (combination of M40 - RCC and M10 - PCC) of 1m dia, 32m depth and 170mm overlap.
- All piles are 32m depth i.e., 4m below from final excavation level.
- 5 level struts are used for supporting of secant pile, horizontal spacing 10m c/c and vertical spacing 4.5m c/c.

Table 1. Properties of structural element.

Structural elements	Grade of Concrete	EA (kN/m)	EI (kN-m ² /m)
RCC Secant Pile (1m diameter)	M40	22.14E+06	645780
Sprayed concrete for primary Tunnel lining 200mm thick	M35	5.19E+06	19720

Table 2. Geotechnical parameters.

Material Type	Unit wt (kN/m ³)	Cohesion c (kPa)	Friction angle	Young's modulus E (MPa)	Poisson's Ratio
Soil	18	1	30	12	0.3
Completely weathered rock	20	27	29	423	0.3
Moderately weathered rock	25	148	55	685	0.3

Following construction stages are considered in the model:

1. In-situ stage
2. Installation of Secant Piles
3. Lowering of water table inside the cut & cover box 1m below – 1st level of strut
4. Excavation of soil up to 1m below 1st level strut
5. Installation of 1st level strut
6. Repeat the stage 3, 4, 5 till the last design strut is installed

7. Excavation of NATM tunnel profile
8. Installation of Primary support
9. Installation of full-strength primary tunnel lining along with wire mesh.

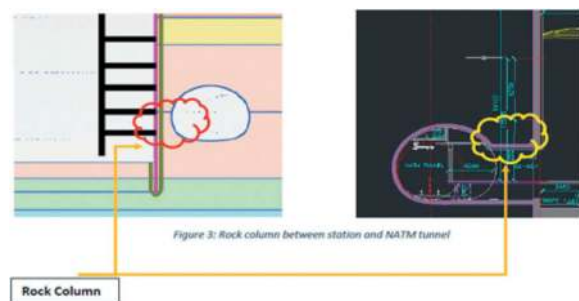

Figure 4. Rock column width.

4 METHODOLOGY

Analysis of the stability of rock column, properties of temporary support system and construction sequence are discussed here.

The geotechnical software PLAXIS 2D was used to study the soil-structure interaction between the cut & cover structure and NATM tunnel and its impact

on rock column stability. The software was used to provide the factor of safety of rock and soil for the proposed construction sequence.

Figure 5. Construction stage PLAXIS 2-D model.

5 ANALYSIS AND RESULTS

Initially rock column of 2.66m width is analysed. The analysis was carried out for this column width, and it was observed that the rock collapses in this scenario. Hence, the width between the cut & cover station box and NATM tunnel was increased to have lower concentration of stresses in the rock column.

Following analysis were performed –

- a) Rock column width of 4m between station and NATM Tunnel Plaxis output for Rock column stability (4m wide) considering 30% Relaxation –

Figure 6. Total displacement after final excavation of cut & cover Box: 43mm.

Figure 7. Maximum Total displacement near ground surface after NATM Construction: 50mm.

Figure 8. Total stress after final excavation of cut & cover Box.

Maximum value = 1822 kPa
Minimum value = -9982 kPa

Figure 9. Total stress after construction of NATM lining.

Maximum value = 1895 kPa
 Minimum value = -10.10×10^3 kPa

Figure 10. The factor of safety with column width 4m between station and NATM Tunnel.

b) Rock column width of 5m between station and NATM Tunnel Plaxis output for Rock column stability (5m wide) considering 30% Relaxation –

Figure 11. Maximum Total displacement near ground surface after final level excavation of cut & cover Box: 32mm.

Figure 12. Maximum Total displacement near ground surface after NATM construction: 39mm.

Maximum value = 1673 kPa
 Minimum value = -8157 kPa
 Maximum value = 1787 kPa
 Minimum value = -9067 kPa

6 DISCUSSION AND CONCLUSION

To understand the complex soil-structure interaction Two-dimensional FEM modelling is used, involving cut & cover excavation with an adjacent NATM

Figure 13. Total stress after final excavation of cut & Cover Box.

Figure 14. Total stress after construction of NATM lining.

Tunnel. It is observed that the excavation of Tunnel adjacent to the cut & cover box excavation influences the ground behavior along with the behavior of earth retaining system.

Geological stratification has major impact on tunnel design. Increase in rock column width, there is reduce of ground settlement and reduce of total stress.

Excavation of tunnel will cause a short-term loss of ground water due to which the unbalanced load path is imposed on earth retaining system of supporting cut & cover excavation. The unbalanced loading conditions increases the displacement of secant pile on the fair side of tunnel excavation. The loss of ground water can be controlled by installing a grout curtain around the tunnel profile before the start of excavation along with recharge wells.

It is observed that the tunnel excavation induces additional stress on the rock column and causes the rock column deformation. After excavation of tunnel, surface settlements increase immediately. The maximum surface settlements are observed immediately behind the secant pile. The width of rock column appears to have no major effect on the magnitude of maximum surface settlements. The slope of settlement trough is influence by the rock column width.

Table 3. Comparison of result of different rock column.

Rock Column width	Total displacement after final excavation of cut & cover Box	Maximum Total displacement near ground surface after NATM Construction	Total stress after final excavation of cut & cover Box	Total stress after construction of NATM lining	FOS
4m Rock Column width	43mm	50mm	Maximum value = 1822 kPa Minimum value = -9982 kPa ²	Maximum value = 1895 kPa Minimum value = -10100 kPa	2.2
5m Rock Column width	32mm	39mm	Maximum value = 1673 kPa Minimum value = -8157 kPa	Maximum value = 1787 kPa Minimum value = -9067 kPa	2.8

Table 4. Actual displacement and stress for 5m rock column.

Rock Column width	Total displacement after near ground surface final excavation of cut & cover Box	Total displacement near ground surface after NATM Construction	Total stress after final excavation of cut & cover Box	Total stress after construction of NATM lining
5m Rock Column width	18 mm	21 mm	Maximum value = 903 kPa Minimum value = -5272 kPa	Maximum value = 988 kPa Minimum value = -5887 kPa

Figure 15. The factor of safety with column width 5m between station and NATM Tunnel.

Adjacent cut & cover excavation has an influence on the behavior of tunnel excavation. Tunnel lining was subjected to higher deformation at the face wall adjacent to the open excavation and deformation increased with reduction in width of the rock column.

From the analysis, it is concluded that the minimum width of rock column between station and NATM tunnel shall be 5m to achieve FOS of 2.8. A sensitivity analysis was carried out for 4m wide rock column, and the analysis was not successful (i.e., FOS < 2.5), confirming that the minimum width of rock column shall be 5m for these geological conditions.

The freezing technique for the world's longest railway tunnel

A. Marottoli, M. Ianeselli, R. Marrazzo*, A. Gallotto, G. Vecchione, M. Cavolo & F. Gallo
Brenner Basis Tunnel BBT-SE, Bolzano-Fortezza, Italy

ABSTRACT: The Brenner Base Tunnel is a railway tunnel infrastructure under construction as part of an Italian-Austrian civil engineering project. It will connect Fortezza to Innsbruck, running under the Brenner Pass. The 'Isarco River Underpass' construction lot, the southernmost part of the entire infrastructure, overcame the major geotechnical difficulties encountered with the use of innovative technologies. These included artificial ground freezing and pre-consolidation of the excavation faces by means of Quick Set Jet Grouting (QSJG) and Roto Injection Controlled Parameters (RICP).

This article focuses on the adoption of artificial ground freezing technology as a consolidation technique for the construction of the four tunnel stretches connecting four shafts under the Isarco river, where the ground is characterised by the presence of loose debris material.

Artificial ground freezing is a 100% eco-friendly technology that, through the use of special cooling fluids circulating in suitable pipes, directly freezes the water in the ground without any product being injected and dispersed into the soil and/or groundwater.

For the Isarco River Underpass, the 'mixed method' was used, i.e. a rapid-freezing phase using liquid nitrogen followed by a longer temperature maintenance phase using brine, switching between the two phases only once the target temperatures defined by the planner had been reached. Before proceeding with the excavation, the drains inside the excavation core were opened in order to empty it and to verify the effectiveness of the freezing process by noting that water inflow had stopped.

Thanks to this solution, the excavation of the four tunnels under the Isarco River was completed without any particular problem, avoiding more invasive interventions such as the temporary displacement of the river and its subsequent repositioning in its natural location.

Keywords: ground improvement, artificial ground freezing, conventional tunnelling, temperature field, heat transfer

1 INTRODUCTION

The Brenner Base Tunnel is a railway tunnel currently under construction within an Italian-Austrian civil engineering project. It will connect Fortezza to Innsbruck, running under the Brenner Pass.

The Brenner Pass is one of the most important links between northern and southern Europe. At 1,371 metres above sea level, it is the lowest pass in the entire Alpine range and for this reason has always been considered strategic from an economic and commercial point of view. In order to cope with the continuous increase in the amount of goods transported, two major transport infrastructures were built: the historic Brenner railway in the second half of the 19th century and, about 100 years later, the A22 Brenner motorway.

150 years after its inauguration, the existing Brenner railway line continues to play a major role as

a connecting axis between Italy and Austria, but its route is very winding and steep, with tight curves and sections with a gradient of 26 ‰. These two factors severely limit train speeds and load ceilings and, considering the cost of the vehicles needed to move the trains, the high consumption of electricity and the long journey times, road transport has been preferred to railway infrastructure for freight haulage, with a consequent increase in environmental impact.

In 1994, the European Union promoted and developed the TEN-T (Trans European Network-Transport) rail transport network, with the aim of shifting the increasingly heavy flow of road traffic onto rail and in order to support the single market, guarantee the free movement of goods and persons and strengthen the growth and competitiveness of the Union. Nine TEN-T corridors have been defined, touching all EU member states and linking the most important seaports

*Corresponding author: Roberta.Marrazzo@bbt-se.com

with railway infrastructure and access to main road arteries.

The Brenner Base Tunnel will be the central element of the Scandinavian-Mediterranean Corridor, running from Helsinki in Finland to Valletta on the island of Malta for a total length of approximately 7,500 km (Figure 1).

Figure 1. European union TEN-T corridors.

The new Brenner Base Tunnel will connect the village of Fortezza, about 50 km north of Bolzano, with the town of Innsbruck in Austria. It is defined as a “Base” tunnel precisely because it will be built at the base of the Brenner Pass at an altitude of 794 m above sea level, with an almost flat and straight route. When completed, it will be 55 km long compared to the 75 km of the existing line, with a maximum slope of approximately 7 ‰ (Figure 2).

Figure 2. Comparison of the existing railway line and the future Brenner Base Tunnel.

On the new track, trains will thus be able to travel at a maximum speed of 250 km/h, cutting journey times from the current 80 minutes to just 25 minutes. Near Innsbruck the new tunnel will connect to the existing bypass around this Austrian city and thus reach a total length of 64 km, holding the record for the longest underground railway link in the world (Marottoli et al., 2022).

2 THE ISARCO RIVER UNDERPASS LOT

The construction of the Brenner Base Tunnel is an important engineering challenge, due to the size and the complexity of the works.

The Isarco underpass construction lot is the southernmost part of the Brenner Base Tunnel before entering the railway station in Fortezza and it is located approximately 1 km north of the town of Fortezza, in the Prà di Sopra neighbourhood (BZ).

The works were awarded in October 2014 to the bidding consortium that included Webuild Italia S.p.a, Strabag S.p.A./AG, Collini Lavori S.p.A. and Consorzio Integra.

The project area lies in the narrow valley floor, which is only a few hundred metres wide and enclosed by steep rock walls. In the middle of this area (Figure 3) we can see the Isarco river, highlighted in light blue, the transport infrastructures of the A22 motorway in green, the State Road 12 in red and the historical Brenner railway line in yellow, all of which therefore represent major interferences with the route of the tunnels, highlighted in blue.

Figure 3. Valley floor and route of the Isarco River Underpass lot.

The works in this lot, which is interdependent with the other lots in the project, include the construction of approximately 4.5 km of two main tubes and two interconnecting tunnels that link to the existing railway line, for a total of approximately 1.7 km. The lot also includes preparatory external works such as re-routing the SS12 state road, the construction of a bridge over the Isarco river, a bridge over the Rio Bianco brook, an underpass below the Brenner railway line, and the construction of the loading/unloading area on the A22, which makes it possible to handle incoming and outgoing transports without interfering with the local road system.

The tunnels are excavated entirely using conventional drilling and blasting techniques and divided into the following main parts (Figures 4):

- line tunnels, even and odd tracks north of the Isarco (in red);
- line tunnels, even and odd tracks south of the Isarco (in green);

Figure 4. Map of the isarco river underpass lot.

- interconnection tunnel with the existing line, even track south of the Isarco (in yellow);
- interconnection tunnel with the existing line, odd-numbered track south of the Isarco (in light blue);
- line and interconnection tunnels, even and odd tracks, below the Isarco river (4 tunnels, in blue);
- southern entrance portals of the Brenner Base Tunnel, located in the area of Fortezza station;
- emergency exit.

In the Isarco Underpass lot, the tunnels are characterised by generally limited overburdens, single- and double-track excavation sections, and extremely variable geological conditions, ranging from excavations through Brixner granite at the beginning and end of the lot to excavations through scree below the water table to the Isarco Underpass, which is driven through alluvial material also below the water table.

In order to cope with these very different geological conditions, different excavation techniques were used:

- “drill and blast”, excavation with explosives: used in the initial and final sections of the lot where the usually compact Brixner granite is present;
- excavation in granular material with advance consolidation: used in sections preceding rock mass characterised by coarse granular material in a sandy matrix with boulders several metres in size, with single-fluid jet-grouting columns and cement injections;
- excavation in granular material with consolidation from ground level: used in the sections near the Isarco River characterised by overburdens of less than 10-12 m in coarse alluvial soils in a sandy matrix with boulders several metres in size, with vertical bifluid jet-grouting columns;
- cut-and-cover tunnels and large shafts (surface area from approx. 800m² to approx. 1600m²) constructed with consolidation from ground level. The shafts were necessary both to execute the freezing work for the river underpass and as starting points for the excavation of the tunnels north of the Isarco. These works were realised with vertical bi-fluid jet-grouting columns for both the walls and the bottom cap, excavated and encased in reinforced concrete with subsequent wall consolidation;
- excavation in granular material with consolidation using artificial ground freezing. This technique will be explored in more detail in the following paragraphs.

3 ARTIFICIAL GROUND FREEZING TECHNIQUE IN THE ISARCO RIVER UNDERPASS

The crucial point of the entire project is the excavation under the Isarco River of four full-bore tunnels, starting from four shafts approximately 30 metres deep and 60-80 metres in diameter (Figure 5).

Figure 5. View from above of the 4 large shafts on the banks of the Isarco River.

The final approved project for the Brenner Base Tunnel envisaged the construction of an underpass beneath the Isarco river with cut-and-cover tunnels and the temporary diversion of the river into a specially constructed concrete basin, the bottom of which was lined with river stones embedded in concrete.

According to the executive design, on the other hand, the underpass was to have 4 tunnels driven from underground, hereinafter referred to as GNIDI, GNBDI, GNBPI and GNIPI (Figure 6), driven with full-section excavation from shafts placed laterally to the riverbed, after consolidation works were carried out using soil freezing technology. Pre-consolidation work was necessary in order to reduce underground water flow velocity and facilitate the freezing phase by acting on the permeability of the soil.

Choosing this method avoided the displacement of the Isarco river and protected the local environment, as only minimal in-bed displacement was required during the dry season to allow for the construction of the works to protect the river itself.

In order to use the freezing technique to consolidate the ground around the 4 tunnels connecting the south shafts to the north shafts, a so-called ‘mixed method’ was adopted, flushing a cooling liquid inside special heat exchangers, hereafter referred to as freezing probes.

Figure 6. Detail of the map of the Isarco river underpass lot.

The starting point for the flushing of the coolant was the walls of the north and south shafts (Figure 7), at the specific section of the tunnel to be driven, in two distinct phases:

- Phase one - liquid nitrogen freezing (open or direct circuit): compressed liquid nitrogen is circulated at a temperature of -196°C inside the freezing probes and dispersed into the

Figure 7. View of the GNBDI south portal and detail of the freezing probes.

Figure 8. View of nitrogen vents.

environment as a gas at a temperature between -100 and -60°C (Figure 8). In this phase there is an accretion of an ice wall around the area to be excavated, with subsequent closure and achievement of the design thickness and temperature;

- Phase two - brine maintenance (closed or indirect circuit): the brine is an aqueous solution of calcium chloride with a freezing point between -40°C and -50°C , which is circulated at an approximate temperature of -35°C . On leaving the freezer probes, after subtracting heat from the ground and warming up by about $2/3^{\circ}\text{C}$, this liquid returns to the refrigeration system to be cooled and sent back to the freezer probes. In this phase, enough calories are extracted from the soil to maintain the geometric dimensions and characteristics of the soil frozen in the previous phase, without increasing its size.

This 'mixed method' was necessary to optimise execution times, minimise freezing times by using the direct nitrogen cycle, and for subsequent temperature maintenance throughout the excavation, waterproofing and final lining of the tunnels. This choice therefore required two separate and adjacent, but obviously complementary, site facilities to manage these two distinct soil freezing phases (Marottoli et al., 2020).

The liquid nitrogen (N_2) storage refrigeration plant included four double-walled tanks, with a storage capacity of 50,000 litres/each, connected in series, therefore with a total storage capacity of 200,000 litres. These tanks were equipped with a liquid nitrogen vaporisation and pressure system that allows the liquid nitrogen to be fed to the freezer probes without the use of a pumping system. The 4 tanks were installed not far from the shafts from which the freezing operations preparatory to the excavation of the 4 tunnels were launched. (Figure 9).

Figure 9. Liquid nitrogen supply to the storage facility.

Compressed liquid nitrogen at -196°C was conveyed from the silos to the two north and south portals at the entrance to the tunnels inside special sealed stainless-steel header pipes that maintained

the nitrogen's physical characteristics until it flowed into the freezer probe.

The brine plant (Figure 10) included three refrigeration units with an installed capacity of 240 kW each, for a total available capacity of 720 kW. Only two of the three installed refrigeration units were used during the freezing maintenance phase, to allow for rotating maintenance of these three pieces of equipment.

Figure 10. Brine storage plant.

The freezing probes consist of two coaxial pipes: the inner pipe, in stainless steel with a diameter of 42 mm and a thickness of 1.5 mm, from which the refrigerant fluid was delivered to the system, and the outer pipe, made of AISI stainless steel with a diameter of 76.10 mm and a thickness of 3.00 mm, through which the refrigerant fluid flowed back to the outside. The two tubes were connected at the head by a special distribution or 'freezing head'.

Prior to the installation of the stainless-steel pipes, sub-horizontal boreholes were drilled from inside the shafts around the perimeter of the future tunnel using drilling equipment specifically designed and engineered for the Isarco River Underpass works; within these boreholes and at the same time as the drilling phase, steel pipes with a diameter of 114 mm were laid, equipped with a disposable drill bit engineered to prevent groundwater from penetrating the pipe itself. These tubes also protected the freezing probes during the subsequent excavation phases.

In order to maintain the interaxis distances according to the design and allow the ice wall to be distributed as evenly as possible, the position of the freezer probes and thus of the corresponding probe holder tubes (114 mm) was constantly measured with a special inclinometer (Gyro by Reflex Instruments) which, by means of gyroscopes and

accelerometers, made it possible to detect and three-dimensionally reconstruct the geometry of each individual probe with an azimuth tolerance of 1%.

To verify the effectiveness of the freezing and maintenance phases, temperatures were monitored by thermometric chains inserted inside the tubes used for the consolidation injections, except for several outermost ones.

The thermometer chains were constructed using fibre-optic technology, which allows a high number of measurement points, with continuous measurements every 25 cm along the length of the probe itself, in order to simplify data management.

3.1 Three-dimensional modelling

For ground freezing to be successful, the need for additional drilling should be assessed on a case-by-case basis, depending on the actual spacing of the probes. To this end, the deflections of all the boreholes intended to house the freezer probes were measured in order to reconstruct a three-dimensional model (Figures 11).

Figure 11. Construction of the 3D model for controlling deviations.

This model also made it possible to assess cases in which the probes came too close to the theoretical excavation profile by taking a minimum distance of 10 cm as a safety reference, below which it was decided not to equip the borehole with the freezer probe, or to equip it with a shorter probe in order to avoid the risk of damaging the probe during excavation operations.

3.2 Design requirement

The design requirements for the excavation of the tunnels were defined as follows: a maintained continuous ice wall with a thickness of at least 1.00 m, considering the temperature limit as -10°C with the non-permeability of the ice wall.

For the first requirement, target temperatures for each thermometer probe were defined by the designer as a function of the actual distance from the freezing probes, using a numerical finite element calculation model (TEMP-W from Geoslope).

The calculations to define the target temperatures were carried out considering the actual ground temperatures measured a few days before the start of the freezing treatment by means of the thermometric chains in place, taking into consideration the location of the probes and their position in relation to the excavation profile and verifying, for each of the measuring points, that the thickness of the frozen ground wall had been reached at temperatures not exceeding -10°C .

For each section analysed (every 3 metres), the crown of freezer probes was divided into sectors, each of which monitored by a particular thermometer probe. Each target, therefore, corresponds to the maximum temperature that can be reached in the sensor in order for the planned thickness of frozen ground to be reached at -10°C at the most critical point in the sector. Such critical points can be caused either by excessive spacing between probes, by abnormal deviations, or by failure to achieve continuity between the probes of opposite fronts.

The use of a numerical finite element calculation model is certainly beneficial, as it is more accurate than purely theoretical models, such as that of

Figure 12. Typical section per executive design showing the location of DR1, DR2 and DR3 drains.

Figure 13 Graphs of the GNIDI KB thermometer probe from the south portal

Figure 13. Graphs of the GNIDI KB thermometer probe from the south portal.

Sanger & Sayles (1979), as it takes into account all the boundary conditions and various factors that would otherwise not be considered (such as, for example, the overlapping effects of two or more freezing probes on the same sensor). However, it should be noted that there are still uncontrollable variables, such as the reliability of deviation measurements, which risk partially negating the effort required to implement such a sophisticated method.

In addition, the thickness of the ice wall is constrained not only by the spacing of the freezing probes but also, and above all, by time and by the quantity of the cooling fluid, and is guaranteed by the analysis of the three-dimensional model and any corrective actions at critical points.

In order to reach the required non-permeability, the drains located within the excavation core, which can be seen in Figure 12, were opened and therefore emptied prior to excavation.

In order to verify the presence of a continuous and therefore impermeable ice wall and, therefore, the effectiveness of the freezing phase, it is crucial that residual flow rates in the soil inside the ice wall be around 0 l/min.

3.3 Temperature analysis

Monitoring of the freezing technique implemented for the 4 tunnels was carried out with the following diagrams, evaluating the temperatures recorded by

the sensors of the thermometric probes every 3.00 m and carefully comparing the measured values with the target values foreseen by the designer.

- *Temperature-Distance from the excavation front*, which shows the trend of the temperatures measured along the thermometric probe as a function of the distance from the section at 0 m. This graphic representation makes it possible to visualise any increases or decreases in temperature and to study temperature evolution as the days go by. This diagram also shows the designer-defined target temperatures for each section;
- *Temperature-Time*, which makes it possible to evaluate for each sensor the temperature trend during the entire freezing process.

By way of example, the graphs referring to the freezing and maintenance phases of the GNIDI tunnel, the eastern interconnection tunnel excavated under the Isarco river, for which the first phase of nitrogen freezing began on 20/09/2021 and was interrupted on 28/09/2021 by the southern portal and on 29/09/2021 by the northern portal, thus totalling 9 days. The interruption of the nitrogen flow is followed by a waiting period that allows the freezing probes to reach, along their entire length, a temperature of around -45°C , i.e. a few degrees higher than phase transition (solidification) temperature of the brine. Brine flow therefore started about 24 hours later for both portals.

The following figure shows the graphs referring to the GNIDI KB thermometer probe from the South portal (Figure 13).

The *Temperature-Distance-to-Front-of-Attachment* graph clearly shows that, for this thermometer probe, even before the nitrogen flow was interrupted, temperatures below the target values visible from the green dashed curve were reached along all points of the probe under investigation.

It is important to note that, as the days pass, the temperature along the entire thermometer probe decreases almost constantly, with lower temperatures, even around -20°C , in the sections furthest away from 0 m. This happens because the furthest sections correspond to the overlap zone of the freezing probes, which is about 2 m, where we also have the effect of the probes from the other shaft.

In this area, the freezing probes are actually staggered so as to create an overlap zone necessary to minimise the risk of intersection.

Furthermore, it is useful to point out that the thermometer sensors, evaluated every 3 m, are different from probe to probe due to the inclination of the shaft front and therefore depend on the actual position with respect to it and to the section considered. For example, at the section at 0 m, the KB probe is 2.02 m from the front and the sensor to be considered, therefore, is the sensor at 2.00 m

The *Temperature-Time* graph shows how, when the nitrogen flow is suspended (dashed green line), there is a rise in temperatures within the frozen soil

shell, with a subsequent drop again following the start of the holding phase with the brine flushing (dashed pink line).

As the days pass, however, one observes a stabilisation at temperature levels compatible with brine circulation (Figures 14).

Figure 14. Graphs of the GNIDI KB thermometer probe from the south portal in the immediate brine phase.

Keeping the brine maintenance phase active, after verifying that the design requirements had been met, the excavation phases began with the demolition of the wall and the shaft structure until reaching the area of ground under the Isarco River, which at that point was well consolidated and dry with a visible band of frozen ground within the excavation profile (Figure 15).

The excavation was carried out with conventional methods, using hydraulic hammers on crawler excavators with an average advancement speed of 2.7 m/day, for excavation depths of approximately 1.00 m and a first stage lining with protective ribs and shotcrete at the contour and face, up to completion of the section.

Tunnel excavation operations lead to a rise in temperature, detected by thermometric probes at the excavation progress. As an example, the following figure (Figure 16) shows the progress of the excavation for the KG probe from the north of the GNIDI during different 24-hour windows, with temperatures rising in the sensors as the chainages progress.

Once the actual excavation phase was completed, during which the temperature trends were constantly monitored, the subsequent construction phases of the tunnels were carried out, including the excavation of

the inverted arch in segments of approximately 12.50 m, the laying of waterproofing sheets and the laying of the reinforcement with the subsequent casting of the final lining, up to the completion of the tunnel (Figure 17).

Figure 15. Band of frozen soil within the excavation profile.

Figure 16. Graph of the GNIDI KG thermometer probe from the north portal during the excavation phases.

Figure 17. Tunnel completion.

It was only after the final lining of the tunnel was completed that brine flushing was stopped, on 08/12/2021, for a total of approximately 70 days.

The timing of the individual work phases for each tunnel section under the Isarco River, which were carried out in partial overlap with each other, was as follows. The preliminary phase, with the pre-consolidation work, permeability tests, measurement of deviations, installation of the freezing probes and equipping of the portals lasted approx. 5 months; the freezing and maintenance phase, with temperature monitoring and drainage tests, lasted approximately 3.5 months and the excavation and lining phase lasted approximately 3 months.

In total, the construction of each individual tunnel took about nine months.

The excavation of the four tunnels under the Isarco River was completed on 07.04.2022 (Figure 18).

Figure 18. Final breakthrough under the Isarco river: GNBDI tunnel on 07/04/2022.

4 CONCLUSIONS

It can therefore be confirmed that the technique of artificially freezing the ground is certainly the best alternative to other consolidation techniques normally used to protect excavations in the presence of water, which would also have involved more invasive and environmentally high-impact interventions, such as temporarily re-routing the river and subsequently returning it to its natural bed. In fact, this technique, where economically feasible, makes it possible to temporarily modify the characteristics of

the soil in terms of both non-permeability and the actual mechanical properties of the soil, both of which are significantly improved, thus enabling the safe excavation and construction of tunnels below the water table and beneath the river bed.

It is important to emphasise that successful freezing takes place in several stages, with the flow of refrigerants being only the final step.

Particular importance must be given to the drilling phase prior to the installation of the pipes and their deflection measurement. In fact, the evaluation of temperature trends can only properly monitor the formation and development of the ice shell, and analyse any

anomalies that may occur, if the drilling deflections are measured correctly and as precisely as possible.

Stability of portal slopes of a diversion tunnel after the Kahramanmaraş, Turkey (Türkiye) February 6, 2023 Earthquakes

Ahmet Ali Mert* & Fatih Caliskan

General Directorate of State Hydraulic Works, Dams and HEPP Department, Ankara, Turkey

ABSTRACT: This study delves into the stability challenges faced by portal slopes in a diversion tunnel, particularly post-Kahramanmaraş earthquakes in Turkey (February 6, 2023). Geotechnical issues, notably slope failures in portal areas, pose significant threats to tunnel safety and operability. The research analyzes both pre- and post-earthquake scenarios, employing methods like limit equilibrium and pseudo-static analyses. The investigation identifies parameters influencing portal slopes and assesses their behavior under static and dynamic loads. Solutions, including the use of fill and slope flattening (terracing) as a rehabilitation method, are proposed based on comprehensive analyses, field studies, laboratory experiments, and topographic data. The findings contribute valuable insights to combat stability problems in tunnel portal slopes, emphasizing their importance for tunnel safety and longevity. The study aims to guide engineers in developing safer and sustainable solutions for diversion tunnel projects, ultimately enhancing the overall stability and performance of portal slopes.

Keywords: Slope stability, Dams, Diversion tunnels, Earthquakes, Limit equilibrium, Pseudo-static analysis

1 INTRODUCTION

In order Slope stability is an important topic in geotechnical engineering that deals with the assessment of the potential failure or deformation of natural or artificial slopes due to various factors, such as gravity, seepage, external loads, seismicity, and weathering (Day, 2006). Slope stability analysis is necessary for the design and construction of various civil engineering structures, such as dams, embankments, roads, tunnels, excavations, and mines. Slope failure can cause significant economic losses, environmental damages, and human casualties. Therefore, it is essential to evaluate the stability of slopes under different conditions and scenarios using suitable methods and tools.

One of the difficult problems in slope stability analysis is the stability of tunnel portal slopes. Tunnel portals are the openings or entrances of tunnels that connect the underground space with the surface. Tunnel portals are often located on steep slopes that are susceptible to instability due to the excavation process and the presence of weak or fractured rock masses. Moreover, tunnel portals may be exposed to dynamic loads from earthquakes, blasting, or traffic that can generate additional stresses and deformations

on the slope. Therefore, tunnel portal slopes need careful design and reinforcement to ensure their safety and functionality (Wang, 2019).

Popescu (2001) conducted a study in which he proposed a concise set of measures to mitigate landslides and recommended a specific format for documenting these landslide remediation efforts (Table 1).

Fatkhiandari et al. (2020) evaluated stability at the Bagong Dam tunnel portals under static and seismic loads using the finite element method. Despite earthquake-induced reductions in the Strength Reduction Factor (SRF), both natural and excavated slopes maintained relative stability.

Oktarina et al. (2023) assessed the stability of Tunnel No. 8 outlet portal under traffic loads, recommending shotcrete reinforcement to prevent instability and landslides in weak rock masses.

Sengkey et al. (2023) analyzed the diversion tunnel portal slopes at Manikin Dam, finding stability issues in the inlet portal slope due to poor mechanical properties of Bobonaro clay.

Huda et al. (2022) studied Lau Simeme Dam's diversion tunnel portals, emphasizing stability under static and earthquake loads. Shotcrete reinforcement was suggested for enhanced stability in poor rock mass conditions.

4	Internal Slope Reinforcement	4.1 Application of rock bolts
		4.2 Installation of micropiles
		4.3 Implementation of soil nailing techniques
		4.4 Use of anchors, whether pre-stressed or not
		4.5 Application of grouting
		4.6 Creation of stone or lime/cement columns

This study examines stability challenges in diversion tunnel portal slopes, focusing on post-Kahramanmaraş earthquakes in Turkey (February 6, 2023). The earthquakes, magnitudes 7.8 and 7.5, caused widespread damage and numerous fatalities. Portal slope failures pose significant threats to tunnel safety. The research utilizes limit equilibrium and pseudo-static analyses for both pre- and post-earthquake scenarios. Limit equilibrium assesses slope stability by calculating the factor of safety, while pseudo-static analysis simplifies seismic slope stability with constant seismic coefficients (Naseer & Evans, 2020; Hammouri et al., 2008). The investigation identifies parameters influencing portal slopes under static and dynamic loads, proposing solutions such as fill application and slope flattening. Fill material enhances stability by increasing normal stress, reducing pore water pressure, and adding

resistance along the potential slip surface (Wang, 2019). The study provides crucial insights for addressing stability issues in tunnel portal slopes, emphasizing their significance for tunnel safety and durability. Intended to guide engineers in developing safer, sustainable solutions for diversion tunnel projects, the research aims to enhance overall stability and efficiency of portal slopes.

2 METHODOLOGY

The dam project involved initial investigations, including 24 foundation borings with a total depth of 1108 m, conducted during the planning stage. These borings were distributed among the dam location (17), two axis locations (17), diversion location (2), spillway route (2), and transmission tunnel (3). In the final project phase, 13 boreholes with a total depth of 400 m were drilled at the dam and construction sites, and 6 boreholes with a total depth of 95 m were drilled at the siphon site on the transmission line. Additionally, 63 pressuremeter tests were performed in 4 boreholes at the dam site.

Parameters for the Rock Mass Rating (RMR) classification method were determined by evaluating field observations, drilling and field studies, literature data, and factors such as weathering, discontinuity conditions, unit boundaries, distribution, and measurements. The RMR method considers parameters related to Rock Quality Designation (RQD), uniaxial compressive strength, joint frequency, joint location, groundwater conditions, and the relationship of the dominant joint system with the slope.

Slope stability analyses were conducted for both inlet and outlet portals, employing the limit equilibrium method for static and seismic conditions (Simplified Bishop, GLE/Morgenstern-Price, Spencer). Pseudo-static slope stability analysis, a simplified approach considering seismic forces as an equivalent static force, was used for seismic conditions. This method assumes instantaneous seismic forces and slope failure under pseudo-static conditions (Duncan and Wright, 2005).

The limit equilibrium analysis involved calculating resisting forces (e.g., frictional forces) and driving forces (e.g., seismic forces, loads) to determine the factor of safety. Analyses considered landslide conditions, landslide prevention support cases, and the aftermath of the February 6, 2023 Kahramanmaraş earthquakes, with corresponding results and recommendations presented.

3 SITE DESCRIPTION

The Ophiolitic complex sediments (Ofk-s) in the project area consist of clay-altered, dispersed, loose, unstable, silicified-radiolarite conglomeratic limestone, and serpentinite blocks. This formation is prevalent at the dam axis, diversion, spillway,

relocation roads, post-siphon end sections of the transmission line, and tunnel portal area. Drillings in this formation (Ofk-s) consistently reveal core percentages between 42% and 71%, with an RQD of 0%, indicating a weak and very weak rock mass.

Numerous landslides, both old and active, along with runoff occurrences are observed at the dam axis, mainly within the sedimentary levels of the Ophiolite Complex (Ofk-s). The high alteration of the unit, coupled with weakly cemented clay, sand, gravel, and block-sized material, leads to water absorption during rainy seasons. This absorption causes clay layers to swell, increasing the mass's weight and resulting in mud flow along the slopes.

Vertical faults have developed in the project area within the Ophiolite Complex and at the junction of this unit and the Midyat Formation. Another important fault is the reverse fault at the junction of the Ultrabasics (Ofk-u) and Volcanites (Ofk -v) within the Ophiolite Complex. The ophiolite unit was observed in the field as weakly to very weakly fractured, fragmented and weathered with the influence of these faults and the Eastern Anatolian fault line.

At the inlet and outlet portals and side slope excavations of the diversion tunnel, it was observed that the unit consists of silicified radiolarite units of the ophiolite complex which is clayified, dispersed, weak-very weak rock in places. The portal location is on the dry stream route and water discharge during rainfall comes to the portal excavation slopes through this stream. This unit is clayified in contact with water such as rain and snow, causing surface flows and landslides.

Below are the obtained geotechnical parameters to be used in analyses.

Table 2. General geotechnical parameters.

Parameters	Cohesion (kPa)	Internal Friction Angle (°)
Very weak altered rock near the surface	25	3
Compacted unsorted material to be used in the embankment	5	25
Rock fill	0	40

Table 3. Ophiolite complex laboratory test results.

Depth (m)	Unit Weight (g/cm ³)	Uniaxial Compression Strength (kg/cm ³)	Modulus of Elasticity (kg/cm ³)	Poisson's Ratio	Point Load Test	
					Is ₅₀ (MPa)	q _u (kg/cm ²)
36.20-36.40	2.57	162.9	41681	0.26	-	-
45.40-45.60	2.55	-	-	-	2.13	521.27
47.00-47.80	2.49	23.00	25641	0.25	-	-

It is recommended to place 1.00 m of rockfill on slopes to prevent yielding and ensure stability. Seismic hazard analysis indicates peak ground accelerations: MDE (Maximum Design Earthquake) = 0.28g, OBE (Operation Based Earthquake) = 0.14g. Borehole results on the tunnel route show weathered ophiolite (0.00-11.00 m) and ophiolite complex (11.00-50.00 m). Groundwater level is 1.10 m. Borehole tests include permeability, pressurized water, and standard penetration tests at various levels. Rock core samples underwent uniaxial compressive strength and point loading tests (Table 3).

Geotechnical parameters for the weak rock of the ophiolitic unit in the diversion section are cohesion in the range of 100-200 kPa and internal friction angle in the range of 15°-25°.

For the ophiolite complex (siliceous shale), 75 kPa cohesion, 20° angle of internal friction, 25 kN/m³ unit volume weight were selected as the strength parameters to be used in the calculations considering the calculations and evaluations made for the values of $m_i = 7$ and $GSI = 32$, uniaxial compression test result 23 kg/cm² from laboratory results, as well as laboratory data and field observations.

3.1 Tunnel inlet

Diversion Tunnel entrance and water intake structure excavations had been completed. Although there was a requirement for typical slope reinforcement if necessary for excavations to be carried out in the open, only the first benches of the tunnel entrance portal were supported with mesh steel and shotcrete in the diversion tunnel entrance excavations. Diversion tunnel entrance portal, water intake structure and route excavation slopes were opened in ophiolitic unit which is weak to very weak rock. The excavations were exposed without support for a long time, and landslides and flows occurred on the slopes due to the effect of water and rainwater in the unit. It was observed that the additional benches opened in the diversion tunnel route excavations were very close to the dam plinth route.

3.2 Tunnel inlet

The exit excavations of the diversion tunnel had been completed, while conduit excavation had not yet commenced. Despite the necessity for standard

Figure 1. View of flows on the right and left slope slopes at the diversion tunnel entrance portal.

slope reinforcement in open excavations, there was an absence of support in the diversion tunnel exit excavations. These excavations, situated in an ophiolitic unit with weak to very weak rock slopes, remained exposed for an extended period without support, resulting in landslides and erosion triggered by water and rainwater. The diversion tunnel exit portal excavation, conducted in proximity to the body skirt, was observed to be opened without diverting the tunnel itself. This proximity to the body, and potentially within it, suggests a deviation from standard excavation practices. Furthermore, water inflows perpendicular to the diversion tunnel route were identified.

Figure 2. View of the diversion tunnel exit portal and slope failure.

The excavations left exposed formed an altered zone in contact with air and water, lead a sliding, and the diversion tunnel exit was closed (Figure 3).

Figure 3. Diversion outlet, in-situ situation on 01.05.2020.

Figure 4. View from the slides on the hillside at diversion tunnel outlet conduit route.

As can be seen in the following figure, during the February 6, 2023 Kahramanmaraş sequential earthquakes, the first M7.5 magnitude earthquake struck the dam area in 0.1g-0.2g ground acceleration range, while it went up to 0.48g during the second M7.8 magnitude shock. This data was observed at the nearest instrumentation station to the dam site (USGS, 2023).

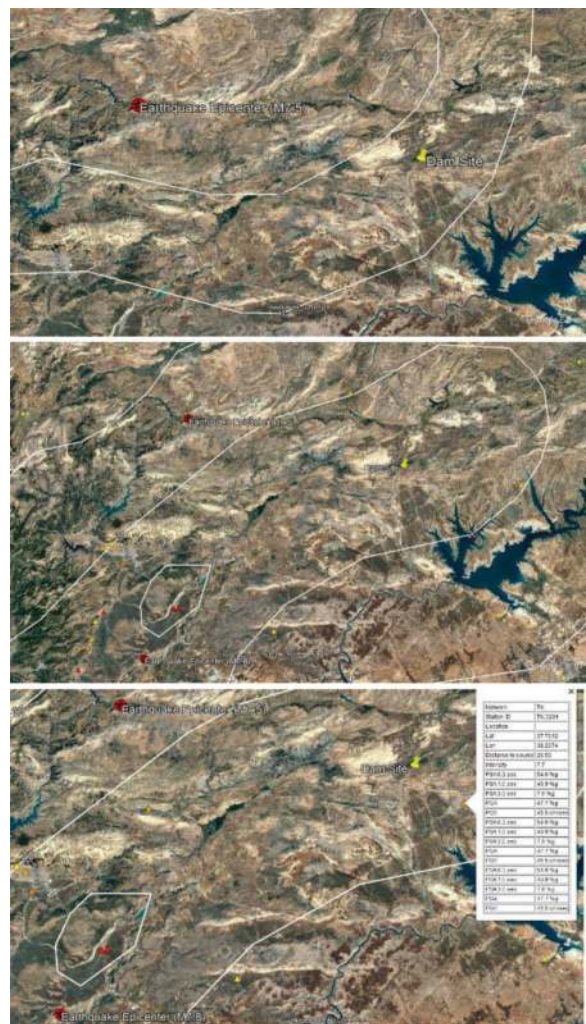

Figure 5. Observed PGA values after M7.5 and M7.8 magnitude earthquakes.

4 SOLUTIONS AND RECOMMENDATIONS

To stabilize the slopes at the diversion tunnel entrance portal, two alternatives were considered. The first involves terracing the slopes at 3H:2V, implementing typical slope support, and incorporating a concrete trapezoidal channel at the base for scour prevention. The existing temporary 1H:1V slopes were part of this alternative. The second alternative proposes a retreat of these slopes, creating a 6.00m base width, constructing a conduit instead of a trapezoidal channel, and covering it with fill before the tunnel entrance. The water intake tower is recommended to be positioned openly on the conduit, away from the portal slope, mitigating potential slope slippage damage.

For the portal excavation, an additional option considers addressing flows at the existing portal location by lowering the excavation slopes and supporting them with a typical support system. In its current state, the portal excavations are at a 1H:1V slope, and flows have occurred. To address this, a design shift to a 3H:2V slope with a 6m high bench and typical support is proposed. The excavation slopes will reach the dam axis and the access road, avoiding the challenges posed by the existing 1H:1V slopes, which are close to the dam plinth line.

The second alternative recommends setting back the temporary 1H:1V slopes on the sides, creating a 6.00m base width, and covering the portal excavation area with fill until the tunnel entrance. The water intake tower is set back 10.00m from the portal to mitigate potential slope slippage risks. The top of the conduit will be backfilled with compacted mineral fill up to the first pallet elevation to form a heel, and the portal slope will be tilted 2H:1V to prevent sliding under the plinth. The excavation slopes are suggested to be arranged with embankment at a 2H:1V slope. Additionally, 1.00m rock filling is recommended to prevent flow and slipping on the embankment, designed in different sections based on the fill load on the conduit.

5 RESULTS AND DISCUSSION

5.1 Stability analysis

0.14g ground acceleration (OBE) was used in the seismic (pseudo-static) analyses of slope rehabilitation. For the actual earthquake comparison, the observed PGA of 0.48g was used.

5.1.1 Inlet

Geotechnical parameters were determined for the unit in the diversion inlet excavations and slope stability analyses were performed. Necessary alternative studies were carried out to ensure the safety of the slopes and it was aimed to make the slopes safe. Regarding the excavated part of the diversion entrance route, the current situation was mapped and the existing excavation and the structures in the

project were processed, and the interaction of the excavations already opened in the field and the body plinth route was evaluated. The following slope stability analyses were performed for the excavations to be carried out at 1H:1V slope gradient. On the ophiolitic complex, which is a weak to very weak rock, a section close to the surface decomposes due to contact with air and water and forms an altered zone. In the analyses, the altered zone formed when the slope surface is left exposed and the situation where the contact of the unit with air and water is cut off with support were also analyzed.

Static and pseudo-static stability analyses are given below for 1H:1V excavation with steel mesh and shotcrete support, where air-water contact on the slope surface is interrupted by weep holes and slope drainage.

Figure 6. Diversion tunnel inlet 1H:1V supported static stability analysis (FS= 1.35 < 1.5).

Figure 7. Diversion tunnel entrance 1H:1V supported seismic stability analysis (FS = 0.96 < 1.1).

Figure 8. Diversion tunnel entrance 1H:1V unsupported static stability analysis (FS= 1.18 < 1.5).

If the slope is 3H:2V for permanent excavations, the slopes cannot be opened as they reach under the plinth and under the dam body. For this reason, since the portal excavations opened with temporary slope slopes of 1H:1V that do not provide stability, the slope stability will be ensured by constructing a conduit instead of a trapezoidal channel until the tunnel entrance and filling the slopes and conduit with fill and the topography reaching its own slope. Backfill slopes will not be steeper than 2H:1V. It is recommended that 1.00 m of rock fill should be placed on the backfill applied on the slope surface in order to prevent it from collapsing with the current.

Static and pseudo-static stability analyses are given below in case of 2H:1V filling after 1H:1V excavation.

Figure 9. Diversion tunnel inlet conduit section static stability analysis (FS= 1.506 > 1.5).

Figure 10. Seismic stability analysis of the diversion tunnel entrance conduit section (FS= 1.118 > 1.1).

It is recommended to apply steel mesh and at least 5cm+5cm shotcrete according to the support type in the project. In the final project, the bolt length is given as 4m, which is not long enough. In this type of soils, the bolts do not work because there is no block, solid rock where the rock bolt will be anchored and the slip surfaces are formed in a wide circle. Due to this reason, it is recommended to lower the slope gradients and reduce the bench heights in terms of stability. In cases where it is not possible to lower the slopes at the entrance section of the diversion (excavations enter into the body), the topography should be brought to its natural slope by passing through a conduit (such as a cut-and-cover tunnel) and backfilling.

The following analysis is not a dam body stability analysis, but an analysis of the interaction between the body and the conduit entrance completed during the construction of the body. According to the height of the body, approximately 4kg/cm² load is applied.

Figure 11. Interaction with the body after conduit backfill in static condition (FS=1.54>1.5).

Figure 12. Interaction with the body after conduit backfill for seismic case (FS=1.23>1.1).

Cleaning excavation will be made in the sliding area and it will be covered again with backfill after the conduit. It is recommended that the new slope excavations to be opened by the conduit should be opened with supports and drainage.

The analysis below corresponds to the model in Figure 12, utilizing an actual PGA of 0.48g from the M7.8 magnitude earthquake as the horizontal ground acceleration. Factors of safety below 0.759 are associated with shallow slope failures, and only critical and deep slope surfaces were evaluated, ensuring a minimum factor of safety of 0.759.

Figure 13. Interaction with the body after conduit backfill for seismic case for 0.48g (FS=0.759<1.0).

5.1.2 Outlet

Geotechnical parameters were determined for the diversion outlet excavations, and slope stability

analyses were conducted to ensure safety. Mapping the current conditions and evaluating the interaction of the body with existing excavations, particularly those in the field, were part of the assessment. Water flowing perpendicular to the conduit's route will be diverted from upper elevations parallel to the valve chamber access road and released into the stream bed.

Cracks and splits were observed in shaft sections leading to the valve chamber. To preserve the valve room road, the first two slopes from the base were analyzed at a 1H:1V slope, while slopes between the third slope pallet elevation and the valve room access road were analyzed at a 3H:2V slope. Slope stability analyses were conducted for excavations at 1H:1V and 3H:2V slope gradients, considering the altered zone and interruption of the unit's contact with air and water when the slope surface is exposed.

Face portal slope stability analyses were undertaken in two sections—the body and diversion sections—ensuring stability. However, in the interest of brevity, face portal analyses are not included in this paper.

In the analysis performed without support in temporary excavation at the critical section of the diversion outlet, the safety factor was 1.18 due to the effect of the altered zone. As also seen in the field, failures occur from the slope surface (Figure 14).

Figure 14. Diversion outlet 1H:1V unsupported static stability analysis (FS=1.18<1.50).

The diversion outlet's critical section underwent analysis with slope reinforcement, utilizing steel mesh and shotcrete during excavations on a 1H:1V slope to obstruct the unit's contact with air and water. It is anticipated that cutting this contact, along with water removal through a drainage system, including head ditches and weep holes in the benches, will prevent the formation of an altered zone. Application of steel mesh, 5cm+5cm shotcrete, and weep holes in the supports was considered. Analysis revealed that the use of short rock bolts did not significantly impact stability, given the wide sliding arc.

Since the safety factor is 1.33 for the first two slope surfaces 1H:1V from the base and 3H:2V for the upper slopes, there will be a stability problem in case of permanent excavation (Figure 15).

Figure 15. Static stability analysis with diversion outlet 1H:1V support (FS = 1.33 < 1.50).

If filling is done only up to the first bench, stability problems will still persist (Figure 16).

Figure 16. Static stability analysis of backfill up to the first bench at the diversion outlet (FS = 1.41 < 1.50).

The slope heel filling on the slope close to the natural slope of the topography was analyzed below. The case of filling with backfill up to the first two bench elevations and supporting the slope surfaces with 2H:1V slope protection embankment is analyzed. In the slope protection embankment, it is recommended to construct a slope protection cover with 1.00m rock fill against surface runoff.

Figure 17. Static stability analysis of embankment up to the first two benches of the diversion outlet (FS = 1.508 > 1.50).

Stability problems will be eliminated if the first two benches are backfilled. The topography approximately reaches its natural slope. Embankments are analyzed as 2H:1V. Embankments should not be constructed at steeper slopes.

Seismic analysis of the slope surfaces in case of 2H:1V embankment and backfilling up to the first two benches is given below.

Figure 18. Seismic condition stability analysis of the embankment up to the first two benches of the diversion outlet (FS = 1.14 > 1.1).

In accordance with the observed PGA of 0.48g, comparable outcomes to those at the inlet portal were noted, with all factors of safety registering below 1, some marginally so. However, these results are not presented here for the sake of conciseness.

6 CONCLUSIONS

Proposed support by terracing and granular fill is working as seen during site visits, even after the major earthquake sequence in the vicinity of the dam site. This method can be used as a cost-effective method in tunnel projects with similar landslide problems.

On the other hand, the fact that the slopes are failing in the analysis but not in reality might be explained by the following reasons:

- The peak ground acceleration value obtained from the earthquake records is very instantaneous and may not be fully representative of the earthquake on the given site conditions,
- Being conservative when selecting parameters,
- The extent to which the topographic model reflects reality,
- Selection of analysis type and earthquake acceleration,
- Material model and stress-strain behavior.

In addition, the possibility of landslides of invisible size and velocity during site visits should not be ignored.

ABSTRACT: In recent years, the construction of undersea tunnels has been booming in China, but it is faced with severe challenges, especially when crossing fault zones. Water gushing, rock instability and other accidents often occur during tunnel excavation due to the fracture of fault zones. Relying on the second undersea highway tunnel in Qingdao Jiaozhou Bay, this paper adopts theoretical derivation, statistical analysis and numerical simulation to study the deformation of the undersea tunnel crossing a fault zone. The main work and results of this research are as follows: (1) The distribution laws of influential parameters of Qingdao Second Tunnel crossing the fault zones were counted up. The depth of seawater, grade of surrounding rock, lining type and excavation method of Qingdao Second Tunnel crossing the fault zones were statistically analysed and the distribution range of these parameters was obtained. A characterization method for the angle and width of tunnel crossing a fault zone was proposed, and the angles and widths of Qingdao Second Tunnel crossing fault zones were calculated and counted. (2) Based on a 2D numerical model and the distribution range of the above parameters, a parameter analysis of the deformation of undersea tunnel crossing fault zones was carried out. The influences of the above parameters on the deformation of the tunnel when undersea tunnel crosses a fault zone was revealed.

Keywords: Undersea tunnel, Fault zone, Numerical simulation

1 INTRODUCTION

In recent years, China has planned and constructed several undersea tunnels, including the Xiamen-Xiang'an Tunnel and the Qingdao Jiaozhou Bay Tunnel, etc. China is gradually gaining the capability to construct undersea tunnels with larger cross-sections, longer lengths, and more complex geological conditions. However, Undersea areas often contain unfavourable geological features like fault zones, where rock formations have low strength, poor stability, and high permeability. The fault zones have reduced load-bearing capacity and also serve as pathways for hydraulic replenishment between the tunnel and the seawater above. Therefore, most accidents in undersea tunnels worldwide, such as collapses and water ingress, are fundamentally caused by the presence of fault zones (Wang et al., 2007).

The Finite Difference Method (FDM) is a numerical technique used to approximate solutions to differential equations. FLAC 3D (Three-Dimensional Fast Lagrangian Analysis of Continua), developed by the American company Itasca, is a three-dimensional explicit finite difference program known for its effective simulation capabilities. Many scholars have proposed mature theories and procedures for numerical simulations of crossing through fault zones in undersea tunnels, including model dimensions (Li et al., 2002), displacement constraints (Wang et al., 2011), element types, constitutive models, model parameters, the generation of initial stress field, and excavation simulations (Zarei et al., 2011). However, there are questions about the reliability of the selection of rock mass elements, fault zone parameters and support structure constitutive models.

*Corresponding author: nijz@tongji.edu.cn

Researchers like Kiani et al. (2016) and Sabagh and Ghalandarzadeh (2020) investigated the impact of tunnel cover thickness, fault angle, tunnel diameter, and lining thickness on the stability of surrounding rocks when crossing through fault zones. Xu et al. (2016) revealed the progressive failure process of rock masses in various parts when crossing through fault zones and analyzed the redistribution of stress caused by tunnel excavation. Yang et al. (2015) established finite element models for undersea tunnel seepage with different cover layer thicknesses, conducting research on water inflow, seepage velocity, pore water pressure, and grouting ring parameter selection during crossing through fault zones. Long (2020), compared and analyzed the effects of permeable and impermeable changes when crossing unfavourable geological formations in undersea tunnels using FLAC 3D software. She summarized the development of the plastic zone, pore water pressure field, displacement field, and water inflow.

For the study of structural forces and deformations when crossing fault zones in undersea tunnels, Han et al. (2021) proposed a limit equilibrium model considering the influence of seepage forces and geological interfaces. They compared this model with numerical simulation results and existing failure mechanisms to determine the ultimate pressure on support structures when crossing through fault zones. Zaheri et al. (2020) conducted a three-dimensional numerical simulation study on the interaction between tunnel linings and strike-slip faults, exploring the influence of soil mechanics properties, tunnel layer thickness, tunnel depth, fault dip angle, and their impact on tunnel mechanical performance. Li et al. (2023) identified three typical failure modes when crossing fault zones in tunnel face excavation: face uplift, local failure and sliding collapse based on Material Point Method (MPM) numerical verification experiments. For construction in fault zones, safer construction methods are often adopted, including strengthening the strength and stiffness of initial support and secondary lining (Li et al., 2007), grouting reinforcement (Zhang, 2007), and timely support.

To prevent accidents like collapse and water ingress and ensure the safety of undersea tunnel construction, especially when crossing fault zones, this study conducted the following research based on the Qingdao Jiaozhou Bay Second Undersea Highway Tunnel project,:

- (1) Statistically analyzed data from the Qingdao Jiaozhou Bay Second Undersea Highway Tunnel project.
- (2) Revealed the structural stress and deformation evolution patterns of undersea tunnels when crossing fault zones based on 2D numerical simulations.

This study employed a systematic approach to scientific research, incorporating methods such as mathematical statistics, theoretical analysis, and

numerical simulations. The specific technical approach is shown in Figure 1.

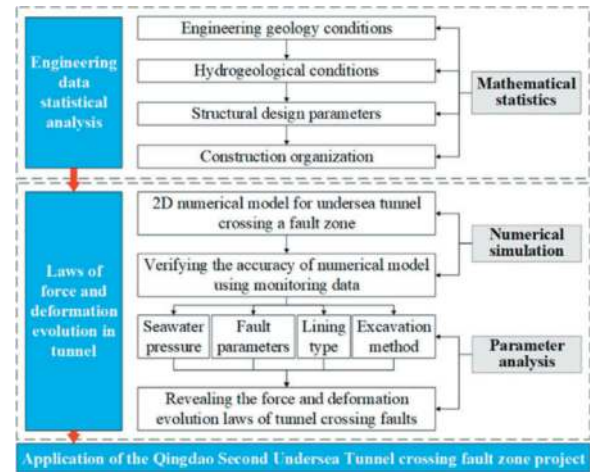

Figure 1. The technical approach of this research.

2 INFORMATION STATISTICAL ANALYSIS OF QINGDAO SECOND UNDERSEA TUNNEL CROSSING FAULT ZONES

2.1 Project overview

The Jiaozhou Bay Second Undersea Tunnel Project connects the main urban area of Qingdao with the West Coast New Area. The tunnel is 14,376 meters long and is constructed using a combination of cut-and-cover, drill-and-blast (west) and shield (east) methods. The standard cross-section of the drill-and-blast section in the mainline sea area has a width of about 15 meters and a height of about 10.6 meters. The designed elevation of the bottom plate ranges from -67.3 to -118.8 meters and the thickness of overburden ranges from 50 to 80 meters. Composite lining structure is mainly employed in the drill-and-blast section of the tunnel.

2.2 The information of fault zones crossed by tunnel

To study the distribution of the angle and width at which fault zones intersect with tunnels, this research has established formulas (1) and (2) for calculating the angle and width of fault zones on tunnel cross-sections precisely intersecting the centre of a fault zone.

$$\varphi = \arcsin \frac{\cot \alpha}{\sqrt{(\cot \alpha)^2 + (\cot \beta)^2}} \quad (1)$$

$$w = \left| \frac{d_0 \sin \alpha}{\cot \beta} \sqrt{1 + (\cot \alpha)^2 + (\cot \beta)^2} \right| \quad (2)$$

Where φ is the fault angle on the cross-section; w (m) is the fault width on the cross-section; α is the fault angle on the side view; β

is the fault angle on the top view; d_o (m) is the fault width on the top view and side view.

Table 1. The information of fault zones crossed by tunnel.

Fault	d_o/m	w/m	$\varphi/^\circ$	Rock grade	Sea depth/m
f9	64	127	116	V	17.45 ~ 19.78
f10	78	142	114	V	20.06 ~ 21.72
f11	25	32	81	V	45.97 ~ 47.08
f12	40	51	81	IV	40.88 ~ 42.95
fc	226	289	83	III ~ V	17.97 ~ 21.32
f13	20	25	82	V	25.35 ~ 26.20
f14	53	60	84	V	13.76 ~ 14.30
Fa	187	386	86	V	12.42 ~ 17.32
f15	186	768	50	V	8.78 ~ 10.00
f16	56	59	84	V	9.00 ~ 9.12

As shown in Table 1, the Qingdao Second Undersea Highway Tunnel crosses 10 fault zones in the sea area, with an impact distance exceeding 935 meters. Each fault zone has various characteristics in the sea depth above, rock mass grade, angle and width of intersection with the tunnel. This research has compiled data on the sea depth and rock mass grade according to the mileage as well as angle and width on the cross-sections according to the number of fault zones crossed by the Qingdao Second Undersea Tunnel, as shown in Figure 2.

It can be found from the figure that 91% of the mileage of the tunnel crossing the fault zones has a seawater depth of less than 25m, while there are also cases where the seawater depth in the upper part of the fault zones is as high as 45~50m(a). 80% of the surrounding rock grade in the part of the tunnel crossing fault zones is IV and V(b), so the self-stability is poor. Most of the fault zones traversed by Qingdao Tunnel intersect with the tunnel at a high Angle(c), resulting in a shortened hydraulic connection path and weak surrounding rock of the crown. All fault zones traversed by the tunnel cover the entire excavation range in the studied section(d).

3 DEFORMATION AND FORCE EVOLUTION LAW OF UNDERSEA TUNNEL CROSSING FAULT ZONE BASED ON 2D NUMERICAL SIMULATION

3.1 Numerical model

In this study, based on Hypermesh and FLAC 3D, a two-dimensional numerical model of the Qingdao Second Undersea Tunnel north line crossing the f10 fault zone (mileage NK8+400) was established (Figure 3). The model size is 200m×200m. Fixed supports are set at the bottom of the model, the normal displacement is constrained on four sides,

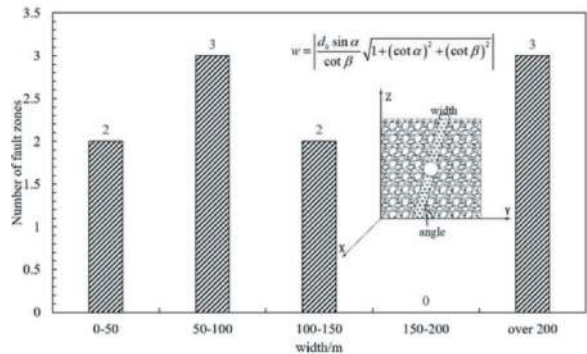

(a) The distribution of sea depth

(b) The distribution of rock grade

(c) The distribution of fault angle on the cross-sections

(d) The distribution of fault width on the cross-sections

Figure 2. The distribution of four characteristics of fault zones.

and the upper plane is free. The bottom and four sides are set as impervious boundaries.

The rock mass and fracture zone are simulated by solid element with the Mohr-Coulomb mechanical constitutive model and the isotropic seepage fluid

Figure 3. The 2D numerical model.

constitutive model. Liner unit and Cable unit were used to simulate the primary support and bolt, respectively. The parameters of rock are shown in Table 2, and the parameters of structural elements are shown in Table 3. Among them, the elastic modulus of steel arch is converted into the elastic modulus of concrete according to the proportion of their areas.

In order to consider the seepage of upper seawater during the tunnel excavation, the fluid-structure coupling model is used for calculation. In this model, displacement of monitoring points in the z-direction are arranged at the crown, shoulder, foot and invert of the tunnel. The xdirections are arranged at the wall of the tunnel.

3.2 Model verification and result analysis

The settlement of crown and shoulder and horizontal convergence in the calculated results are compared with the site construction monitoring data in the NK8

Table 3. The parameters of structural elements.

Parameter	Liner element	Cable element
Elastic modulus/GPa	35.26	206
Poisson's ratio	0.2	/
Cross-sectional area/m ²	/	2.53×10^{-4}
Tensile strength/MPa	/	400

+400 mileage of the tunnel. The results are shown in Table 4.

As can be seen from the table, the results of monitoring items are relatively similar, and the maximum relative error is 4.17%, less than 5%, so it can be verified that the model has high reliability.

The computed cloud image of tunnel displacement in z-direction and x-direction and the construction step with maximum stress is shown in Figure 4 (The deformation is magnified by a factor of 100). It can be found that the entire section of the tunnel has shrunk. The position with the greatest displacement as well as the greatest settlement is the crown. The position with the greatest horizontal convergence is the wall. The maximum stress of the surrounding rock appears after the second excavation step. The minimum principal stress at the left shoulder is the largest, about -101.5kPa.

3.3 Parameter analysis

Respectively change the angle and width of fault zone crossed by tunnel to find out the variation trends of tunnel deformation with them, which is shown in Figure 5. The deformation of each typical part of the tunnel increases first and then decreases with the increase of the width of the fault zone. With the increase of fault zone angle, the displacements of

Permeability coefficient /cm·s ⁻¹	3.47×10^{-6}	5.79×10^{-6}	2.31×10^{-4}	3.47×10^{-4}

Table 4. 2D model verification.

Monitoring item	Monitoring data/mm	Simulation result/mm	Absolute error/mm	Relative error/%
Crown settlement	-11.8	-12.0	0.2	1.69
Shoulder settlement(left)	-8.6	-8.5	0.1	1.16
Shoulder settlement(right)	-8.9	-8.7	0.2	2.25
horizontal convergence(left)	7.2	7.5	0.3	4.17
horizontal convergence(right)	-7.3	-7.6	0.3	4.11

crown, shoulder and wall gradually increase, while the displacements of foot and invert decrease slightly.

Respectively change the cohesion and friction angle of the fault zone (rock 79-1) crossed by tunnel to find out the variation trends of tunnel deformation with them, which is shown in Figure 6. With the increase of cohesion and friction angle of fault zone,

the deformation of surrounding rock obviously decreases and then tends to be stable. The deformation values of the left and right shoulder, wall and foot of the tunnel are gradually close. Because the ratio of cohesion or friction angle between the fault zone and the surrounding rocks both sides is gradually close, the model is gradually close to the symmetric state in the calculation.

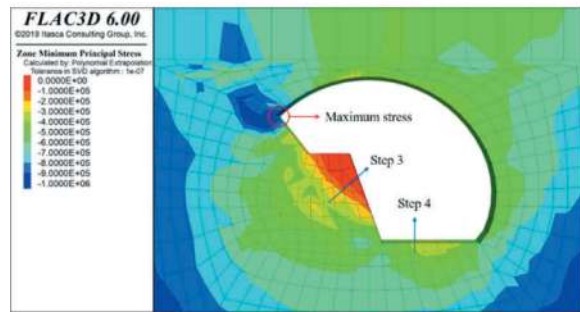

Respectively change the depth of seawater to find out the variation trends of deformation and the maximum internal force of the tunnel with it, which is shown in Figure 7. When the depth of seawater changes, the deformation mode of the tunnel crossing the fault zone does not change but still shrinks in the whole section. The displacement increases with the increase of sea depth. Among them, the invert rise is most affected by sea water depth change. The maximum internal force in each monitoring point of the section is stable after decreasing.

4 CONCLUSIONS

Based on the statistical analysis, numerical simulation and parameter analysis of Qingdao Second Undersea Tunnel crossing the fault zone, the following main conclusions are reached:

- (1) 91% of the tunnel crossing fault zones have a seawater depth of less than 25m. 80% of the surrounding rock grade of the tunnel crossing fault zones is IV and V. Most of the fault zones intersect with the tunnel at a high Angle. All fault zones cover the entire excavation range in the studied section.
- (2) The entire section of the tunnel has shrunk. The position with the greatest displacement as well as the greatest settlement is the crown.
- (3) The deformation of the tunnel increases first and then decreases with the increase of fault zone width. With the increase of fault zone angle, the displacements of crown, shoulder and wall gradually increase.

Research on surrounding rock by shallow tunnelling in Boulder-Cobble Mixed Formation: Instability characteristics and control strategies

Yiwen Qin*

Chang'an University, School of Highway, Xi'an, China

ABSTRACT: The construction of shallow tunnels has become increasingly challenging due to the complex geological conditions encountered, particularly in boulder-cobble mixed (BCM) formations found in river terraces. To understand the deformation characteristics of these formations, it is necessary to study the instability and failure evolution process of unlined tunnels in BCM formations. This research systematically investigates the failure evolution process and the variation laws of surrounding rock stress and displacement through a physical model test under 1g conditions. The study findings reveal a grouped pattern of movement in the collapsing movement. During the evolution process of instability, the surrounding rocks formed pressure arches multiple times, resulting in a clear development of staged deformation. The instability of the pressure arch zone leads to an expansion of the loose zone in the surrounding rocks, particularly in the tunnel vault area. To prevent the collapse of surrounding rocks effectively, it is suggested to control the stability of the first-formed pressure arch. Based on the instability evolution characteristics of the surrounding rock, strategies for preventing and controlling collapse are summarized and refined.

Keywords: Tunnel engineering, Boulder-Cobble Mixed formation, Progressive destruction, Pressure arch, Model test

1 INTRODUCTION

In recent years, the escalating demand for road construction in various topographical settings, including river terraces, floodplains, and piedmont areas, has given rise to increasingly intricate geological conditions during tunnel construction. This complexity is particularly pronounced when tunnels are being excavated in formations characterized by a mixture of boulders and cobbles, commonly referred to as boulder-cobble mixed (BCM) formations, often prevalent in river terraces. BCM formations consist primarily of boulders (particles exceeding 200 mm in diameter), pebbles (particles ranging from 20 to 200 mm in diameter), sand, gravel, and clay. Notably, giant particles (those exceeding 60 mm in diameter) comprise more than 50% of the entire formation, rendering it a composite material that exhibits properties falling between rock and soil. Furthermore, the degree of cementation within the formation is notably poor. When exposed to water, fine particles are susceptible to erosion and loss, further compounding the challenges associated with tunnelling in BCM formations. Consequently, the process of tunnelling in BCM formations is fraught

with difficulties, characterized by sluggish progress and elevated safety risks.

Several significant research endeavors have been undertaken to elucidate the key considerations for preventing and controlling tunnel accidents within such formations. Wang et al. (2013) investigated the deformation and stability of sand cobble strata underlying immersed tunnels. Cui et al. (2016) compiled an insightful summary regarding the issue of sludge management during the construction of shield tunnels within water-rich sandy cobble strata. In a study by Zhu et al. (2010), the progressive failure behavior of weak surrounding rock was examined, considering variables such as section size, groundwater influence, and the effects of blasting vibrations. Furthermore, Lai et al. (2016) delved into the realm of reinforcement testing for sleeve valve tubes within sandy cobble strata. Their work determined crucial grouting parameters for advancing curtain grouting during tunnel excavation. In a separate investigation, Zhang et al. (2015) conducted model tests for deep and shallow tunnels, confirming that deep tunnels generally do not reach the surface. In contrast, shallowly buried tunnels are prone to surface ground collapse. Another essential aspect He

*Corresponding author: qinyiwen@chd.edu.cn

et al. (2012) addressed involved the study of ground settlement patterns resulting from shield tunnelling in sandy cobble strata, incorporating field measurements and model testing. Additionally, Zhang et al. (2012) employed numerical analysis to estimate the impact of shield tunnelling within sandy cobble strata on tunnel alignment and the surrounding land surface. These studies collectively contribute to a comprehensive understanding of tunnel construction challenges and accident prevention in formations of this nature.

The above summary reveals several key observations: (1) Currently, research efforts related to tunnel collapses in BCM formations or sandy cobble strata primarily concentrate on treatment measures and causal analyses of accidents; (2) Investigations into the arching effect of tunnel surrounding rock heavily rely on numerical analysis methods, which may not comprehensively capture the entire process of surrounding rock deformation the tunnel (Kamata and Mashimo 2003); (3) Existing model tests have not systematically explored the formation and development of pressure arches during tunnel collapses and failures within BCM formations; (4) Importantly, the monitoring data from current tunnel construction operations highlight the significant impact of water on the stability of tunnel surrounding rock. Nevertheless, the influence of rainfall on the stability of tunnel surrounding rock is seldom addressed in existing research. To delve into the collapse process of tunnels in BCM formations, a similar simulation test in a 1g environment was conducted to investigate the evolution of collapses during tunnel excavation and the impact of rainfall on the stability of tunnel surrounding rock. This research seeks to uncover the variation patterns in stress and displacement fields during the tunnel failure process within BCM formations and propose key considerations for preventing and managing tunnel collapses under similar geological conditions.

2 PROJECT DESCRIPTION

A highway tunnel is situated about 500 meters west of Nianggai Village in Daxiang Township of Lhasa, China. The length of the tunnel is more than 500 m and the span of the tunnel is 13.06 m. The buried depth of the whole tunnel is 7-33 m, with an average of 20 m. The topography of tunnel area belongs to the river terrace. Geological survey report showed that formations of tunnel excavation are dense BCM formation and middle dense stratum. In BCM formation, the content of cobbles is more than 20%, the content of boulders is more than 40%, and the content of total giant particles is between 60%~80%. The middle of the tunnel passes through the debris flow gully, in which there are streams and perennial flowing water, which recharge groundwater to BCM stratum on both sides. The permeability of the strata is strong, and the groundwater level is greatly affected by rainfall.

3 EXPERIMENT

Taking the framework-pore structure which is the most representative of BCM formation as an example, a similar simulation test in 1g was carried out to study on the evolution of collapse during tunnel excavation and the influence of rainfall on the stability of tunnel surrounding rock.

3.1 Similarity theory

The experiment used dimensional analysis which is based on Buckingham's π theorem (Buckingham 1914). The theorem appropriately describes a relationship between physical variables and fundamental dimensions. It is pointed out that any physical equations can be transformed into equations of dimensionless quantities (Russo et al. 2017). The physical variables that need to be considered in this experiment included: the parameters of geometry (L), stress (σ), strain (ε), displacement (δ), the Young's modulus (E), density (γ), Poisson's ratio (μ), cohesion (c) and internal friction angle (ϕ).

The similarity constant (C) is the ratio of the same physical quantity between the prototype and the model. Simple deformation of the relationship between the similarity constants obtained from the equilibrium equation, geometric equation and physical equation can establish the following similarity conditions:

$$C_\sigma = C_\gamma C_L \quad C_\delta = C_\varepsilon C_L \quad C_\sigma = C_c C_\mu \quad (1)$$

$$C_\varepsilon = 1 \quad C_\phi = 1 \quad C_\mu = 1 \quad (2)$$

Considering that the size of the whole model must be larger than the scope of the stress field of the surrounding rock readjusted after tunnel excavation, and considering the feasibility and economy of the test, the ratio of geometric 60 was finally chosen. At the same time, considering that the model is usually made of the same type of material as the prototype, the ratio of density 1 was chosen. The ratio of geometric and the ratio of density are substituted into formula group (1), so that the ratios of all physical quantities could be obtained. The ratios are shown below:

$$C_\varepsilon = C_\mu = C_\phi = 1 \quad (3)$$

$$C_E = C_\sigma = C_\delta = C_c = 60 \quad (4)$$

3.2 Similar materials

Considering that the mechanical properties of BCM surrounding rock differ greatly from rock or soil medium, which is mainly manifested large porosity, high deformation modulus, large internal friction angle and small cohesion. The deformation of surrounding rock is mainly caused by the moving between particles. Therefore, the key to achieve the simulation results is to satisfy the similarity of particle gradation between prototype and model. Based on the

typical particle size composition of tunnel surrounding rock in the geological prospecting data of the project, similar materials of BCM surrounding rock were prepared by mixing quartz sand with different mesh numbers, barite powder with different mesh numbers, vaseline and water. Geotechnical tests were carried out to determine the relevant parameters of different mix ratios, and the final selection of similar materials of BCM surrounding rock was 2-4 mesh quartz sand: 10-20 mesh quartz sand: 20-40 mesh quartz sand: 150 mesh barite powder: 600 mesh barite powder = 3.68: 3.59: 1: 1.08: 0.96. The physical parameters of prototype materials and similar materials measured by geotechnical tests are shown in Table 1.

Table 1. Physical parameters of BCM surrounding rock.

Parameter	Prototype	Model
Internal friction angle (°)	4700	40
Cohesion (kPa)	4800	39
Poisson ratio	4900	38
The Young's modulus (MPa)	5000	38

3.3 Model equipment

This test used a model box made of a tempered glass, and the sides were fixed with wooden boards. Its dimension was 1.5 m in length, 0.62 m in breadth, and 1.5 m in depth. The tunnel excavation hole was reserved in the middle and lower part of the glass. The measured physical quantities in this test mainly included the stress of surrounding rock and the internal deformation of surrounding rock. The stress measurement of surrounding rock adopted earth pressure cell, and the data acquisition adopted JM3813 type static strain gauge.

3.4 Experiment design and procedures

According to the actual project, the test simulated the excavation of the tunnel with a depth of 33 cm and a span of 22 cm. Firstly, the model box was filled with similar materials and making the formation fully consolidated under the action of gravity. Then the tunnel excavation was carried out. In BCM formation, the bench method has many advantages in construction convenience, construction progress and less disturbance, which is the first choice of tunnel excavation method (Lai et al. 2016). In this model test, the method of tunnel excavation was short bench method. The excavation height of the upper and lower bench was about 5 cm. Each excavation footage was 5 cm. The whole excavation process was kept at constant speed until the tunnel transfixion. After the surrounding rock was stabilized, the rainfall process was simulated by slowly adding water 30 kg to the surface of the model, and the amount of water added was about 5 kg each time.

To monitor the stress of surrounding rock during whole test process, a longitudinal measurement section

was set up in the middle of the tunnel. On this section, several earth pressure cells were set up at the vault and side wall of the tunnel. The layout of measurement section and measuring points is shown in Figure 1.

Figure 1. Sketch of measuring points for model test.

3.5 Results and analysis

3.5.1 Analysis of shape characteristics of collapse arch

As can be seen from Figure 2, three times of collapse occurred during the test, and each collapse formed the short-term stable collapse arches until the final ground collapse. In view of the fact that the shape of collapse body is the premise and foundation for determining the ultimate supporting force and collapse load, it is necessary to make a thorough analysis and study on it.

To study the shape of the collapse arches formed in the test process, the photographs of the short-term stable collapse arches were fitted respectively. The concrete steps are as follows: (1) Drawing scatter plots uniformly along the collapsed contour, and establishing a plane right-angle coordinate system with the vertex of collapse arch as the origin of the coordinate; (2) Measuring the coordinates of each point and using Origin software to fit the curves. The fitting curves of the collapse arches are shown in Figure 2.

Figure 2. The fitting curves of the collapse arches. a. The first collapse arch; b. The second collapse arch; c. The third collapse arch.

The fitting results showed that the fitting degree was above 0.85, which represented that the polynomial function selected was reasonable. Three fitting curves can be well described by the quadratic parabola ($y = ax^2 + bx$). With the enlargement of the collapse area, the absolute value of the parameter a was increasing and the absolute value of the parameter b

was decreasing. It can be seen that the collapse developed upward and tended to be symmetrical gradually. Table 2 showed the heights and spans of three collapse arches. It can be seen that the height of the collapse arch increased significantly until the ground collapse was formed; the span increased more obviously in the first two collapses, and it almost did not increase any more in the third. It showed that the collapse arch changed dynamically with the tunnel excavation and underwent a cyclic process of first formation, then destruction, formation again. From the point of view of treatment of collapse, strong support measures should be taken immediately after the first small-scale collapse, so as to control the height of the collapse within a small range, thereby reducing the load required for support and lining.

Table 2. The height and span of three collapse arches.

Condition	Height (cm)	Span (cm)
First collapse arch	9.22	12.75
Second collapse arch	21.86	17.62
Third collapse arch	28.15	17.93

3.5.2 Variation law of surrounding rock stress

Figure 3 depicted the change of stress in surrounding rock above the vault during tunnel excavation. The surrounding rock stress in the figure represented the changed value relative to the initial stress, not the absolute value of stress (Figure 4 was the same). The positive value indicated that the stress increased, and the negative value indicated that the stress decreased. It can be seen that before the tunnel was excavated to the measurement section, the vertical and horizontal stress of the surrounding rock above the vault increased slightly and the closer to the measurement section, the more obvious the increase was. This was due to the stress redistribution of the surrounding rock in front of the section to form the “beforehand arch”, that was, the surrounding rock had already shown arching effect in front of the section. After tunnel excavation, the stress in surrounding rock above the vault decreased obviously, and the more close to the vault, the more obvious the stress decreased. The surrounding rock near the GD1 was completely loosened, resulting in the pressure gauge falling off. The stress of the outermost GD5 was almost zero during the whole excavation process and the other measuring points were negative, which represented that the disturbed area above the vault had a large area and had spread to the surface.

In the process of tunnel excavation, the horizontal stress of GD6 underwent two times changes of rising firstly and then falling. These two drastic changes of stress corresponded respectively to the time when the partial drop of blocks above the vault and the pressure gauge at the GD1 falling off. It

demonstrated that it was theoretically feasible to predict the surrounding rock deformation by monitoring the stress changes inside the surrounding rock. The trends of GD7 and GD8 were basically the same, but the stress change of GD7 near the vault was larger. Research results (Zhu et al. 2010) had shown that the horizontal stress of surrounding rock decreases in the range of pressure arch, and the stress increases in the surrounding rock outside pressure arch due to the load borne by radial transmission. Therefore, the horizontal stress rising area of surrounding rock was taken as the range of pressure arch in this paper. Both the horizontal stress of GD9 and GD10 were close to or slightly greater than zero, which indicated that these two points belonged to the range of pressure arch and the internal boundary of the arch was at the position where the stress change was zero between GD9 and GD10.

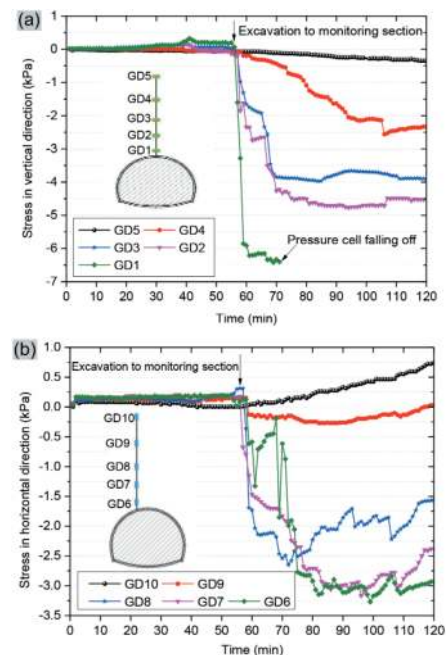

Figure 3. The change of stress in surrounding rock above the vault during tunnel excavation. a. Vertical stress; b. Horizontal stress.

Figure 4 illustrated the change of stress in surrounding rock of the side wall of the tunnel during tunnel excavation. It can be seen that before the tunnel was excavated to the measurement section, the vertical stress of each point on the survey line changed very little and the horizontal stress increased more significantly, which was consistent with the stress variation law of the surrounding rock above the vault. After tunnel excavation, only the vertical stress of BQ1 linear decreased and the vertical stresses of BQ2-BQ5 were not affected by excavation during the whole test process, which revealed that the disturbed area of the side wall of the tunnel was small. The horizontal stresses of BQ6-BQ8 close to the side wall of the tunnel increased

obviously, while BQ9 and BQ10 far from side wall of the tunnel were almost unaffected by the excavation. It was presumed that the BQ6-BQ8 belonged to the range of pressure arch and the horizontal stress of BQ7 increased most remarkably. To sum up we know the outer boundary of the arch was at the position where the stress change was zero between BQ8 and BQ9. The above analyses of the vertical and horizontal stress of surrounding rock revealed that the surrounding rock was in the order of disturbed area, inner of pressure arch, and initial stress area from inside to outside.

Figure 5 showed the change of stress in surrounding rock above the vault after adding water. The surrounding rock stress in the figure represented the changed value relative to stress after excavation stability (Figure 6 was the same), and excluded the data of GD1 which had been dropped. It can be seen that before the first collapse occurred, the vertical pressure of GD2-GD4 increased continuously to the peak value, while the vertical pressure of GD5 still decreased. The first collapse occurred shortly after the horizontal stress of GD6-GD8 increased to the peak value, which resulted in the pressure gauges at GD1, GD6 and GD7 falling off. Without taking no measures to deal with the situation after the first collapse, the vertical pressure of GD4 and GD5 continued to decrease and the horizontal pressure of GD8 and GD9 also decreased. The vertical stress of GD3 firstly decreased and then increased to the extreme value, and the second collapse occurred soon after the extreme value was reached. The collapse range was further expanded, which resulted in the pressure gauges at GD3, GD4, GD8 and GD9 falling off. The third collapse occurred in the process of cleaning up the falling body. It can be seen that the surrounding rock stress sharply increased before the first collapse, and decreased continuously during the development stage of the later collapse.

Figure 6 illustrated the change of stress in surrounding rock of the side wall of the tunnel after adding water. It can be seen that the vertical stress curves of BQ1 and BQ2 were like sine curve and the two curves changed successively during the whole collapse process. The change trend of BQ3 was basically the same as the change trend of BQ2 and BQ1, but the amplitude of the former was smaller. The vertical stress of BQ4 and BQ5 fluctuated near the X axis during the whole collapse process, which represented that these two points were basically not affected by collapse. When the vertical stress of BQ2 reached the maximum value, the first collapse occurred and then the second collapse occurred when the vertical stress of BQ1 and BQ2 reached the minimum value. At last, the third collapse occurred in the process of cleaning up the falling body. The horizontal stress of BQ6 increased all the time during the whole collapse process; the horizontal stress of BQ7 increased first and then decreased, and the maximum value of horizontal pressure was between the first collapse and the second collapse.

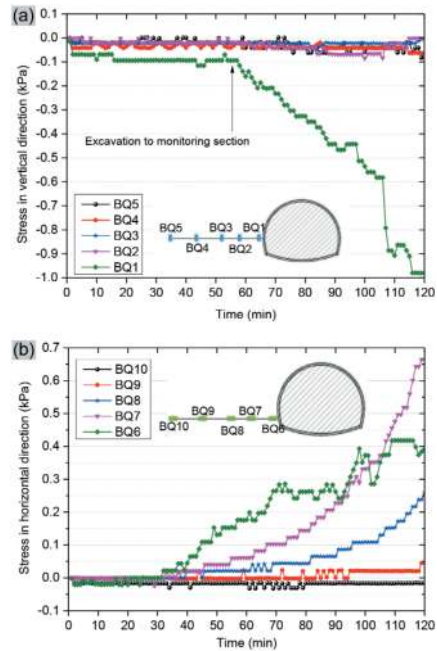

Figure 4. The change of stress in surrounding rock of the side wall of the tunnel during tunnel excavation. a. Vertical stress; b. Horizontal stress.

Figure 5. The change of stress in surrounding rock above the vault after adding water. a. Vertical stress; b. Horizontal stress.

The changes of horizontal stress of BQ8-BQ10 were very small, which demonstrated that these three points were basically in the initial stress area.

According to the test results, the development of the outer boundaries of the pressure arches and collapse arches were drawn, as shown in Figure 7. The failure behavior of the surrounding rock in the

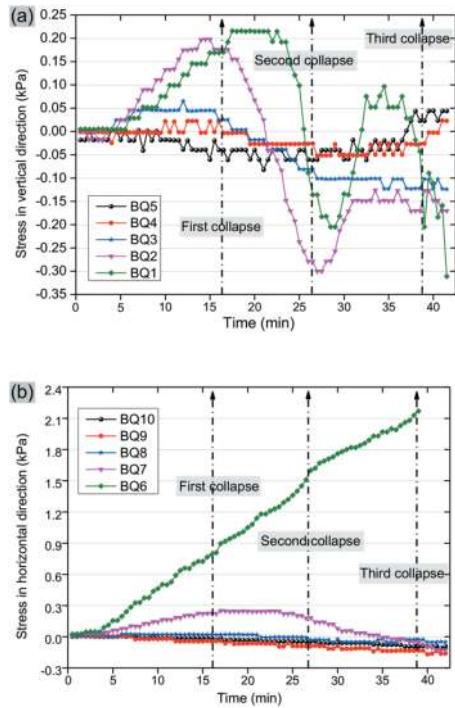

Figure 6. The change of stress in surrounding rock of the side wall of the tunnel after adding water. a. Vertical stress; b. Horizontal stress.

tunnel exhibited a progressive nature, mainly reflected in the formation of pressure arches and collapse arches during the local collapse of the surrounding rock above the tunnel vault and the subsequent collapse of the entire range. Both the internal pressure arch and the external collapse arch are load-bearing structures that can exert their compressive performance through self-stress adjustment (Guo and Zhou 2012; Chen et al. 2011). After forming the loose zone on the inner side of the tunnel, the arch structure is formed to bear the sharply increased load caused by the loosening of the surrounding rock. This effectively inhibits the deformation of the surrounding rock, and each stage of collapse ends with the formation of a collapse arch. The pressure arch expanded outward with the continuous expansion of the collapse area, and, in particular, the expansion at the vault was more significant than that at the sidewall. From the experimental results, the height of the pressure arch formed during the second time was expanded by 150% compared to the first time, while the span was only expanded by 25%.

4 DISCUSSION

4.1 Failure mechanism of BCM surrounding rock

The failures of BCM surrounding rock mass are mainly caused by the deformation incompatibility between framework grains and fine materials, which causes differential rotation between the two types of components. The yielding and failure in the interface

Figure 7. The development of the outer boundary of the arch and collapse arch in the process of collapse.

area gradually develop from local to overall failure, resulting in partial sliding of some framework grains relative to others along the yield interface. For the tunnel face, the failures of the surrounding rock are caused by the compression-shear and tensile failure of the surrounding rock above the vault, supplemented by the compression-shear failure of the surrounding rock around the sidewall. This is consistent with the test phenomena, i.e., the effect of the damage of the top surrounding rock is greater than that of the sidewall surrounding rock of an unlined tunnel in a BCM formation.

In addition, disturbing external factors, such as seepage and vibration, can accelerate the loosening and softening of the interface area, making it more susceptible to failure. Many scholars have conducted soil tests on samples composed of mixed particles with different water contents, and the results show that ϕ and c of the soil both decrease significantly as the water content increases (Qin et al. 2022b). When the formation is rich in water, the friction coefficient between particles and the bonding ability of the cementitious material decrease significantly compared with the dry state. In addition, the piping phenomenon may occur in the BCM formation under the action of groundwater, where the debris of medium and fine sand between large-sized cobbles and boulders will flow into the excavation face with the water, causing changes in the microstructure of the soil mass, such as the transformation from more compact framework-dense type soil mass to less stable framework-pore type soil mass. For shallow tunnel construction, it is essential to ensure a dry excavation environment (Fang et al. 2012). On the one hand, this can improve the working environment inside the tunnel, increase work efficiency, and, more importantly, it is an effective reinforcement measure for the BCM formation. In practical engineering, before the tunnel construction, the well-point dewatering can be carried out in sections with high groundwater (Qin et al. 2022a). This technology involves using a vacuum pump and wellpoints installed in a pattern around the construction site. The wellpoints create a low-pressure zone around them, and the vacuum pump draws water from the soil into the wellpoints, lowering the groundwater level below the construction working face as much

as possible to meet the need for dry construction. In addition, appropriate post-excavation grouting procedures during tunnel excavation can also effectively play a role in water blocking.

4.2 Failure evolution process of the unlined tunnel under BCM formation

It can be determined from the strength parameters of the BCM formation that ϕ was much weaker than c . A higher ϕ value increases the friction resistance due to soil particle contact (Terzaghi 1920). Therefore, in the absence of disturbance, an unlined tunnel in a BCM formation exhibits certain self-stability.

However, under an external disturbance (the action of gravity or hydrodynamic force), the local surrounding rock of the tunnel vault exhibits tensile failure, which is characterized by the continuous falling of particles; moreover, due to the compression-shear failure in the interior area, the falling particles may cause a large continuous piece of the surrounding rock to suddenly fall. With the adjustment of stress in the surrounding rock, the first pressure arch is formed on the surrounding rock above the tunnel vault, which greatly shares the load of the self-weight of the upper stratum and hinders the development of surrounding rock collapse. Its obvious feature is the formation of a short-term stable collapse arch. Therefore, in the early stage of collapse, the deformation of the surrounding rock will not be very rapid. The initial failure pattern is indicated by stage 1 shown in Figure 8. With the passage of time or continuous disturbance by external factors, the temporary equilibrium state in stage 1 is broken, and the collapse continues to develop upward. During the process of collapse development, the fracture surfaces in the surrounding rock gradually connect with each other, and the connected fracture surfaces lead to a larger range of collapse. During this process, the pressure arch initially formed in the surrounding rock begins to transfer upward. During the entire collapse process, the surrounding rock may experience the balance and instability process of the pressure arch many times, and the formation of each pressure arch has a certain hindering effect on the collapse of the BCM surrounding rock. The collapse of the surrounding rock at this stage exhibits obvious stage characteristics due to the action of the pressure arch, and the failure pattern is indicated by stage 2 shown in Figure 8. As the arch structure of the surrounding rock develops to the surface and gradually disappears, the collapse of the surrounding rock begins to develop rapidly. This failure pattern is indicated by stage 3 shown in Figure 8. Through the analysis of the entire collapse evolution process of the BCM surrounding rock, several characteristics can be extracted, which are crucial for selecting an appropriate tunnel support system.

a) Suddenness. Without any disturbance, the unlined tunnel segment in BCM formation can remain stable. However, this stability can be

Figure 8. Failure evolution process of an unlined tunnel under a BCM formation.

easily disrupted by external disturbances such as continuous excavation or rainfall, causing the surrounding rock above the tunnel vault to collapse suddenly. Although such formations exhibit high bearing capacity characteristics, their strength is prone to weakening due to natural loose features. Therefore, excavating the tunnel face directly without taking pre-support/pre-reinforcement measures is not recommended in actual tunnel construction.

- b) Staging. During the collapse evolution of the surrounding rock, stress adjustments and transfers occur multiple times along the periphery of the tunnel profile, resulting in the formation of numerous pressure arches, making the collapse of the soil exhibit stage-wise characteristics. Each appearance of the arch structure has a certain inhibitory effect on the deformation development of the stratum. Still, the effect gradually weakens, manifested as the time for self-stabilization after each periodic collapse is gradually shortened. Therefore, controlling the stability of the first-formed pressure arch is the preferred measure by which to prevent tunnel collapse in BCM formations effectively.
- c) Grouping. The collapse movement of the surrounding rock exhibits a grouping behavior characterized by a three-phase composite structure of “disturbed zone-pressure arch zone-initial stress zone.” After the formation of the disturbed zone on the inner side of the tunnel, the external arch structure is immediately formed to bear the transferred soil pressure timely. Conversely, the instability of the pressure arch zone leads to the enlargement and extension of the disturbed zone soil, particularly in the vault area of the tunnel. Therefore, when small-scale soil collapses occur in tunnel construction, timely measures should be taken to reinforce the area and control the collapse range within the shallow disturbed zone to avoid further damage to the deep pressure arch zone and to trigger a large-scale collapse.

4.3 Insight into the optimized support strategy

Choosing a suitable support structure system that matches the characteristics of strata deformation and failure is essential to control the collapse of the surrounding rock mass in tunnel engineering. The collapse of the surrounding rock mass in BCM exhibits

sudden, staged, and grouped features. To control the collapse of the surrounding rock mass, it is essential to promptly cut off the path of displacement and stress transmission during the collapse process. The pressure arch is a self-adjusting protection method formed during the surrounding rock mass deformation process. It can delay the deformation and damage of the BCM stratum in a short period and has a natural inhibitory effect on the development of surrounding rock deformation. Therefore, controlling the stability of the first-formed pressure arch is the preferred measure to prevent tunnel collapse in the BCM stratum. In practical tunnel construction, the stability control of the pressure arch is mainly achieved through two approaches (as shown in Figure 9). The first approach involves strengthening the supporting arch-feet to mobilize the surrounding rock's carrying capacity in the pressure arch area. The second approach involves limiting the development of arch height to help the loose surrounding rock bear the load.

Figure 9. Control strategies for BCM surrounding rock collapse.

a) Enhance the strength of the supporting arch-feet. The soil arching effect describes the redistribution phenomenon of soil under shear stress, which mobilizes its shear strength and transfers the vertical load to the stable areas at the sides of the arch feet (Terzaghi, 1936). Researchers have found that the conditions for forming pressure arches include the development of shear stress in the soil and providing stable support at the arch feet (Guo and Zhou, 2012). For tunnels excavated by the sequential excavation method, the pressure arch formed in the surrounding rock is located around the tunnel crown profile, with a similar outer shape to the tunnel crown (Handy, 1985; Chen et al., 2011). It has been proven in many engineering practices that the instability of the arch structure is mainly caused by the failure of the tunnel excavation at the arch feet (Chen et al., 2013; Xiao et al., 2014). Hence, in tunnel construction in the BCM stratum, the stability of the surrounding rock at the arch-feet area should be the primary focus of control and monitoring. The tunnel support system should take appropriate measures to improve the bearing capacity of the surrounding rock at the arch-feet area, fully mobilizing the soil bearing capacity in the pressure arch zone.

b) Limit the development of arch height. Based on the grouping collapse characteristics of the surrounding rock, it can be inferred that the stability of the external pressure arch will gradually decrease as the loose zone of the surrounding rock inside expands. When the pressure arch zone becomes unstable, the loose zone of the surrounding rock will significantly expand outward. Therefore, for the tunnel construction in the BCM formation, appropriate pre-reinforcement or pre-support measures should be taken to assist the loose surrounding rock in bearing the load while minimizing disturbance to the surrounding rock caused by tunnel excavation, e.g., by avoiding intense construction disturbance activities, such as continuous drilling.

5 CONCLUDING REMARKS

- (1) BCM formations are a common discontinuous medium consisting of high-strength framework grains such as boulders and cobbles, as well as low-strength filling materials such as sand and clay. Due to its significant heterogeneity, there is often incongruous deformation between the coarse and fine particles, resulting in yield failures in the interface regions between them. When tunnels are excavated, the surrounding rock in the vault area is subjected to both compressive-shear and tensile stresses simultaneously, making it more prone to failures than the sidewall area.
- (2) Experimental results demonstrate that the unlined tunnel section in a BCM stratum is stable under normal conditions. Nonetheless, it can become unstable and collapse when subjected to external disturbances, such as continuous excavation or rainfall, causing the surrounding rock above the vault to loosen and collapse. The collapse motion of the surrounding rock follows a grouped movement pattern, which consists of three phases: the disturbed zone, pressure arch zone, and initial stress zone. Throughout the instability evolution process, pressure arches repeatedly form in the surrounding rock, leading to clearly staged deformation development.
- (3) The instability of the pressure arch zone can lead to an increase and expansion of the loose zone, particularly in the tunnel vault area. To prevent tunnel collapse effectively in BCM formations, it is suggested that controlling the stability of the first-formed pressure arch is the preferred measure based on the deformation and failure characteristics of the surrounding rock. The main objective of support intervention is to mobilize the bearing capacity of the surrounding rock in the

pressure arch zone and enhance the bearing capacity of the loose zone by reinforcing the strength of the supporting arch-feet and limiting the arch height development.

ABSTRACT: Tunnel excavation with TBMs have turned into the favourite option for the construction of long tunnels to supply the demand for greater utilization of underground spaces, especially in urban areas. During TBM advancement, the face-stabilizing pressure is one of the most important factors for the proper controlling of ground movement as high face pressure often leads to surface upheaval whereas low face pressure might lead to collapse of the face and ultimately large surface settlement. Based on a recent semi-empirical formulation that describes the relation of the stress–strain behaviour of soils, the following paper is presented with the goal to provide an approach for the evaluation of surface settlement due to application of TBM face pressure, hence an aid tool for indicating tunnel face instability. Attention and alarm limits are also presented to consider uncertainties of geotechnical parameter of the groundmass. First, a brief presentation of the formulation for correlation of TBM face support pressure and the immediate surface settlement is given and then a procedure for continuous accompany of TBM excavation is provided as well as the bound limits. Finally, a case study of a tunnel construction for a metro system is presented here to offer a better understanding of the use of the present concept.

Keywords: Surface settlement, Face pressure, Tunnels & Tunnelling

1 INTRODUCTION

Nowadays the construction of tunnels in urban areas constitutes a good solution to meet the demands for new infrastructure and utility networks (i.e. water, gas, electricity, sewage, etc.) to the people that live in the cities. Two types of tunnels construction are majorly implemented in urban areas.

Tunnel boring machines (TBMs), compared with sequential tunnels, turn the most adopted tunnel construction method specially for the construction of long linear infrastructure assets and capability for minimizing the effects of ground surface movements.

No doubt the construction of tunnels by TBMs or sequential tunnels induce deformations on the

groundmass that propagates into the surface in the form of settlements. These deformations can cause damages to nearby buildings, infrastructures or utility networks thus drawing the attention to the estimation of ground movement.

The settlement trough, in which is known this deformation, can be estimated by considering an empirical approach (Peck, 1969; Attewell and Woodman, 1982; New and O'Reilly, 1991; Celestino et al., 2000), analytical solution (Litwinski, 1957; Loganathan and Poulos, 1998), numerical approaches (Lee and Rowe., 1990; Shin et al., 2002 and Fagnoli et al., 2015) or modelling test (Atkinson and Potts, 1977; Mair & Taylor, 1997; Meguid et al., 2008).

*Corresponding author: victor.rattia@sener.com.br

Regarding specifically the construction of tunnel with TBMs, Mair and Taylor (1997) stated that the most common procedures to minimise ground movement are based on methods to stabilise the tunnel face against groundmass instability by applying internal support pressure in the excavation chamber.

By considering the statements indicated above, the present paper is intended to offer an approach for estimation, during tunnelling, of tunnel face instability by the use of monitoring surface settlements in order to indicate in which manner groundmass behave ahead of the tunnel face.

The goal of this proposal is to provide an additional tool for decision aid in the establishment of a control of groundmass response during tunnel construction by the application of a formulation proposed by Rattia et al. (2022) which relates the maximum surface settlement with the applied support pressures that use an analogy with the hyperbolic behaviour of stress–strain curves of soils.

As an example of application of this method a step-by-step procedure is described and applied into two tunnels projects built with TBM: Extension of Line 1 to the new Fair of the Milan metro system and the Milan underground pass railway line in Italy, and the Bangkok MRTA project in Thailand.

2 MODELLING SURFACE SETTLEMENT

Tunnelling causes settlements at the surface due to changes in the state of stress of the groundmass around the excavation. Typical representation of this movement, in the transverse direction, was first introduced by Peck (1969) and later Attewell and Woodman (1982) by proposing an empirical model based on the Gaussian probability density function.

Regarding surface settlements due to TBM tunnelling, Atkinson (2007), based on centrifuge test results, observed that correlations between the surface settlement and the applied face support pressure could be obtained because low face pressure would cause large settlement and if a high face pressure is applied this would produce small surface settlement.

2.1 The correlation approach for describing surface settlement due to TBM tunnelling

Figure 1 shows a schematic representation of the behaviour of groundmass response due to TBM tunnelling observed by Atkinson (2007). During tunnelling, if the applied TBM support pressure (P) is equal to the estimated initial support pressure for tunnel-face stability (P_0), the surface settlement should be negligible. The initial portion of the settlement curve corresponds to predominantly elastic behaviour. The onset of plastic behaviour is identified as when the settlement curve approaches the asymptote given by P_{min} (the minimum applied TBM support pressure before face collapse may occur). Relatively larger settlements or even face collapse may occur when the applied TBM support pressure reaches P_{min} , which is not necessarily zero.

Figure 1. Settlement curve caused by tunnelling (Rattia et al., 2022).

According to Rattia et al. (2022), the behaviour can be mathematically expressed by a hyperbolic equation as follows:

$$\frac{S_{max}}{D} = \frac{a_s(P_0 - P)}{b_s(P_0 - P) - 1} \quad (1)$$

Where, S_{max} is the maximum surface settlement (mm), D is the tunnel diameter (mm), P is the applied TBM support pressure (kPa), P_0 is the estimated initial TBM support pressure for face stability (kPa), corresponding to null displacement, as and b_s are best-fit parameters.

The value of P_0 , applied along the tunnel axis, may be estimated based on the limit equilibrium method (Anagnostou and Kovári, 1994, 1996) or on limit analysis approaches (Carranza-Torres, 2004; Davis et al., 1980), among other methods reviewed by Guglielmetti et al. (2008).

Also, according to Rattia et al. (2022), the values of best-fit parameters (a_s and b_s) are expressed, in terms of drained and undrained conditions, as:

$$a_s = 1/E'_{ur} \quad (2a)$$

$$a_s = 1/E_{ur} \quad (2b)$$

Where, E'_{ur} and E_{ur} are the unloading–reloading elastic moduli (kPa) for drained and undrained conditions, respectively.

$$b_s = \frac{1 + \sin \phi'}{2c' \cos \phi' + 2(P_0 - u_{w0}) \sin \phi'} R_f^* \quad (3a)$$

$$b_s = \frac{1}{2S_u} R_f^* \quad (3b)$$

Where, c' is the effective cohesion (kPa), ϕ' is the effective friction angle (degrees), u_{w0} is the pore-water pressure at the tunnel axis (kPa) and S_u is the undrained shear strength (kPa). $R_f^* = R_f/(C/D)$,

where R_f is the constant failure ratio proposed by Duncan and Chang (1970), which value is less than unity and is independent of confining pressure.

2.2 Consideration of soil variability

Kulhawy (1992) and Phoon and Kulhawy (1999a) explained that ground properties are subjected to uncertainties due to inherent ground variability, measurement error and transformation uncertainty. An appropriate description of these uncertainties is needed for the evaluation of geotechnical problems, especially when dealing with tunnelling projects due to groundmass variability results of scattered ground displacements.

To consider this situation, Rattia et al. (2022) proposed an expression based on the definition of a lower and upper bounds of the settlement curve as follows:

$$\left(\frac{S_{max}}{D}\right)_{upper\ bound} = \frac{a_{s90}(P_0 - P)}{b_{s90}(P_0 - P) - 1} \quad (4)$$

$$\left(\frac{S_{max}}{D}\right)_{lower\ bound} = \frac{a_{s10}(P_0 - P)}{b_{s10}(P_0 - P) - 1} \quad (5)$$

Where, a_{s90} and b_{s90} correspond to the 90th percentile and a_{s10} and b_{s10} correspond to the 10th percentile.

3 METHODOLOGICAL APPROACH

The proposed methodology is built upon a deterministic analysis of the variables for the computation of system performance variables. The output response of the system performance of the process is assumed to be represented by the maximum surface settlement (S_{max}) obtained from the model presented by Rattia et al. (2022).

Figure 2 shows proposed framework for assessment of tunnelling induced ground movement during TBM excavation. Three components are required to build an efficient model analysis of TBM performance to compare with the real surface settlement campaign. The first component is the estimation of the initial TBM face support pressure. The second component is model construction. The last component is the comparison of estimated model of surface settlement with the real surface settlements measure.

3.1 Estimation of initial face support pressure – P_0

To minimize the effects of tunnel construction with TBMs, especially in urban areas, a need for application of a support pressure is essential to maintain face stability. In this approach the TBM support pressure is called initial face support pressure (P_0) because constitute the first stage to initiate the representation of the model herein proposed.

As presented in Figure 2, first is necessary to collect information about the project, including the

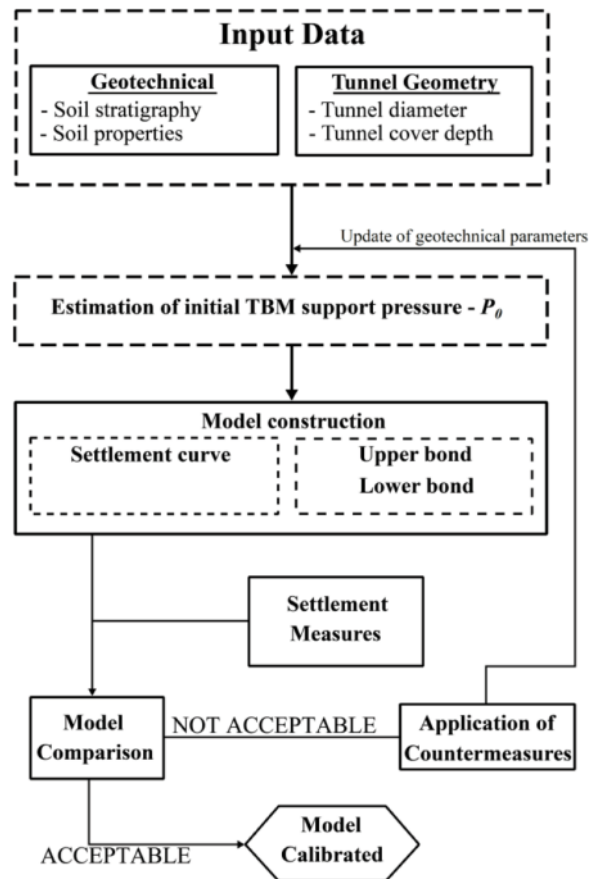

Figure 2. Proposed framework for accompanied of surface settlement.

following: (i) site exploration data (e.g., quantification of soil layers and water level) for establishing input data such as material properties and model geometry and (ii) the type of tunnel excavation methods to be used (sequential or mechanized), which will indicate the expected type of ground movement.

To estimate the initial face support pressure, an extensive bibliography of methods exists and can be used in this approach. These are mostly based on limit equilibrium methods – LEM (Anagnostou and Kovári, 1994, 1996) or limit analysis (Carranza-Torres, 2004; Davis et al., 1980), known as analytical methods, and 2D or 3D numerical analysis also known as numerical methods. Guglielmetti et al. (2008) provided an extensive review of the analytical methods that could be used in the approach here proposed. As Numerical methods for the estimation of P_0 require a large computation effort, this type of method won't be considered.

3.2 Model construction

Once P_0 is estimated, either by using limit equilibrium method or limit analysis, the following procedure is to build the settlement curve according to Equation 1, as well as to represent in the model the upper and lower bounds of the settlement curve characterized by Equations 4 and 5.

3.3 Model comparison

In this last process a comparison of the surface settlement model with data regarding surface settlement is made. Two decisions are possible based on the analysis outcome:

- i. The measured values of surface settlement are not within the limits foreseen in the model and therefore not acceptable. An application of countermeasures is necessary: (a) e.g., update of input variables (geotechnical parameters) to adjust/recalibrate the model if groundmass shows negligible deformation; and/or (b) ground treatment to assure face stability if groundmass shows potential mechanism of collapse.
- ii. The measured values of surface settlement are within the limits foreseen in the model and therefore acceptable. This means that the model is well calibrated according to ground mass properties showing agreement between the theoretical model and the observed values of surface settlement.

4 APPLICATION AND ANALYSIS OF THE PROPOSED MODEL

The present chapter is intended to show an example to illustrate the application of the proposed concept. The hyperbolic model (Equation 1) and the bound limits (Equations 4 and 5) were used to evaluate surface settlement as a function of support pressure.

This approach was applied to the Extension of Line 1 to the new Fair of the Milan metro system and the Milan underground pass railway line in Italy (Antiga and Chiorboli, 2009), and the Bangkok MRTA project in Thailand (Suwansawat and Einstein, 2006).

Table 1 summarizes the features of each case history collected from the literature. Basic input

information regarding the tunnel geometry and the type of groundmass is indicated. Table 1 also presents the results of estimation of geotechnical parameters estimated based on Equations 2 and 3. The adopted values of R_f was of 0.8 and 0.9 for the sand and clay type soil mass, respectively. Values of P_0 were iteratively estimated by using the LEM until find a value that adequately represent the model with the data for each case history.

Figures 3 to 5 show the best-fit results for each case history using the equations presented by Rattia et al. (2022). A good agreement of the model with each case history data can be observed where values of R^2 were higher than 0.8.

Regarding soil variability representation, values of Coefficient of Variation (CoV), estimated through monitoring data, were used to estimate the upper and lower bounds. It can be observed that the CoV , on each case history, provided an adequate indicator for defining the soil variability limits that affect the development of surface settlement response due to TBM tunnelling.

In relation to geotechnical parameters, even though values of geotechnical parameters were not indicated by Antiga and Chiorboli (2009) and Suwansawat and Einstein (2006), different literature were consulted to allow a comparison with the data just obtained. Table 2 shows presents a summary of geotechnical parameters for the cities of Milan and Bangkok, used for the analysis of tunnelling projects different tunnelling projects performed in these cities.

As it is possible to observe from Table 1 and 2, a good agreement was achieved between the data estimated from the analysis of the case histories with the values collected from literature, indicating that the approach here presented could be used as a complementary tool for the analysis of surface settlements during TBM tunnelling.

5 CONCLUSIONS

The present paper was aimed to propose a practical approach for the control of TBM performance and groundmass influence through the estimation of surface settlement based on the applied TBM face support pressure during excavation.

The proposed approach is based on the formulation presented by Rattia et al. (2022), which also

Table 2. Published data of geotechnical parameters for the cities of Milan and Thailand.

Reference	Country	Type of soil	Geotechnical parameters		
			E'_{ur} (kPa)	c' (kPa)	ϕ' (°)
Fagnoli et al. (2015)	Milan Italy	Gravelly sand	144000	0	33
Surarak et al. (2012)	Bangkok Thailand	Stiff clay	30000	11.5	28

considers the inherent variability of soil properties through the definition of lower and upper bounds.

Three case studies, from previous published work in Italy and Thailand (Antiga and Chiorboli, 2009; and Suwansawat and Einstein, 2006), were presented to validate the approach here presented. It can be observed that the model adequately represented the groundmass behavior for each case study.

Furthermore, a reasonable estimation of geotechnical parameters from the data of each respective case study was obtained if compared with theoretical values also collected from others published works in Italy and Thailand, respectively (Fagnoli et al., 2015; and Surarak et al., 2012).

Finally, the authors believe that the proposed framework constitute a valuable tool in TBM tunneling project because offers a procedure for recalibration of the settlement model as far as new monitoring and TBM face pressure data are incorporated enabling a real time information for the decision making.

ACKNOWLEDGMENTS

The authors recognized the importance of publication. Without this wouldn't be possible to have an overview of the concepts, variables, and approaches for analyzing tunnel face stability, ground movement and finally, to allow the development of new theories and approaches for solving tunneling problems. The authors hope that also this publication might contribute to the tunnelling industry as the publications did in this work.

The authors would also like to acknowledge the financial support of the Brazilian Research Agency – CNPq as well as the IFG (Instituto Federal de Goiás).

Jet grouting soil improvement to excavate a tunnel under passing the A4 Milano-Venezia motorway for the extension of the line 1 of the Milan metro

M. Silvestri & D. Chirulli

More Engineering s.r.l., Milano, Italy

ABSTRACT: The extension of the line 1 of the Milan Subway to the N-E outskirts of city entailed the execution of bored tunnels for a global length nearly 2 km in difficult geotechnical and hydrogeological context. The tunnels are built using conventional tunneling systems with partial and full face excavation. The excavation of the top section, above water level, of the tunnels requires the consolidation of the crown and of the face by sub-horizontal jet-grouting columns in order to obtain a band of consolidated soil suitable to guarantee a discharge arc. After the excavation of the top section the treatment of the lower part is done by injections that have to guarantee soil improvement and water tightness, then, the excavation of the lower section part happens. The work was found to be extremely complex for the presence of incoherent soil (sand and gravel) in an extremely variable hydrogeological context with water table level suddenly changing of some meters in a few months. In order to overcome these critical issues and assure greater safety and continuity of the works, the Contractor and its Consultant developed a detailed design proposal based on an observational approach, which considered several possible hydrogeological scenarios and staged excavations over small stretches. This article presents the solutions adopted in terms of interventions (consolidation, excavation and lining) in correspondence of the route where the section underpasses the important infrastructure of the A4 motorway.

Keywords: Tunnelling, Jet Grouting, soil improvement, monitoring, incoherent soil

1 INTRODUCTION

The growing need for transport infrastructures has led to a stronger and stronger growth in the use of underground spaces in highly populated contexts.

The common presence of soils with poor mechanical characteristics, groundwater interfering with excavations and pre-existing structures has led to major improvements in the construction technologies, in the design techniques and in the construction materials. In these areas, that is in the cases in which the conditions of stability and water tightness of the excavation can be guaranteed only using important stabilization systems, there has been the exponential growth of the “mechanized” excavation systems, in particular in the equipment field with face stabilization systems (EPB Shield, Slurry Shield).

At the same time, despite the technological advances made in the field of soil consolidation and waterproofing systems, the “traditional” excavation

systems have been relegated, to interventions of reduced extension, that is to the cases in which the road of the mechanized excavation is not economically reasonable.

Cases of urban excavation under difficult geotechnical conditions made with traditional excavation systems are increasingly rare.

An interesting experience of the application of the conventional tunneling systems with a full-face excavation with jet grouting consolidation soil is presented below; it relates to the realization of the extension of the line 1 of the Milan Subway in difficult geotechnical and hydrogeological context.

The work was found to be extremely complex for the presence of incoherent soil (sand and gravel) in an extremely variable hydrogeological context with water table level suddenly changing of some meters in a few months and limited overburden.

The undercrossing of the important A4 motorway in operation, completed the project framework.

*Corresponding author: a.antiga@more-engineering.it

2 GENERAL DESCRIPTION OF WORK

The project to extend line 1 of the metro from Sesto FS to Monza is part of a broader framework for strengthening the public transport system in the north of Milan.

It is aimed at ensuring a valid alternative to the strong private traffic currents coming from the Brianza and important road axes such as the A4 motorway and the SS n. 36 and at the same time, serves areas for which a strong urban development is expected.

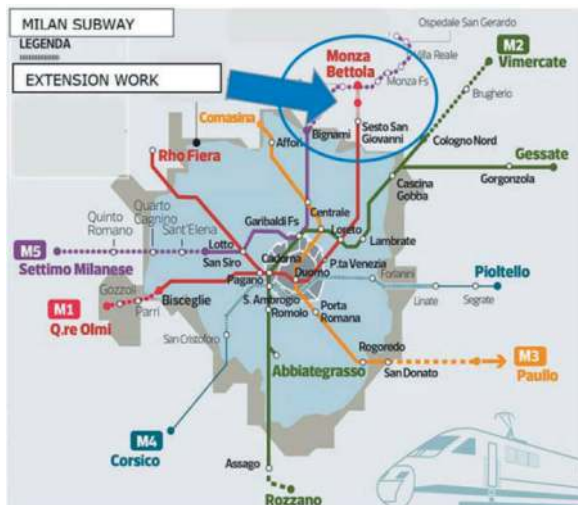

Figure 1. Milan subway key map.

The extension of the M1 subway line in a northerly direction beyond the current Sesto FS terminus represents the most qualifying and functional element of the reorganization of the public system in the hinterland areas that most directly insist on the Milan-Monza route.

From this point of view, the extension of M1 plays a dual and important role: on the one hand, it guarantees interconnections at the local level between areas of future significant urbanization and, on the other, contributes to improving the interrelations between Milan and the most representative poles of the northern hinterland. The route covers the territories of the Municipalities of Sesto San Giovanni, Cinisello Balsamo and Monza.

The intervention extends for about 1800 meters and includes:

- 2 sections of cut-and-cover tunnel (total length: 300 m);
- 2 underground stations: Sesto Restellone and Cinisello-Monza;
- 4 bored tunnels (total length: 1207m);
- 5 shafts.

The route of the line in question intersects the planned extension of line 5 of the Milan Metro at the Cinisello-Monza station.

The amount of works is worth about 90.000.000 €.

The contract for the completion of construction works has been awarded in 2017 by De Sanctis Costuzioni S.p.A.

Contracting Authority: Metropolitana Milanese S.p.A. on behalf of the Milan Municipality.

In Figure 2 it is showed a key plan of the extension works.

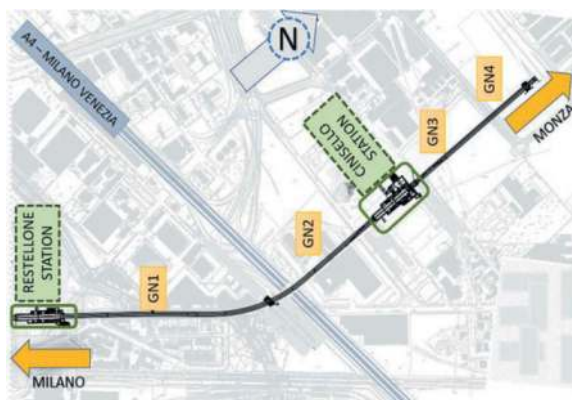

Figure 2. Key plan of the extension works.

3 THE UNDER PASSING OF THE A4 MOTORWAY

The route of the line in question intersects the A4 motorway from pk 13+769.49 to pk 13+846.97. In this section the tunnel is named "GN02". The overburden is approximately 15 m.

The A4 is a motorway which connects Turin and Trieste via Milan and Venice and passes north of Milan. is one of the most trafficked motorways of Italy with an ADT (Average Daily Traffic) of about 250.000 vehicles.

In this context it was important to limit the value of surface settlements. For this reason, as described below, a complex monitoring system had set up.

4 GEOLOGICAL AND GEOTECHNICAL FRAMEWORK

The subsoil of the Milan area consists of alluvial deposits within which different zones can be recognized located at increasing depths and with different granulometric characteristics.

In the area of our interest, located just north of the city, a well-known lithological unit is present up to a depth of about 40 meters; it consists of a gravel-sandy granular deposits with diffused pebbles and occasional silty-sandy layers. The intercalations of silty-sandy lenses are limited to a thickness of few meters. The mechanical characteristics of this unit are characterized by a zero cohesion value and a moderately high friction angle. The mechanical characteristics are essentially well-known and uniform in the whole area.

In detail, below the backfill soil, with an average thickness of 0.50 m, we can recognize two layers of interest for the works in question, up to the maximum depth of interest (40 m):

Formation SLG (Silty sand with gravel) (0.5÷6.0 m b.g.l.)
19 ÷ 20 kN/m³ unit weight
30 ÷ 33 ° friction angle
c' = 0 kPa drained cohesion

Formation GS (silty-sandy gravel) (6.0÷40.0 m b.g.l.):
20 kN/m³ unit weight
35 ÷ 38 ° friction angle
c' = 0 kPa drained cohesion

5 HYDROGEOLOGY FRAMEWORK

The main and crucial theme in defining the hydrogeological framework is the level of groundwater to be taken as a design reference: this determines in a decisive way the safety conditions, the costs and construction times.

The aquifer is characterized by high transmissivity and permeability values, equal to approximately 0,01 m²/s e a 0,001 m²/s. They determine its remarkable productivity, with specific flow values of (10÷25) l/s for lowering the aquifer level of one meter.

Over the last decades the trend of the piezometric level in the Milan area has been strongly influenced by the social evolution. The level of the groundwater has been known since the beginning of the 50s thanks to the piezoelectric map of the Province of Milan drawn up in 1958 and subsequently constantly updated. From the late 1970s, we began to see an upward shift in the piezometric levels in conjunction with an exceptional period of rainfall combined with a reduction in industrial water withdrawals due to the reduction in industrial activity. Since 1976, a cyclical (still ongoing), slow and progressive climb has begun, with approximately fifteen years cycles, due to the closure or relocation of numerous industries with consequent relocation of the water withdrawal points in areas far from the urban center. This hydrogeological context has been causing a negative interaction between groundwater and underground infrastructures for decades.

It conditions, in a significant way, the construction of all underground works in the Milan area. This is also due to the possible sudden variations (pluri-metrical in one month) due to the high permeability and hydraulic transmission of the Milanese aquifer.

6 WORKS CHRONOLOGICAL HISTORY

6.1 *First public contract (2011)*

In 2011, the first Contract, for the L1 extension works, was awarded to a Joint Venture in a design-build contractual framework. Unfortunately, between the tender (2009) and the assignment of works (2011), the water

table level increased for more than 4 m with a foreseeable increasing trend. Therefore, the Contractor had to deal with the actual recorded water table level. With the new water level configuration, the tunnel excavation was affected by significant water inflow. For this reason, the new design was characterized by important and massive ground improvement. The project was drafted and approved in 2011; tunnel excavation works began in 2012 after the excavation of the stations and shafts up to the excavation level of the bored tunnels.

6.2 *Works stop (2014-2017)*

When the works production had reached about 30% the financial difficulties of the JV Contractor, and the sudden further rise in the aquifer led to the termination of the contract at the end of 2014. The abandonment of the site, without the completion of the ground improvement treatments, followed the contract termination. This, combined with the endless increase of the water table, caused inexorably the flooding of the executed works (Figures 3, 4).

Figure 3. Flooding of the executed works.

In spring 2015, the groundwater level reached its peak, with a 5–6 m increase over year 2011 (year of the JV Detailed Design) values and 12–13 m increase over year 2008 (year of tender design final approval) values.

The period (2013-2015) was characterized by large fluctuations in the groundwater level. For all these reasons the Owner had to prepare an integration of the Final Design to reassign the works. The Owner also stated to insert in the new construction contract the obligation for the new contractor to develop the new Detailed Design considering the actual groundwater levels and its foreseeable trends (this was because after the peak of 2015 the levels of groundwater recorded show a downward trend).

6.3 *Second public contract (2017)*

According to the Italian law, in case of contractual termination of the awarded contractor, the works

Figure 4. Flooding of the executed works.

Contract can be entrusted to the second ranked company.

By this assumption the second ranked contractor manifested its availability for the completion of the work.

In June 2017 a new contract was signed between the Municipality of Milan (Owner, legally represented by Metropolitana Milanese S.p.A.) and De Sanctis Costruzioni S.p.A. (Contractor).

7 OBSERVATIONAL METHOD

An element that characterized the project was the strong variation in the groundwater level, which from 2012 to the present day has seen fluctuations first rising and then falling to approximately 4m ($\pm 4m$).

All this considered, a technical table was opened which involved Client, Contractor and Designer to identify the design approach to be adopted in the Detailed Design.

In the light of the Client's Final Design, the contractual obligations and the actual variability of the hydrogeological hypotheses, the Contractor and his Consultant considered appropriate to study a proposal for a Detailed Design based on an Observational Method with the aim of reducing the risk in terms of time and cost of the project and increasing the safety factors of the tunnel works.

This was achieved by:

- i. introducing a variability of the ground improvement interventions and of the execution phases;
- ii. defining a rational and binding sequence of the work phases with well-defined activities to be completed in a well-determinate period;
- iii. defining a realistic gradient increase of the water table level;
- iv. using an "active monitoring system" during construction to combine the previous three points and adapt the design to the actual site conditions.

For further details, please refer to the article developed by the same themselves at WTC2020 (Iagulli G., Silvestri M., Messineo L., Antiga A.. An

application of the Observational Method to deal with sudden water level changes: the 4 tunnels for the extension of the line 1 of the Milan subway. ITA-AITES World Tunnel Congress, WTC2020 and 46th General Assembly Kuala Lumpur Convention Centre, Malaysia 15-21 May 2020).

8 TECHNICAL SOLUTION FOR THE A4 UNDERPASS

The excavation of the GN02 tunnel was carried out between March and November 2022. Throughout this period, the groundwater level remained below the bottom excavation level. This condition, in accordance with the observational method, made it possible to advance with a full-face excavation.

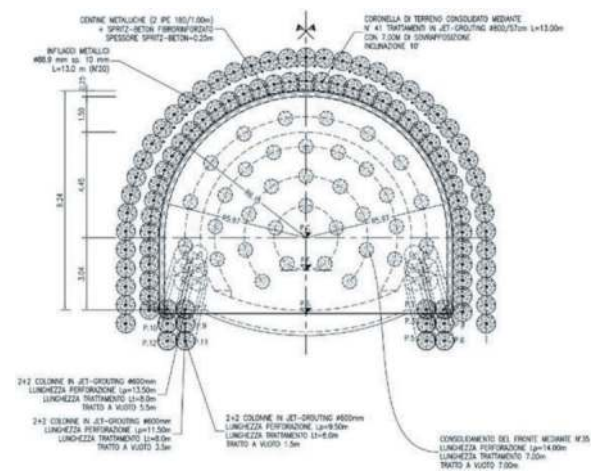

Figure 5. Cross section.

Figure 6. Longitudinal section.

For a typological section, the stabilization interventions and the executive phases are the following (figures 5, 6):

1. soil improvement intervention around the excavation section profile by means of sub-horizontal jet-grouting columns (800 mm) length 13.0 m (1);
2. face stabilization by sub-horizontal jet-grouting columns (600 mm) length 14.0 m (2);

3. temporary lining: steel ribs 2 IPE180/1.0 m + sprayed concrete (thk 0.25 m) reinforced with steel fibers; sprayed concrete (thk 0.10 m) reinforced with steel fibers in the excavation (3);
4. excavation of the face operating for segments (max length 6.0 m with single steps length 1.0 m);
5. inverted arch: reinforced concrete (thk 0.90 m);
6. internal lining: reinforced concrete (thk 0.50÷1.5 m).

9 JET GROUTING

For the realization of the soil treatments with jet grouting columns at the contour and at the face, the single fluid system was used: in this system, the cement mixture acts as both the disintegrating fluid and the column constituent material.

The average operating parameters used for the construction of the columns are as follows:

- pressure 400 bar
- water cement ratio 1.0
- nozzles n.2, Ø3 mm
- rotation speed 15/20 rpm
- ascent speed 50 m/h
- flow rate 3 l/s
- Marsh viscosity 28 sec
- density 1.55 gr/cm³

These parameters were fine-tuned by means of a specific test field carried out prior to the start of the works. In particular, the following tests were carried out:

- checks of the injection mixture (density, Marsh viscosity, preparation of test specimens for the verification of compressive strength at 7 days and 28 days);
- check on already completed columns (core drilling for compressive strength at 28 days) (Figure 7).

Figure 7. Treated soil samples.

According to the specifications, the required compressive strength of the consolidated soil had to be ≥ 5 MPa. The following table summarizes the results obtained. It can be seen that the value of the cylindrical compressive strength is much higher (minimum ≈ 30 MPa, maximum ≈ 40 MPa) than required.

Table 1. Laboratory test results on specimens.

Sample	Dimension (mm)		Density	fc
	Diameter	Height	kN/m ³	MPa
C1	94	94.3	24.17	30.99
C2	94	94.1	23.44	30.59
C3	94	94.3	24.29	37.59
C4	94	94.2	23.31	39.81

Figure 8. Consolidation of the tunnel face.

10 MONITORING SYSTEM

The GN02 tunnel undercuts the operating A4 motorway by approximately 50 m with a maximum overburden of 15 m. In this context, it was of great importance to control the deformations of the road-bed induced by excavation operations. For this reason, a complex monitoring system called ‘OF Tunnel’ was installed, derived from the patented ‘OF System’, devised by NTSG (New Tech System Generation; Rome, Italy), which also installed and operated it during the works. The system uses a very small set of fiber-optic sensors, allowing them to be installed inside the materials, making them fully

Figure 9. View from the A4 motorway (in red the underpass).

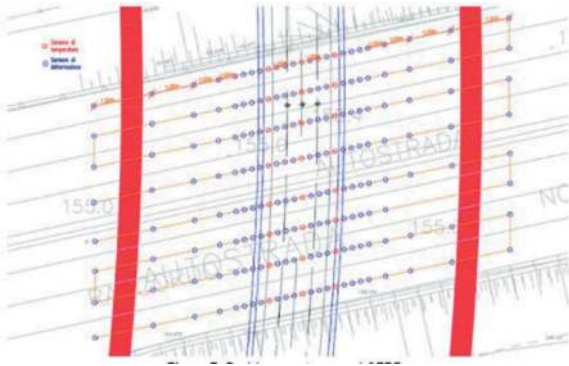

Figure 10. Optical sensor layout.

integrated with the object to be monitored. NTSG has developed a mathematical model, implemented in proprietary software, that calculates the values of the recorded parameters in real time using the data collected by the optical sensors. The 'OF' System has been patented in Italy and Europe.

In order to monitor subsidence, fiber-optic sensor arrays had been installed in cylindrical glass fibre RODs (GFRP) arranged as in Figures 10 and 11, one for each lane, 100m long, with 35 strain sensors and 3 temperature sensors for purging thermal effects.

The strain sensors were spaced 1m apart in the 16m centre (8m right and 8m left) above the subway for a total of 17 strain sensors. Outside the 16m excavation area, on each side were arranged in order 2 strain sensors spaced at 2m, 1 sensor at 3m, 5 sensors at 5m and finally 1 sensor at 10m, for a total of 9 sensors per side (18 in total in addition to the central 17). In total, each GFRP had 38 sensors, as three thermal sensors were associated with the deformation sensors, two at the ends of the GFRP and one in the centre, which were required to purge the data from thermal effects. In order to measure the deformation of the road surface, the GFRPs had been installed inside tracks approximately 10cm wide and at a depth such that they are approximately 10cm inside the road embankment. The connection between the GFRPs and the optical interrogator was via a multi-fiber link. The optical interrogator acquired the measurements taken by the sensors inside the GFRPs at a sampling rate of 1-100Hz and analyses the acquired data in real time.

Obviously, the system described was also sensitive to deformations of the infrastructure caused by vehicular traffic. However, the substantial difference between subsidence phenomena and deformations due to vehicular traffic lies in the time period that characterises them and in the type of deformation. The deformations to which the GFRP was subjected due to subsidence phenomena vary slowly over time and stabilise once the subsidence had settled, generating a permanent type of deformation. In the case of vehicle transit, the deformations were limited to a short time interval and of an elastic type. In order to calculate the actual deformations of the road surface due to ground subsidence, the deformations

undergone by the GFRP were purged of the time effects circumscribed to short time intervals of an elastic type, so that only deformations that tended to increase in a stable manner over time (over slow time scales of long duration) were considered.

In addition, it had to be taken into account that asphalt changes its elasticity considerably due to temperature, generating different deformations on the substructure under the same load. In order to overcome problems of plastic deformations of the superstructure caused by the increase in exposure temperature, it was necessary to calibrate the behaviour of the superstructure at varying temperatures.

The system was equipped with a specific software that processes the data acquired by the sensors and sends it to an online computer platform that allows you to study against time the collected data, compare them with expected data, process predictive analyses, and configure alarm thresholds for absolute, relative and time values. The alarm thresholds entered were evaluated by means of numerical analyses described in the next section.

Figure 11. Array traces in the roadbed.

A typical visualization of the system on the roadbed is shown in Figure 12. The green dots at the sensors indicated that the measurement is below the alarm thresholds.

Figure 12. Status of sensors on the online platform.

11 NUMERICAL ANALYSIS

As mentioned in the previous section, the installed monitoring system required the evaluation of the expected subsidence values at the roadbed induced by the excavation of the tunnel. In particular, it had been necessary to evaluate the development of

subsidence as a function of the distance from the tunnel face from each individual sensor of the monitoring system. These values constituted the input of the Monitoring System described above.

The evaluation of the settlements and the study of the interaction of the structure (support and soil improvement interventions) with the soil and the aquifer, for the geotechnical and structural design of the excavation sections, had been conducted by means of a FEM analysis with the Plaxis calculation code. 3D analyzes were performed with simulation of the main construction phases (jet grouting face improvement, jet grouting soil improvement around the excavation, excavation, provisional lining, inverted arch, final lining).

Figure 13. 3D FEM model.

Figure 14. 2D FEM model.

These 3D analyzes allowed:

- the dimensioning of consolidations and the verification of the stability of the excavation conditions with reference to the conditions at the excavation face;
- determination of the expected deformation levels both tunnel face and tunnel cross section;

- the definition of the deconfinement curves for the calibration of 2D equivalent plane deformation models. In addition, 2D analyzes were carried out to determine the detailed design stresses on the structural elements.

In detail, from the three-dimensional modelling a series of matrices containing the values of the expected subsidence could be extracted, depending on the position of the excavation front, in the position of the individual sensors part of the eight arrays positioned on the roadbed.

The matrices had been implemented in the monitoring system platform. So proceeding, in each phase of work, the System was able to compare the value of the failure detected by the single sensor with that calculated, providing, in the event of exceeding the design limit, alert messages sent by the platform to all the actors involved in the work (building company, designer, concessionaire) by instant emails.

12 THE CONSTRUCTION PHASE

Prior to the commencement of excavation activities, an Emergency Management Plan had been implemented with the purpose of defining the operational procedures to be adopted with reference to the deformation behaviour detected, the monitoring system foreseen and with specific reference to the actions to be taken in the event of threshold values exceeding.

The threshold limit values for the parameters monitored defined the type of action to be implemented in order to identify and execute the necessary actions to prevent deformation phenomena detrimental to the functionality of the motorway infrastructure.

Figure 15. Construction phase.

Specifically, the following limit values were defined:

- of “warning and alarm” derived from the design analyses that modelled the effects of excavation in the surrounding mass in terms of expected deformations;

- of “immediate intervention” this value, superior to the design value, was provided directly by the motorway infrastructure concessionaire and set equal to 2 cm, considering it as a limit, beyond which, possible critical situations could arise for the operation and functionality of the motorway infrastructure.

During the course of the work, the data from the sensor monitoring system were constantly monitored and weekly monitoring reports were produced containing:

- processing of monitoring data acquired during the work week from the Sensor Monitoring System;
- the processing of monitoring data acquired during the work week from other conventional monitoring systems installed in the work area;
- the critical analysis of the values recorded by the monitoring systems according to the progress of the works;
- the punctual adaptation of the planned design solution for the consolidation, excavation and lining of the tunnel according to the data collected from monitoring.

The followed approach allowed to offer greater guarantees and reliability in terms of risk management related to the execution of the project (timing of the work and execution costs) both for the Client and for the Contractor.

Thanks to the presence of a capillary monitoring system, it was also possible to rationalise the quantities and the dimensioning of the ground improvement treatments with a significant economic optimisation of the works cost.

During the course of the works, no deformations were recorded on the roadbed such as to require the interruption of work or the slowing down of the operation of the motorway infrastructure.

Figure 16. Works completed.

The works were carried out regularly and on schedule, thus confirming the validity of the solutions adopted during the design phase.

The last excavation diaphragm was demolished on 8th December 2022 (Figure 16).

ABSTRACT: The vertical pre-reinforcement bolt method is used to stabilize the ground above tunnels with shallow overburden to prevent ground surface subsidence and to stabilize slopes. However, it cannot be said to establish a quantitative design method for this application due to the variety of design concepts. In this paper, a study is conducted to examine quantitative characteristics by using model test and numerical analysis. Results shows the vertical pre-reinforcement method can improve the continuity of ground and decrease shear strain of ground by the distance of reinforcement. It also indicates the application leads to the change in the apparent rigidity of the ground. The relationship between the reinforcement conditions and the effect of this method was also clarified.

Keywords: Mountain tunnel, Auxiliary method, Vertical pre-reinforcement bolt, Model test, Numerical analysis

1 INTRODUCTION

General support member of the conventional tunneling method in mountain tunnel currently consists of shotcrete, rock bolts, and steel arched support. The confirmation of load-bearing capacity of surrounding ground is effectively brought by the stabilization of the groundmass for excavation. In recent years, due to the advantages of economical efficiency and flexibility of construction, auxiliary methods have been increasingly used in urban areas and shallow overburden where the ground strength is not sufficient for improving the safety of construction, as well as the efficiency.

Auxiliary method is a general one for the means of stabilizing tunnel, that is, the face stabilization, the constraint of ground surface settlement, the countermeasure against ground water and the protection of the surrounding environment. This makes it possible to apply the mountain construction method in conditions where the ground is poor and weak, such as fault zone or fracture zone in ground, urban area and shallow overburden area.

Vertical pre-reinforcement bolt method is thought as one of the auxiliary methods. This method reinforces the ground around tunnel by inserting bolts

from the surface of scheduled excavation area and its surroundings. This method is expected to improve the safety of tunnel excavation, prevent ground surface settlement, and stabilize slopes above the tunnel.

In recent years in Japan, there have been several cases in which the method has been adopted with the objective of stabilizing the slope, especially at the portal zone, Suzuki et al. (1990) and Inoue et al. (1993), and there have been cases in which the method has been used in combination with other auxiliary methods such as forepoling and face shotcrete. In the design of pre-reinforcement bolt, the shear resistance is thought to increase by using it to maintain the stability of the slope behavior, which is not large in scale.

On the one hand, previous studies, such as Amemiya et al. (2022) and the experience of the past construction results have shown that the materials to reinforce are effective due to axial resistance, which prevents loosening of ground caused by tunnel excavation and stabilizes surrounding ground. In other words, unified design method has not yet been established due to the various approaches to design.

In this paper, the mechanism of this method is discussed and the influence of bolting conditions is examined in order to propose a quantitative and

*Corresponding author: yuto0224tate@gmail.com

rational design method for vertical pre-reinforcement bolt. Specifically, the changes in the fundamental behavior of the ground due to the application of the vertical pre-reinforcement bolts were examined by model test and numerical analysis for its application to actual tunnel construction.

2 RESEARCH METHODS

2.1 Model tests

In order to investigate the changes in the fundamental behavior of the ground due to the application of vertical pre-reinforcement bolts, model tests were conducted to simulate two types of tunnel excavation and bolting.

2.1.1 Models and materials

Figure 1 Shows the outline of the model test apparatus. It consists of a tunnel model, a load measurement system such as load cell and data logger, and a displacement measurement system with digital camera. Also the image analysis was done using the result of the picture to grasp the ground movement. Aluminum bar are used for the ground model and the chains with metal ball simulates the vertical pre-reinforcement bolts in Figure 1. The tunnel was

Figure 1. Outline of the model test apparatus.

acrylic model and its height and width was 100 mm. The tunnel diameter D could be defined 100 mm. Figure 2 shows the for excavation simulation, 5 PTFE sheets of 0.2-mm-thick and 17 PTFE sheets of 0.3-mm-thick were wrapped around the tunnel model. Totally 22 PTFE sheets are pulled out with every one sheet after piling up aluminum bars and setting the tunnel model. By extracting the sheet, aluminum bars around the tunnel move in direction to the tunnel center and the occurrence of displacement is regarded as tunnel excavation.

Figure 2. Simulation of tunnel excavation.

Table 1 shows the physical properties of the model tests. Previous studies with aluminum bar laminates as the ground indicate that aluminum bars of 1.6 mm and 3.0 mm in diameter with a weight mixture ratio of 3:2 results in an internal angle of friction of almost 30 degrees, which is close to sand's one, based on shear tests of the aluminum bar laminates (Murayama et al., 1969). The same diameter and mixing ratio were used because many experiments have been conducted using similar aluminum bar mixtures. Ball chains were used as reinforcement. The reinforcement was selected based on the following considerations: (1) if the bending rigidity of the reinforcement is too large, the two-dimensional experiment will not be able to reproduce the natural deformation behavior of the ground; (2) from the measurement results in the field, it is considered that the vertical pre-reinforcement bolts will be their effect by the axial force of the bolts (Shiroma et al., 2006). Therefore, it is reasonable to use materials for reinforcement in which axial forces are dominant in the ground; (3) metal ball chains have good friction with aluminum bars and high reproducibility due to no change in physical properties even after repeated use.

2.1.2 Model test method

Model test procedure is as follows. Firstly, the tunnel model wrapped with all of prepared PTFE sheets is placed on the centre. Using an acrylic plate,

Table 1. Characteristics of the ground material.

Material	Aluminium alloy
Length [mm]	100
Diameter [mm]	$\phi_1 = 1.6, \phi_2 = 3.0$
Weight ratio	$\phi_1 : \phi_2 = 3 : 2$
Unit weight [kN/m^3]	21.4
Cohesion [kN/m^2]	0.00
Angle of internal friction [degree]	30

tensioned the metal ball-chains are fixed in place by hand. Aluminum bars are laid out from the bottom in 1cm thick increments. Markers for image analysis are placed every horizontal and vertical distance of 2cm centered in the tunnel, 30cm wide and high to the ground surface. They are placed every 2 cm on the ground surface. A cross-section of the ground is photographed each time the PTFE sheet is pulled out. The width of reinforcement was targeted in this study. Table 2 shows the case of the model test and the definition of placement situation in Figure 3.

Table 2. Case of the model test.

Case #	Reinforcement spacing[mm]	Reinforcement width
#A	No reinforcement	
#B	15	3.3D
#C		0.9D
#D		0.45D x 2 for sidewall

Figure 3. Definition of reinforcement placement in the model test.

2.2 Numerical analysis

Numerical analysis using finite difference method (Code: FLAC3D) was conducted where auxiliary construction methods are required.

2.2.1 Numerical analysis models

Figure 4 Shows the numerical analysis models. It includes the analysis area and the reinforcement condition. The ground category was assumed to be a poor one in Japanese technical standard, assuming portal zone where this method is often applied, and the

ground was modeled using elastic-plastic model based on the Mohr-Coulomb failure criterion. The overburden is set to 1D (D:tunnel excavation width, 11.3 m) in all cases. In the case of a relatively shallow overburden, the analysis area was set to 2D from the side of the tunnel downward, 5D to the side, and 10D. The tunnel excavation method was assumed to be the full-section method with an auxiliary small bench, the length of 1m. The unit excavation length was also set at 1m. The temporary support such as shotcrete and so on was installed 1m behind the face. The lower half was excavated 3 m behind the upper face, and invert excavation was performed 3D behind the face. These excavation cycles were repeated until the tunnel reached 116 m in length, at which point the analysis was terminated.

Figure 4. The numerical analysis model.

2.2.2 Physical property values of the numerical analysis

Table 3 shows the physical property values used in the analysis. For elasticity modulus and Poisson's ratio, the values used for modeling in poor ground category from the technical guideline shown by technical guideline of highway company, were used. For angle of internal friction and cohesion, values that have been shown to significantly reduce displacement of vertical pre-reinforcement bolts from previous studies were applied in this analysis. The tunnel section was based on Japanese highway standards, using the standard tunnel portal zone for a two-lane tunnel cross section as a reference. The tunnel supports were modeled using Shell elements as composite members with equivalent stiffnesses of shotcrete and steel arched support calculated.

Figure 5 Shows the conditions for bolting. Vertical pre-reinforcement bolts were modeled with beam elements, and properties were set using D32 rebar, which is frequently employed. Bolts were placed at equal intervals throughout the longitudinal section of the tunnel model.

2.2.3 Analysis cases

The analysis cases are shown in Table 4. The effectiveness of the application of the method and its effect on the behavior will be studied when the width and location of the concrete placement are different.

Table 3. The physical property values.

Model	Structural element	Elastic modulus	Poisson's ratio	Angle of internal friction	Cohesion
Ground	Solid	50 MPa	0.40	30 degrees	20 kPa
Tunnel support	Shell	8.90×10^3 MPa	0.20	-	-
Inverted arch	Shell	4.00×10^3 MPa	0.20	-	-
Reinforcing materials	Beam	2.05×10^5 MPa	0.30	-	-

3 RESULT

3.1 Result of the model test

The results of model tests are shown below. In model tests, each case was tested multiple times. Then, the ground surface settlement shown below is an average value of all experiments without clearly abnormal tendencies, as it was confirmed that there was little variation. The maximum shear strain in the ground is shown only for one representative case, because it is difficult to show the average value, and the trend of strain distribution is selected to be easy to understand.

3.1.1 Maximum shear strain distribution

Figure 6 Shows the maximum shear strain distribution for each case. In Case B, where the width of the

Figure 6. Result of maximum shear strain distribution from model test.

tunnel was sufficiently larger than the excavation diameter, there was a change in the distribution of strain compared to Case A, where was fundamental case and no reinforcement, and Case C, where the width of the reinforcement was almost the same as the excavation diameter, the area of strain in the upper part of the tunnel became narrower.

3.1.2 Displacement vector

Figure 7 Shows the displacement vectors in the ground for each case. For Case B and C, there was a change in distribution compared to Cases A. The distribution of displacements from the tunnel to the ground surface became more uniform. For Case D, the displacement in the upper part of the tunnel is not uniform. In this respect, the trend of the displacement distribution differs depending on the width of reinforcement.

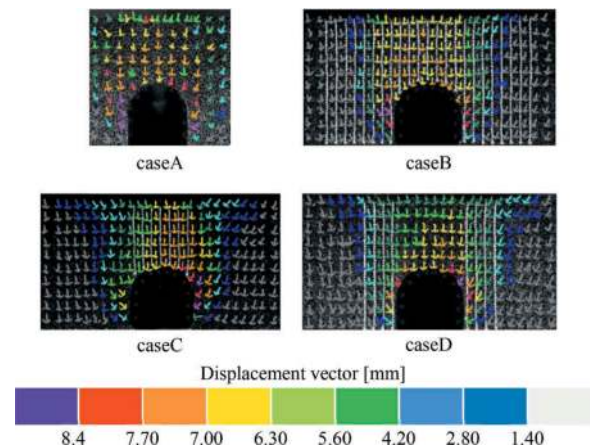

Figure 7. Result of displacement vector from model test.

3.2 Result of the numerical analysis

The results of the numerical analysis are shown below. In comparing the cases, the cross section in the center of the analytical model (at the 60 m depth point) was focused.

3.2.1 Result of the ground surface settlement

Figure 8 Shows the relationship between the distance from the center of the tunnel and the final settlement for each case. In all cases where the reinforcement was applied, the final subsidence of the ground surface decreased. The maximum reduction of ground surface subsidence by the method was 38% in Case B with a 3.0D casting width, 29% in Case C with a 1.0D casting width, and 6% in Case D without casting on the side of the tunnel, indicating that the displacement reduction effect was greater in Cases B and C with reinforcement above the tunnel.

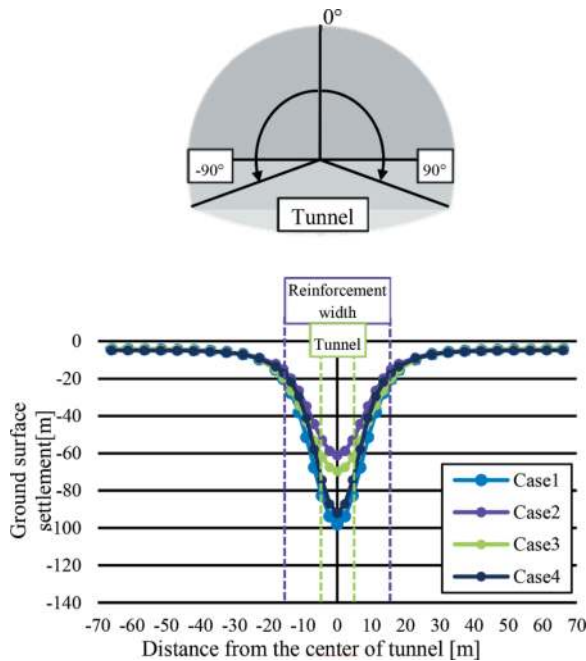

Figure 8. Result of ground surface settlement from analysis.

3.2.2 Result of the bending moment in the tunnel support

Figure 9 Shows the distribution of bending moments in the tunnel support in each case. For both installed widths, the bending moment of the support near the tunnel crown is reduced by the application of the reinforcement. There is little difference in the bending moment generated in the support structures between Case B and Case C. However, the distribution of bending moments in the case of casting only in the upper part of the tunnel is similar to that of the case in which vertical reinforcement is not applied. Furthermore, in the case of the sidewall, the bending moment increases from the shoulder to the spring line area.

Figure 9. Result of the bending moment in the tunnel support.

ground is unified by the bolts is smaller, and only the upper part of the tunnel behaves as a single unit. Case D, in which bolts are not placed above the tunnel, is considered to indicate that the tunnel is not expected to be effective in integrating the ground above the tunnel.

When the bolts are placed only at the top of the tunnel, the ground above the tunnel can be integrated, but bolts on the sides of the tunnel are necessary to redistribute the stresses in the ground above the tunnel in a stable manner and improve the stability of the tunnel. However, when bolts are placed only on the sides of the tunnel, the stability of the ground around the tunnel is not expected to be improved. In other words, the vertical reinforcement bolt above the tunnel are considered to unify the ground, while the bolts at the sides of the tunnel are considered to be responsible for stress transmission.

4.2 Numerical analysis

Result of the numerical analysis indicates that the bolts above the tunnel mitigate stress changes in the ground and prevent loosening, and that the bolts on the sides of the tunnel transfer the load from the top of the tunnel to the ground and also mitigate stress changes in the ground. These results suggest that the bolts above the tunnel mitigate stress changes in the ground, thereby preventing shear failure of the ground and loosening of the ground due to tunnel excavation, and that the ground behaves as a single unit. It is also inferred that the lateral bolts transfer the load above the tunnel to the ground, resulting in a stable stress change in the ground with respect to the tunnel structure. This method enables stable tunnel excavation and suppresses ground deformation by mitigating stress changes in the ground through the use of vertical reinforcement. This method is expected to be effective in reducing ground surface subsidence and tunnel displacement.

4 DISCUSSION

4.1 Model tests

In Case C, where reinforcement bolt was placed only in the upper part of the tunnel, the extent to which the

5 CONCLUSION

By increasing the width of the pre-reinforcement bolting area, the area where deformation of the ground can be suppressed and also expanded horizontally, and a wider range of ground displacement suppression

effects can be expected. This method of construction mitigates the stress changes in the ground, and the ground tends to behave as a certain mass and shear strain is suppressed. This suggests that the application of this method makes the ground behave as a continuum and improves the apparent properties of the ground, and that a simple design using the numerical analysis is applicable to examine its effect by considering the installation of bolts in this method as a change in the apparent stiffness of the pile.

This study does not include an in-depth discussion of the whole physical properties of the ground. Therefore, further study is needed to determine the degree of improvement of the ground and the relationship between the physical properties of the applied ground and the effectiveness of this method and the conditions under which the ground is placed. In addition, the mechanical behavior of this method, including the relationship with the results of measurements at actual tunnel, should be clarified to realize a rational and quantitative design of this method.

Marble sludge in two-component grout applications

Carmine Todaro*, Andrea Carigi, Marilena Cardu & Daniele Peila
Politecnico di Torino, Turin, Italy

ABSTRACT: The two-component grout is currently the most used backfilling technology in shield tunnelling applications. The technology is widely used all around the world thanks to its versatility. In fact, by properly calibrating dosages and types of raw ingredients, the technical specifications proper of a certain construction site can be easily satisfied. In this work, an innovative two-component grout mix design is introduced, in which a marble sludge is added to component A of the two-component grout system as a new ingredient. The marble sludge, obtained during the cutting process of ornamental stones in marble quarries is commonly considered a waste, an environmental problem that must be correctly managed. The idea of the authors was, hence, to use the marble sludge as an ingredient in the two-component grout, by physically blocking it in the gelling reaction and making it permanently part of the backfilling material, confined between the bored medium and the lining extrados.

In this paper, a laboratory test campaign on the potential use of marble sludge in the two-component grout technology is reported. A standard two-component grout and the innovative one have been compared according to standardized testing protocols. Outcomes highlight that the innovative grout has similar properties compared to the standard one and that the addition of marble sludge does not worsen the grout's properties.

Keywords: two-component grout, backfilling, marble sludge, waste reduction

1 INTRODUCTION

At present times, the two-component grout is the most used backfilling technology in mechanised tunnelling, using shielded machines.

During the tunnel excavation and the machine advancement, a gap is continuously created from the difference in diameter between the head of the machine and the lining extrados. This gap is inevitable since this geometrical peculiarity is essential and allows for the assemblage of the segments in linings under the protection of the shield, as well as avoiding potential machine block due to convergence of the excavated medium.

This gap, commonly called annulus, has an order of magnitude of centimetres and is schematically shown in Figure 1.

Different technologies can be used for the complete filling of the annulus (Grasso et al., 2023) but two-component grout is undoubtedly the most popular all around the world, due to its aptitude for preventing and controlling surface settlements (Fagnoli et al., 2013). This feature is guaranteed by an almost instantaneous gelation of the grout: the material after the

Figure 1. Annulus. Modified from thewes and budach (2009).

gelation starts immediately to improve its mechanical and elastic properties (Oggeri et al., 2021; Todaro and Pace, 2022).

The technology is based on two liquid components: the component A and the component B. The first is a cement-based material made up of cement, water,

*Corresponding author: carmine.todaro@polito.it

bentonite and retarding/fluidifying agent, while the second is commonly a solution of sodium silicate. Recently, new ingredients have been experimentally introduced to component A production such as, for example, fly ash, blast furnace slag, and industrial solid waste (André et al., 2022; Schulte-Schrepping and Breitenbücher, 2019; Song et al., 2020, Song et al., 2022).

These last studies were the starting point for this research, meaning that the idea to re-use something considered industrial waste was followed. In detail, the new ingredient selected to produce the component A has been the marble sludge, typical waste coming from the cutting process of ornamental stones. The choice was dictated by the nature of the marble sludge, composed mainly of calcium carbonate (CaCO_3) and directly available with a grain size distribution suitable for the proposed application. This material is produced in large amounts in marble quarries (Cobo-Ceacero et al., 2019): On average, for each cubic metre of marble exploited, 50-95 L of marble sludge is obtained. This material must be correctly managed, and the cost for its disposal significantly impacts the marble quarry business.

In this work, a preliminary test campaign is presented concerning the use of marble sludge powder as a raw ingredient for the production of component A. In the following paragraphs, the term “marble sludge” refers more specifically to the powder of marble, naturally produced during the cutting operation performed in a dry way (no water or other lubricants added).

Starting from a mix design typically used in construction sites for the two-component grout production, two different dosages of marble sludge have been tested to produce the grout. To verify the feasibility of using this new ingredient in the two-component grout technology, the component A properties, the reaction of gelation, and the hardened grout have been tested according to a standardised testing protocol (Todaro et al., 2019). The results of the grout prepared with the marble sludge have been compared to those of the reference mix.

2 THE ISSUE OF THE MARBLE SLUDGE

Considering the ornamental stone processing chain, the cutting operations are important since blocks of huge dimensions (m^3 of order of magnitude) are split into easily transportable slabs, suitable for further processing (Figure 2, left). Taking into account the Italian scenario, marble quarries are by far the most common, yet other types of ornamental stone quarries are also present on the national territory. For the reason of “abundance”, authors have selected marble sludge as an experimental ingredient in this study (Figure 2, right).

Figure 2. Chain cutting machine used for splitting the marble blocks in slabs (on the left) and the marble sludge obtained during this cutting operation (on the right).

Considering only the Carrara marble basin, hundreds of thousands of tons of marble sludge are produced every year due to the huge production of blocks (about 900,000 tons/year) of one of the finest marbles in the world. This big production inevitably leads to big amounts of produced marble sludge. Additionally, the environmental problem associated with marble sludge disposal is challenging, especially in the area where quarries operate.

From this scenario, the authors' idea has been conceived, while considering the new big tunnel projects that are going to start in the next years in Italy according to the National Recovery and Resilience Plan funding: use the marble sludge in the backfilling phase in shielded mechanised tunnelling.

If, from one side, the environmental positive impact of “trapping” the marble sludge in a grout is practical, the calibration of the two-component grout mix design for using the marble sludge as an ingredient is a complex phase from the other side, considering the sensitive balance between compounds. The two mix designs presented have been calibrated not only to maximize the dosage of marble sludge but also to try to improve the mechanical performances of the obtained grout.

3 MATERIALS AND METHODS

The test campaign has been organised in two different parts: the first aimed to assess the properties of component A only and the gel time, while the second aimed to test the mechanical performance of the gelled grout at a short curing time. The short curing time is intended for no more than 3 hours after the casting. The procedure for preparing component A, for the sample casting and the used mix designs are reported in the following.

3.1 Used materials

To produce the two-component grout, Portland Cement type CEM I 52.5 R (CEN, 2011) was used. The accelerator, retarding/fluidifying agents, and

bentonite were provided by Mapei company. The marble sludge was instead provided by the “Rock cutting laboratory”, part of the “Geomechanics and Geotechnology laboratory” of the Politecnico di Torino.

3.2 Component a production and sample casting

The component A production was carried out by using a laboratory stirrer, according to the procedure described in Todaro et al. (2019) and hereinafter shortly summarised in Table 1.

Table 1. Mixing procedure.

Phases	Impeller rotation speed (rpm)	Duration (min)
Start – only water	800	/
Bentonite mixing phase	2000	7
Marble sludge mixing phase	2000	if the marble sludge is added, the mixing time should be calibrated for obtaining a suitable mix
Cement mixing phase	2000	3
Mix of retarder/ fluidifying agent – End	2000	2

The mix designs used are reported in Table 2. Those where the marble sludge is used are “1M” and “2M”, while “R” is the reference mix design. Dosages are expressed in kg/m^3 .

Table 2. Mix designs.

Ingredient	1M	2M	R
Cement	230	230	230
Bentonite	30	30	30
Marble sludge	50	100	/
Water	834	816	853
Retarding/fluidifying agent	3.5	3.5	3.5
Accelerator	81	81	81

When component A was obtained, the sample casting was performed manually. The metered amount of components A and B were prepared in two different tanks, followed by quickly pouring component A inside the tank holding the component B, and later pouring all the grout into the empty tank, which led to the final step of emptying the grout (still liquid) into the sample moulds.

Used samples have dimensions in compliance with CEN (2016) (40*40*160 mm).

3.3 Performed test

The characterisation of component A, the reaction between components A and B, and the hardened grout at short curing time have been studied in accordance with the well-established, detailed procedure reported in Todaro et al. (2019). Briefly, the characterisation of component A was assessed by measuring the unit weight and the flow time on the fresh component A (i.e. within 10 minutes after the production) while the bleeding was assessed after 1, 3, and 24 hours after the component A production. The gelation of the grout obtained by turbulently mixing component A and component B has been assessed by measuring the gel time. Finally, the hardened grout has been characterised by assessing the surface compression strength (SCS) after 1 and 3 hours of curing.

3.3.1 Unit weight

The unit weight was assessed by using a mud balance (Figure 3), according to the standard ASTM D4380 (2020).

Figure 3. Mud balance used for the unit weight assessment. (Todaro et al., 2023).

3.3.2 Flow time

The flow time was assessed by using the Marsh funnel (Figure 4), in line with UNI 11152-13 (2005). This test provides indications on the viscosity of the tested material. The outcome of the test is the time spent by 1 L of mortar to flow through the funnel. The higher the viscosity of the mortar, the higher the flow time.

Figure 4. Marsh funnel used for the flow time assessment. (Todaro et al., 2023).

3.3.3 Bleeding

The bleeding test allows the evaluation of the physical stability of component A. The test has been carried out according to UNI 11152-11 (2005). A standardised cylinder is filled with 1 L of component A, to which particles of cement tend to settle on the bottom of the cylinder due to the gravity force,, leaving a layer of water on the top of the surface. After a certain time, the volume of the segregated water is measured (V_w), and by computing the ratio on the whole volume of 1 L (V_t), the bleeding index is computed, expressed as a percentage according to equation (1):

$$Bleeding = \frac{V_w}{V_t} (\%) \quad (1)$$

Figure 5. Bleeding assessment. (Todaro et al., 2023).

3.3.4 Gel time

The gel time has been assessed by following the experimental procedure proposed by Todaro et al. (2019) and used also by André et al. (2022). Once the quantities of components A and B are metered and prepared according to the mix design, component A is poured into component B; after that the whole material is quickly poured again in the empty tank and so on with subsequent series of pouring. The time recorded started when the first contact between components A and B occurred, and ended when the grout is not able to flow.

3.3.5 Surface compression strength (SCS)

The surface compression strength (SCS) has been assessed according to the procedure proposed by Todaro et al. (2020). A dynamometer was equipped with a flat circular bit having a surface of 177.9 mm² (A in equation 2) (Figure 6).

The test consists of the penetration of the bit orthogonally on the cast surface of the grout (previously cast in moulds with the shape in compliance to CEN (2016) and cured for 1 or 3 hours in a sealed environment) till a penetration of 5 mm is reached. The maximum force (F in equation 2) reached during the test is recorded. SCS is consequently computed according to equation (2) where F is expressed in N.

Figure 6. Dynamometer used for the surface compression strength assessment during the test. Todaro et al. (2020).

$$SCS = \frac{F}{A} \quad (2)$$

According to the reference standard, tests have been performed without demould samples. At least 6 tests were carried out for each assessment performed after 1 hour, while between 3 and 6 determinations were performed for testing after 3 hours of curing. The reason for a higher number of assessments at 1 hour of curing is related to the higher dispersion observed.

4 RESULTS

The obtained outcomes are summarised in Table 3.

Table 3. Used mix designs.

Mix design	1M	2M	S
Unit weight (kg/L)	1.20	1.27	1.17
Flow time (s)	36.0	38.0	34.5
Gel time (s)	7	4	8
SCS 1h (MPa)	0.38	0.45	0.41
SCS 3h (MPa)	1.65	1.71	1.62
Bleeding 1h (%)	0.3	0.0	/
Bleeding 3h (%)	0.68	0.00	1.04
Bleeding 24h (%)	3.10	2.40	2.09

5 DISCUSSION

Taking into account the unit weight, an increment of values is recognised for 1M and 2M compared to R. The higher weight for a fixed volume of the considered component A is due to the replacement of a certain amount of water with the marble sludge. However, values of 1.2-1.3 kg/L are typically

accepted in construction sites, therefore it can be stated that compliance has been respected.

On the other hand, a significant reduction in gel time was observed. If for 1M the reduction is only of 1 s (a time lapse consistent with the test error), the gel time of 2M is half of those of R. The value of 4 s is very short, hardly applicable in standard practices, and not commonly acceptable in construction sites. Probably, the gelation between components A and B is affected by the presence of the marble sludge that plays an active role as a further booster of the reaction.

Considering the flow time, a slow increase has been observed (about 4 % and 10 %, respectively for 1M and 2M) compared to the flow time of the mix R, but then again, these values are accepted in common practice.

Optimal results have been obtained for the bleeding test, despite the presence of the marble sludge and consequently the tendency of these particles to segregate (similarly to the concrete ones), bleeding values are lower than 1% after 3 hours and abundantly lower than 8% (the threshold commonly fixed for construction sites) after 1 day.

As for the strengths at short curing time, 2M seems to be more performant than R: values greater than about 10 % and 6 % compared to the reference mix design have been obtained for a curing time of 1 hour and 3 hours respectively. Differently, 1M exhibits similar results compared to R (for 1 hour of curing, the strength was lower than that of the reference mix).

6 CONCLUSIONS

This work describes a preliminary test campaign where marble sludge, a material considered as waste in the ornamental stone supply chain, is reused in a tunnelling application. The preliminary nature of the work is related to the used mix designs; in fact, starting from a real two-component grout mix, no variations on dosages of raw ingredients have been applied: only the water has been replaced by the marble sludge in a quantity dictated by the sludge dosages and the respective unit weights. This choice was dictated by the need to check the potential impact of the new ingredient on the two-component grout technology by monitoring the reference parameters and their “fluctuations” in presence of the new ingredient.

Despite this limitation, the results highlighted the concrete possibility of giving the marble sludge a noble use as an ingredient in the two-component grout technology, as backfilling in tunnelling applications. No breach has been actually identified, granted that the gel time could extend by increasing the dosage of the retarding/fluidifying agent. It is also important to note that an increment of the retarding/fluidifying agent could allow the increase of the marble sludge dosage that, according to the

presented results, could turn into higher strength performances. In conclusion, the preliminary outcomes reported in this study highlight that the innovative grout has similar properties to the standard one and that adding marble sludge does not worsen the grout’s properties.

Results presented in this paper should be considered as a first step of the research since further analyses on mechanical and elastic performance at long curing time should be carried out before transferring the technology to a pilot construction site.

The research is currently on-going.

ABSTRACT: Takimurozaka Tunnel is a 5.0 km long tunnel that passes through the Aso Caldera. As the design passed through low-intensity sections, high-standard support patterns and auxiliary methods were adopted using numerical analysis. The results of the study of two characteristic patterns are reported here.

Keywords: overburden, special ground, unconsolidated ground, analytical verification, Standard registration

1 INTRODUCTION

Mt. Aso is known for its large caldera and magnificent outer rim, which is one of the largest in the world. National Highway 57, which crosses the Aso Outer Rim from east to west, is an important route connecting Oita and Kumamoto prefectures (Figure 1). However, the topography and geology of the area make it susceptible to icing in winter and to disasters, making it an urgent issue to improve the roadability and traffic safety. In addition, the Takimurozaka road (L = 6.3 km) was planned because of the frequent occurrence of slope disasters due to recent extreme weather conditions, resulting in road closures for up to 40 days. The Aso Caldera in the proposed area is a huge caldera of about 320 km², measuring about 25 km from north to south and 18 km from east to west, formed by four eruptions between 270,000 and 90,000 years ago. The outer topography of the caldera is a plateau with a very gentle slope (1-3°) created by the Aso pyroclastic flow on the eastern side. On the west side, the old volcanic mountain-side consists of slopes of about 10°, with pyroclastic flow plateaus bordering the outer caldera.

2 OUTLINE TUNNEL

When designing the tunnel, the route was carefully selected based on geological surveys, nearby construction results, and disaster history. As a result, the tunnel length is 4.8 km with a longitudinal gradient of 4%.

Figure 1. Plan location map (Aso Caldera).

The main tunnel is a large cross-section tunnel with an excavated cross-section of over 100 m², and the evacuation tunnel is a small cross-section tunnel with an excavated cross-section of about 20 m². The

geology of the tunnel is Quaternary pyroclastic flow deposits formed during the eruptive cycles of Aso Volcano. The geology is characterized by the fact that the hardness varies with the degree of fusion and that fragile pore sediments are distributed between the pyroclastic flow deposits formed during each eruptive cycle and are composed of pre-Aso volcanic rocks with uniaxial compressive strength of about 2.0N/mm^2 (tuffaceous hornblende), pyroclastic flow deposits (Aso-1 to Aso-4) and their pore sediments are distributed.

3 PROBLEM OF TUNNEL

3.1 Overview of the geology of the Pre-Aso Volcanic Rocks (PA: Tuff breccia)

The PA consists of pyroclastic rocks composed of pyroxene andesite lava and tuffaceous conglomerate that erupted about 85 years ago. The andesitic lava is relatively hard in rock fragments but is generally fractured and clumpy to flaky. The tuffaceous conglomerate consists of tuff containing fine pebbles and cobbles 10 to 30 cm in diameter. The matrix consists of well-consolidated clay to sandy soil.

3.2 Overview of the geology near the Aso-4/3 pore deposits (Aso-4/3)

It is distributed along the national highway between Aso-3 and Aso-4 at an elevation of about 760 m, but continuity is poor. The geology consists of volcanic ash and pumice fall deposits with thicknesses ranging from a few centimeters to tens of centimeters.

3.3 Summary of problems in each geology

In the pre-Aso volcanic rocks (PA), the soil cover is 200 m, the unit volume weight is 21.1 kN/m^3 , and the uniaxial strength is $3,000 \text{ kN/m}^2$, resulting in a strength ratio of 0.7. The Aso-4/3 pore deposit (hereinafter referred to as Aso-4/3) has a soil cover of 60 m, a unit volume weight of 16.7 kN/m^3 and a uniaxial strength of 50 kN/m^2 , giving a strength ratio of 0.05. Since the soil strength ratio is less than 1 for both geological types, appropriate support structures and auxiliary construction methods were considered. Ground constants were calculated based on the results of triaxial compressive strength tests and horizontal load tests in the borehole at the site. The groundwater distribution in this tunnel was assumed to be such that Aso-1/2 is impermeable and there is little groundwater in the PA layer. The Aso-4/3 layer is also impermeable, and groundwater was assumed to be present above this layer, but no rainfall rise was observed in the groundwater monitoring wells.

4 ANALYTICAL STUDY OF SUPPORTING STRUCTURES FOR EACH FORMATION AT DESIGN

4.1 Analytical study

For the above-mentioned PA and Aso-4/3, appropriate support structures and countermeasures were investigated using analytical methods.

The countermeasures were studied using 2D and 3D numerical analysis. First, the tunnel portal support structure was confirmed, followed by the fore piling, long face bolt, high-strength support structure, early closure, and invert shape modification, in that order. The results, As shown in the table below, the Invert shape should be close to a circle, and for Aso-4/3, the area of the fore piling was set at 180 degrees. The evacuation shaft was also studied in the same way, and the support structure was determined.

Table 2. List of support patterns to be adopted.

	shotcrete	Rockbolt	Steel	Lining	Inveret shape	Auxiliary method
D 1	20cm	6m@1m	H-150	40cm	-	-
PA	E-2 35cm	6m@1m	HH-200	40cm	Lower 1m	Fore piling(120°) Face bolt(@1.5m) early closure
Aso-4/3	E-3 25cm	-	HH-200	40cm	Lower 1m	Fore piling(180°) Face bolt(@1.5m) early closure

Figure 7. Support pattern of PA(Evacuation tunnel).

Figure 8. Support pattern of Aso-4/3A(Main tunnel).

Figure 9. Support pattern of Aso-4/3(Evacuation tunnel).

4.2 Considerations in the PA layer

In the PA Formation, Aso-1 with high strength is distributed in the upper part, and the numerical analysis by FEM indicates that a complete soil cover is applied. As shown in Chapter3, the outcrops of the PA Formation are composed of alternating layers of tuff and tuff, and the strength of the tuff is high at the gravels and low only at the base of the tuff, so it is unlikely that only tuff will appear on the tunnel face. Therefore, it is unlikely that only tuff will occur on the tunnel face. Therefore, the extension of the ground classification at the time of design was set in the E pattern, where 20% of the PA layer is bad.

Figure 10. 2D analytical model in PA layer.

5 CONSTRUCTION RESULTS IN THE PA LAYER

5.1 Results of main tunnel

The results of the construction showed that the D I pattern was sufficient for the support structure. Pore volcanic ash (Aa) was distributed in some areas at the boundary between PA and upper Aso-1, and when this area appeared at the crown range, a fore-piling was required. The initial displacement speed of the A measurement (displacement of the upper half of the inner cavity) exceeded the control level II of D I of No201+5.0. The D II pattern was adopted, and the invert was early closure.

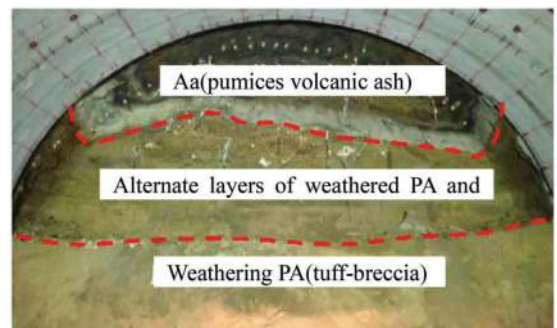

Photo 7. Status of face (No.199+10).

5.2 Results of evacuation tunnel

Similar to the main tunnel, DII (early closure) was used in areas where the initial displacement rate of the internal air displacement measurement was high and the displacement was contained. The DII pattern was used when the tuff was almost completely within the tunnel cross-section.

Photo 13. Status of face (TD608).

Figure 18. Longitudinal geologic section at Aso-4/3.

Figure 19. Measurement results Aso4A(PF).

Figure 20. Measurement results Aso4A(B).

In addition, subsidence at the top of the tunnel, thought to be caused by rainfall in the previously constructed section, showed a tendency to re-sink. As a result of additional boring to analyse the cause, it was determined that the tunnel was constructed on a geological structure where a large amount of groundwater existed to the south of the main tunnel, and after rainfall, spring water collected like an underground river, causing the displacement due to water pressure. Therefore, a drainage bore was made to

Figure 21. Additional measures in Aso-4/3.

lower the groundwater. In addition, the tunnel lining was reinforced with steel bars to ensure that the water pressure would not cause problems even if groundwater were to affect the tunnel in the future.

Figure 22. 3D geological model.

Figure 23. Geological transects.

Figure 24. Drained borehole.

6.2 Results of measurement B

In Aso-4/3, a preliminary analysis was performed and the following results were obtained. At that time, fore piling was designed at 180°, which is different from the normal range (120°), and the validity of the design was confirmed.

As a result, the shotcrete stress was approximately 9 N/mm² greater than the analytical value, while the steel arch stress was 225 N/mm² less. Since axial forces of approximately 1,000 kN were generated, it is assumed that flexural stress sharing also occurred in the shotcrete. It is concluded that the effect of 180-degree fore piling occurs.

Figure 25. Shotcrete stress and steel arch stress during analysis.

7 CONCLUSION

The design and construction results are generally as expected. However, at the location of Aso-4/3, the top-end settlement has not converged and additional leg piles have been added; this phenomenon occurs when Aso-4/3 is below the invert, although the 3D analysis was performed to the extent that Aso-4/3 appears on the face. The Aso-4A(W) sand and gravel layer, which is worse than expected, appeared on the tunnel face, and it is believed that the top-end settlement did not converge because the geology was as bad as Aso-4/3, requiring auxiliary construction methods and early closure and because the bad layer continued in the lower part.

Future designs should pay special attention to the geological conditions at the boundary for risk management. For example, borings should be added, and the geology of the boundary area should be classified based on the assumption that the geology is poor.

State of the art of soil conditioning technology for earth pressure balance shield tunnelling

Zeen Wan*, Shuchen Li, Shisen Zhao, Kai Qiu & Sihaowensong Hao
China University of Mining and Technology, Xuzhou, China

ABSTRACT: Shield has become the mainstream method for tunnel construction due to safety and high efficiency. However, due to the complex and changeable underground environment, the earth pressure balance shield (EPB) shield tunnelling faces many problems, such as mud cake and clogging in the clay strata, spewing in the water-rich sandy pebble strata, and tool wear in the hard strata. The above problems have seriously affected construction safety and efficiency, and soil conditioning technology is the key to solving them. To fully understand the state of the art of soil conditioning technology, this paper summarizes the relevant research at home and abroad through many literature reviews. The preconditions and causes of various problems are expounded and the current status and development history of the conditioning agents are summarized. The results show that there are many kinds of soil conditioning agents with uneven performances at present, lacking qualitative evaluation indexes and unified testing standards. The soil conditioning scheme shall be selected according to the strata characteristics. However, soil conditioning technology is mainly based on experience, and lacks scientific selection criteria. Finally, this paper proposes the soil conditioning technology based on the strata suitability combined with the latest research results, which can provide some theoretical guidance and reference value for shield tunnel construction.

Keywords: Earth pressure balance shield, Soil conditioning, Laboratory test, Strata suitability

1 INTRODUCTION

Recently, shield tunnelling has become the mainstream construction method for tunnel construction. It has a wide range of applicability in different geological conditions, high construction safety, and is suitable for the complex and ever-changing underground environment of cities (Liao et al., 2009; Dias and Kastner 2013; Herrenknecht et al., 2011; Wei et al., 2020). Due to the complex underground environment, varying soil conditions, and abundant groundwater in tunnel construction, EPB shield tunnelling faces many challenges, such as clogging, spewing, soil discharge detention, and abrasion (Li et al., 2014; Thewes 1999; Thewes and Hollmann 2016; Langmaack and Feng 2005; Langmaack and Lee 2016; Burbaum 2009; Gharahbagh et al., 2014), as shown in Figure 1.

Soil conditioning is the most direct and efficient method to address the issues. The purpose of soil conditioning is to adjust the excavated soil in the tunnel face, spoil chamber and screw conveyor into a “plastic-flow state” (Peila 2014; Xiao et al., 2015; Mair et al., 2003; Merritt et al., 2003; Barbero et al., 2012). This aims to achieve

Figure 1. Challenges for EPB shield tunnelling: (a) clogging, (b) spewing, (c) soil discharge detention and (d) abrasion.

smooth spoil discharge, maintain pressure balance, prevent adhesion and surging and ultimately achieve a gradual decrease in water and soil

*Corresponding author: zeewan@cumt.edu.cn

pressure along the spoil discharge direction (Xu et al., 2020; Maidl 1995). A significant amount of research has been conducted on soil conditioning. This research has focused on different approaches for soil conditioning in various ground conditions, utilizing theoretical analysis, experimental studies, and numerical simulations. However, the current research on soil conditioning, both domestically and internationally, is often focused on addressing specific issues. There is a lack of systematic studies on ground adaptability for soil conditioning, and the field of soil conditioning lacks a unified set of standards and conditioning criteria.

This review aims to summarize the existing solutions and limitations for common challenges in soil conditioning. It will also provide an overview of commonly used soil conditioning agents and their technical parameters. Additionally, it will outline the experimental methods, indicators, and evaluation criteria for soil conditioning. After conducting a comprehensive literature review, soil conditioning techniques that are adapted to different ground conditions will be proposed. By gaining an understanding of the latest research developments in this field, this review will provide references and insights for future, more complex and in-depth research in the field of soil conditioning.

2 THE DEVELOPMENT OF SOIL CONDITIONING AGENTS

To achieve a plastic flow state in the excavated soil and meet the adaptability requirements of shield tunnelling, it is necessary to inject a certain number of chemical agents at the cutter head, the excavation chamber, and the screw conveyor. This helps to adjust the properties of the excavated soil to meet the requirements for efficient discharge, as shown in Figure 2. In addition to considering the adaptability to the ground conditions, it is also essential to research the properties of soil conditioning agents. As shown in Figure 3, the development of soil conditioning agents has evolved from simple water to a variety of additives. In the 1980s, Japan took the lead in using foaming agents as additives in shield tunnelling. Since then, this approach has gradually been adopted and promoted in various countries. In the 21st century, a system has emerged with foaming agents as the primary additive, supplemented by other additives.

Figure 2. Purpose of soil conditioning.

Figure 3. Development history of soil conditioning agents.

2.1 Water and bentonite

Water, as a low-cost and easily accessible additive, was initially used in soil conditioning. However, it has certain limitations, and its effectiveness is limited to specific ground conditions. Adding excessive amounts of water can affect the soil transportation on the conveyor belt. Bentonite slurry, commonly used in slurry pressure balance (SPB) shield tunnelling, is also widely applied as a soil conditioning agent in EPB shield tunnelling. Some scholars have conducted experiments on the conditioning of coarse-grained soil with bentonite (Mair et al., 2003; Maidl 1995; Williamson et al., 1999). After the hydration of clay minerals, such as montmorillonite, in bentonite, a hydrated compound is formed that exhibits viscosity, expansion, impermeability, and thixotropic properties. Bentonite can agglomerate the coarse particles of the soil, improve the impermeability of the soil mass, and prevent spewing. Bentonite is not suitable for all strata, and it often needs to be used in conjunction with other chemical agents. These may include foaming agents, anti-clay agents, polymers, and other additives.

2.2 Foaming agents

Foaming agents have the widest range of applications (Leinala et al., 2002). They can be used in fine-grained clay strata as well as in sandy and gravelly strata. Generally, foaming agents are diluted with water to a concentration of 2% to 3%. The diluted solution is then foamed through a foam-generating system and injected into the front of the cutter head, excavation chamber, and screw conveyor. This allows the injected foam to mix with the excavated soil, improving the flowability and plasticity of the excavated soil. Foaming agents are primarily composed of surfactants, water, and other additives. Regarding the mechanism of action of foaming agents, Leinala 2002 and Jancsecz 1999 have suggested that the main component surfactants consist of both hydrophobic chains and hydrophilic groups. Using electrostatic adsorption, the charged soil particles relate to water molecules, reducing the surface tension of water and preventing contact between clay particles. This enhances the plasticity and flowability of the soil. Common foaming agents are mostly anionic foaming agents. However, as shown in Figure 4, foaming agents with a combination of anionic and non-ionic

surfactants have a higher packing density, resulting in more stable foam (安井克豊 et al., 2014). They also have a longer half-life and are more favourable for mixing and contact with the soil, leading to better conditioning effects (Ross 1946).

Figure 4. Surfactant molecules and foaming mechanism (Leinala 2002; Jancsecz 1999; 安井克豊 et al., 2014).

Researchers have conducted numerous studies on the foaming performance testing of foaming agents, ranging from qualitative observations to quantitative evaluations. Ross and Suzin 1985 initially proposed a visual assessment method for mechanically agitated foaming. Later, the Ross-Miles quantitative testing method was introduced in collaboration with Suzin. The foaming rate is evaluated based on the volume of generated bubbles, and the foam decay time is recorded as a stability evaluation indicator. Chen et al reviewed the experiments and indicators used to evaluate the foaming performance of foaming agents, both domestically and internationally. Through comparative analysis, they identified factors that affect foam stability. The half-life time (HT) is commonly used as a relatively intuitive and rapid evaluation indicator for foam stability. The foam half-life is defined as the time it takes for the foam to decay to half of its initial volume from the beginning of foaming (EFNARC, 2005). It is generally required that the HT of the foaming agent used should be greater than 5 minutes. A longer half-life of foam injection into the cutter head significantly increases the effective interaction time with the soil, which is beneficial for cutter head excavation and continuous muck removal. The HT of foam is influenced by factors such as the type of foaming agent, foaming agent concentration, foaming rate, and parameters of the foaming machine (Diego et al., 2019).

2.3 Dispersants

The high plasticity characteristics of clay strata are correlated with their mineral composition, porosity, and water content (Wu 2018; Kim et al., 2019; Liu et al., 2018). When the soil is predominantly composed of finer clay particles such as montmorillonite and kaolin, it exhibits higher cohesive strength. Macroscopically, it appears as larger cohesive soil masses and clay lumps, making it difficult for groundwater to infiltrate. During shield tunnelling excavation, the clay adheres to the cutter head tools, blocking the cutter head openings. Prolonged

compression can lead to the formation of hardened clay cakes, which can adversely affect excavation efficiency (Wan et al., 2021). Dispersants can be classified as cationic, anionic, or non-ionic based on the charge carried by the surfactant. Currently, there are few types of dispersants used in shield tunnelling construction. The high-performance dispersant and polymer anti-adhesive agents were independently developed by our research group, both of which are anionic anti-adhesive agents. Because foaming agents have limited dispersing effects, dispersants are used as a new additive for preventing clay cake formation. The mechanism of dispersants is shown in Figure 5. Dispersants work by introducing high-density negative charges to the surface of clay aggregates, which can reduce the attractive forces between clay particle molecules and prevent the re-aggregation of separated clay particles. After dispersion, the clay particles or small clay aggregates are enveloped by the surfactants in the foaming agent, forming a barrier. The foam provides wrapping, support, and lubricating effects, facilitating the sliding of the clay aggregates against the metal surface. This promotes the transportation of excavated soil.

Figure 5. Schematic diagram of the mechanism of dispersants.

2.4 Polymers

During EPB shield tunnelling in permeable strata such as cobblestone and medium-coarse sand, there is a risk of spewing disasters when the groundwater is abundant and the water pressure is high. Ordinary foaming agents or bentonite alone cannot withstand high water pressure and prevent blowouts, as shown in Figure 6. Instead, polymers are required as effective additives for spewing prevention and they absorb free water by binding with water molecules. Soil-structured polymers adjust the soil properties and improve the soil's aggregation ability. They are suitable for the conditioning of coarse-grained soil (Mori 2016). Natural polymers such as starch, modified natural polymers such as carboxymethyl cellulose (CMC) and polyanionic cellulose (PAC), as well as synthetic polymers are used for soil conditioning (Milligan 2000).

A polymer produced from a single type of monomer is called a homopolymer, while a polymer produced from two or more different monomers is

called a copolymer. The higher the molecular weight of the polymer, the greater its aggregation effect, which can serve as an indicator to evaluate its performance. Many scholars have studied the use of common polymers as spewing prevention agents for shield tunnelling (Moss 1978; Moody 1992; Lyon 1999). They compared the advantages, disadvantages, and application methods of different types of polymers. Li et al., 2022 developed a high molecular weight polymer with a weight of 3.5 million and conducted transmission electron microscopy scanning experiments (TEM scanning) to demonstrate its chain-like aggregation structure. The mechanism of polymers is shown in Figure 7. The long chain structure of high molecular weight polymers allows them to adsorb and entangle soil particles of different sizes. The hydrophilic groups on the polymer chains form connections with water molecules, absorbing excess free water. Through the adsorption of polymer clusters, the different sizes of aggregates, fines, and water molecules are interconnected and aggregated, thereby improving the water resistance of the treated soil and reducing the likelihood of blowout accidents. The polymer adheres to the surface of soil particles, resulting in a significant increase in viscosity.

Figure 6. Principles of spewing prevention for different agents.

Figure 7. The action mechanism of polymers (Li et al., 2022).

2.5 Anti-wear agents

The wear of the cutter head, cutting tools, and screw conveyor for shield tunnelling in sand and gravel strata has been brought to the forefront. How to improve the service life of equipment is of great importance. Relevant scholars have explored various physical methods to protect the equipment, such as altering the material properties of the cutting tools to enhance their toughness to adjust the cutting parameters based on geological conditions to reduce tool wear (Zhang et al., 2013; Wei 2004). To reduce the frequency of tool replacement, another approach is to use additives to lubricate and protect the cutting tools, thereby reducing the contact area between the tools and the gravels. This helps to improve the wear resistance of the tools

or mechanical equipment. The above-mentioned foam and bentonite also have certain lubricating properties, which can contribute to a certain degree of wear resistance. Furthermore, as a type of polymer, anti-wear agents can effectively reduce friction and wear, as shown in Figure 8. They can be injected into the cutter head and earth chamber along with the foam or bentonite slurry. During the soil conditioning process, they can cover the cutting tools and screw conveyor, providing lubrication and cooling to achieve the desired reduction in wear. In addition, its effect of reducing dust and clogging can also improve the service life of the cutting tool (Alber 2008; Li et al., 2019).

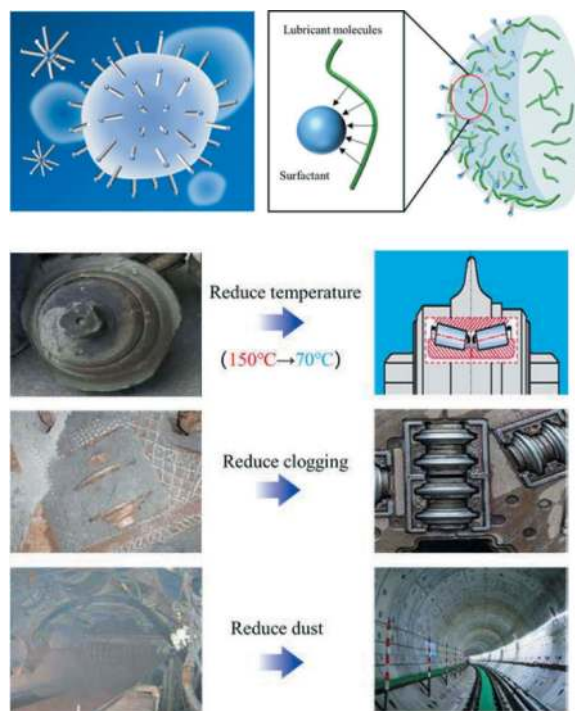

Figure 8. The action mechanism of anti-wear agents (Alber 2008; Li et al., 2019).

2.6 A summary of the conditioning agents

Based on the mechanisms and performance of the commonly used ground conditioning agents in shield tunnelling, each type of conditioning agent has its specific application range and is suitable for the conditioning of certain types of soil. Table 1 summarizes and categorizes the mechanisms of action, advantages, disadvantages, and applicable geological strata of various ground conditioning agents. Chemical soil conditioning agents have gradually become indispensable functional materials in soil balance shield tunnelling construction. For complex geological strata, a combination of different conditioning agents may be necessary. However, the selection process requires continual verification. Additionally, there are various types of conditioning agents available, with varying quality, thus necessitating standardized quality testing standards

Table 1. Summary and application scope of soil conditioning agents.

Agents	Effect	Advantage	Disadvantage	Strata
Water	Cooling, lubrication, and regulating water content	Cheap and convenient	Poor conditioning effect	Dry soil and rock
bentonite	Improving the workability and preventing spewing	High expansibility, supplementing fine-grained components	Poor treatment effect under high water pressure conditions	Coarse-grained strata
Foaming agents	Introducing gas to improve soil flow-plasticity	Lubrication, reduce adhesion, and improve soil fluidity	Easy to lose under high water pressure conditions	All strata
Dispersants	Reducing viscosity and dispersing	Solve clogging and mud cake issues	Dispersion takes a certain amount of time	High viscosity strata
Polymers	Agglomeration, reducing permeability, and preventing spewing	Capable of withstanding high-water pressure	Powdered polymers have poor solubility and are prone to clogging the pumping pipeline	Water-rich sandy strata
Anti-wear agents	Lubrication, clogging reduction, and cooling to protect the equipment	High effect of friction-reducing	Immature technology	Hard rock strata

3 APPLICATION OF SOIL CONDITIONING TECHNOLOGY

Due to the complexity of shield tunnelling construction strata, researchers have expanded the scope of soil conditioning from single sand and gravel or clay strata to include composite strata soil conditioning. In general, EPB shield tunnelling is suitable for excavating soil with a fine-grained content (>0.06 mm) exceeding 30%. Among them, clay-silt and silty-sand strata primarily composed of fine-grained soil are the most suitable strata for EPB shield tunnelling construction. These strata do not require any conditioning or simple water addition to meet the requirements of shield tunnelling excavation. As the coarse-grained content increases, the permeability also increases. In such cases, it is necessary to improve the water tightness of the soil by adding clay particles to supplement the fine-grained content. Currently, there is limited research on the adaptability of soil conditioning agents for various strata both domestically and internationally. More often, the conditioning schemes for specific strata are determined based on engineering experience. For instance, Langmaack and Feng 2005 proposed the adaptability range of soil conditioning agents based on long-term construction experience. Based on soil classification and particle size distribution, when dealing with finer-grained soils such as clay and silty soils, a combination of foaming agents and anti-stick agents is chosen for conditioning. This helps to prevent the formation of mud cakes on the cutter head and in the soil chamber. When the soil is silty or consists of fine sand, foaming agents can be used for conditioning alone to enhance the slurry discharge capacity. When the soil consists of medium-coarse sand and small-grained gravel, a combination of foaming agents and polymers can be used for

conditioning to enhance soil impermeability and prevent surges. When dealing with large-grained gravel strata where fine-grained soil or other fine aggregates are lacking, it is necessary to add a certain amount of bentonite. In this case, the use of foaming agents and polymers in combination with bentonite can be applied for conditioning. This helps to prevent surges and provides lubrication for the cutting tools.

Soil classification and particle size distribution form the basis for selecting soil conditioning agents. The adaptability of various soil conditioning agents proposed by Langmaack is fuzzy, and they do not consider water pressure conditions. Therefore, based on engineering practices, Maild U 1995 proposed a range of strata adaptability for soil conditioning. It suggests that different soil conditioning agents have their own strata adaptability, which needs to be selected based on soil particle size distribution and water pressure conditions, as shown in Figure 9(a). When the particle size distribution curve is located in region A, the soil has a smaller particle size and a fine particle content of more than 30%. It mainly consists of impermeable soil. When the consistency index (I_c) ranges from 0.4 to 0.75, the soil exhibits good plasticity. In other cases, water, low-viscosity bentonite or polymers, and foam can be used for suitable conditioning. In region B, the permeability of the soil is greater than that of region A. During actual construction, when the permeability coefficient $k > 10^{-5}$ m·s⁻¹ and the water pressure $p < 2$ bar, foam, polymer solutions, and fine-grained clay can be used for conditioning. When the soil particle size distribution curve is located in region C, the strata with water pressure below the groundwater level are not suitable for EPB shield tunnelling. Soil falls in region D mainly consist of coarse-grained soil particles. Due to their extremely high permeability, it is not possible to establish earth pressure balance during excavation.

Therefore, all soil conditioning methods are ineffective in this case. Budach and Thewes 2012 have made modifications to the suitability of Maild's soil strata through extensive experiments, as shown in Figure 10. If the particle distribution curve of the soil falls within range I and the fine-grained clay content is greater than 5%, a soil pressure balance shield tunnel using only foam as the ground conditioning agent is generally suitable for tunnel excavation below the groundwater level. For soil strata with particle size distribution curves falling within range II, effective conditioning can be achieved by using additional additives such as polymers or clay solutions. This can help meet the requirements for soil adaptability and facilitate the use of earthwork. These additives can alter the plastic flow behaviour of the soil, providing sufficient workability, compressibility, and low permeability. If the particle distribution curve of the soil falls within both range I and range II, then it is necessary to simultaneously meet the above requirements. If the soil grading curve falls within range III, and the soil meets the requirements of workability and compressibility after conditioning but fails to meet the requirement of a permeability coefficient $<10^{-5} \text{ m}\cdot\text{s}^{-1}$, it is necessary to excavate above the groundwater level. If the particle size grading curve falls outside the range of I to III, it is necessary to reconsider whether to choose a soil-pressurized balanced shield machine for construction. The sand soil used in the test falls between regions I and II in terms of grading, and it requires the use of foaming agents alone or in combination with polymer, slurry, etc., for conditioning. Additionally, the water pressure should be less than 3 bar.

Figure 9. Soil conditioning based on engineering experience (Maild U 1995).

Although the above-mentioned study provides some guidance for soil conditioning construction, it still has certain limitations. For example, the actual crossing of strata by shield tunnelling is more complex, and the delineation between different types of soils is not clear. The occurrence of groundwater can vary significantly with the seasons. Therefore, to overcome the limitations of the current empirical-based soil conditioning schemes, our research team

Figure 10. Soil conditioning based on tests (Budach and Thewes 2012).

has proposed a dynamic soil conditioning technology system based on extensive experiments and engineering validations (Li et al., 2019, 2022; Wan et al., 2021, 2022), as shown in Figure 11. Due to the varying factors considered in selecting soil conditioning schemes for different strata, the entire strata are divided into sandy strata, clay strata, and rock strata. For sandy strata, the soil permeability is the main consideration. Based on the permeability coefficient, the sandy strata are divided into generally permeable strata ($k < 10^{-4} \text{ m/s}$), highly permeable strata ($k = 10^{-2} \sim 10^{-4} \text{ m/s}$), and extremely highly permeable strata ($k > 10^{-2} \text{ m/s}$). Foaming agents, bentonite, and high-molecular-weight polymers are used in combination to reduce permeability and prevent water inflow. The specific selection of conditioning parameters depends on the permeability. For cohesive strata such as silty clay, and weathered mudstone, the cohesion of the soil should be the main consideration. The strata can be classified according to I_c as follows: soft ($I_c < 0.5$), medium soft ($I_c = 0.5-0.75$), medium hard ($I_c = 0.75-1.00$), and hard ($I_c > 1.00$). By combining dispersants and foaming agents, the clay particles can be dispersed effectively, achieving the effect of preventing clay cake formation. For rock strata, the division is primarily based on the abrasion coefficient (CAI) of the strata. The strata can be classified as follows: low abrasion ($CAI < 2.3$), medium abrasion ($CAI = 2.3-3.5$), and high abrasion ($CAI > 3.5$). Therefore, it is necessary to select foaming agents and abrasion-resistant agents for conditioning based on CAI. Shield tunnel construction involves complex and variable geological conditions, which often include composite strata instead of homogeneous ones throughout the entire cross-section. Therefore, it is necessary to take a comprehensive approach and consider the interactions between different strata. The proposed dynamic soil conditioning technology system still has certain shortcomings, mainly due to a lack of corresponding construction standards. In actual construction, it is still necessary to consider factors such as site-specific geological conditions, performance parameters of the soil conditioning agents, and the performance of the shield tunnelling machine.

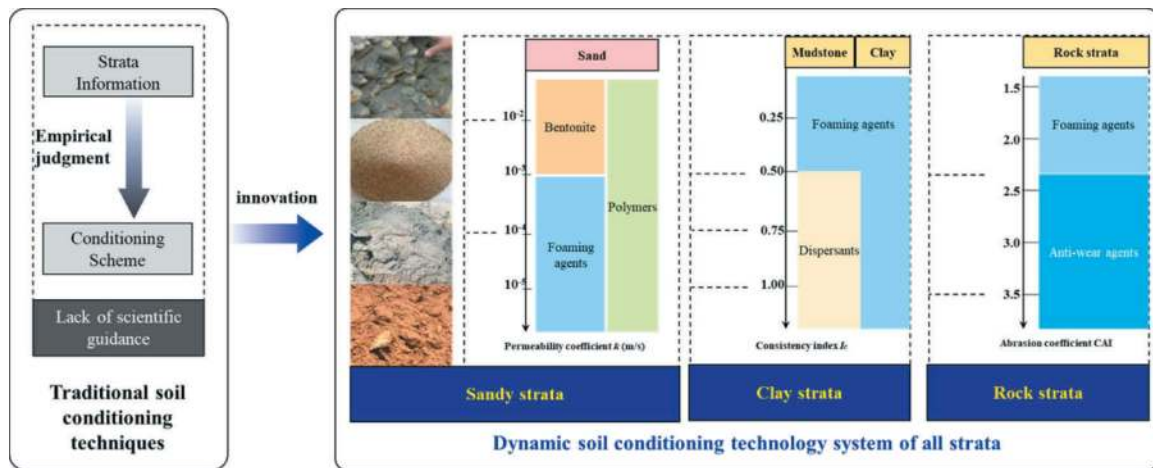

Figure 11. Dynamic soil conditioning technology system of all strata.

4 CONCLUSIONS

This article focuses on the safe and efficient tunnelling process of EPB shield tunnelling. Based on the characteristics of the traversed strata, the problems encountered in soil conditioning process are categorized into three main types: high cohesion strata with clay cake formation, water-rich strata with spewing, and hard rock strata leading to tool wear. The purpose of soil conditioning for EPB shield tunnelling is to transform the soil into a “flow-plasticity” state that can be accepted by the machine. The development history of soil conditioning agents, from none to various types available at present, has been summarized. The types and characteristics of these conditioning agents are outlined. Based on the application results of soil conditioning and the latest research achievements, a comprehensive strata-adaptive dynamic soil conditioning technology system is proposed. With the continuous development of shield tunnelling technology, soil conditioning techniques have also been evolving. However, there are still several areas of research that need to be explored:

- (1) Soil conditioning agents have gradually become indispensable functional materials in shield tunnelling. However, the use of poor-quality conditioning agents can directly affect the safety and efficiency of tunnel construction. Currently, there is an urgent need to establish testing standards or protocols for conditioning agents.
- (2) Due to the complexity of construction environments, shield tunnelling often involves traversing multiple layers of composite strata. Although this article proposes a comprehensive strata-adaptive dynamic soil conditioning technology system, it still requires a significant number of field experiments to validate its effectiveness.

ABSTRACT: The application of a displacement field at the excavation boundary is a widely used and effective numerical technique to compute tunnelling-induced displacements. The principal assumption of this method is that the deformed tunnel shape is similar to the original one, i.e., circular, while its bottom remains fixed in its original position. In this paper, three-dimensional numerical analyses are described to propose a more suitable criterion for very shallow and large-diameter tunnels, characterized by two separated elliptical contraction shapes for the upper and lower parts of the tunnel section. Furthermore, quantitative description of the deformed pattern is provided, and the relationship of contraction and translation parameters with tunnel depth-to-diameter ratio is summarized and validated against monitoring data. The results show that the most appropriate deformation pattern for very shallow and large tunnels is characterized by an elliptical shape in the upper section and a circular shape in the lower part. The new approach provides a more realistic prediction of the surface displacement field if compared to that predicted by using the homothetic contraction of the tunnel section.

Keywords: Tunnel excavation, Displacement-controlled method, Large and shallow tunnel, Soil displacement, HSsmall model

1 INTRODUCTION

TBM-EPBs are often used in urban tunnel construction, generally resulting in very limited ground displacements. However, accurate prediction of excavation-induced movements is essential to avoid any damage of nearby surface and subsurface structures (Mair, 2008). Previous research has utilized various prediction methods, including empirical approaches (Peck, 1969), quasi-analytical solutions (Loganathan and Poulos, 1998), centrifuge experiments (Hagiwara et al., 1999) and numerical simulations (Nguyen et al., 2021; Yang et al., 2023). The displacement-controlled method (DCM) has proved to be an effective approach if the focus is on ground displacements rather than on structural forces in the tunnel lining (Boldini et al., 2018). When combined with advanced soil constitutive models, such as the

Hardening Soil model with small-strain stiffness (HSsmall), very satisfactory results can be obtained also for small values of volume loss (Fagnoli et al., 2015). In this respect, the setting of a reasonable excavation boundary contraction pattern is of utmost importance (González and Sagasetta, 2001).

Different displacement pattern assumptions have been suggested in the past. Sagasetta (1987) proposed an isotropic convergence pattern towards the centre of the tunnel boundary. Cheng et al. (2007) introduced a widely adopted Circular DCM that accounts for both circular contraction and vertical translation of the tunnel boundary, as shown in Figure 1. It should be noted that this method was developed for subway tunnels, typically characterised by small diameters and large depths. It is based on the following assumptions: 1) the convergence is not uniform; 2) the deformed tunnel shape is similar to the

*Corresponding author: wenhui.yang@uniroma1.it

initial shape; 3) the convergence point is located between the converged tunnel centre and invert.

The Circular DCM has been successfully applied in predicting surface settlements induced by tunnelling in free-field conditions, as well as in studies of tunnel-structure interaction (Amorosi et al., 2014; Boldini et al., 2018). However, some researchers have pointed out that the tunnel excavation profiles are not always circular (Loganathan and Poulos, 1998; González and Sagaseta, 2001; Marshall et al., 2009). In practice, they are influenced by various factors, such as construction conditions, soil properties, anisotropic state of stress, etc... Considering non-uniform tunnel contraction, such as ovalization (Tamagnini et al., 2005), can contribute to more accurate predictive results. For shallow-buried large-diameter tunnels, for which larger stress and stiffness variations are expected with depth.

In this study, a series of numerical parametric analyses are conducted to investigate the influence of tunnel diameter and burial depth on the deformed tunnel profile especially for shallow-buried and large-diameter tunnels. Results show that as the depth to diameter ratio, H/D , decreases, the tunnel profile changes from a uniform circular contraction to a non-uniform contraction, with the upper part gradually assuming an elliptical shape. When H/D is less than 1.5, the profile stabilizes, exhibiting a contraction pattern with an elliptical shape of upper part and a circular shape of lower part. These numerical simulation findings have been validated using a real case study.

2 IMPACT OF TUNNEL DIAMETER AND AXIS DEPTH ON THE FINAL EXCAVATION BOUNDARY PROFILE

2.1 Adopted methodology

In practical constructions, the complexity of the engineering environment often makes very challenging the pre-installation of monitoring points for accurate deformation observation at the excavation face. Centrifuge experiments represent a feasible alternative, but they are typically associated to high costs and certain limitations in parameter

Figure 1. Commonly used circular DCM (modified from Cheng et al., 2007).

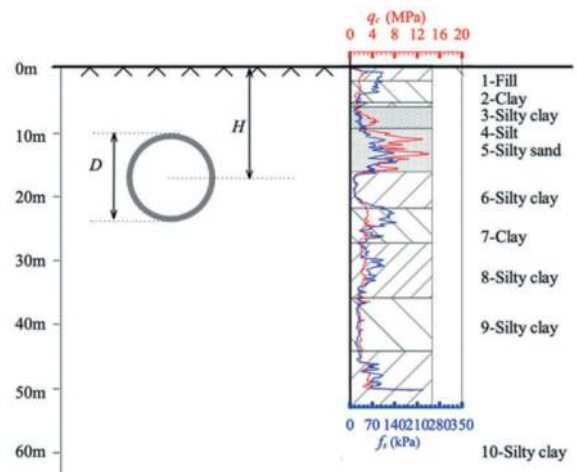

Figure 2. Geotechnical model at the tongjing road tunnel site.

Figure 3. Numerical model.

settings. The finite element code Plaxis offers a viable solution to simulate the tunnel volume loss by assigning a contraction rate (C_{ref}) to the TBM shield, without pre-determining the final tunnel contraction pattern. The equilibrium state is reached during the iterative calculation process, and the final deformation profile is related to the stiffness of the surrounding soil (Plaxis, 2020). In this study, this method is adopted to obtain the final deformation profile of the tunnel.

2.2 Description of the reference case

The geotechnical model adopted in the numerical simulations refers to the Suzhou Tongjing road tunnel project. The soil profile at the construction area is shown in Figure 2. The soil is divided into 10 different layers, namely: 1- fill, 2- clay, 3- silty clay, 4- silt, 5- silty sand, 6- silty clay, 7- clay, 8- silty clay, 9- clay, and 10- silty clay. The TBM-EPB tunnel passes through layers 4- silt, 5- silty sand, 6- silty clay and 7- clay. The water table is at 1.5m below the ground surface and the pore pressure distribution is hydrostatic. During simulation of tunnel excavation, soil layers 1, 4, and 5 are set as drained, while other soil layers are set as undrained.

2.3 Detail and validation of the finite element model

In order to obtain a more accurate representation of the excavation boundary profile, a 3D step-by-step numerical tunnel excavation is implemented in Plaxis. This model incorporates detailed modelling of the TBM-EPB and the tunnel lining (Figure 3). Solid elements are used for the soil and the lining, while plate elements are employed to simulate the machine shield. Considering the symmetry of the model, only half model is created for numerical simulation. The finite element discretization consists of over 38411 elements. In the vicinity of the tunnel face, the mesh is refined to better handle significant stress and strain gradients in that region. Interaction surfaces are established between the tunnel lining and the soil, as well as between the shield machine and the soil (Figure 3). The face pressure and grouting pressure of shield follow a linear distribution with depth and are set equal to the total horizontal stress and total vertical stress at those locations, respectively.

The HSsmall constitutive law is adopted to get accurate numerical results. Table 1 and Table 2 shows the parameters of HSsmall model and the assumed values: all the values are calibrated on laboratory and in-situ tests data (Yang, 2023). The elastic model is used for the lining and the shield (the values of parameters are listed in Table 3). The construction process is modelled using a sequential excavation scheme (Fargnoli et al., 2015).

The tunnel diameter (13.2 m) and axis depth (16.7 m) also refer to very shallow and large Suzhou Tongjing road tunnel. C_{ref} is set equal to 0.45% based on field surface settlement monitoring results. The corresponding surface volume loss, $V_{l,s}$, results to be 0.48% using a Gaussian distribution curve with a width parameter $K = 0.6$ (Figure 4). It can be observed that the numerical calculation results are in good agreement with the semi-empirical and monitoring results, indicating the reliability and accuracy of the numerical model used in this study.

2.4 Numerical results

In order to investigate the influence of tunnel diameter and depth on the tunnel deformation profile, a series of parametric analyses are conducted, according to the tunnel characteristics listed in Table 4. The non-dimensional parameter H/D is used to analyse the combined effects of tunnel diameter and axis depth.

Figure 5 shows the impact of tunnel diameter on the tunnel deformation profile, having fixed the axis depth, $H = 16.7$ m, while Figure 6 that of the axis depth with a constant diameter, $D = 13.2$ m. In both cases, tunnel displacements are amplified by 100 times and normalized with respect to the tunnel radius. Results indicate that when H/D is relatively large, the tunnel profile appears to uniformly converge into a circular shape, which is consistent with the findings of Cheng et al. (2007). However, as H/D

Figure 6. Final excavation boundary profile for different tunnel axis depths and $D = 13.2$ m (scale: 1:100).

unaffected by changes in H/D , maintaining a circular contraction. This observation is consistent with the results observed by Lueprasert et al. (2023). When H/D reaches 1.5, the profile shape stabilizes. These results indicate that the tunnel profile is strongly influenced by both tunnel diameter and axis depth and is closely related to H/D . The upper and lower parts of the tunnel can deform independently.

3 PARAMETERS DESCRIBING THE DEFORMATION PATTERN OF SHALLOW-BURIED AND LARGE-DIAMETERS TUNNEL

3.1 The deformation pattern

Based on the analysis mentioned above, a deformation pattern of shallow-buried and large-diameter tunnels is proposed, as illustrated in Figure 7. In these cases, the deformed tunnel profile exhibits an elliptical shape in the upper part and a circular shape in the lower part. For a more quantitative description of the deformed shape and its extension to more general cases, three variables are introduced: the ratio of the vertical and horizontal axis of the upper part - n_1 , the ratio of the vertical and horizontal axis of the lower part - n_2 , and the overall tunnel translation magnitude - β . A circular contraction corresponds to values of n_1 and n_2 equal to 1. $\beta = 0$ indicates no vertical translation, while $\beta = 1$ implies that the tunnel invert is translated to its initial position, i.e. that the tunnel is fixed at its bottom.

3.2 The deformation parameters

Figure 8, Figure 9, and Figure 10 illustrate the relationships between H/D and the tunnel profile deformation parameters n_1 , n_2 , β , respectively. As shown in Figure 8, when $H/D < 1.5$, n_1 remains relatively stable at 0.9963 and when $H/D > 1.5$, n_1 increases with H/D and is likely to reach 1.000 at $H/D = 5$. As shown in Figure 9, n_2 is basically unaffected by the axis depth and tunnel diameter, with a stable value of 1.000, which means that the lower half tends to contract into a circular shape, as observed before. The bottom point

of the tunnel profile is not fixed at its original position but experiences a certain degree of uplift. Numerical simulations show that the overall tunnel translation rate β usually stabilizes at 0.10 (Figure 10).

In summary, for the shallow large tunnels ($H/D < 1.5$), the convergence parameters of tunnel profile, n_1 and n_2 are taken as 0.9963 and 1.000 respectively. For deep or small tunnel ($H/D > 5$), the values of n_1 and n_2 approach 1.000 and the tunnel profile can be considered to be circular. For other tunnel conditions ($1.5 > H/D > 5$), n_1 can be set between 0.9963 and 1.000. It should be noted that these two parameters should not be rounded, and at least four decimal places should be retained.

4 RESULT VALIDATION

To further validate the proposed deformation pattern and its parameters, a series of numerical simulations are conducted using a single-step excavation method to simulate tunnel excavation without considering the tunnel lining, as in Boldini et al. (2018). The prescribed displacements at the excavation boundary are determined using the parameters obtained in Section 3.2, i.e. $n_1 = 0.9963$, $n_2 = 1$, and $\beta = 0.10$. These displacements are then applied to the numerical simulation of the Tongjing road tunnel excavation.

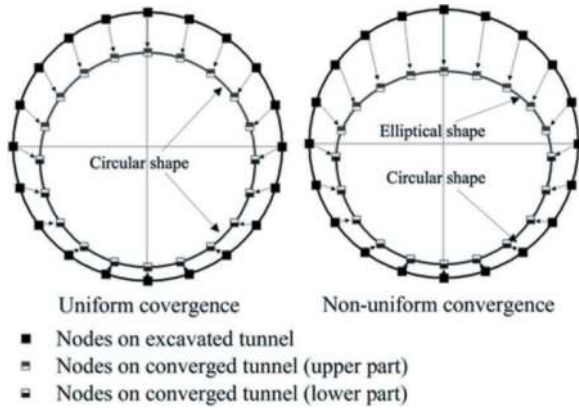

Figure 7. Schematic diagram of the displacement pattern.

Figure 8. Relationship between n_1 and H/D .

Figure 9. Relationship between n_2 and H/D .

Figure 10. Relationship between β and H/D .

Figure 11. Comparison between the predicted surface settlement trough calculated with the bi-elliptical DCM and that with the circular DCM.

As shown in Figure 11, the implemented procedure successfully reproduces the ground settlement profile, showing an excellent agreement with monitoring data. This indicates that the proposed deformation assumptions are reasonable. Furthermore, Figure 11 also shows the predicted range of surface settlements for deformation parameters n_1 ranging from 0.9950 to 1.0000. It illustrates the significant

potential of the proposed deformation model, capable of predicting various settlement curves, with the non-uniform convergence mode offering a more realistic prediction of surface displacement compared to the circular tunnel convergence ($n_1=1.0000$).

5 CONCLUSIONS

Based on series of parameter analyses, this paper proposes an improved deformation pattern for very shallow and large tunnels, which considering independent deformations of the upper and lower tunnel sections. Furthermore, it introduces quantitative parameters to describe the tunnel deformation pattern and derives parameter values suitable for shallow and large-diameter tunnels for specific geotechnical conditions. The deformation assumptions and associated parameter values are validated by comparing the predicted surface displacement with monitoring data from a real case-history. Three key conclusions are obtained from this study:

- (1) as H/D decreases, the tunnel profile gradually transitions from uniform circular contraction to non-uniform contraction and stabilizes when H/D reaches 1.5, with the upper part forming an ellipse and the lower part contracting into a circle;
- (2) three variables, the ratio of the vertical and horizontal axis of the upper part and lower part - n_1 and n_2 - and the overall tunnel translation magnitude - β , can be used to describe the deformed tunnel shape. For shallow and large tunnels in the soil conditions described in this paper, n_1 , n_2 and β are 0.9963, 1.0000 and 0.10, respectively;
- (3) the proposed approach provides a more realistic prediction of the surface displacement field; as such, it has a significant potential of reproducing various settlement trough shapes caused by the excavation of large-diameter shallow-buried tunnels if compared to that predicted by adopting a circular tunnel contraction.

Stability numerical investigation of laminated and randomly discontinuous flat roof

Paraskevi Yiouta-Mitra* & Emmanouil Vougioukas

National Technical University of Athens, Greece

ABSTRACT: The behavior of laminated geological formations is governed by interbedding low tensile and shear strength which leads to separation and sliding respectively. These geological formations are commonly encountered in the construction of hydropower plants or in the mining industry for specific deposit types as well as in underground marble and limestone quarries. When the rock layers are internally discontinuous, their behavior significantly diverges from that of a beam succession. In this research, the behavior of multilayered randomly discontinuous with discrete fracture networks (DFN) roof in low overburden underground excavations is numerically investigated and compared to the behavior of single and multiple continuous or voussoir layers. A set of numerical analyses with the discrete element method are performed in UDEC and quantification of the multilayering effect is produced for the unsupported discontinuous roof. The control of stresses and displacements by active reinforcement or passive support of the roof is of great interest. A second set of numerical analyses for the quantification of the reinforcement effects of pre-tensioned rockbolting and the passive support of shotcrete are also performed. Conclusions are drawn with respect to the degree of decrease of displacements magnitude in correlation to the support method. For continuous layers it is observed that the reinforcement of the roof reduces the vertical displacements to a lesser extent whereas for randomly fractured bedding layers, best support results are achieved by shotcrete.

1 INTRODUCTION

The design of underground mines and caverns must consider geological, economical and safety aspects in the design stage. In mining, the case of tabular deposits is often the reason to select room and pillar or longwall mining methods. For the former, minimization of surface subsidence is paramount but with a simultaneous maximization of the recovery. Although pillars are the main support elements in a room and pillar scheme, their dimensioning must always be performed in conjunction with roof stability of chambers, especially if retreat mining is to be performed afterwards. According to Ghasemi et al. (2012), the main parameters contributing to roof fall in room and pillar retreat mining involve, among others, parameters such as the roof rock structure and quality and the panel width. Sherizadeh (2016) mentioned that different mechanisms can affect the stability of the roof and successful roof control can only be obtained if the failure mechanism is identified and understood properly. He performed a series of three dimensional distinct element analyses and concluded that the roof rock joint shear strength parameters have significant effect on the roof stability, whereas the rock-mass tensile strength had negligible effects.

Generally, in cases of excavations performed in horizontally stratified rock, a rectangular cross-section is the obvious economic selection. The structure of the roof rock has a considerable effect on the stability of the excavation and the choice of the support measures. The strata separate due to self-weight and deflect to the point of fracture, while at the same time the load is transferred to the supports of the roof, i.e. the abutments. The deformations of layered roof prior to collapse used to be greatly underestimated because fracturing and transition to a voussoir roof was not considered. Bedding controls the strength of rock by defining beams or plates that span large openings. On the other hand, discontinuities define blocks of rock that may fall from the sides and roof of underground hard rock excavations. When the roof is in a fractured post-elastic state, the mechanisms of failure change to buckling, crushing and slip. Multi-layered buckling has been investigated analytically (Yiouta-Mitra & Sofianos, 2018a), experimentally (Talesnic et al., 2007, Zhang et al., 2012) and numerically (e.g. Nomikos et al., 2002, He & Zhang, 2015, Yiouta-Mitra & Sofianos, 2018b, Abousleiman et al., 2020, Le and Oh, 2022).

The characterization of the discontinuities themselves, i.e. number of discontinuity sets, and for each

*Corresponding author: antipaxos@metal.ntua.gr

set, persistence, orientation spacing, location, shape and size plays an important part in the evaluation of the mechanical behavior of the roof. In this research, a numerical discrete element scheme is used to explore the effects of multiple randomly fractured and multi-jointed layers in comparison to their continuous horizontally bedded and vertically fractured analogs and their response to reinforcement techniques. The DFN geometrical parameters are selected with a view to maintain as prominent mechanism of failure the discontinuous nature of hard rock underground roof.

2 NUMERICAL MODEL

The distinct element code UDEC is selected to model the behavior of the stratified roof of an underground opening. The basic validation of the models has been performed in a previous numerical investigation (Yiouta-Mitra & Vougioukas, 2023) for the case of a single layer of limestone roof in gravitational field, comparing the results with the analytical solution for a fixed-end beam under its self-weight (Yiouta-Mitra & Sofianos, 2009). Three geometrical variables are considered in the current research; the number of layers, the number of vertical joints and the presence of a DFN with specific fractal characteristics to create a network at the project scale.

The model was partly of finer grid in the areas of interest for a better approach in relation to the analytical solution. Indicative grid setups can be seen in Figure 1.

Figure 1. Indicative rockmass and discontinuities grid model setup for two cases: (a) 5-layer model with overburden and vertical joints at spacing 2.5 x the layer thickness (b) two-layer continuous model with DFN joints at project scale.

Simulations are performed for the case of continuous and cracked (vertical or random DFN discontinuities) stratified roofs, in limestone rock, shallow underground openings. Therefore the top boundary is free, while the side boundaries limit the horizontal displacements to simulate the far field. For a faster convergence of the model, fixed boundaries are applied at the bottom. Strong rock was considered so as to ensure that shear failure at the discontinuities would take precedence over the rock mass failure. The M-C failure criterion was prescribed for the discontinuities as well as the rock. The mechanical properties are summarized in Table 1.

The bedding stiffness values are selected according to a wide range of bibliographic references (e.g. Bastola & Clugh, 2015) and the joint stiffness values are calculated according to Itasca (2022) for the specific numerical model parameters and the assumption of very stiff joints with no infilling material. As mentioned earlier, three geometrical parameters were varied in the models; the number of layers N was varied from 2 to 5, the crack spacing M was varied from 0.5 to 2m, giving ratios of crack spacing M to thickness t equal to 5;2.5;1.25;0.625 and the DFN was varied between 0 and 1, indicating existence or not.

The span was 4 m and the layer thickness 0.4m. For each roof case, the displacement of the excavation lower fiber was measured and the center point deflection monitored.

3 UNSUPPORTED ROOF RESULTS

3.1 Two layers below massive rock overburden

The numerical models with 2 layers amounted to six cases, a case of two continuous beams, four cases of a surplus of vertical crack sets spaced at $sj/t = 5, 2.5, 1.25$ and 0.625 and finally a case of a surplus of DFN. The deflections on a scanline at the lower fiber of the roof is depicted in Figure 2 for all cases. The lowest deflections were attained by the continuous beams while largest by the DFN case. It is clear that the random fracture network also produces unexpected and irregular patterns of deflections, contrary to a normally spaced discontinuity set. The effects of vertical joints spacing was found to be very small compared to the impact of the presence of a random project-scale fracture system. The numerical solution has provided a clear insight into the small differentiation between different vertical joints' spacing schemes, which is in accordance to the observations of previous research (Yiouta-Mitra & Sofianos, 2018).

Table 1. Mechanical properties of rock and discontinuities.

	c (MPa)	ϕ (deg.)	k_n (GPa/m)	k_s (GPa/m)	Density (g/cm ³)	G (GPa)	K (GPa)	E (GPa)
Rock	6.7	42			2.7	11.05	22.62	25.5
Bedding	0.1	30	10	1				
Joints	0	30	3700	370				

Figure 2. Scanline of displacements on immediate roof. The irregular curve corresponds to the random fracture network.

Figure 3 depicts the displacement vectors and the joint plane separation for the case of the DFN layered model. It becomes obvious that a wedge is formed around the center of the opening, which causes the irregularity in the deflections of the respective scanline in Figure 2.

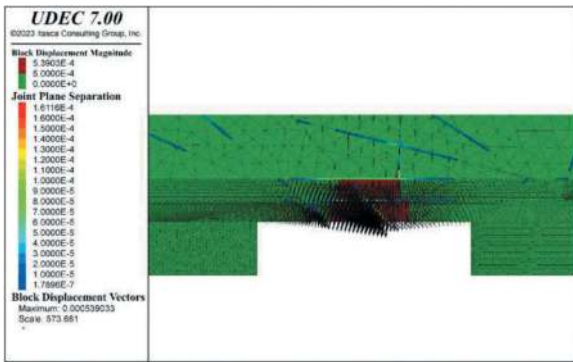

Figure 3. Roof deflections and crack separation for the DFN model with 2 layers.

3.2 Five layers with and without overburden

In this section two slightly different models were developed in order to detect the effects of the overburden in the case of shallow multi-layered excavations. It was interesting to note the beneficial effects of the existence of the overburden, even as thin as the total of the layered imminent roof. Figure 4 contains the comparison of these cases, where it may be seen that both the randomly cracked roof as well as the sparsely spaced vertical joints' set depict deflections of similar magnitudes. In the case of no overburden over the five layers, the roof actually fails because it slides on the pre-existing cracks. The same happened with the randomly fractured roof but it has not been included in Figure 4 because the displacement magnitudes far exceeded the other cases and would dwarf them. The multi-layered roof depicted larger deflection, as expected, compared to a roof of fewer layers. Another interesting observation in Figure 4, is to notice that when the vertical joints are more closely spaced, the deflections lessen. This is more obvious in the case

with no overburden, otherwise, as noted in the previous paragraph, the effect of joint spacing on the immediate roof bending is less critical than other parameters. The formation of large blocks, equivalent to sparse but persistent jointing is the most detrimental to the stability of the flat jointed and layered roof.

Figure 4. Effect of overburden on the stability of shallow layered roof.

The comparison between the behaviour of a combined vertical joints and randomly cracked multi-layered roof to the separate case has given better insight the mechanisms affecting the behaviour of blocky rockmass over rectangular openings. As can be seen in Figure 5, when there are no substantial vertical joints, the forming wedge is “trapped” between the rotating sidewalls and all contact separations as well as roof deflections remain low (Figure 5a). In the case of the combination to a vertical joints set though (Figure 5b), despite their sparse distribution, sliding is enabled along their surfaces and since multiple layers are present, their weight overcomes the shear strength of the joints and the roof slides almost entirely vertically. Evidently, the wedge has detached since its displacement is in the order of magnitude of centimetres. Further, the area around the wedge has also displaced in the same order of magnitude, a difference order of magnitude of 2 with respect to the previous case. Similar observations are valid for the combinations of DFN combinations to smaller joint spacing.

4 SUPPORTED ROOF RESULTS

Specific cases of unsupported roof were selected to test the effectiveness of bolts and shotcrete support schemes with varying properties and layouts.

4.1 Active bolts ideally simulated

The roof of a layered underground opening is best reinforced with pre-tensioned bolts. The reinforcement

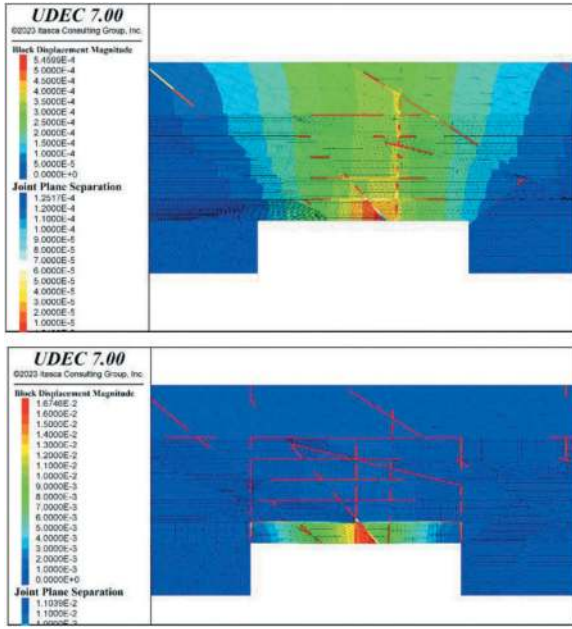

Figure 5. Response of five-layer roof (a) with DFN flat roof and (b) with DFN and vertical joints sparsely spaced at $s_j/t=5$.

aims at eliminating the separation of the lower layers by hindering the slipping between them. Thus, it forces individual continuous layers to function as a single solid roof. It has been verified that the response of the cracked roof is differentiated from that of the continuous layers. The active bolts are ideally simulated as concentrated compressive forces applied at the points of bolt installation.

For each case of multi-layered roof, the tightening of the layers with maximum required pretension $P_{b, \max} = 141\text{kPa}$ is performed, on a $1 \times 1\text{m}$ grid. The pretensioning force was calculated to prevent slip between the layers and was ideally simulated by applying a compressive force at the points of the bolt installation, such that would create shear strength equal to the shear stress of equation (1) at the level of the discontinuity:

$$P_b = \frac{\tau_{\max}}{\tan\varphi_j} \quad (1)$$

where τ_{\max} the maximum shear strain developed in the layers, i.e. shear stress that only depends on the roof span and φ_j the bedding friction angle.

The bolting pattern was varied between vertical and inclined bolts on the sides and the second one was the most effective 1×1 pattern. Figure 6 contains indicative results for the case of 2-layer roof for the two extreme cases of joint spacing, $s_j/t=5$ and $s_j/t = 0.625$ respectively. Similar support effects were recorded for all joint spacing layouts as can be seen in Table 2, were all cases are reported for the two-layer roof. The displacement reduction achieved was higher in the case of more sparsely jointed layered roof.

Table 2. Deflection reduction for two-layer roof with ideally pretensioned bolts.

S_j/t	5	2.5	1.25	0.25
Amelioration	51.74%	49.91%	45.59%	46.43%

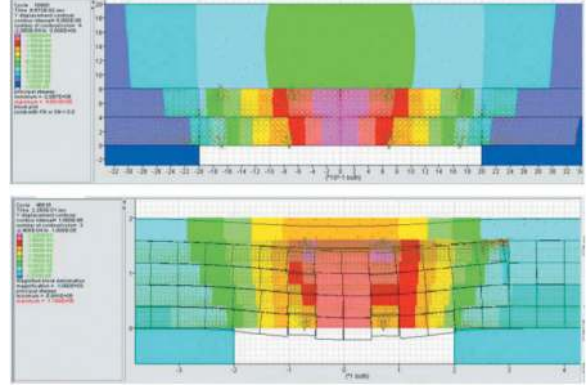

Figure 6. (a) Support with ideal vertical pretensioned bolts for 2-layer roof and (b) for 4-layer roof and side inclined bolt pattern.

4.2 Shotcrete support

Shotcrete is integrated into the excavation-support cycle of underground mines but also of many civil works. Its capacity is generally acting under four mechanisms, adhesion, direct shear, punching shear and flexure. These mechanisms are interdependent for their development. For example, if adhesion between the applied shotcrete and the rockmass is maintained, the failure will occur in direct shear. Otherwise, if it lost, flexural failure of the shotcrete layer will take place. In the specific case of layered and jointed hard rock formation of the current research, these four mechanisms are most applicable, since the rock mass failure is controlled by the orientation and shear strength of the discontinuities and not by overstressing. The large blocks are generally designed to be supported by rock bolts, it is mostly the smaller key blocks that shotcrete is called to support. The combination of rock bolts and shotcrete limits the kinematic freedom of unstable rock blocks and controls the unravelling of a blocky roof.

Thus, for the worst case scenario of five layers and the presence of a random fracture network, shotcrete was selected as appropriate support measure to be examined on its own. Four shotcrete schemes were applied. The first was standard shotcrete of 10 cm thickness, the second 20 cm and the third 15 cm but with practically unbreakable shotcrete-rock interface adhesion.

The varied properties of the shotcrete are depicted in Table 3. The difference between the four schemes is mainly the shotcrete thickness that has been varied from 10 to 20 cm. The adhesion role was also tested

and found to be quite significant in comparison. It is characteristic that Schemes 2 and 21 of shotcrete properties gave the highest roof reinforcement. Figure 7 contains the efficiency chart of all schemes as a percentage amelioration of the unsupported deflection of the roof.

Table 3. Properties of shotcrete in S.I. [N;m].

Scheme	1	2	21	3
Thickness	0.1	0.2	0.1	0.2
Normal coupling Stiffness	1E9	1E11	1E11	1E9
Shear coupling stiffness	1E9	1E11	1E11	1E9
Coupling cohesion	1E6	1E8	1E8	1E6
Coupling tension	1E6	1E8	1E8	1E6

Figure 7. Percentage amelioration of deflection with shotcrete support for the randomly fractured layered roof.

Figure 8 depicts the supported flat roof and how the shotcrete, contrary to the rockbolts, creates a gradual, bending curve for the highly anisotropic randomly fractured roof. The shear forces in the shotcrete layer are maximized close to the protruding wedge that is formed in the middle of the roof. It is the point where failure is expected to take place for thinner layer or insufficient adhesion.

It must be noted that direct shear failure of the shotcrete will happen for a combined bolt and shotcrete application in the case of five layers with no overburden and vertical joints occurring at the abutments. This can be easily averted though, if the pattern of the bolts is the inclined one for the outer bolts and the loss of the shear strength of the joints is thus counteracted.

Figure 8. Shear forces and structural displacements of shotcrete for scheme 3.

5 CONCLUSIONS

A parametric numerical analysis has been conducted with a view to investigate the response of multi-jointed layered media to the bolt and shotcrete reinforcement technique as compared to randomly fractured layered media.

The varying parameters were geometric, while mechanical properties of rock and joints have been maintained at representative values for hard rocks in low overburden, low stiffness of bedding planes and stiff vertical joints. The numerical models were validated against analytical solutions for continuous and voussoir beam roof. The results of the numerical generalization to multiple multi-jointed layers has shown that the lowest cracked layer is of paramount importance to maintaining lower stresses and displacements to the upper layers. The response of the multiple stacked voussoir beams is different from that of the randomly fractured in that the roof is more likely to form unstable wedges of various sizes. Stabilisation by rock bolts is always a method that yields satisfactory results. Shotcrete was also found to function well so long as adhesion is satisfactory, usually around 0.5 – 1 MPa and sufficient thickness of shotcrete.

It is concluded that the reinforcement of the roof either by rockbolts, shotcrete or their combination, achieves the decrease of vertical displacements and abutment stresses, for blocky flat roof with systematic or random fracture patterns. Monitoring of the roof stresses and displacements is a good preventive measure for the case where change of the bolting pattern or shotcrete thickness is required due to structural changes of the roof.

ABSTRACT: This paper addresses the issue of the dynamic responses of a shallow tunnel in liquefiable ground subject to multiple shakings. The topic is of special importance, because earthquakes often strike the same geological location repeatedly in a short period. The current study is based on a centrifuge test of four consecutive shakings, where a rectangular tunnel is buried in saturated Hostun sand in plane-strain conditions. The OpenSees platform and the PM4Sand constitutive model are employed to replicate the experimental results, including the displacements, the pore pressures, and the accelerations of the soil-structure system. The validated numerical model is then reconfigured for more realistic resemblances to the boundary conditions of an actual engineering site. Further analysis is also performed, placing the emphasis on the uplift of the tunnel with different permeability coefficients of the ground.

Keywords: Liquefaction, Multiple-shakings, Numerical modelling, Soil-structure interaction

1 INTRODUCTION

It is very likely in a seismic event that the structures would experience a series of consecutive shakings in a short period of time. Since the dynamic behavior of the soil is usually stress-path dependent, the soil-structure interaction (SSI) would also differ because of the shaking histories of the excitation. The scenario to be studied in this paper is a shallow tunnel in liquefiable ground subject to multiple shakings. The OpenSees platform (Pacific Earthquake Engineering Research Center, 2021) and the PM4Sand constitutive model (Boulangier and Ziotopoulou, 2017) are employed to construct a plane-strain numerical model based on a centrifuge test of four consecutive shakings. The test-validated numerical soil-structure system is then reconfigured for more realistic resemblances to the boundary conditions of an actual

engineering site, and further analysis is performed mainly regarding the uplift of the tunnel with different permeability coefficients of the ground.

2 THE CENTRIFUGE TEST

A series of centrifuge shaking table tests were conducted at the Schofield Centre, University of Cambridge by Miranda et al. (2023). Four physical models were prepared and tested, among which the first one is to be numerically simulated in this paper. An illustration of this centrifuge test model is shown in Figure 1. The centrifugal acceleration was 60g, so the scaling factor was 1:60. The following descriptions and the numerical models are both of the prototype scale unless stated otherwise.

*Corresponding author: zhang.j@xjtu.edu.cn

As can be seen, a rectangular tunnel, made of aluminum sheets, was buried in saturated Hostun sand 5 m below the surface. A rigid container was adopted to allow displacement measurement by particle image velocimetry (PIV). Therefore, to mitigate the boundary effects of the container, two layers of absorbent material were attached to the sidewalls. After an initial equilibrium was reached during the swing-up, four shakings were fired consecutively. They were EQ1, EQ2, EQ3, and EQ4, whose accelerograms and Fourier spectra are shown in Figure 2. The intensities of the first three shakings are increased through the amplitudes, which are 0.06g, 0.11g, and 0.43g, respectively. The fourth shaking, however, has an amplitude of 0.45g, similar to that of EQ3, but it has five more full cycles in the waveform.

During the shakings, the acceleration responses, the vertical displacements, and the pore pressure data are registered by the sensors denoted as ACC#, PIV#, and PPT# in Figure 1, respectively.

Figure 1. The centrifuge test model.

3 THE NUMERICAL SIMULATION

The numerical simulation of the centrifuge test is carried out employing the OpenSees platform. The finite element model is shown in Figure 3.

The majority of the model, i.e., the Hostun sand and the absorbent layers, are modelled by 2021 quadrilateral $u-p$ coupled elements (McGann and Arduino, 2012). The nominal element size is 0.5 m. The constitutive model PM4Sand is used to capture the non-linear behavior of the liquefiable Hostun sand, whose parameters are listed in Table 1. The detailed calibration process could be found in Zhang et al. (2023). The absorbent layers are considered elastic with a Young's modulus of 800 kPa, a Poisson's ratio of 0.46, and a mass density of 1.65 Mg/m^3 (Popescu and Prevost, 1993).

The tunnel lining is modelled by 54 elastic beam elements, defined around the interior of the rectangular hollow within the sand. The two translational degrees-of-freedom of the tunnel elements are equalled to those of the surrounding sand. Their material properties are a Young's modulus of $7 \times 10^7 \text{ kPa}$ and a linear mass density of 15 Mg/m .

The computation takes two stages. The first stage is the application of the gravitational field. Sufficient step time is given for the soil-structure system to reach an initial equilibrium. In the second stage, the four consecutive shakings depicted in Figure 2 are inputted from the lateral sides and the base of the model. Although the duration of each shaking is shorter than 20 s, they are all given the step time of 200 s. Hence, stage two has 800 s in total.

As has been stated, the test data include the acceleration responses, the vertical displacements, and the pore pressures. The data of four key positions are compared with the numerical results in Figure 4. They are the acceleration responses by ACC7, the pore pressure data by PPT4, the settlement of the ground surface by PIV-B, and the average uplift of the tunnel by PIV-CD. The latter two are trivial in

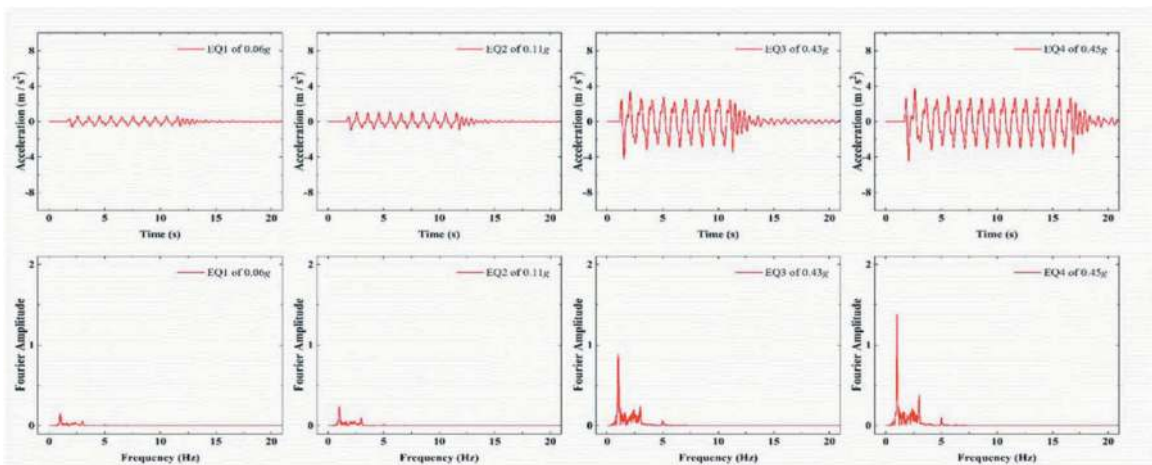

Figure 2. The input excitations.

Figure 3. The finite element model.

the first two shakings, so they are absent in EQ1 and EQ2. Other than that, the centrifuge test data have been replicated by the numerical simulation with reasonable accuracy. Thus, the validity of the numerical simulation is verified.

Table 1. Constitutive parameters of the Hostun sand.

e_{\max} : maximum void ratio	1.049
e_{\min} : minimum void ratio	0.648
D_r : relative density	54 %
G_0 : shear modulus constant	719
Q : critical state line parameter	8.4
R : critical state line parameter	0.78
ϕ_{cv}^* : critical state effective friction angle	33.8°
ν : Poisson's ratio	0.31
h_{po} : contraction rate parameter	0.07
ρ : mass density	1.96 Mg/m ³
k : permeability coefficient	6×10^{-4} m/s

4 THE NUMERICAL INVESTIGATION

The validated numerical soil-structure system is used for further investigation on the subject matter. However, for more realistic resemblances to the boundary conditions of an actual engineering site, it needs to be reconfigured. Firstly, the horizontal width of the liquefiable ground is extended to 100 m, which is more than 10 times the width of the tunnel. Then, the two absorbent layers are removed. Most importantly, differing from the boundary conditions of the rigid container, the seismic excitations are solely inputted from the base of the model. The two lateral sides are defined as periodical boundaries, which better represent the shearing deformations of the ground.

It has been noticed in a previous study that the rigid container could mitigate the effect of the input shakings (Zhang and Bilotta, 2023). Hence, to achieve a similar level of liquefaction to that of the Hostun sand in the centrifuge test,

the original input excitations in Figure 2 are scaled by a factor of 0.35 in the reconfigured numerical model with the new boundary conditions.

The constitutive parameters in Table 1 are kept, except that the permeability coefficient ranges from 1×10^{-4} m/s to 1×10^{-3} m/s. Thus, a series of numerical simulations are computed, where the emphasis is placed on the variation of the permeability coefficient. The resulting changes are mainly discussed of the uplift of the tunnel and the pore pressure on the midpoint of the base slab, which are plotted in Figure 5.

The first two shakings, i.e., EQ1 and EQ2, are relatively light. In the centrifuge test, they were intended to increase the homogeneity of the Hostun sand and to probe the elastic characteristics of the soil-structure system. Their peak accelerations are smaller than 0.04g in the new simulations. Although there is some excess pore pressure accumulation, the Hostun sand does not reach full liquefaction. Hence, instead of floating up, the tunnel even exhibits some minor settlements.

The uplift of the tunnel only starts to manifest in the third shakings. Due to the greater amplitude of the input excitation, there is a sharp increment in the excess pore pressure. Before full liquefaction is reached by the Hostun sand, the uplift of the tunnel has already begun. There is a clear trend that smaller permeability of the sand would lead to larger uplift of the tunnel. In the case of $k = 1 \times 10^{-3}$ m/s, the tunnel exhibits significant settlements in the last shaking. This is in conformity with conventional perceptions, because sand of smaller permeability is easier to liquefy, and the accumulated excess pore pressure is harder to dissipate, thus sustaining a longer full liquefaction. Consequently, the Hostun sand would provide enough buoyant force for the tunnel to gradually overcome its self-weight and the resistance of the surrounding soil. This is clearly demonstrated by the pore pressure data in the last two shakings. The excess pore pressure of the green curve of $k = 1 \times 10^{-4}$ m/s is the last to dissipate, and the dissipation is also the slowest. Even in the first two lighter shakings, the excess pore pressure of the green curve exhibits an observable increment, while the others are almost flat. Interestingly, the differences between $k = 3 \times 10^{-4}$ m/s and $k = 1 \times 10^{-4}$ m/s are only seen on the pore pressures not on the uplifts of the tunnel in the third shaking. The differences in uplifts do not become significant until the last shaking. This could be related to the larger excess pore pressures of $k = 1 \times 10^{-4}$ m/s in the first two shakings. The sand of the smallest permeability coefficient is presumed to be more densified. Hence, the uplift of the tunnel in the following shaking is mitigated. However, in the last shaking, the prolonged input excitation amplifies the effect of limited drainage, resulting in a much greater uplift of the tunnel.

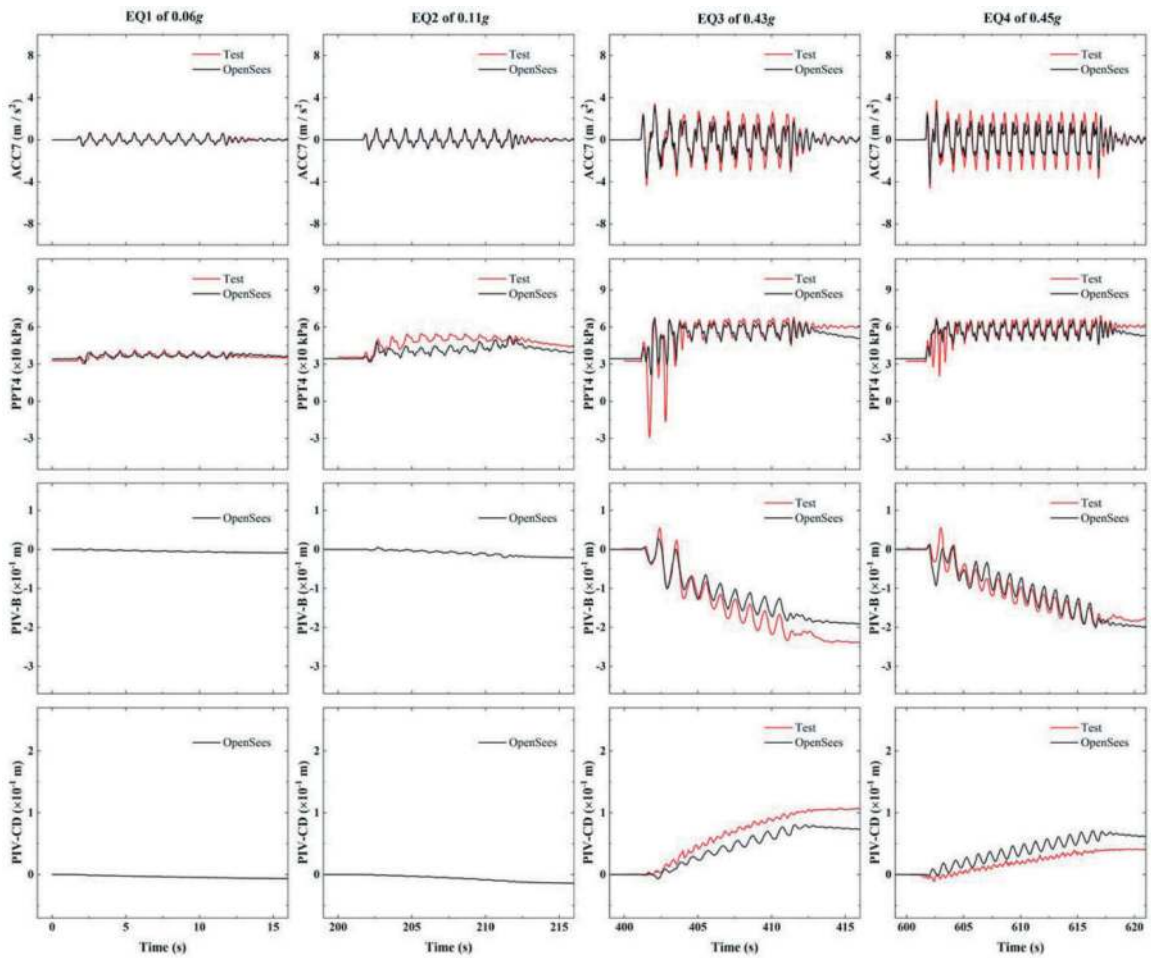

Figure 4. The comparison of the numerical results and the centrifuge test data.

Figure 5. The uplift of the tunnel and the pore pressure on the midpoint of the base slab in the investigative numerical simulations.

5 CONCLUSIONS

Two-dimensional plane-strain numerical models are constructed employing the OpenSees platform and the PM4Sand constitutive model. The numerical simulation is validated against the data of a centrifuge shaking test.

The test-validated numerical soil-structure system is reconfigured for more realistic resemblances to the boundary conditions of an actual engineering site.

Further analysis is performed, placing the emphasis on the uplift of the tunnel with different permeability coefficients of the ground.

There is a clear trend that smaller permeability of the sand would lead to larger uplift of the tunnel. However, the exact responses of the tunnel are also dependent on the shaking histories of the excitation.

ABSTRACT: The full-face mechanized method is one of the main development directions of the construction technology of tunnels excavated by the drilling and blasting method in China, and it is also the basis of intelligent construction technology of drilling and blasting tunnels. However, the significant increase of excavation area led to the reduction of tunnel face stability (especially in soft and fractured ground), which affect the popularization of the full-face mechanized method. Therefore, establishing the stability evaluation and control method for tunnel faces is the key issue to realize the full-face mechanized method in soft and fractured ground. To solve these issues, the model test and theoretical analysis methods are used to clarify the failure mechanism of tunnel face and reinforcing mechanism of advanced supports. First, the progressive failure mechanism and the failure mode of tunnel faces as well as the synergetic reinforcing mechanism of advanced supports are explored. Then, the calculation model and design method of the combined advanced support are established for tunnels excavated by the full-face mechanized method. The research results can provide theoretical support for the popularization of the full-face mechanized method.

Keywords: failure mechanism, tunnel face, pipe roof, face bolt, design of advanced supports

1 INTRODUCTION

The full-face mechanized method is one of the main development directions of the construction technology of tunnels excavated by the drilling and blasting method in China, and it is also the basis of intelligent construction technology of drilling and blasting tunnels. However, the significant increase of excavation area led to the reduction of tunnel face stability (especially in soft and fractured ground), which affect the popularization of the full-face mechanized method. Therefore, establishing the stability evaluation and control method for tunnel faces is the key issue to realize the full-face mechanized method in soft and fractured ground. Therefore, many advanced support techniques have been developed to provide safe excavation in conventional tunnelling, such as pipe roofing and face bolting (Lunardi, 2008). Many studies have been conducted to investigate the reinforcing mechanism of these techniques and the instability of the tunnel face.

Several authors have studied tunnel stability through numerical simulations (di Prisco et al., 2020; Li et al., 2015; Ng and Lee, 2002; Paternesi et al., 2017; Peila, 1994; Perazzelli and Anagnostou, 2013; Yoo, 2002; Yoo and Shin, 2003). The results show

that pipe roofing and face bolting could reduce face extrusion, change the soil's stress condition ahead of the tunnel face, and effectively improve the face stability. Pipe roofing and face bolting has optimum parameters (including overlap length, density, and axial rigidity), maximizing the reinforcing effect. However, the soil stress redistribution due to pipe roofing and face bolting were rarely considered in these studies. Moreover, the simulation results were dependent on the adopted material models and the parameters and should be validated by other methods. Experimental studies (including n-g and 1-g tests) provided an effective way to validate the numerical models and explore the face instability mechanism.

Experimental tests have been conducted by several authors (Al Hallak et al., 2000; Calvello and Taylor, 1999; Chambon and Corte, 1994; Date et al., 2008; Di Prisco et al., 2018; Kamata and Mashimo, 2003; Takano et al., 2010; Yoo and Shin, 2003), and the reinforcing effect of pipe roofing and face bolting is intuitively shown. The results agree with those from numerical simulations, indicating that pipe roofing and face bolting can significantly reduce the face's extrusion and improve its stability. There is indeed an optimal reinforcement length beyond which improvements in the reinforcement effect are

*Corresponding author: xiao.zhang@swjtu.edu.cn

not apparent. The extent of the failure zone and the required support pressure to stabilize the tunnel face are reduced by this technique. However, the failure process of reinforced faces was not measured due to a lack of measurement techniques.

Theoretical studies have been carried out to efficiently analyse the reinforcement behaviours of face bolts and pipe roofs. There are mainly two kinds of theoretical analysis methods for assessing the stability of a reinforced tunnel face, including the limit analysis method and the limit equilibrium method. Oreste and Dias (Oreste and Dias, 2012), Anagnostou and Perazzelli (Anagnostou and Perazzelli, 2015) and Perazzelli and Anagnostou (Perazzelli and Anagnostou, 2017) proposed computational methods based on the limit equilibrium method, in which the failure surface in front of a tunnel face is assumed to be an inclined plane. Pan and Dias (Pan and Dias, 2017) and Qian et al. (Qian et al., 2019) analysed the safety factor of a reinforced tunnel face in combination with the upper-bound limit analysis method and the strength reduction technique. However, only one reinforcement measure is considered in these models. In practical engineering, face bolting and pipe roof techniques are usually comprehensively employed, but there is no theoretical model that considers the simultaneous effect of these two measures.

To address these issues, a series of model tests with different reinforcement parameters were conducted with a 31 cm diameter tunnel in this work. The model tests were performed by considering a dry granular material (dry sand). Based on the model test results, the failure mechanism of reinforced faces is revealed and a design method of advanced supports for tunnels excavated by the full-face mechanized method is proposed.

2 THE STRATEGY OF LABORATORY TEST

2.1 Test instrument

In a darkness room were the model tests performed. Using a non-invasive technique, particle image velocimetry (PIV), the ground's displacement was measured. A Nikon D610 digital camera (24 megapixels, 6016 px4016 px) and two 100 W spotlights were used to capture the images. These images were later post-processed by the PIV software PIVlab by Thielicke and Stamhuis (2014). In Figure 1(b) and (c), the internal dimensions of the box were 1.0 m × 0.6 m × 1.5 m, and the front wall was a 1.2 cm thick hardened glass. The inner and outer diameters of the half tunnel model made of a plexiglass half-cylinder were respectively 31 cm and 33 cm. A half-circle piston of the same material was employed to support the tunnel face, its thickness 2 cm and diameter 30.5 cm. The piston and a load cell were connected by a steel bar, and the load cell is connected by a threaded rod constrained by a threaded flange. Thus, the piston could be retracted by turning the handle to simulate the instability of the face. Moreover, as shown in

Figure 1(b) and (d), a rectangular hole and a series of circular holes were respectively cut in the glass and drilled at the piston for bolt and pipe installation. The diameters of the holes at the piston and half-cylinder are respectively 4 mm and 5 mm, and the spacings between adjacent holes are respectively approximately 2 cm and 1 cm.

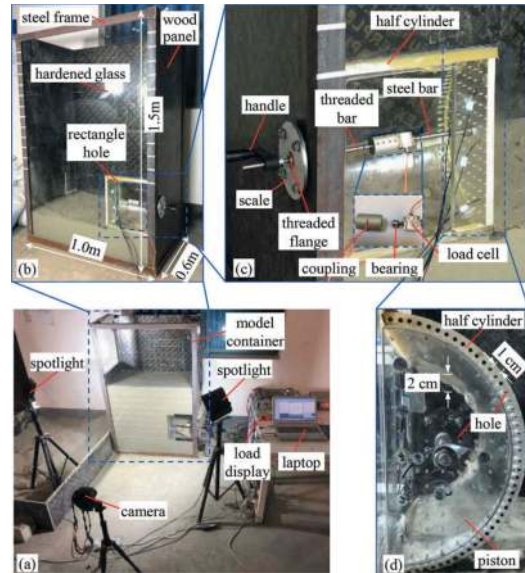

Figure 1. (a) Test instrument; (b) model container; (c) model tunnel and (d) piston and half-cylinder.

2.2 Test materials

Sand from the Minjiang River in Sichuan Province, China, was applied in this work. Figure 2 shows the grain size distribution. The sand is of medium density, namely the relative density being 0.58. A more detailed listing of the material properties is in Table 1.

Figure 2. Grain size distribution of sand.

As shown in Figure 3, fibreglass bars 1.0 mm in diameter and 1.0 D (310 mm) in length were used as the bolting material. Additionally, to increase the friction between the bolt and soil, a layer of 0.2 mm–0.5 mm quartz sand was glued around the bolt with epoxy resin. The outer diameter of the bolt was approximately 3 mm. The elastic modulus E_b and tensile yield strength T_b of the bolt are 25 GPa and 581 MPa, respectively. The ABS pipe with outer

Dilatancy angle	Φ (°)	8.8			

diameter of 6mm, wall thickness of 1.5mm and length of 1.0 D (310 mm) were used as the pipe material, and the elastic modulus E_p is 2 GPa.

Figure 3. Reinforcement materials.

2.3 Testing procedure

In Figure 4(a), layers of 7.5 cm thickness were installed with a drop height of 10 cm. According to the layout of bolts in Figure 4 and diameter, bolts were installed through the rectangular hole and the circular holes layer by layer, and pipes were installed layer by layer through the circular holes at the half-cylinder. During the tests, the piston was slowly pulled out by turning the handle to control the collapse of the tunnel face. For face displacement $s \leq 1$ mm, $1 \text{ mm} < s < 3$ mm and $3 \text{ mm} \leq s \leq 16$ mm, the displacement increments were 1/24 mm, 1/8 mm and 1/4 mm, respectively. Besides, it is important to prevent any sand from entering the model tunnel. Therefore, the piston and a sponge-layer of 2mm thickness were pasted together and plastic foil was wrapped around the half-cylinder and piston, see Figure 4(b).

3 THE RESULTS OF MODEL TESTS

3.1 Face failure process and pattern

To assess the face failure process and pattern, the incremental shear strains of soil were analysed in

this section. The shear strain concentration area can identify the shear bands.

In the unreinforced case, as shown in Figure 5(a), when $s=1$ mm the failure zone in front of the tunnel face was formed, initiated from the tunnel invert and the tunnel centre to the tunnel crown along the vertical direction. The sliding boundary of the failure zone consists of an arch line (upper failure zone) and a curved line (lower failure zone). At this moment the support pressure reached the limit support force (see Figure 5), which means that the peak strength of sand was mobilized, and the tunnel face was in the limit equilibrium state. With an increasing s , the upper failure zone gradually extended towards the ground surface. In this process, the support pressure gradually increased to the residual support pressure (see Figure 5), which was caused by an enlargement of the failure zone and the dilatancy of the sand. Finally, when $s=15$ mm, the upper failure zone reached the ground surface, and a chimney-like part (upper failure zone) and a wedge-like part (lower failure zone) could be distinguished. The failure angle θ is approximately 73° , and the extent of the failure zone in front of the face is approximately $0.29 D$.

In the bolt reinforced case, as shown in Figure 6, the development progress and shape of the failure zone were similar to those of the unreinforced case, except that the extent of the failure zone was smaller and the sliding boundary was steeper. Specifically, the configuration of the failure zone was also a chimney-wedge-type mechanism, which indicates that the theoretical Horn model (Horn, 1961) is also applicable to the stability analysis of a reinforced tunnel face. The extent of the failure zone was approximately $0.22 D$, the failure angle was approximately 78° . The results indicates that the stability of the tunnel face was increased by face bolting.

Figure 4. (a) Prepared ground, (b) pipes installation and (c) bolts installation.

Figure 5. Incremental shear strains of soil for an unreinforced tunnel face.

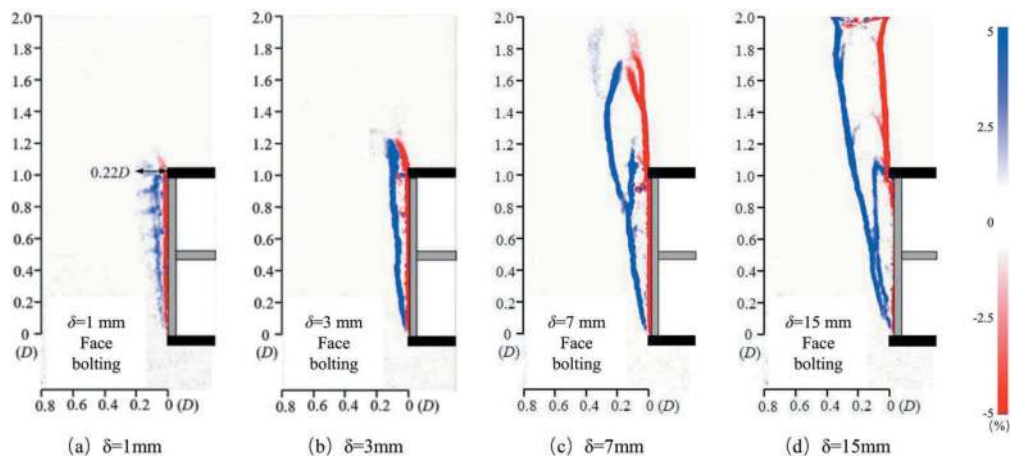

Figure 6. Incremental shear strains of soil for a bolt reinforced tunnel face.

In the bolt reinforced case, as shown in Figure 7, the development progress and shape of the failure zone were similar to those of the unreinforced case. Compared with the condition without reinforcement (see Figure 5), under the pipe roof reinforcement, only the failure surface appears in the soil in front of the tunnel face, while no obvious failure surface appears in the soil above the tunnel face, indicating that the pipe roof restricts the deformation of the soil above the tunnel face, reduces the soil pressure on the tunnel face, and improves the stability of the tunnel face. The instability range of surrounding rock in front of the palm face is $0.29 D$, indicating that the pipe roof reinforcement has little effect on the failure range of the tunnel face, but can effectively reduce the failure range above the palm face, thus reducing the soil pressure.

3.2 Reinforcing mechanism of pipe roofing and face bolting

According to the model test results (see Figure 6), the force mode of a bolt reinforced tunnel face is shown in Figure 8. The bolt supporting force F_b increases the anti-sliding force F_2 and improves the stability of the tunnel face. The anchoring system of face bolt is

composed of three parts, namely soil, grout and bolt. Therefore, there are five failure modes of face bolt in theory, namely: (1) Failure mode I, tensile failure of the bolt; (2) Failure mode II, shear failure of the bolt-grout interface in active area; (3) Failure mode III: shear failure of the soil-grout interface in active area; (4) Failure mode IV: shear failure of the bolt-grout interface in stable area; (5) Failure mode V: shear failure of the soil-grout interface in stable area. Therefore, the supporting force F_b of the face bolt should take the minimum bearing capacity corresponding to the five failure modes:

$$F_b = \min(F_I, F_{II}, F_{III}, F_{IV}, F_V) \quad (1)$$

where F_I is the ultimate bearing capacity of a face bolt under the I failure mode.

According to the model test results (see Figure 7), the force mode of a pipe roof reinforced tunnel face is shown in Figure 9. Due to the load transfer effect of the pipe roof, the soil pressure on the palm surface decreases from F_q to $\alpha_p F_q$ (α_p is the reduction coefficient of soil pressure, $0 < \alpha_p < 1$), resulting in the decrease of the sliding force F_1 . Therefore, the stability of the tunnel face is improved.

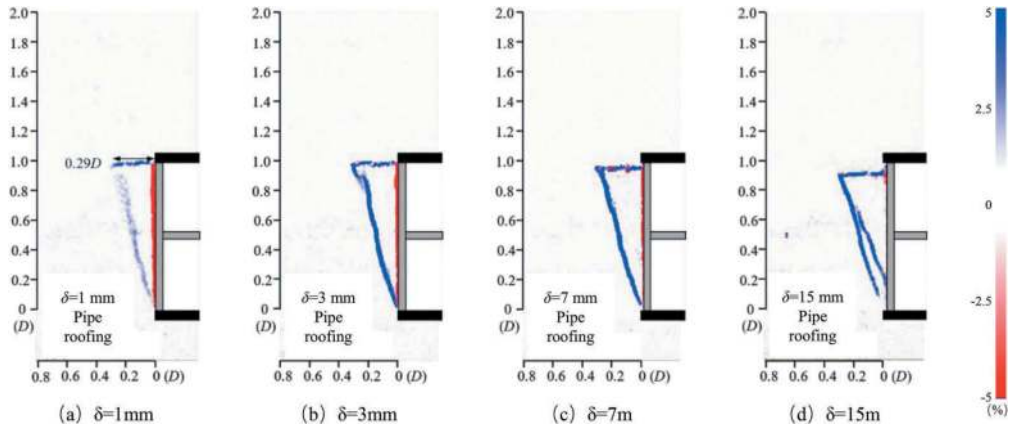

Figure 7. Incremental shear strains of soil for a pipe roof reinforced tunnel face.

Figure 8. Force mode of a bolt reinforced tunnel.

Figure 9. Force mode of a pipe roof reinforced tunnel.

4 THE ESTABLISHMENT OF THEORETICAL MODEL

4.1 Failure mechanism of a deep buried tunnel face

For a deep buried tunnel face, the failure zone above the face is arched, and the failure surface in front of the face is linear or logarithmic spiral. The angle between the bottom of the failure surface and the horizontal direction is about $\pi/4 + \varphi/2$ (φ is the friction angle of the ground). As shown in Figure 10, based on the classic prism-wedge model (Horn, 1961), a three-dimensional stability analysis model of the tunnel face is proposed, in which two kinds of advance support

Figure 10. 3D tunnel face stability analysis model.

measures (pipe roofing and face bolting) are considered. The tunnel face is subjected to the earth pressure, sliding force and anti-sliding force (front and side).

4.2 Stability analysis model for a tunnel face reinforced by advance support

4.2.1 Calculation method of stability coefficient K of tunnel face

It is assumed that the ground is perfect rigid plastic material that meets Mohr-Coulomb strength

Figure 11. Force analysis of tunnel face.

criterion. As shown in Figure 11, the height and width of the tunnel face is D and B , respectively; the length of unsupported span is L_e . According to the force analysis of the tunnel face, the equation for the stability coefficient of the tunnel face is derived based on the limit equilibrium method as follows:

$$K = \frac{P_1 + \beta_1 F_c}{\beta_2 (F_w + \alpha_1 F_q)} + \beta_3 \geq [K] \quad (2)$$

$$F_c = \frac{cBD}{\sin \theta_0} + 2D^2 \cot \theta_0 \left[c + \lambda \left(\frac{2}{3} q + \frac{D\gamma}{3} \right) \tan \varphi \right] \quad (3)$$

$$F_w = \frac{D^2 B \gamma \cot \theta_0}{2} \quad (4)$$

$$F_q = qB(D \cot \theta_0 + L_e) \quad (5)$$

$$\beta_1 = \frac{1}{\sin \theta_0 \tan \varphi + \cos \theta_0} \quad (6)$$

$$\beta_2 = \frac{\sin \theta_0}{\sin \theta_0 \tan \varphi + \cos \theta_0} \quad (7)$$

$$\beta_3 = \frac{\cos \theta_0 \tan \varphi}{\sin \theta_0} \quad (8)$$

$$\theta_0 = \frac{\pi}{4} + \frac{\varphi}{2} \quad (9)$$

where K is the face stability coefficient; $[K]$ is the design stability coefficient of tunnel face, with the value of 1.15; F_c is the shear force on the failure surface; F_w is the weight of tunnel face; F_q is the vertical force exerted by the underlying ground; c is the cohesion of the ground; q is the earth pressure; γ is the bulk density of the ground; θ_0 is the failure angle of tunnel face; λ is the lateral pressure coefficient; β_1 , β_2 and β_3 are the coefficients related to φ ; P_1 is the support force of face bolt; α_1 is the load transfer coefficient of pipe roof.

4.2.2 Calculation method of load transfer coefficient of pipe roof α_1

According to the relationship between the overlapping length L_{plap} of the pipe roof and the disturbance length $D \cot \theta_0$ in front tunnel face, it can be divided into the following two conditions:

(1) $L_{plap} > D \cot \theta_0$, as shown in Figure 12 (a), the load on the tunnel face is the reaction force of the pipe roof;

(2) $L_{plap} \leq D \cot \theta_0$, as shown in Figure 12 (b), the load on the tunnel face within the overlapping length is the reaction force of the pipe roof, and that outside the overlapping length is the earth pressure.

Figure 12. Force analysis of the tunnel face reinforced with pipe roof.

According to the ratio of the load on the tunnel face before and after pipe roofing, the formula of α_1 is obtained

$$\alpha_1 = \begin{cases} \frac{R_q}{S_p q (D \cot \theta_0 + L_e)} & L_{plap} \geq D \cot \theta_0 \\ \frac{R_q + S_p q (D \cot \theta_0 - L_{plap})}{S_p q (D \cot \theta_0 + L_e)} & L_{plap} < D \cot \theta_0 \end{cases} \quad (10)$$

where R_q is the total reaction force of the pipe roof within the disturbance length, which can be calculated by elastic foundation beam theory (Selvadurai, 2013); S_p is the spacing of pipe roof.

4.2.3 Calculation method of support force of face bolt P_1

As shown in Figure 13, there are five failure modes of the fiberglass bolt on tunnel face (Anagnostou and Perazzelli, 2015): (1) tensile failure of the bolt; (2) shear failure of the bolt-grout interface in active area; (3) shear failure of the soil-grout interface in active area; (4) shear failure of the bolt-grout interface in stable area; (5) shear failure of the soil-grout interface in stable area.

Figure 13. Force analysis of the tunnel face reinforced with bolt.

The calculation formula of the bolting force P_l is as follows:

$$P_l = \sum_{i=1}^{i=n_b} P_{li} \quad (11)$$

$$P_{li} = m_{bi} \times \min(P_{11i} P_{12i} P_{13i} P_{14i} P_{15i}) \quad (12)$$

$$P_{11i} = \frac{\pi d_b^2 f_b}{4} \quad (13)$$

$$P_{12i} = \pi d_b l_{li} f_t \left(2 + \frac{11.7 d_b}{l_{li}} \right) \quad (14)$$

$$P_{13i} = \pi d_h l_{li} \tau_m \quad (15)$$

$$P_{14i} = \pi d_b l_{li} f_t \left(2 + \frac{11.7 d_b}{l_{li}} \right) \quad (16)$$

$$P_{15i} = \pi d_h l_{li} \tau_m \quad (17)$$

where, P_{li} is the bolting force of the i th row bolt; n_b is the number of bolt rows; P_{11i} , P_{12i} , P_{13i} , P_{14i} and P_{15i} is the bolting force of the i th row bolt corresponding to the five failure modes above; m_{bi} is the number of bolts in i th row; f_b is the tensile strength of bolt; d_b is the bolt diameter; f_t is the design value of the tensile strength of grout material; l_{li} is the anchorage length of the i th row bolt in the active area; l_{li} is the anchorage length of the i th row bolt in the stable area; d_h is the diameter of the anchor hole; τ_m is the shear strength of the grout-soil interface.

5 VERIFICATION

Based on the upper bound solution proposed by Leca and Dormieux (Leca and Dormieux, 1990), a safety factor analysis model of a tunnel face reinforced with an umbrella arch was established by Wang and Jia (Wang and Jia, 2009). To verify the accuracy of the proposed model, the calculation results are compared with those calculated by Wang and Jia (Wang and Jia, 2009). The values of k_g and k_s are assumed to be 40 MPa/m and 110 MPa/m, respectively. As shown in Figure 14, the safety factor increases with increasing cohesion, and the results of the two methods are in good agreement. The average difference between the results calculated by the proposed method and the limit analysis method is approximately 3.50%, and the maximum difference equals 8.68% at $c=50$ kPa.

Figure 14. Comparison between the proposed model and the limit analysis method.

Pan and Dias (Pan and Dias, 2017) investigated the safety factor of a reinforced tunnel face by the numerical method and the limit analysis method. The safety factor is automatically calculated by the command for the strength reduction technique in FLAC^{3D}. To verify the accuracy of the proposed model, the calculation results are compared with those reported by Pan and Dias (Pan and Dias, 2017). As shown in Figure 15, the calculation results of the three methods have a similar trend in that the safety factor increases with the friction angle. Compared with the numerical method, the average differences in the results calculated by the proposed method and the limit analysis method equal 6.59% and 6.57%, and the maximum differences equal 10.79% and 14.45%, respectively.

Figure 15. Comparison between the proposed model, FLAC^{3D} results and limit analysis method.

6 CONCLUSIONS

- (1) The progressive failure mechanism and the failure mode of tunnel faces as well as the synergetic reinforcing mechanism of advanced supports are explored.

- (2) A safety factor analysis model and a concise design flow for a reinforced tunnel face are established for the preliminary design of tunnels.
- (3) The results calculated by the proposed model agree very well with those of the limit analysis methods and numerical software. For a tunnel face reinforced with an umbrella arch, the average difference between the safety factors of the proposed method and the limit analysis method is approximately 3.50%. For a tunnel face reinforced with face bolts, compared with the results from FLAC3D, the average difference of the proposed method equals 6.59%.

Key technologies and safety analysis of deep foundation pit construction in a sea area

Ziqiang Zhao* & Shanshan Gao

SGIDI Engineering Consulting (Group) Co., Ltd., Shanghai, China

ABSTRACT: The Shenzhen-Zhongshan Link used temporary cofferdams and artificial permanent land areas as the foundation platforms for deep foundation pit construction in a sea area, facing a series of complex engineering problems such as internal displacement of cofferdams, thick sand filling, thick sludge layers, and an ultra-close distance underpass of the Guangzhou-Shenzhen Coastal Expressway. Through key construction technologies such as foundation reinforcement treatment, casing drilling and grouting pile enclosure, earthwork layered excavation control, support servo automatic axial force compensation, and combined with information monitoring data results, the deformation patterns of the deep foundation pit support system at important construction nodes were analyzed. These verified that key construction technologies under complex sea conditions were crucial for ensuring the safety of deep foundation pit support systems and important buildings. Finally, the construction risks were successfully resolved.

Keywords: Sea area, Deep foundation pit, Deformation control, Monitoring and safety

1 INTRODUCTION

As an important cross-river channel connecting Shenzhen and Zhongshan, the Shenzhen-Zhongshan Link is about 30 kilometers from the Humen Bridge in the north and 38 kilometers from the Hong Kong-Zhuhai-Macao Bridge in the south. It integrates a tunnel, island, bridge and underwater workings, and is a national key project in the “China 13th Five-Year Plan” (Song Shenyou et al., 2020). Under complex marine environment conditions, the deep foundation pit engineering of the island tunnel is faced with a series of complex challenges. Firstly, a temporary cofferdam construction in the sea area is affected by long-term internal and external water pressure differences and ocean tidal power, which will continue to shift the cofferdam. The safety of the temporary cofferdam directly determines the safety of the deep foundation pit construction. Secondly, there are some poor formation conditions such as loose sand fill and creep of a thick silt layer, so it is very important to ensure the safety of the tunnel foundation pit, especially that running in close proximity to the bridge of the Guangzhou-Shenzhen Highway along the Pearl River. Thirdly, there is a deep silt layer along the expressway bridge. When the foundation reinforcement construction is carried out near the pier, the effective control of the

extrusion deformation of the pier during the grouting process is crucial to protect the safety of the existing bridge in operation.

Three previous projects, the Wuhan East Lake Tunnel Project, which is the longest lake tunnel in China (Xu Shunping et al., 2013), the important cross river channel Ruyifang Tunnel Project in Guangzhou (Xu Jiangping, 2019), and the Boao Tunnel in Hangzhou (Gong Wei, 2019) have successfully applied the cofferdam system to solve the problem of open excavation foundation pit construction in water bodies. These provided a reference for the implementation of deep foundation pit engineering in the cofferdam construction section of the Shenzhen-Zhongshan Link. In recent years, there are more and more deep foundation pit projects adjacent to sensitive structures in urban construction. The application of an active servo system has solved the problem of excessive deformation caused by deep foundation pit enclosure structures to some extent (Zhao Ziqiang, 2017; Sun Jiuchun et al., 2019; Zhang Lingxi et al., 2023), and also provided a reference for the implementation of active servo systems in this project. Once again, the disturbance test of adjacent bridge piers during the construction of high-pressure rotary jet grouting piles (He Dawei et al., 2023) and the application practice of bridge pier correction engineering (Pan Zhenhua, 2016) provide

*Corresponding author: zhaoziqiang@sgidi.com

valuable experiences for predicting the potential deformation risks of reinforcement construction in advance. On the basis of existing engineering practice experience, this article analyzes and summarizes the key technologies of soft soil deep foundation pit engineering in the sea area.

2 KEY TECHNOLOGIES FOR DEEP FOUNDATION PIT CONSTRUCTION IN COFFERDAM CONSTRUCTION SECTION

2.1 Temporary cofferdam and deep foundation pit

In order to construct the foundation pit excavation working face in the deep-sea area, a temporary cofferdam is set up around the foundation pit, and then a land basin is formed by draining the seawater inside the cofferdam as the construction site for the deep foundation pit. The temporary cofferdam in the construction section has a perimeter of approximately 1393.4m, with a maximum width of approximately 116m on the west side and approximately 206m on the east side. The double-row steel sheet pile cofferdam type is adopted, and steel tie rods are used to connect the inner and outer rows of steel sheet piles. The width of the cofferdam is 10m, the elevation of the cofferdam body is +3.00m, and the top elevation of the outer row of steel sheet piles is +6.00m. To avoid scouring at the bottom of the slope, a rubble layer is set up on the upstream side of the cofferdam. A counter-pressure soil slope is set up on the downstream side of the cofferdam, and the slope surface is protected by concrete bags. The average elevation of the sea surface outside the temporary cofferdam is about +0.52m, and the elevation of the ground level inside the cofferdam is about -3.5m~-5.0m.

The foundation pit of the main tunnel in the cofferdam section is approximately 490m long, 46.20m~74.43m wide, and the excavation depth is approximately 13.21m~17.96m. The cofferdam section adopts two forms of foundation pit enclosure structures: 1-meter-thick underground diaphragm walls and steel pipe piles. The support forms are arranged in 3-4 layers of reinforced concrete support and steel support according to different depths. The typical profile of the temporary cofferdam and deep foundation pit in the construction section is shown in Figure 1.

Figure 1. Typical profile of temporary cofferdam and deep foundation pit.

2.2 Safety analysis of temporary cofferdam and deep foundation pit

In the early stages of the project, in order to evaluate the safety of the temporary cofferdam and its embedded deep foundation pit in the cofferdam construction section, the general finite element analysis software ZSOIL was used to construct a typical profile model of the middle area of the cofferdam construction section. The excavation structure of the foundation pit and the deformation of the corresponding temporary cofferdam in the corresponding area were calculated under different excavation depth conditions. The numerical model after the completion of the foundation pit project is shown in Figure 2.

The numerical simulation analysis results in Figure 2 show that after the completion of the foundation pit project, the maximum horizontal displacement of the deep layer of the foundation pit enclosure structure is about 43mm, and the displacement of the top of the temporary cofferdam steel sheet pile towards the direction of the foundation pit is about 95mm. Both the temporary cofferdam and the foundation pit are in a safe and controllable state.

The results from the monitoring data for the points corresponding to those indicated in the numerical model in Figure 2, show a deep horizontal deformation curve for the foundation pit enclosure structure (Figure 3) and a similarly deep horizontal displacement deformation curve for the cofferdam structure (Figure 4).

The measured data curve in Figure 3 shows that after the completion of the tunnel foundation pit, the cumulative maximum horizontal displacement of the deep layer of the retaining structure is 56mm, and the maximum depth is located near the third foundation pit support. The measured data curve in Figure 4 shows that the cumulative maximum horizontal displacement of the deep layer of the temporary cofferdam is 93mm, with the maximum value located at the top of the cofferdam. The full measured data results during the process are reported in the article "Deformation Analysis of Marine Cofferdam and Embedded Deep Foundation Pit Engineering" (Liu Di et al., 2023). The numerical simulation results in Figure 2 above are seen to be consistent with the measured results in Figures 3 and 4, validating the correctness of the numerical simulation results in the early stage of the project, indicating that risk assessment through numerical simulation analysis is feasible in the early stage of the project. At present, the deep foundation pit project in the sea area has been successfully completed, and the deep foundation pit project and temporary cofferdam in the sea area have withstood the construction test, indicating that the plan of constructing temporary cofferdams for deep foundation pit construction in the sea area is safe and feasible.

Figure 4. Measurement result of deep horizontal displacement of the temporary cofferdam.

3 DEFORMATION CONTROL TECHNOLOGY FOR FOUNDATION REINFORCEMENT ADJACENT TO THE HIGH-SPEED BRIDGE ALONG THE PEARL RIVER

3.1 Foundation reinforcement treatment

An artificial island area of approximately 353,800 square meters was formed in the sea area through manual sand filling. During the process of land

reclamation, the deep sediment at the bottom of the sea area was consolidated using pre-load compaction combined with plastic drainage plates. The geological survey results showed that the strength of the sludge layer at the bottom of the island area made it difficult to meet the requirements for deformation control of the subsequent artificial island deep foundation pit excavation, which would have an impact on the safety of the foundation pit. Especially for the deep

foundation pit project on artificial islands that crosses the high-speed bridge along the Pearl River, deformation control is extremely strict. Taking the area where the F ramp tunnel foundation pit crosses the high-speed bridge along the Pearl River as an example, the thickness of the sludge layer in this area exceeds 14m. In order to enhance the soil strength in the passive area during the excavation process of the foundation pit, it is important to reduce the deformation of the foundation pit retaining structure towards the inside of the foundation pit, and control the displacement of the bridge piers caused by the deformation of the adjacent foundation pit retaining structure. This is done using high-pressure rotary jet grouting piles to reinforce the sludge layer in the foundation pit before excavation, and the reinforcement is carried out to the top surface of the fully weathered rock layer.

3.2 Deformation control technology for reinforcement of foundation

During the construction process of reinforcing the deep sludge layer of the foundation near the bridge pier area, the bridge piers are affected by grouting pressure compression, which can cause displacement towards the direction of compression. When the bridge pier continues to move too much in the same direction, it may lead to cracking and other defects of the bridge pier structure. In order to solve the problem of excessive deviation caused by foundation reinforcement construction on one side of the bridge pier, symmetrical tracking grouting is synchronously carried out on the opposite side of the bridge pier, which corrects the deviation of the bridge pier through the squeezing force generated by the opposite side foundation reinforcement. The result is that the total displacement of the bridge pier is within a controllable range. This process needs to be guided by precise pier deformation monitoring data for correction. The construction control site is shown in Figure 5, with reinforcement grouting equipment installed on the north and south sides of the bridge pier for symmetrical grouting.

Figure 5. Symmetrical reinforcement grouting construction on both sides of bridge piers.

Taking the reinforcement construction of the 50 # bridge pier foundation near the south side of the F ramp foundation pit as an example, the cumulative horizontal displacement curve of the two monitoring points of the 50 # bridge pier during the foundation reinforcement construction process is shown in Figure 6.

Figure 6. Duration curve of cumulative horizontal displacement of pier 50 #.

From the displacement duration curve of the bridge pier in Figure 6, it can be seen that during the initial stage of foundation reinforcement, the unilateral forward grouting construction caused significant compression deformation on the adjacent bridge pier, and the bridge pier produced a relatively significant displacement towards the south. At this time, the cumulative horizontal displacement change of the bridge pier exceeded 3mm, which is close to the warning value of the bridge pier deformation control. In order to prevent the continuous deformation of the bridge pier towards the south caused by the continued reinforcement construction, construction was suspended on site. After analyzing the reasons for the deformation of the bridge pier, construction measures were taken to add grouting equipment on the opposite side for symmetrical correction grouting. The displacement of the bridge pier was restored. Finally, the safety of the adjacent piers during the reinforcement treatment of the foundation pit was ensured.

4 DEFORMATION CONTROL TECHNOLOGY FOR DEEP FOUNDATION PIT EXCAVATION IN SENSITIVE DEFORMATION AREAS

4.1 Support active servo system

The Shenzhen-Zhongshan Link design includes 4 ramp tunnels and 1 main line tunnel on the east artificial island formed by sea reclamation, achieving connectivity with other highways. The tunnels on the island are all open excavation foundation pit projects. The deep foundation pits such as the main tunnel, F-ramp tunnel, and H-ramp tunnel are all adjacent to

the existing Guangzhou-Shenzhen Coastal Expressway. The foundation pit enclosure structure in the three underpass areas are about 0.6m~3.4m away from the bridge pier cap. During the excavation process of the foundation pit, the deformation control of the bridge pier is extremely strict. During the excavation process of the deep foundation pit, the steel support active servo system is used to compensate for the loss of support axial force, in order to reduce the deformation caused by the foundation pit enclosure structure, to ensure the safety of adjacent bridge piers. The active servo system consists of a control system (as shown in Figure 7) and a servo thruster (as shown in Figure 8). The servo thruster is mainly installed on top of the steel support and can automatically retract according to the oil pressure to compensate for the axial force of the steel support. The control system can automatically control the expansion and contraction of the servo thruster based on the changes in the support axis force, to compensate for the steel support axis force within a stable range. The active servo system mainly transmits the compensating axial force of the support system to the enclosure structure through the steel fence, and forms a large stress distribution in the contact area with the enclosure structure, which requires high strength of the enclosure structure. The retaining structure of the deep foundation pit near the underpass area adopts a locking steel pipe pile with a diameter of 1.40m,

Figure 7. Active servo control system.

Figure 8. Steel support active servo system.

and a bored pile is embedded inside the steel pipe pile to enhance the stiffness of the retaining structure, in order to meet the requirements of stress intensity applied by the support active servo system.

4.2 Analysis of deformation control in deep foundation pit excavation

Taking the deep foundation pit of the east artificial island main tunnel crossing the high-speed bridge along the Pearl River as an example, this paper elaborates on the control effect of the active servo system in the deformation of the foundation pit enclosure structure. The horizontal distance between the outer side of the deep foundation pit enclosure structure in this area and the bridge pier cap is about 0.93m~1.83m, and the excavation depth is about 14.30m~15.51m. The enclosure structure adopts a lock buckle steel pipe pile with a diameter of 1.4m, and the steel pipe pile is embedded with drilled cast-in-place piles. The foundation pit is designed with four layers of support, with the first layer being concrete support and the second to fourth layers being steel support. The steel support is equipped with an active servo system. The typical profile of the deep foundation pit is shown in Figure 9.

Figure 9. Profile of deep foundation pit crossing the high-speed bridge along Pearl River.

To understand the deformation of the retaining structure towards the inside of the deep foundation pit during excavation, one deep horizontal displacement monitoring hole is set up on both sides of the pit. At the same time, monitoring points for pier displacement are also set up on the pier columns on both sides of the bridge to understand the deformation of the pier during the entire excavation process of the foundation pit. Selecting the deep horizontal displacement monitoring hole data of the retaining structure on the north side of the foundation pit, the deep horizontal displacement change curves for key time nodes such as the installation of each support and the completion of the bottom plate and main structure of the tunnel, are shown in Figure 10.

Figure 10. Key time nodes displacement curve of deep horizontal displacement of the north side envelope structure.

From the curve in Figure 10, it can be seen that during the excavation stage of the foundation pit, the deep horizontal displacement of the retaining structure continues to increase towards the direction of the foundation pit. As the excavation depth increases, the trend of displacement towards the pit becomes more obvious, and the cumulative maximum position depth also moves downward with the excavation surface. After the installation of the steel support active servo system is completed and the support axial force compensation is carried out, the deep horizontal displacement deformation trend above the support position is significantly suppressed. Through the active servo system, the deep horizontal displacement of the deep foundation pit enclosure structure is basically controlled within 2cm, which is about 40% less than the maximum deep horizontal displacement of the adjacent foundation pit enclosure structure without this technology.

The time-dependent deformation curve of the cumulative variation of the above deep horizontal displacement monitoring points at the depth of the first layer support to the fourth layer support position is shown in Figure 11.

From Figure 11, it can be seen that, firstly, during the excavation stage of the foundation pit, the deep horizontal displacement of the retaining structure shows a significant increasing trend. When the lower steel support servo system plays a role, the deep

Figure 11. Deep horizontal displacement duration curve of the retaining structure at the depth of each support position.

horizontal displacement increment of the retaining structure at the upper support position significantly decreases. The deformation increment of the retaining structure mainly occurs in the lower earthwork excavation area. Therefore, the deep foundation pit should be excavated in layers and the supporting system should be erected in time to effectively reduce the deformation of the enclosure structure. Secondly, the active servo system undergoes stress release before dismantling, during which the deep horizontal displacement of the retaining structure slightly increases. When the first reinforced concrete support is dismantled, the stress release is more concentrated, and there is a small sudden change in the upper part of the retaining structure, which then tends to stabilize.

Selecting the displacement monitoring points GSD53-2 and GSD54-2 on the south and north sides of the bridge piers respectively, and Figure 12 shows the cumulative value change duration curve of their foundation pit construction phase.

Figure 12. Pier displacement duration curve.

From Figure 12, it can be seen that during the excavation phase of the foundation pit, the bridge pier continues to move towards the foundation pit direction due to deformation of the foundation pit's retaining structure. However, after the completion of the excavation, the displacement of the bridge pier shows a significant reduction in its increasing trend. When the first layer of reinforced concrete supports are removed, the bridge pier displacement slightly increases with the sudden change of the retaining

structure, and then tends to stabilize. Finally, the cumulative horizontal deformation near the bridge pier is basically controlled at 2mm. Compared to the historical trend curves in Figures 11 and 12, it can be observed that the deformation trend of the bridge pier displacement is basically consistent with the deformation trend of the adjacent retaining structure. This indicates that the use of a steel support servo system can effectively control the deformation of adjacent bridge piers and ensure their safety.

5 CONCLUSIONS

Based on the engineering practice of solving construction problems, this article deeply analyzes the effectiveness and safety of the key technology application in response to the main issues facing the deep excavation project for the Shenzhen-Zhongshan Link, and draws the following conclusions:

- (1) The scheme of constructing a deep excavation construction work platform through temporary cofferdams in the sea area is safe and feasible.
- (2) When reinforcing the foundation in a thick sludge layer next to a bridge pier, a symmetric tracking grouting method was used on both sides of the bridge pier, combined with monitoring results of bridge pier displacement to dynamically correct the deviation, which effectively solved the problem of single-side extrusion deformation of the bridge pier.
- (3) The active servo system can achieve dynamic compensation of steel support axial force, effectively solving the problem of excessive deformation of the deep foundation excavation retaining structure under ultra-close distance and ensuring the safety of adjacent bridge piers

Data-driven stability analysis and uncertainty quantification of surrounding rock mass for tunnel

Hongbo Zhao* & Lin Zhang*

School of Civil Engineering and Geomatics, Shandong University of Technology, Zibo, China

ABSTRACT: Stability analysis is essential to the design, construction, and long-term safety operation of tunnel engineering. Numerical models have been widely applied to tunnel engineering. Meanwhile, uncertainty is a severe threat to tunnel stability analysis. However, numerical models are too time-consuming for large-scale projects, and conventional stability analysis cannot deal with uncertainty in practical tunnel engineering. This study developed a data-driven uncertainty quantification model to improve the efficiency of stability analysis and deal with uncertainty. A reduced-order model was utilized to construct the data-driven model and capture the mechanical and deformation properties of the surrounding rock mass in the tunnel. Probabilistic programming was adopted to evaluate and quantify the uncertainty of the surrounding rock mass during tunnel construction. A circular tunnel was used to verify and illustrate the developed method using an analytical and numerical solution. The results show that the uncertainty of surrounding rock mass could be quantified scientifically and that the developed method captures the mechanical mechanism under uncertainty. Then, the developed method was applied to practical tunnel engineering to demonstrate its performance. The results further proved that the developed method provides a scientific, helpful, and promising tool to characterize the properties and physical mechanism of the surrounding rock mass under uncertainty in the tunnel.

Keywords: Tunnel, Stability analysis, Data-driven model, Uncertainty quantification, Probabilistic programming

1 INTRODUCTION

Stability analysis of the surrounding rock mass is critical to the tunnel's design, construction, and operation. Meanwhile, uncertainty is an inherent property of the tunnel surrounding rock mass and directly impacts the stability analysis, safe construction, and the long-term safety of the tunnel. To scientifically evaluate the stability of the surrounding rock mass, various methods, such as analytical models, numerical models, machine learning, etc., have been developed in the past decades. The probabilistic method has also been developed to deal with the uncertainty. However, applying it to practical tunnel engineering is inaccessible due to repeated stability calculations during the traditional probabilistic analysis.

The analytical model has a rigid theory for stability analysis and can scientifically characterize the deformation and failure mechanism of surrounding rock mass. However, due to its many assumptions and conditions, the analytical model can only be applied to tunnels with simple

geometric shapes and homogeneous rock formations. It is not easy to do practical tunnel engineering due to the complex geometric and geological conditions. Numerical models, such as the finite difference method and finite element method, provide very accurate predictions of the mechanical behavior of geomaterials and the stability of geotechnical engineering structures (Jing & Hudson, 2002). However, a numerical model is too time-consuming in the practical tunnel. It hinders its application in practical tunnels, especially the analysis that requires a lot of calculation, such as back analysis and reliability analysis. The surrogated model provides an efficient model to approximate the response, such as deformation, strain, stress, etc., of tunnel surrounding rock mass (Fazio et al., 2017; Bozzano et al., 2012; Lv et al., 2017; Sun et al., 2018; Yu et al., 2007; Zhang & Yin, 2014; Zhao & Yin, 2009; Zhao & Yin, 2016). Various surrogated models have been developed to approximate the response of surrounding rock mass, such as deformation, safety factors, and support stress of

*Corresponding author: bxhbzhao@hotmail.com; hbzhao@sdut.edu.cn

supporting structures in tunnels. With the machine learning and artificial intelligence technology, various machine learning methods such as Artificial neural networks (ANN), support vector machine (SVM), relevant vector machine (RVM), etc., have been used to capture the complex, nonlinear relationship between the response of surrounding rock mass and their influence factors. However, these models did not characterize the physical mechanism of the tunnel deformation and failure.

Recent developments in data science provide an excellent way to reveal the mechanism behind data and deal with uncertainty (Lecun et al., 2015). Data sciences have been successfully applied in various fields (Veer & Bernards, 2008; Severson et al., 2019; Alipanahi et al., 2015; Huys et al., 2016; Markus et al., 2019). Recently, a reduced order model (ROM) was developed with some knowledge about the engineering structure under consideration. Uncertainty quantification has also been used in the engineering field. This study developed a ROM-based data-driven model and uncertainty quantification to capture the response of surrounding rock mass in a tunnel and deal with the uncertainty.

This study developed a data-driven stability analysis and uncertainty quantification model for tunnel engineering by combining numerical model, ROM, and uncertainty quantification. The remainder of this paper is organized as follows. Firstly, the ROM-based data-driven model is introduced in detail. Then, the basic idea, theory, and procedure of the developed model were presented briefly. In Section 4, the data-driven model was verified and illustrated by a circular tunnel and applied to a practical tunnel. Finally, results and conclusions are presented and discussed based on the study results.

2 DATA-DRIVEN MODEL AND UNCERTAINTY QUANTIFICATION

2.1 ROM

Recently, the ROM was developed to approximate the relationship between design variables and field variables in the engineering system. Generally, the ROM represented the field variables as follows (Audouze et al., 2009):

$$\tilde{u}^h(x, \theta) = \sum_{k=1}^K \beta_k(\theta) \varphi^k(x) + \tilde{g}(x, \theta) \quad (1)$$

$$\tilde{g}(x, \theta) = \begin{cases} g(x, \theta) & \text{on } \partial\Omega \\ 0 & \text{elsewhere} \end{cases} \quad (2)$$

where $\tilde{g}(x, \theta)$ is an extension of the boundary conditions in the whole domain. $\varphi^k(x)$ can be represented in the following equation.

$$\varphi^k(x) = \sum_{j=1}^K r_j^k w_j(x) \quad (3)$$

According to the ROM algorithm, a set of discrete solutions (snapshots) of a physical problem was obtained based on the experimental design and numerical model. Then, spatial Gram matrix M^x was generated in the following form.

$$M_{ij}^x = (w_i \cdot w_j), \quad i, j = 1, 2, \dots, J \quad (4)$$

Where $w_j = u^h(\theta_j) - \tilde{g}(\theta_j), j = 1, 2, \dots, J$ ($w_i \cdot w_j$) is the scalar product between w_i and w_j . The positive eigenvalues of M^x are arranged in descending order.

$$\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_J \geq 0 \quad (5)$$

The first K eigenfunctions $\varphi^k(x), k = 1, 2, \dots, K$ associated with the first K eigenvalues provide the orthogonal principal direction of snapshots. K can be determined by the following equation.

$$\frac{\sum_{i=1}^K \lambda_i}{\sum_{i=1}^J \lambda_i} > k \quad (6)$$

where k is the user-specified tolerance. In this study, k was taken to be 0.99999.

For any $x_i, i = 1, 2, \dots, I$, and $\theta_j, j = 1, 2, \dots, J$, Equation 1 can be transferred to the following form.

$$\tilde{u}^h(x_i, \theta_j) = \sum_{k=1}^K \beta_k(\theta_j) \varphi^k(x_i) + \tilde{g}(x_i, \theta_j) \quad (7)$$

The unknown coefficient β can be obtained by solving the penalized minimization problem.

$$\min_{\beta_j \in R^K} \left\| u^{h,j} - \varphi \beta_j - \tilde{g}_j \right\|^2 + \mu \left\| \beta_j \right\|^2 \quad (8)$$

for which β_j can be obtained by solving the following normal equation:

$$(\varphi^T \varphi + \mu I_K) \beta_j = \varphi^T (u^{h,j} - \tilde{g}_j), j = 1, 2, \dots, J \quad (9)$$

where μ is a small regularization parameter.

To unknown design variables θ and space variables x , the field variables can be obtained from the ROM model.

$$\tilde{u}^h(x, \theta) = \sum_{k=1}^K \beta_k(\theta) \varphi^k(x) + \tilde{g}(x, \theta) \quad (10)$$

where the coefficient $\beta_k(\theta)$ is expanded using the RBF as Equation (9):

$$\beta_k(\theta) = \sum_{j=1}^J \alpha_{jk} \psi \left(\frac{|\theta - \theta_j|}{\sigma} \right) \quad (11)$$

For any $\theta_{j'}, j' = 1, 2, \dots, J$, Equation (10) can be obtained based on Equation (9).

$$\sum_{j=1}^J \alpha_{jk} \psi\left(\frac{|\theta_j - \theta_j|}{\sigma}\right) = \beta_{kj'} \quad (12)$$

where $\beta_{kj'}$ has been obtained using Equation (7). The above equations can be written in the compact form of Equation (11).

$$A\alpha_k = \beta_k \quad (13)$$

in which the unknown coefficient α_k can be solved using following equation.

$$(A^T A + \mu I_J)\alpha_k = A^T \beta_k, \quad k = 1, 2, \dots, K \quad (14)$$

2.2 Uncertainty quantification

Uncertainty quantification is a significant research field for engineering systems and was applied to computational fluid dynamics in 1986 (Guide, 1998). Monte Carlo simulation is commonly used with a precise algorithm for Uncertainty quantification (Hiriyur et al., 2011), but this approach requires significant computation times. Other Uncertainty quantification algorithms, among others, are polynomial chaos expansion, Karhunen-Loève expansion, and Bayesian methods. A new generation of Markov chain Monte Carlo (MCMC) sampling techniques, such as Hamilton Monte Carlo (Duane et al., 1987) and no-U-turn sampler, can be well adapted to high and complex posterior distributions, and many complex models can be applied without understanding fitting methods. PyMC3 is an open-source uncertainty quantification Python package (Salvatier et al., 2016). In this study, PyMC3 was adopted to deal with the uncertainty during the stability analysis of the tunnel.

3 DATA-DRIVEN STABILITY ANALYSIS AND UNCERTAINTY QUANTIFICATION FOR TUNNEL

This study developed a data-driven model to evaluate the stability of the tunnel by combining the numerical model and ROM. Then, PyMC3 was utilized to quantify the uncertainty during the stability analysis based on MCMC. The data-driven model was utilized to build the surrogated mode for stability analysis to improve the efficiency of uncertainty quantification.

3.1 Data-driven surrogated model for tunnel stability analysis

The physical model presents the nonlinear function mapping of the tunnel response and its influence factor. In this study, ROM-based data-driven was adopted to approximate the nonlinear. The data-driven model $DD(X)$ can be defined in the following form.

$$DD(X) : R^N \rightarrow R^Q \quad (15)$$

$$Y = DD(X) \quad (16)$$

where $X = (x_1, x_2, \dots, x_N)$, $x_i (i = 1, 2, \dots, N)$ denotes the design variables, which is the influence factors of tunnel response and $Y = (y_1, y_2, \dots, y_N)$ is a Q dimension vector of response field of tunnel.

In order to construct $DD(X)$, some snapshots need to be collected according to the ROM algorithm. This study used a numerical model and a Latin hypercube sampling method to generate snapshots.

3.2 Uncertainty quantification

To evaluate the uncertainty of stability analysis, PyMC3 was adopted to evaluate the response of the surrounding rock mass and their uncertainty based on the data-driven model. The predicting response u is presented in normally distributed observations, whose expected value is σu and is a nonlinear function of the uncertainty of the surrounding rock mass, which is approximated by the data-driven as follows.

$$u \sim \tilde{N}(\mu_u, \sigma_u^2) \quad (17)$$

$$\mu_u = DD(X) \quad (18)$$

Uniform distribution $[X_l, X_u]$ was applied to the surrounding rock mass properties (X). X_l and X_u are the lower and upper bounds of X , respectively. According to the nature of tunnel engineering, other distributions, such as normal distribution, can also be selected based on the known information and knowledge.

$$XU(X_l, X_u) \quad (19)$$

PyMC3 is used to refine the above model, and the uncertainty of surrounding rock response based on a data-driven model is obtained.

3.3 Procedure of the developed model

This study utilized ROM, a data-driven model, to approximate the response of the tunnel surrounding rock mass and quantify the uncertainty by combining it with ROM, PyMC3, and a numerical model. PyMC3 is used to deal with the uncertainty based on MCMC. Data-driven improves efficiency with high accuracy. The procedure of the developed model is explained below (Figure 1).

Step 1: Collect the tunnel information and data such as the geological conditions, engineering scale, known parameters, numerical model and its boundary conditions, etc.

Step 2: Generate the sample points (snapshots) using LHS to compute the surrounding rock mass response at each sample point. Snapshots consist of the sample points and their response.

Step 3: Based on the snapshots, build the data-driven model to approximate the nonlinear function mapping of the response of the surrounding rock mass and its influence factors.

Step 4: Conduct the uncertainty quantification using PyMC3 based on MCMC.

Step 5: Obtain and quantify the uncertainty of the surrounding rock mass property and the corresponding response.

Figure 1. The flowchart of the developed method.

4 APPLICATION

4.1 Numerical example (Zhao and Chen, 2021)

This study utilized a circular tunnel with a radius of 1 meter to verify and illustrate the ROM-based data-driven model. The linearly elastic and perfect plastic was applied to the surrounding rock mass in the tunnel. The numerical model of the tunnel was calculated based on the Mohr-Coulomb criterion and associated flow rules in the plane strain conditions. The elastic model, Poisson's ratio, cohesion, and angle of rock mechanical parameters were 6.8 GPa, 0.2, 3.45 MPa, and 30°, respectively. The in-situ stress of the tunnel surrounding the rock mass is 30 MPa. According to the abovementioned procedure, a numerical model was used to build snapshots for ROM. Only a quarter of the tunnel was analyzed due to the symmetry (Figure 2). The numerical modeling included 900 elements and 1,822 nodes.

Figure 2. Numerical model for circular tunnel.

This study's design variables included the elastic modulus, Poisson's ratio, cohesion, friction angle, and geo-stress. Deformation and stress of the surrounding rock mass were the field variables. LHS was utilized to generate 50 sets of design variables. The FLAC3D model was used to calculate the corresponding field variables of each design variable. The snapshots consisted of the design variables and the field variables. The deformation and stress field could be obtained using the ROM-based data-driven model. The relative errors of horizontal deformation and stress are shown in Figure 3 and Figure 4, respectively. The maximum relative error of horizontal deformation was about

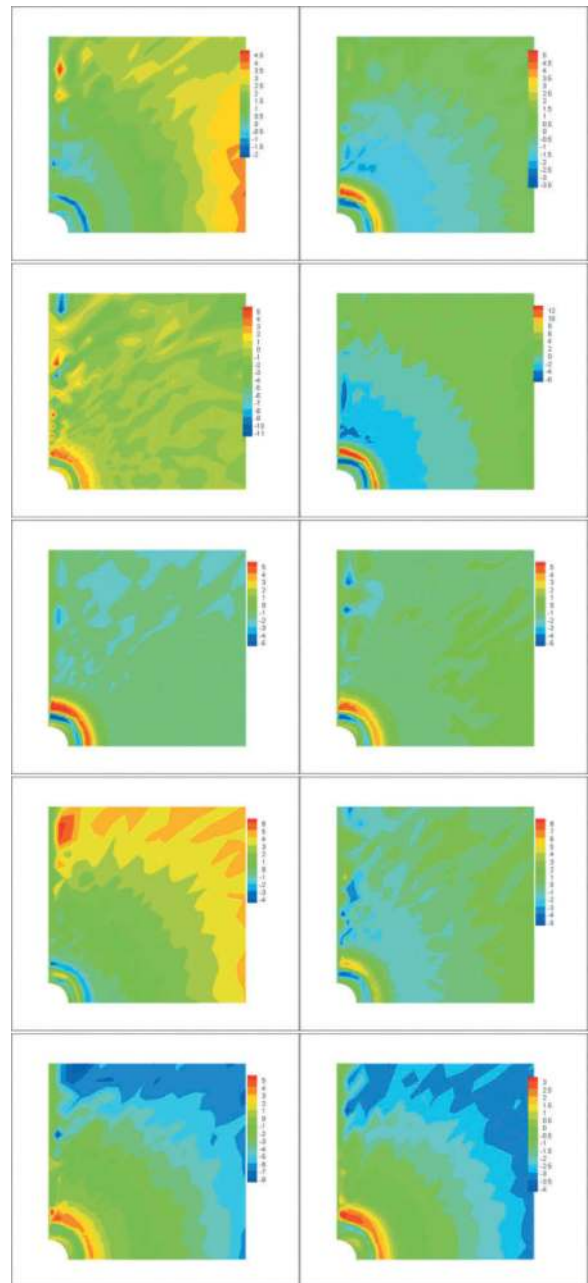

Figure 3. The relative error of horizontal deformation for snapshots.

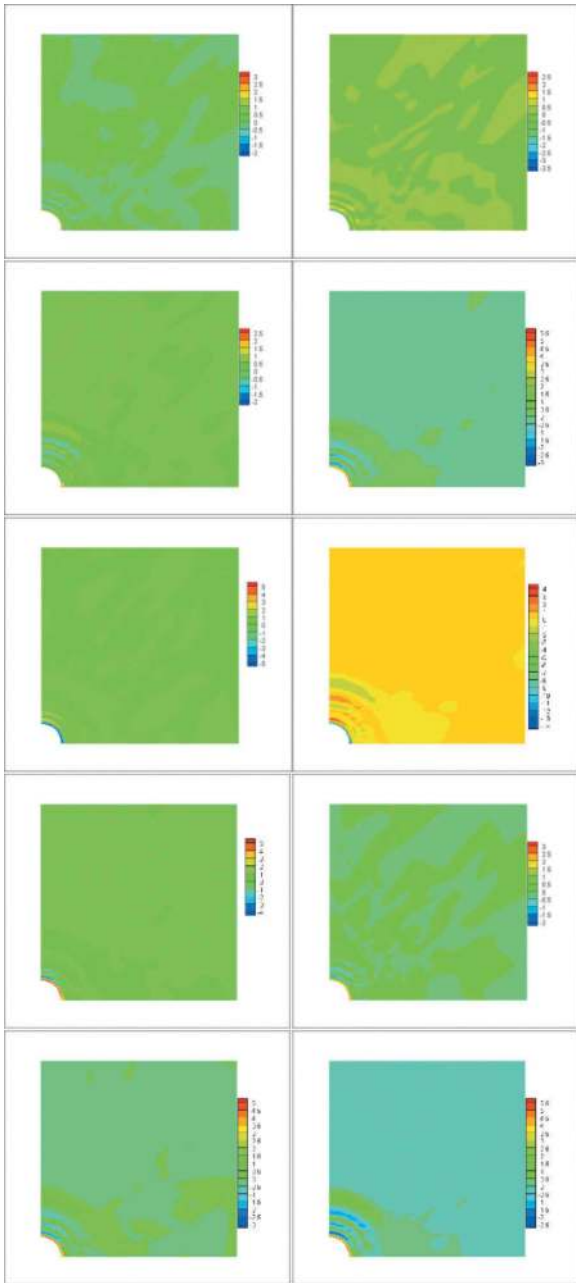

Figure 4. The relative error of horizontal stress for snapshots.

12%, and the relative error was less than 10% for most snapshots. The maximum relative error of horizontal stress was about 7%, and the relative error was less than 5% for most snapshots. These results showed that the ROM for most snapshots produced solutions that were in excellent agreement with those from numerical modeling. The results showed that the data-driven model can be selected as a surrogated model for approximating the deformation and stress field in the tunnel.

To further verify and illustrate the performance of the data-driven model, one case, which is different from the snapshots, was analyzed. The results were compared to the numerical and analytical models. Figure 5 shows the relationship between the

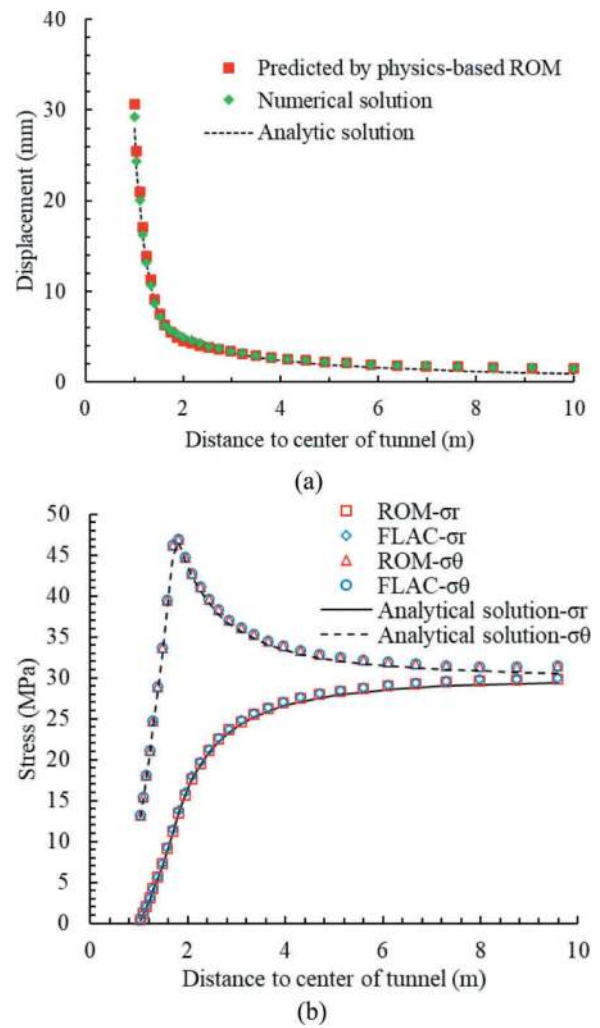

Figure 5. Comparisons of predicted deformation and stress of surrounding rock mass by data-driven model and other techniques. (a) Deformation (b) Stress.

Figure 6. Comparison of the deformation field of a circular tunnel predicted using data-driven model and a numerical model.

deformation and stress in the different positions of the surrounding rock mass. It proved that the results agreed with the analytical and numerical solutions.

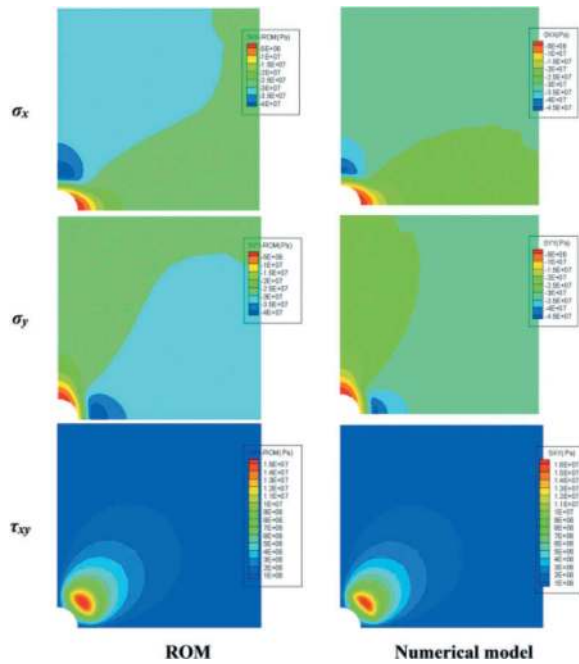

Figure 7. Comparison of the stress field of a circular tunnel predicted using the data-driven model and a numerical model.

Furthermore, the data-driven model captured the deformation and failure mechanism of the tunnel well.

The deformation and stress of the surrounding rock mass predicted by the data-driven models were compared with predictions from the numerical model in Figures 6 and 7. The deformation and stress field predicted by the data-driven were in excellent agreement with the predictions of the numerical model. It further showed that the data-driven model characterized the deformation and failure mechanism induced by tunnel excavation well.

4.2 Goupitan tunnel (Zhao et al., 2021)

The Goupitan Hydropower Station, located in Wuijiang, Guizhou Province, China, is a landmark electricity transmission project from west to east of the province. The preliminary design report of the project stated that the tailwater tunnel of the underground powerhouse on the right-hand bank and the construction diversion tunnel pass through a soft claystone rock mass. An experimental tunnel was excavated to investigate the rheological behavior of the claystone. The width, height, and buried depth of the tunnel were 2 m, 2 m, and 70 m, respectively. Some monitoring sites were set to observe the deformation of the surrounding rock during excavation. The tunnel is excavated through a rock layer S_{2h}^{1-2} ; the S_{2h}^{1-1} stratum lies about 3 m below the tunnel, and layer S_{1q}^1 lies 30 m above it (Figure 8a). A monitoring borehole $4^\#-6^\#$ was drilled at the 11.6 m position in the tunnel to the depth of 7 m, of which section $4^\#$ was horizontal, section $5^\#$ is inclined

Figure 8. Goupitan tunnel (a)Geology profile, position of experimental tunnel; (b)The position of monitored borehole and point.

at 45° , and section $6^\#$ is vertical. Five monitoring points numbered 1 to 5 were located in the borehole at 0, 1, 2, 4, and 6 m, respectively ((Figure 8b)).

In this study, the efficiency was improved by using a surrogate model constructed by the data-driven model to replace the numerical model. In the present study, a uniform design was used to generate a set of 42 samples. Fast Lagrangian Analysis of Continua (FLAC) software was adopted to calculate the deformations of the surrounding rock mass. The width and maximum height of the model are both 100 m in the X- and Y-directions to minimize boundary effects. The boundary conditions were defined such that the Y-direction base and the left- and right-hand X-direction were fixed, and the top of the model was free. The average density of rock mass γ is $0.0265 \text{ MN}\cdot\text{m}^{-3}$. This model assumed the upper S_{1q}^1 rock mass to be elastic, with an elastic modulus of 28 GPa and Poisson's ratio of 0.25. Rock masses S_{2h}^{1-1} and S_{2h}^{1-2} were assumed to be Burgers material,

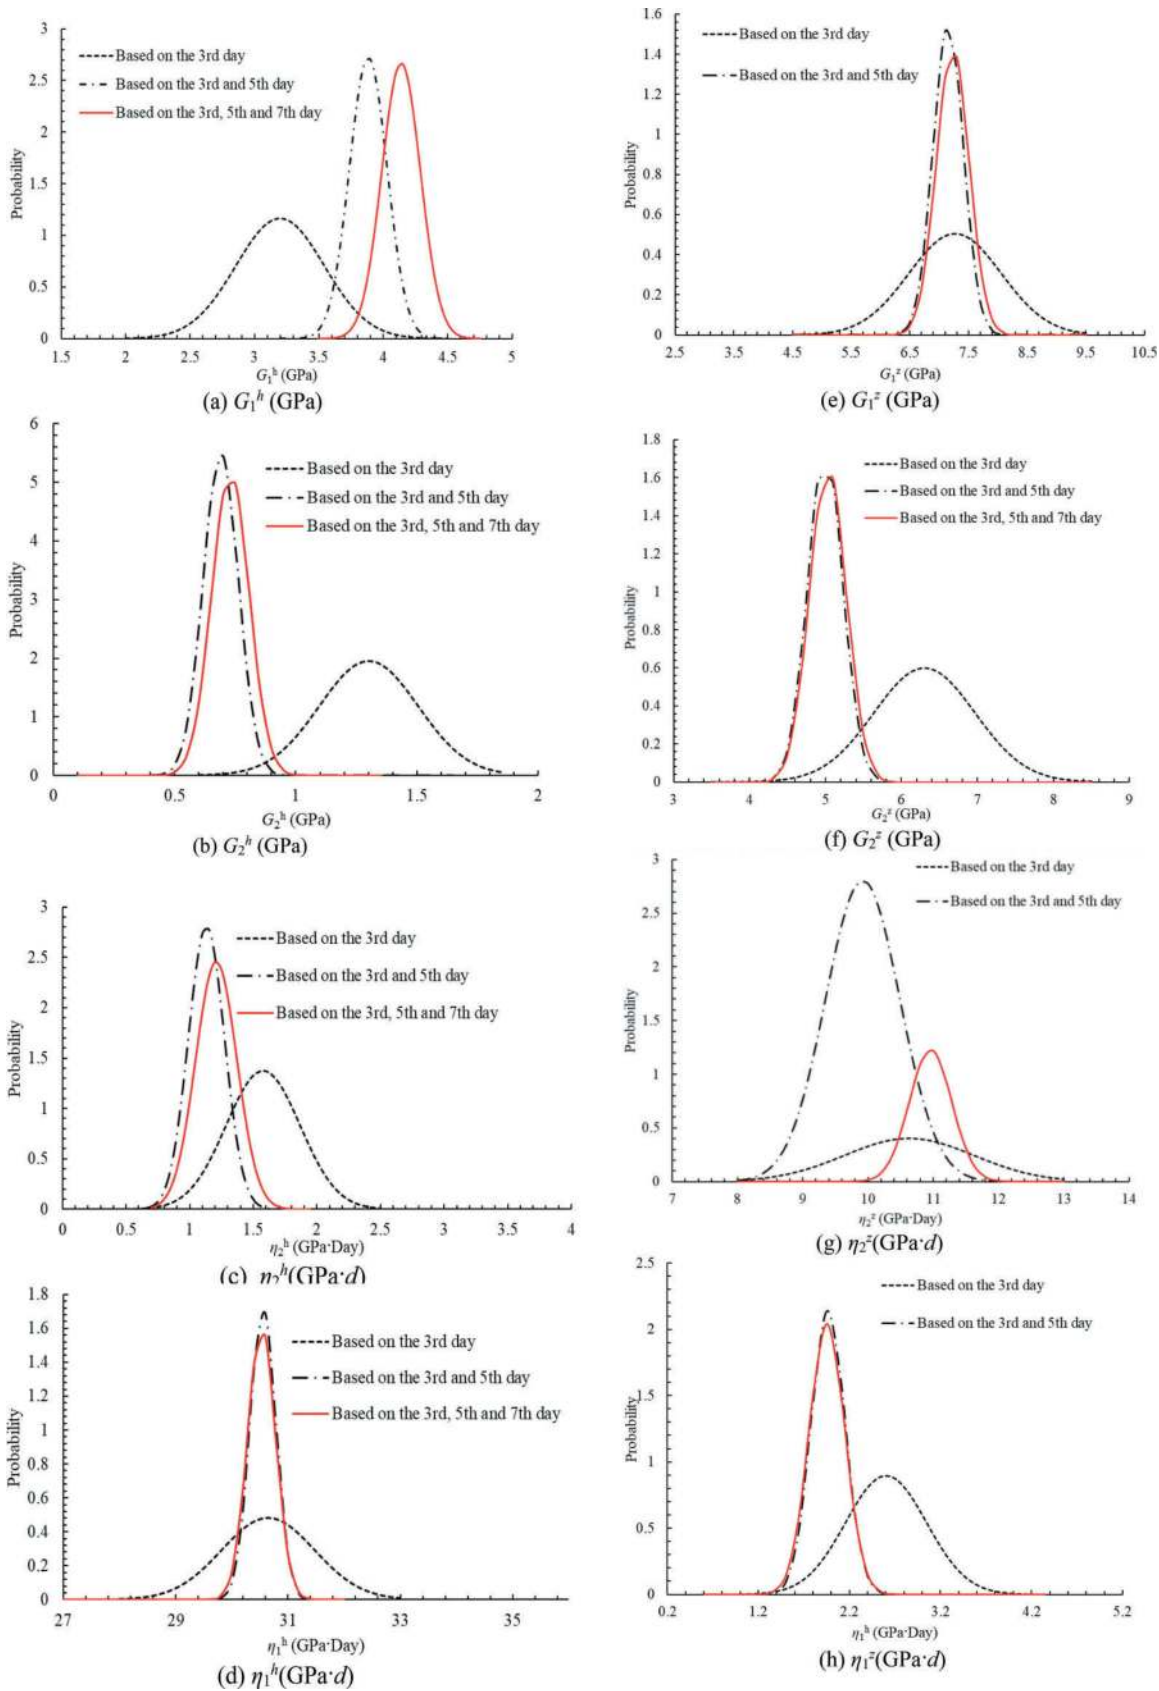

Figure 9. Obtained parameters and their uncertainty.

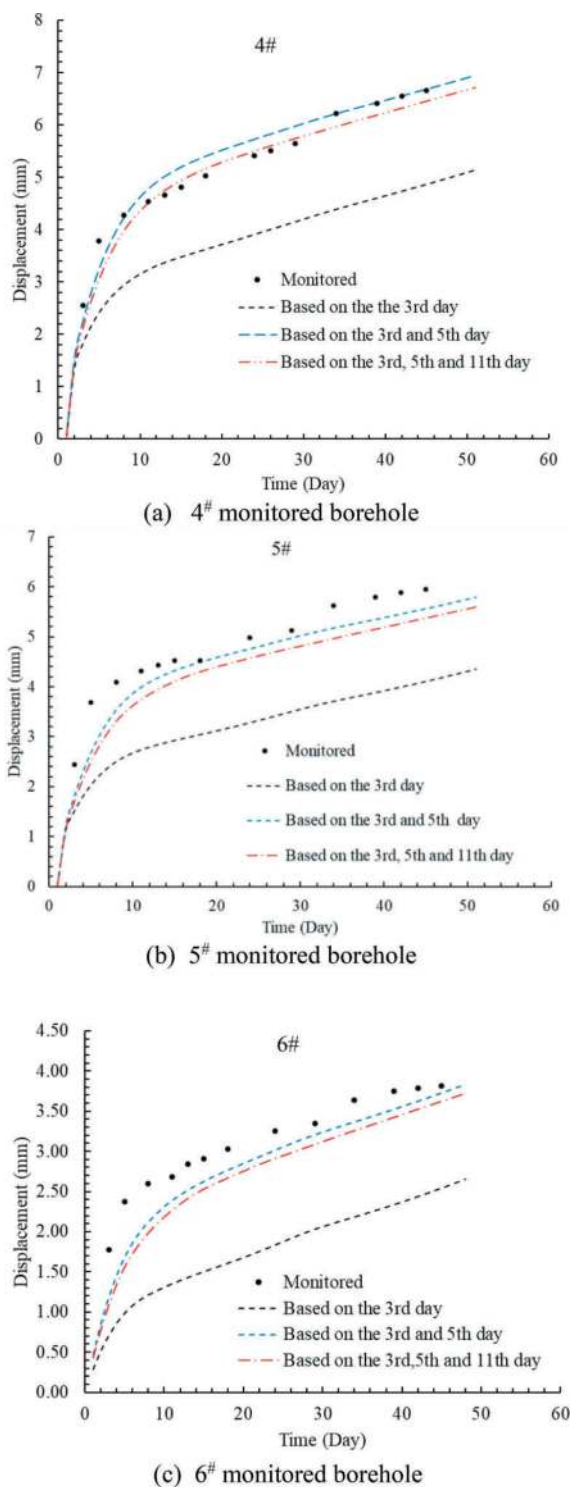

Figure 10. Comparison between monitored displacement and predicted using obtained parameters.

and their rheological properties were determined using the back analysis. Based on the displacement of the surrounding rock mass on days 3, 5, and 11 in the monitored boreholes 4[#] and 6[#], the rheological parameters of S_{2h}^{1-1} and S_{2h}^{1-2} and their uncertainties were quantified using MCMC (Figure 9). The deformation of the surrounding rock mass was investigated based on the rheological parameters of the

Burgers model. The displacements of the monitored borehole were then predicted by a numerical model that used these rheological parameters. They are compared in Figure 10, in which it is evident that the predicted displacement approached the monitored displacement more closely with increasing time. It confirms that more monitored information helped determine the mechanical behavior of the rock mass. The predicted displacements for days 3 and 5 and days 3, 5, and 11 are in excellent agreement with the monitored values, showing that the obtained rheological parameters closely reflected the mechanical behavior of the rock mass surrounding the tunnel.

5 CONCLUSIONS

This study developed a data-driven model to evaluate and deal with the stability of the tunnel and its uncertainty. The results were in close agreement with the monitored data from the experimental tunnel, showing that the uncertainties inherent in the tunnel are reasonably evaluated using this approach, confirming that the data-driven model provides an efficient and effective scientific approach to stability and uncertainty analysis in the tunnel. The key findings of this work include:

- (1) The data-driven model characterized well the complex and nonlinear function mapping relation between the response of tunnel surrounding rock mass and their influence factor. The data-driven model provides an excellent way to capture the deformation and failure law of the surrounding rock mass in the tunnel.
- (2) The uncertainty quantification is a scientific and reasonable method to describe and analyze the uncertainty during tunnel excavation. The PyMC3 software package is a reliable tool for uncertainty quantification and is also helpful for other uncertainty analyses in rock mechanics and engineering.

ABSTRACT: In the tunnel subproject of the Caobao Road Expressway Project, the main body of the tunnel is planned to be constructed through using a 15m diameter slurry balance shield. The project shall make a way in between regions including Puhuitang, Haishangxin Village, and the Outer Ring Expressway, the complex surrounding environment is deemed to place obstacles to the underground passage of the shield. With references from actual practices of the Cao Bao Road Express New Construction Project underpassing the Hai Shang Xin Village and the Outer Ring Road Expressway, the presented work established a 3D elastic finite element analysis model using PLAXIS, simulations which returned a development pattern of housing and viaduct subsidence caused by shield construction during the shield crossing stage. In addition, different grouting pressures were simulated to study the effect of grouting on the ground building. The work shall provide insights into establishing feedback systems for deformation and reducing ecological impact in similar ultra-shield tunnel projects crossing ancient building complexes and railway throat areas.

Keywords: shield tunnel, numerical simulation, subsidence control, grout, PLAXIS

1 INTRODUCTION

Currently, underground space development technology has matured, with urban transportation mainly utilizing two forms: underground rail transportation and underground expressway transportation. In comparison to ground transportation and elevated roads, underground expressways alleviate traffic congestion and occupy less urban space, reducing the impact on the ecological environment.

Due to the urgency of developing underground spaces and constructing underground transport, scholars both at home and abroad have conducted extensive research on shield penetration through existing structures. They have reached comprehensive conclusions on the impact of shield excavation problems. The research methods used by the scholars mainly involve three approaches: model testing, numerical simulations, and on-site monitoring.

The similarity theory is primarily applied in establishing a shrinkage model for shield excavation through model testing. In a geotechnical centrifuge simulation of the shield construction process, Yang et al. (2021) obtained data on the surface railway

settlement resulting from shield excavation. Nabizadeh and Mojtahedi (2021) also conducted model tests to explore the interaction between earthquake-induced fault deformation and soil deformation caused by shield tunnel excavation. Finite element numerical simulation is a prevalent approach for analyzing the deformation of the surrounding environment resulting from tunnel construction. Luo et al. (2020) developed a three-dimensional fluid-soil fully coupled mathematical model using FORTRAN through excavation of a finite element method to anticipate the ground settlement and pore water pressure changes induced by construction. Some scholars have integrated numerical simulation with other techniques to develop a thorough evaluation of shield excavation from various viewpoints. The frequently used ones include combining actual monitoring data with numerical simulation results. For instance, Hossain et al. (2016) conducted an objective analysis using elastic-plastic finite element numerical simulation, wherein they modified the pre-existing two-dimensional model to simulate the tunnel excavation process. They researched the impact of the tunnel excavation on existing buildings, existing tunnels, and the interaction of twin-tube tunnels. On the

*Corresponding author: 2232529@tongji.edu.cn

other hand, Sheng et al. (2019) examined the convergent displacement and damage characteristics of circular tunnels that were deeply buried through model experiments. They combined numerical simulation with a continuous numerical simulation to study the damage law of the tunnel perimeter rock. On-site monitoring employs a diverse array of tools, including 3D laser scanning (Ma & Zhao, 2019), Insar (Zhang et al., 2022), and other technologies, to track the deformation and settlement of buildings during construction and in existence. From the monitoring data collected, the precise and actual response of the tunnel excavation on the building can be determined.

According to scholarly research, numerical simulation has rapidly advanced in recent years, with its primary benefit being its systematic and three-dimensional dynamic analysis, making it well-suited for analyzing issues related to shield tunneling under complex geological conditions.

Based on the new construction of the underground expressway on Caobao Road in Shanghai, this thesis uses PLAXIS 3D geotechnical engineering finite element analysis software to establish a numerical simulation model. This model analyzes the settlement and deformation of ground structures throughout the entire process of the tunnel passing through Haishangxin village and S20 viaduct. The information gathered is based on theoretical analysis and numerical simulation, ensuring a comprehensive and objective evaluation of the project. Analyze the settlement variations in the building under various grouting pressures. Enhance construction techniques to diminish ground settlement, guarantee the safety and dependability of the underground building's shield tunnel, and propose solutions and references for future construction of similar large-scale shield tunnels.

2 PROJECT OVERVIEW

2.1 Background

The new mainline expressway project on Caobao Road spans 7.18 kilometers, including a critical underground tunnel section stretching approximately 5.1 kilometers. Construction employs the mud-water balance shield machine. This study examines the impact on the surface structure during tunnel excavation either under or through the surface. The selected simulation area is illustrated in Figure 1. In this section, the Caobao Road Tunnel is only 3.6 meters away from Maritime New Village, while S20 elevated is only 1.0 meters away. Excavation of the tunnel is expected to have a significant impact on the surface structures.

2.2 Tunnel structure

The Caobao Road Tunnel's main line is composed of a single-bore shield that has a cross-section of "3

Figure 1. Modelled area: shield tunnel through Maritime Village and Outer Ring Road S20.

layers, two directions, 6 lanes". This is an exclusive thoroughfare for minibuses as illustrated in Figure 2. The shield is fashioned with a single-layer lining that has an outer diameter of 15m, an inner diameter of 13.7m, and a tube sheet thickness of 0.65m. And it adopts a ring width of 2m.

Figure 2. Cross-sectional structure of Caobao Road Tunnel.

2.3 Geological condition

Shanghai is situated in the lower course of the Yangtze River and is a prototypical deltaic sedimentary plain resulting from river influence. The soil layer within a depth of 40 meters comprises predominantly soft clay and sandy soil with a chalky texture. Shanghai is situated in the lower course of the Yangtze River and is a prototypical deltaic sedimentary plain resulting from river influence. The geological strata differ significantly across various districts, with a high groundwater table. The proposed area generally has a ground elevation of 4.0-5.5m. The underground diving level is buried at a depth of 1.4-3.3m, while the pressurized water is buried at a depth of 3.0-11.0m. The shallow area contains methane gas, quicksand phenomena, thick fill, bright and dark hills, and other undesirable geological conditions.

Figure 3. Cross-sectional structure of Caobao Road Tunnel.

3 NUMERICAL SIMULATION

The chosen finite element software for numerical simulation in this paper is PLAXIS 3D. PLAXIS 3D is particularly suitable for simulating the shield tunnel excavation process and is also effective in simulating shield tunnel construction steps. The software has numerous advantages in geometric modelling, structural modelling, and construction simulation which makes it widely used in the numerical simulation of shield tunnel boring construction.

3.1 Numerical calculation model construction

In order to streamline the simulation process and speed up computation time, the following assumptions have been incorporated into the numerical simulation of the shield tunnel as it penetrates existing ground structures:

- (1) Assuming that the soil is a continuous, uniform, isotropic ideal elastic-plastic body, ignoring the inhomogeneity of the soil layer, and assuming that the soil layer is uniformly distributed as a horizontal layer, according to the research of Yang Min(1992), the modulus of elasticity of the Shanghai area should be taken to be 2.5-3.5 times of the compression modulus, and in the numerical simulation should be taken as a higher one, so it adopts 4 times for the simulation;
- (2) Neglect the soil structure stress field, only consider the self-gravity stress field;
- (3) The ground building is simplified, and the building is simplified as a beam-column structure, and the viaduct is simplified as a column-slab structure;
- (4) Considering that the modulus of elasticity of reinforced concrete is much larger than that of soil, a linear elasticity model is used to simulate the shield tube sheet and beam-column plate, which is regarded as an elastic body;

- (5) Considering the effect of shield tube sheet joints, the overall stiffness of the tube sheet is discounted according to the modified inertia method. In the cross section, the discount factor is usually 0.6~0.8 according to the experience, and this numerical simulation adopts 0.8 as the discount factor.
- (6) The whole process of tunnel construction is simulated by using construction sequencing instead of the original continuous cycle construction process, and the construction process is simulated by changing the material type of the unit.

3.2 Ontological modelling

Shield excavation involves the interaction between soil and structure, and accurately simulating this relationship is crucial for successful modeling. The key lies in accurately simulating the interaction between the media.

Figure 4. Geotechnical tests and geostructural stiffness versus strain plots.

From the relationship between strain and stiffness of typical soil in geotechnical tests and structures (Figure 4). This study, conducted with the use of standardized testing methods, aimed to determine the correlation between soil strain and stiffness under various loading conditions. The results showed a strong positive relationship between strain and stiffness, indicating that the stiffness of the soil increases as strain increases. These findings have significant implications for the design and construction of geotechnical structures, as well as for improving our understanding of soil mechanics. It appears that conventional geotechnical tests typically simulate model results under the influence of substantial strains. However, tunnels often exist between large and small strains. When considering the size of the actual shield structure and soil structure defects, it seems that the soil experiences significant strain. Moreover, MC model calculations generate more conservative and secure results in comparison to HSS/HS models, and they also feature a quicker calculation process. Therefore, the decision was taken to employ the MC model for simulation. The decision to employ the MC model for simulation was made due to its faster processing time.

The shield pipe sheet and ground building materials were simulated via a linear elasticity model founded on a generalized form, which employs Hooke's law. This model is based on Hooke's law, which states that stresses and strains change linearly when materials are stressed. The finite element simulation is founded on the subsequent fundamental equations:

$$\sigma = D\varepsilon$$

σ – stress component vector;
 ε – vector of strain components;
 D – the elasticity matrix.

3.3 Material and construction parameters

3.3.1 Material parameters

To achieve accurate simulation of actual engineering excavation, determination of soil-related parameters is crucial. Table 1 displays the relevant data for the selected soil parameters, as reported by the engineering geological investigation. The groundwater table is located 2.5m below the surface.

To more accurately simulate the on-site situation, the model size must be taken into account while also considering the scope of excavation and minimizing the impact of model boundaries. Additionally, careful control of calculation amounts is necessary. The numerical simulation model dimensions were established as follows: 100 meters for the soil and structure in the horizontal direction, 300 meters in the longitudinal direction (tunnel excavation direction), and 70 meters in the vertical direction for soil depth.

Concrete strength for ground-level buildings was determined taking into account the actual construction age of the structure and used to calculate related parameters. Refer to Table 2 for building-related material parameters.

In addition, according to the design report, the parameters of the new construction of underground expressway on Caobao Road are taken as shown in Table 3.

According to the relevant formula of Peck's sinkhole in Figure 5 (Peck, 1969):

It is feasible to estimate the extent of the impact of tunnel excavation on the S20 outer ring viaduct.

$$i = \frac{Z}{\sqrt{2\pi} \tan\left(45 - \frac{\beta}{2}\right)^\circ}$$

Where:

i – Width coefficient of sinkhole, in m
 Z – depth of the tunnel, in m
 β – angle of internal friction of the ground around the tunnel

After calculating an effect range of 81.30 meters, a bridge length of 100 meters was chosen for analysis to ensure safety and reasonability.

The simulation focused on a residential building using a beam-column frame structure. A column-plate unit simulation was used to model the S20 elevated. Due to the bridge deck plate's stiffness being larger than the soil body, the stiffness of the bridge deck plate was set to a high value. The computational model displayed in Figure 6 presents the final outcome, with

boundary conditions set such that the surface is free, the bottom is fixed entirely, and the side is fixed normally.

3.4 Tunnel construction simulation

After constructing the soil and surface structure models and setting the tunnel model parameters, it is necessary to generate a finite element mesh to mesh the soil environment and surrounding

Figure 6. Calculation model of shield penetrating residential buildings and elevated structures. (Blue round tubes are tunnels, brown colour is negative interface)

structures. A pre-stage involves generating initial ground stress in the synchronous grouting simulation to construct the existing ground structure. The shield is first advanced 6 meters to indicate its proximity to the project site, after which the design for tunnel construction is initiated.

Initially, the excavation process involves freezing the soil layer within the shield machine's tunneling range, which is 15 meters in diameter, to indicate completion of the layer excavation. Then, activate the negative interface, plate activation (simulating the shield body location), and activate the shield loss cone shrinkage, with axial increment and 0% shrinkage at the shield's head. Finally, activate the working face pressure to proceed.

From the second stage of construction to the sixth, the loss of vertebrae contraction was altered in sequential increments of 0.1%, 0.2%, and so on, reaching 0.5% at the sixth stage (i.e., the final stage), and the loss pattern of the formation was changed to unity. This was done to account for the gradual contraction resulting from the progressive decrease in diameter during conical shield excavation and to stabilize the pressure at the excavation site.

The seventh construction step simulates the grouting ring, at which point the shield has already passed through this ring and requires freezing of the plates, negative interfaces, and conical shrinkage to simulate the shield leaving the ring completely. At the same time, the grouting pressure is activated to indicate that grouting has begun, and the jacking pressure is activated to reflect the jacking effect on the tunnel.

In the eighth step of the construction process, the grouting pressure and jack pressure are stopped, indicating the completion of grouting. Then, the tube sheet material is activated to initiate the original process of constructing the tunnel tube sheet assembly.

This process starts with the material in the previous position, and the simultaneous grouting simulation is finished.

During the shield tunneling process simulation, the shield tunnel will be divided into 4m sections in the construction step. The first step will be the initial construction of the first ring, followed by the first construction of the second ring and the second construction of the first ring in the second step, and so on. The construction process will be divided into 72 steps. The last step will be the final construction of the last ring, indicating the end of tunnel construction. In the initial phase, it is necessary to reset small strains and displacements to zero to eliminate deformations resulting from the initial and additional ground stresses, thereby forming the initial ground stress field.

In the secondary grouting simulation, we must incorporate the ninth through eleventh construction steps. The ninth step of tunnel construction remains the same as the eighth, representing the typical process after excavation by shield. In the tenth step, grouting pressure is reinstated to simulate secondary grouting after the shield's forward movement. The eleventh and final step freezes the grouting pressure, marking the completion of secondary grouting. Simultaneously, the complete construction process will undergo an equivalent increase of three steps.

Figure 7 Below displays the conclusive results of the partial meshing and partial construction steps.

Figure 7. Schematic diagram of construction steps.

With continuous shield advancement, synchronous grouting of the shield tail is necessary to fill the gap between the tube sheet of the shield tail and the soil body. This gives soil pressure that ensures the structural integrity of the surrounding soil and prevents excessive deformation. The goal is to control settlement and protect existing surrounding structures. Technical terms will be explained upon

first use. Based on engineering construction experience, grouting pressure is typically taken at 1.1 to 1.2 times the hydrostatic soil pressure. To capture the influence of grouting on the control of tunnel deformation and the surrounding environment, this numerical simulation incorporates simulations of two distinct grouting pressures:

- (i) -100 kN/m^2 at the top of the tunnel, with a growth rate of -20 kN/m^2 per meter with the depth of the tunnel
- (ii) -500 kN/m^2 at the top of the tunnel, with a growth rate of -20 kN/m^2 per meter with tunnel depth.

The direction of grouting pressure is away from the centre of the tunnel.

4 RESULT

4.1 Haishangxin village settlement

In the instance of synchronous grouting, utilizing grouting pressure (i), the graph below displays the highest settlement of the building's floor with excavation steps (since the shield machine is farther from the building, the changes in settlement are minor, therefore reacting to the first 40 construction steps, and highlighting the area of concentration of the problem).

Figure 8. UngROUTED settlement plan of Haishangxin village.

According to this, the following characteristics can be analysed:

- (1) The study reveals two important characteristics: firstly, settlement of the building floor experiences a sharp rise once the shield machine enters the influence range of the building and reaches the maximum settlement value.
- (2) Buildings closer to the tunnel excavation axis display a larger settlement value, while distance reduces the impact of tunnel excavation on buildings. Technical abbreviation meanings have been clarified throughout the text.
- (3) Settlement gradually decreases and stabilizes at a consistent level once the shield machine exits the building's influence range. Adhere to

standard language structure and use unbiased and objective language. Maintain proper formatting and citation style. Avoid using colloquial terms or informal expressions. Precise and clear vocabulary should be utilized when possible. Grammatical accuracy and correct spelling and punctuation are essential. Technical term abbreviations will be explained upon initial use.

- (4) The maximum settlement of the building's floor is -56.008mm.

In the case of grouting pressure(ii), the settlement of the base plate of the building is shown in the Figure 9 below:

Figure 9. Grouted settlement plan of Haishangxin village.

According to this, the following characteristics can be analysed:

- (1) Increasing the grouting pressure within a certain range can effectively reduce the settlement of the building;
- (2) The settlement trend after increasing the grouting pressure is basically the same as the original trend.
- (3) The maximum settlement of the bottom slab of the building is -9.657mm.

4.2 S20 viaduct settlement

In the case of synchronous grouting, using grouting pressure (i), the settlement of the bridge abutment is shown in Figure 10 (taking into account the last thirty construction steps):

It can be seen that the basic law of the bridge settlement and the settlement law of the building are basically the same, both of which are that the settlement increases after the shield machine enters the influence area of the bridge pier (bearing platform), and the settlement reaches the maximum value when the shield machine moves to the vicinity of the building directly below. The maximum settlement of the bridge pier is -84.054 mm.

In the case of synchronous grouting and grouting pressure (ii), the settlement of bridge abutment is shown in Figure 11:

Figure 10. Ungrouned settlement plan of S20.

Figure 11. Grouted settlement plan of S20.

It can be obtained that the settlement of bridge bearing platform is -16.173mm.

4.3 Results and control standards comparison

In order to comprehensively consider the relevant factors and reduce the influence of the excavation process on the ground elevated buildings and complexes, the settlement deformation of the ground buildings caused by the shield machine should be controlled in millimeter level, within $\pm 10\text{mm}$. For the bridge, according to the 80m width calculated by Peck sinkhole, the maximum slope should be less than 1/4000, and the maximum settlement deformation of the bridge should be controlled within the range of $\pm 20\text{mm}$.

After numerical simulation, it can be seen that in the case of grouting pressure (ii), the settlement of the final shield penetrating the affected residential building is controlled within $\pm 10\text{mm}$, and the settlement of the S20 outer ring road viaduct is also controlled within $\pm 20\text{mm}$.

In the actual project, it is necessary to consider further control measures to ensure the stability of the excavation surface, reduce the settlement of ground structures caused by the shield underpass, and ensure the safe construction of the project.

5 DISCUSSION

This paper takes the under-construction Caobao Road underground expressway project as the research object, collects relevant data according to the existing research results, establishes a numerical calculation model of tunnel boring with reasonable assumptions by using PLAXIS, and analyzes the impact of settlement on the existing ground building structures during the tunnel boring process of the shield tunnel of the Caobao Road underground expressway. At the same time, in combination with the existing targeted settlement control measures, it will be verified that grouting can be used to reduce the impact on the ground structure during the tunnel boring of the urban super-large diameter shield tunnel to ensure the safety and stability of the ground structure. Based on this result, it provides some reference for reducing the degree of ecological impact when oversized diameter shield tunnels pass through building complexes, traffic choke areas, and other similar projects.

This paper exploratively analyses the impact of grouting on surface buildings during underground large-diameter shield excavation through engineering-related content. However, due to the complexity of the actual situation of the project, there are certain limitations, which should be studied and improved in the following aspects.

- (1) The residential building and the S20 outer ring elevated structure are simulated using a basic frame structure. However, this is a considerably simplified process, and it cannot precisely portray the deformations of the physical building. Therefore, a thorough analysis and compilation of relevant information is necessary to optimize the model.
- (2) This paper only considers the impact of shield excavation on the ground results during this section of the project. Long-term consolidation and sub-consolidation on the underground tunnels after the construction process are not simulated. The study only accounted for temporary deformation following grouting control, neglecting the

long-term effects. It is necessary to conduct prolonged observation and analysis to guarantee the stability of the underground tunnel and ground structure following the shield crossing.

Rock bolt design, A numerical parametric study

Sajjad Anwar & Aadev Mann

AECOM New Zealand, Auckland, New Zealand

Somaye Sadeghian

AECOM Australia, Sydney, Australia

ABSTRACT: This paper presents result of the numerical parametric study undertaken for the design of the rock bolts for mined tunnelling application using three widely used two-dimensional geotechnical software in the industry i.e., (1) Rocscience software RS2 (formerly known as Phase2), based on the Finite Element Method, (2) Bentley software Plaxis2D, also based on the Finite Element Method; and (3) Itasca software UDEC, based on the Distinct Element Method. The numerical analyses are undertaken using both discontinuum and continuum media. The parametric study is undertaken on example three mined tunnels located at proximity. The results are assessed in term of the rock bolts axial (tension) force and ground total displacement. No shotcrete support is considered in the model. The results of axial force and total displacement of each software are compared, and recommendations are provided for the key input parameters consideration, which will ensure consistent results across three software platform.

Keywords: Rock Bolt

1 INTRODUCTION

Rock bolting is the most widely used means of rock support for underground excavations, including mining, tunnelling, and other types of engineered caverns. Rockbolts have been used for rock reinforcement for a long time, but many are still confused on how rock bolts perform in the rockmass (Li. C. C., 2017). Many different types of rock bolts are available in the market. It can be a problem to choose the most appropriate types of bolts for a given rock condition if one does not have a good knowledge of rock bolts. Rock bolting design is indeed mainly based on experience, and it appears that rock bolting design is simply a business of selection of rock bolt types and the determination of bolt length and spacing, but one essentially uses, either explicitly or implicitly, a methodology in a specific rock bolting design.

No attempts are made in this paper to summarise the design principles and methodologies of the rock bolts, but rather present a numerical design for the single rock bolt type i.e., a fully bonded rock bolt type in three widely used two-dimensional (2D) geotechnical software in the industry i.e., (1) Rocscience software RS2 (formerly known as Phase2), based on the Finite Element Method, (2) Bentley software Plaxis2D, also based on the Finite Element Method; and (3) Itasca software UDEC, based on the Distinct Element Method.

The numerical analyses are undertaken using both discontinuum and continuum media. The parametric study is undertaken on example three mined tunnels located at proximity. The results are assessed in term of the rock bolts axial (tension) force and ground total displacement. No shotcrete support is considered in the model. The results of axial force and total displacement of each software are compared, and recommendations are provided for the key input parameters consideration, which will ensure consistent results across three software platform.

2 FULLY BONDED ROCK BOLT TYPE

A fully bonded rock bolt represents a bolt type where no failure at rock/grout interface and grout/bar interface can occur. The axial force of the bolt in tension is main governing failure criterion. The axial force along the bolt is determined from the elongation of the bolt element. If the length of a bolt element L , is increased by Δu then the induced tension force in the bolt is given by:

$$F = \frac{AE}{L} \Delta u$$

Where: F is Bolt Axial force in tension, A is cross sectional area of the bolt, E is modulus of elasticity

of bolt material, L is rock bolt length in consideration and Δu is bolt elongation. The failure criterion of the fully bonded bolt in the modelling is considered as elastic perfectly plastic, this mean residual strength is equal to peak strength after yielding strength is reached.

Each software has different bolt type to model fully bonded rock bolt failure behaviour. This has been discussed in following section.

3 FULLY BONDED ROCK BOLT TYPE MODELLING

3.1 RS2 software

In Rocscience software RS2 fully bonded rock bolt type can be modelled using Fully Bonded Bolt Type. The key input required to model this bolt type is shown in Figure 1.

Type	Data
Bolt Diameter (mm)	
Bolt Modulus, E (kPa)	
Tensile Capacity (kN)	
Residual Tensile Capacity (kN)	
Out-of-Plane Spacing (m)	
Pre-Tensioning Force (kN)	
Constant Pre-tensioning Force in Install Stage	<input type="checkbox"/>
Joint Shear	<input type="checkbox"/>

Figure 1. RS2 Software fully bonded bolt type input window.

The standard fully grouted rock bolt bar diameter is available in 20, 25 and 32mm. For this paper the steel grade 500MPa bolt with bar diameter of 25mm is considered. The bolt modulus depends on material type, which for steel is around 200GPa and 60GPa for Glass Fibre Reinforced Plastic (GFRP) dowels. The input tensile capacity of the rock bolt shall be entered as ultimate tensile strength for temporary short-term application or where yielding (elongation) of the rock bolts are allowed. For permanent long-term application or where yielding (elongation) of the rock bolts are not allowed, the design yield strength shall be entered. The tensile capacity of the rock bolt is simply equals to bolt cross sectional area (A) times the rock bolt material ultimate or design yield strength. e.g., the ultimate and design capacity of the 25mm steel bar whose yield strength (f_y) is 500MPa is around 245kN and 163kN respectively. The design tensile capacity is estimated using the factor of safety of 1.5 in accordance with British Standards Institution (bsi) BS 8081:2015+A2:2018. The bolt spacing and pre-tensioning requirement are based on design requirements. The check box for the joint shear is applicable for discontinuum model only. If the Joint Shear check box is selected, then RS2 will account for bolt-joint interaction. For

details regarding the Pre-Tensioning Force and implementation of bolt-joint interaction, see RS2 online documentation section. When the spacing of the rock bolts are specified, the output force in the rock bolt is determined by software by multiplying the spacing i.e., it is a force per bolt and not per meter. Axial forces in tension are positive in RS2 software.

3.2 Plaxis 2D software

Until Bentley issued Plaxis 2D version 2022, rock bolts was often modelled using embedded beam element, without realising the limitation of the default interface input properties. The embedded beam element does not function as fully bonded rock bolt type. The strength and stiffness of the rock/grout interfaces are accounted for – the bolt is not assumed to remain fully bonded to the rock, and interface effects are considered. The failure of an embedded beam element occurs in both tension and shear along rock grouted interface.

The Plaxis reference manual clearly warn the user that the default values of the interface stiffness factors are valid for bored piles, which are loaded statically in the axial direction and behaviour of the surrounding soil is modelled using the Hardening Soil model with small-strain stiffness. The phreatic level is assumed to be located at the ground surface. These values should be modified if the conditions in the model are different from the ones assumed to derive the default values. However, most engineers overlook these limitations and model rock bolts using the default values of the interface stiffness factors and end up underestimating rock bolt tensile forces when compared against RS2 software fully bonded bolt type forces. For details regarding the embedded beam formulation, see Plaxis 2D reference manual. The key input required to model embedded beam in Plaxis 2D software is shown in Figure 2.

The authors of this paper have undertaken sensitivity study and would like to propose interface stiffness factor defaults values to be replaced with 100 for axial, lateral and base stiffness factor to get axial tensile forces in the embedded beam element similar to RS2 fully bonded bolt type.

Rock bolt generally do not have base resistance and very limited lateral resistance; therefore, these inputs can safely be ignored. If the failure mechanism at the bolt/grout interface is desirable, then the diameter shall be for bolt diameter than hole diameter. But if the failure mechanism at the rock/grout interface is desirable, then the diameter shall be for hole diameter than bolt diameter. N_p and M_p are the maximum limit for the elastoplastic behaviour of an embedded beam. Where N_p is taken similar to tensile capacity of the bar as discussed above under fully bonded rock bolt type of RS2 software. The M_p can simply be estimated using the yield strength (f_y) of the material time the sectional modulus (Z).

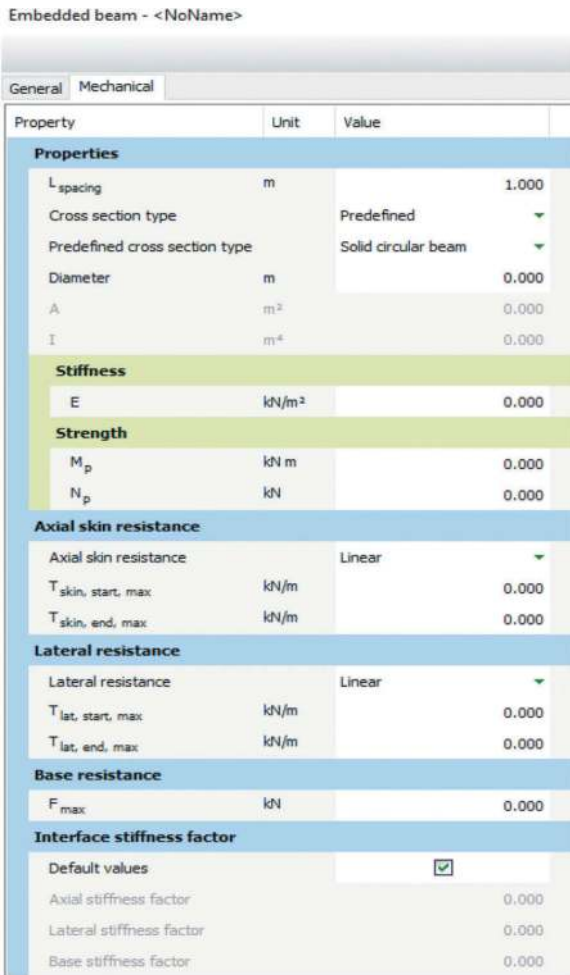

Figure 2. Plaxis 2D embedded beam input window.

The axial skin resistance (T_{skin}) is the bond strength at rock/grout or bolt/grout interface. This is further discussed below in UDEC software section. When the spacing of the embedded beam element are specified, the output force in the embedded beam is determined by software by multiplying the spacing i.e., it is a force per embedded beam and not per meter. Axial forces in tension are positive in Plaxis 2D software.

In Plaxis 2D version 2023, Bentley has introduced a new structural element for rock bolt modelling known as “Cable bolts”. Differently to embedded beams cable bolts only work under axial forces, therefore, bending moments and shearing resistance are not part of the basic behaviour of cable bolts. The key input required to model cable bolt type is Plaxis 2D software is shown in Figure 3. The Figure 3 provided call outs for explanation and similarities to RS2 fully bonded bolt type inputs. When the spacing of the cable bolts are specified, the output force in the rock bolt is determined by software by multiplying the spacing i.e., it is a force per bolt and not per meter. Axial forces in tension are positive in Plaxis 2D software. The axial stiffness E and tension limit $N_{p,tens}$ control the axial behaviour of the cable

element. The shear stiffness, the cohesive strength and friction angle are the bond properties (Figure 3) controlling the shear behaviour of the grout annulus. If the failure mechanism at the bolt/grout interface is desirable, then the diameter shall be for bolt diameter than hole diameter. But if the failure mechanism at the rock/grout interface is desirable, then the diameter shall be for hole diameter than bolt diameter. For fully bonded behaviour, the box shall be checked (Figure 3). When checked no bond failure (plasticity) takes place. Also, the strength distribution is set as uniform by default with high value stiffness and strength parameters. The bond stiffness, k_s is such cases has limited effects on calculation process.

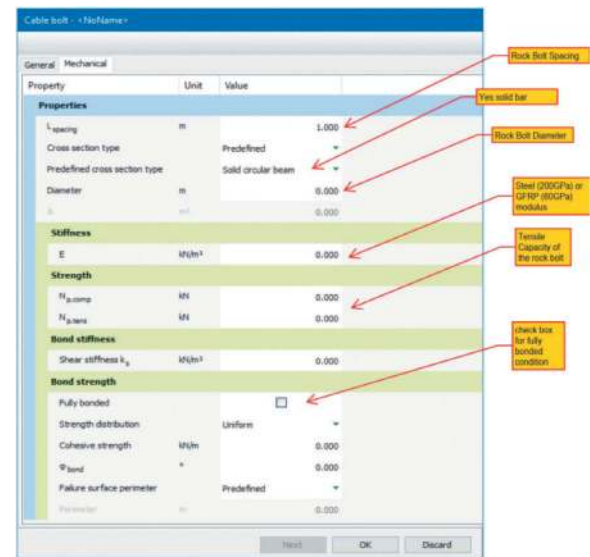

Figure 3. Plaxis 2D cable bolt input window.

3.3 UDEC software

UDEC software developed by Itasca Consulting Group Inc., allow for the use of structural elements to simulate rock bolts. In effect, two types of rock bolt models, i.e., the “Cable” and the “Rockbolt” elements, are used to account for the properties of both bolt and grout. For practical purposes, the main difference between these two approaches is that the “Cable” element does not provide any resistance to bending, whereas the “Rockbolt” element provides resistance against bending. Cable elements are suitable for modelling rock bolt in which tensile capacity is important, and for which axially directed frictional interaction with the rock mass occurs.

When the spacing of the rock bolts are specified, the output force in the rock bolt is determined by software by multiplying the spacing i.e., it is a force per bolt and not per meter. Axial forces in tension are negative in UDEC Software. The main difference in UDEC modelling for the rock bolt is that the failure mechanism is elastic-perfectly plastic with a strain limit.

The critical properties that result in the different bolt behaviour in UDEC than the fully bonded rock bolt type in RS2, embedded beam and cable bolt in Plaxis 2D are:

- (1) Bond shear capacity;
- (2) Bond (shear) stiffness; and
- (3) Rupture Strain limit.

The bond shear capacity is calculated using $\pi(D + 2t)(\tau)(Q_b)$, where D = Rock Bolt diameter; t = grout annular thickness; τ = bond strength assumed approximately one-half of the uniaxial compressive strength of the weaker of the rock and grout. According to BS8081:2015+A2:2018, the ultimate bond strength at rock/grout interface can be taken for design as 10% to 30% of rock uniaxial compressive strength with limit to 4MPa. For this study to get fully bonded behaviour, the bond strength assumed approximately one-half of the uniaxial compressive strength of the grout. Q_b = the quality of the bond between the grout and rock and value ranges from 0 to 1. The $Q_b = 1$ is taken for perfect bonding in this study. The Bond (shear) Stiffness (k_s) is calculated using $2\pi G / \ln(1 + \frac{2t}{D})$, where G = grout shear modulus, D and t defined above.

4 PARAMETRIC STUDY

4.1 Numerical model geometry and material properties

For parametric study an example of three mined tunnels located at proximity are model as shown in Figure 4. The tunnels are horseshoe shaped with span of approximately 15m and height of 10.5m. The side rock pillar is around 23m with crown pillar of 15m. The overburden depth is 50m from crown level of top tunnel. Model side and bottom boundaries are approximately 5 times of tunnel span and height respectively from the tunnel side walls and bottom tunnel invert level to overcome boundary effects. Side boundaries are fixed in horizontal direction and free to move vertical direction, whereas the bottom boundary is fixed in both horizontal and

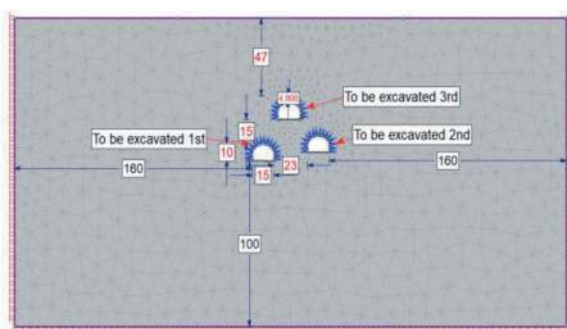

Figure 4. RS2 continuum numerical model for parametric study.

vertical direction. Top boundary is free in both vertical and horizontal direction. No groundwater is modelled, as tunnel are considered drained.

Ground properties are assumed isotropic and homogenous with in situ stress ratio of 1.5. The numerical model geotechnical design parameters are summarised in Table 1.

Table 1. Geotechnical design parameters.

Geotechnical parameters	Material Properties
Rock Type	Igneous Rock
Intact Rock Unconfined Compressive Strength (UCS) - MPa	50
Geological Strength Index (GSI)	45
Hoek Brown intact rock Material Constant (m_i)	25
Disturbance Factor (D)	0
Modulus Ratio, MR	325
Intact Rock Modulus (E_i) - GPa	16
Rock Mass Modulus (E_m) - GPa	5
Intact Rock Shear Modulus (G_i) - GPa	
Rock Mass Shear Modulus (G_m) - GPa	
Poisson's Ratio (ν) -	0.25
Bulk Unit Weight (kN/m^3)	27
Failure Criterion	Hoek and Brown (2002)

4.2 Numerical model set up

Both continuum and discontinuum ground model conditions are considered. For continuum model in RS2 and Plaxis 2D software, the design parameters as provided in Table 1 are used. The input GSI downgraded the intact rock strength and modulus parameters automatically in the software. This degradation of the strength and modulus account the closely spaced discontinuities. The continuum RS2 model is shown in Figure 4.

For discontinuum model in RS2 and UDEC software joints are explicitly modelled, hence input of GSI and consequently degradation of the strength and modulus of intact rock properties are not required. Interlocked rock blocks are modelled using intact rock strength and modulus properties. Two set of crossed joints at inclination of 30 and 60 degrees are considered. Joints are spaced at 1m using normal distribution with standard deviation of 1m. Relative minimum and maximum considered as 0.9 and 3m. Joints end points at boundaries are considered closed. The discontinuum RS2 and UDEC models are shown in Figure 5.

The joints are considered free of infill material, walls are in contact and surface rough or irregular undulating. The slip criterion for the joint is considered in accordance with Barton and Bandis. The input parameters for joints are provided in Table 2.

In UDEC, the discontinuum medium is represented as an assemblage of discrete blocks while the

discontinuities are treated as boundary conditions between blocks. Large displacements along discontinuities and rotations of blocks can occur. UDEC utilizes an explicit solution scheme that can model complex, nonlinear behaviours. Models may contain a mix of rigid or deformable blocks. Deformable blocks are defined by a continuum mesh of finite-difference zones, with each zone behaving according to a prescribed linear or nonlinear stress-strain law. The relative motions of the discontinuities are also governed by linear or nonlinear force-displacement relations for movement in both the normal and shear directions. In RS2, a rock mass can also be modelled as a discontinuum model, RS2 use Goodman, R.E., et al (1968) joint elements for this purpose. These difference between RS2 and UDEC may result in different calculated displacements in the model and axial force in the bolts.

Table 2. Geotechnical design parameters.

Geotechnical parameters	Material Properties
Joint Compressive Strength (JCS) - kPa	37,500
Joint Roughness Coefficient (JRC)	3
Residual Friction Angle (ϕ) - Degrees	33
Mean joint spacing, L (m)	1
Normal stiffness (kn) – kN/m ³	7.27E+06
Shear stiffness (ks) – kN/m ³	4.55E+06

Both K_n and K_s are estimated in accordance with Barton (1972) methodology, according to which:

$$k_n = \frac{E_i E_m}{L(E_i - E_m)}$$

$$k_s = \frac{G_i G_m}{L(G_i - G_m)}$$

Where E_i = Intact rock modulus, G_i = Intact rock shear modulus, E_m = Rock mass modulus, G_m = Rock mass shear modulus and L = Mean joint spacing.

4.3 Rock Bolts

Rock bolts are modelled with length of 4m at spacing of 1.9m in plane and 1.9m out of plane direction. Rock Bolt assumed to be 25mm in diameter, comprised of steel material with ultimate yield capacity of 245kN.

1. Rock bolts in RS2 continuum and discontinuum model are modelled using fully bonded bolt type. A fully bonded Tieback bolt type option of the RS2 software with inputs parameters similar to

(a) RS2

(b) UDEC

Figure 5. Discontinuum numerical model for parametric study.

UDEC is also considered for the discontinuum model. The inputs parameters are shown in Figure 6(a) and 6 (b).

2. Rock bolts in Plaxis 2D continuum model are modelled using cable bolt structure element with inputs parameters shown in Figure 6 (c). The shear stiffness value has no impact on the analysis when the fully bonded option is checked. For parity with UDEC input shear stiffness value taken equal to bond shear stiffness value. The rock bolt in Plaxis 2D continuum model are also modelled using embedded beam element and run with interface factors set as default and equal to 100 as shown in Figure 6(d) and (e) respectively. T_{skin} value is taken similar to bond shear capacity value in UDEC software. The M_p is the maximum bending moment which the bar can take which is equal to steel strength times the section modulus and estimated as 0.8 kNm. N_p is the maximum axial force capacity of the bar and taken equal to 245kN.
3. Rock bolts in UDEC are modelled using cable structure element with inputs parameters shown in Table 3.

The command line for cable element properties in UDEC software is given below:

Table 3. Cable bolt properties in UDEC software.

Geotechnical parameters	Material Properties
Grout Young's modulus, E ($f'c=40\text{MPa}$)	32.8 GPa
Grout Poisson's ratio, ν	0.2
Grout shear modulus, G $G = E/(2(1+\nu))$	13.7 GPa
Grout annular thickness, t	10mm
Bolt diameter, D	25mm
Tensile yield strength (steel)	245kN
Hole Diameter (D+2t)	45mm
Grout Compressive Strength	40 MPa
Steel Young's Modulus	200 GPa
Tensile strain limit (default value from UDEC)	0.25
Coupling shear stiffness, (Bond Shear Stiffness see section 3.3)	1.46e11 N/m
Coupling shear cohesion (Bond Shear Capacity see section 3.3)	2.83e6 N/m

struct cable property cross-sectional-area $4.91e-4$ density $7E3$ rupture-tension-strain 0.25 yield-tension $245E3$ young $2E11$ grout-stiffness $1.46e11$ grout-strength $2.83e6$ spacing 1.9 .

4.4 Model Construction Sequence

Tunnels are excavated following the staged construction sequence shown in Figure 4. Each tunnel is excavated in 3 stages.

Stage 1: Stress initiation – no ground relaxation.

Stage 2: Ground Relaxation – 75%. (Based on GRC type analysis using similar model parameters as mentioned in Table 1)

Stage.3: Installation (activation) of tunnel support (Rock Bolts only)

Stage.4: Full relaxation (100%) of ground.

4.5 Analyses results

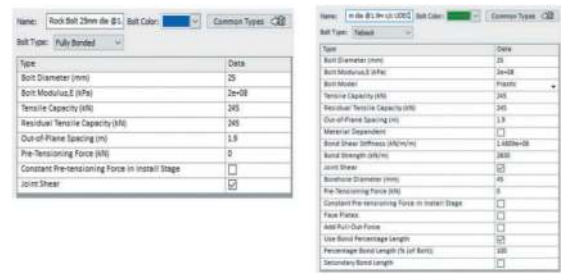

The results of axial force and total displacement of each software are extracted and compared, and recommendations are provided for the key input parameters consideration, which will ensure consistent results across three software platform.

The output results of tunnel total displacements from each software are shown in Figure 7. The output results of rock bolts axial (tension) force from each software are shown in Figure 8.

5 DISCUSSION

5.1 Total maximum displacement

With reference to analysis results shown in Figure 7 (a) and (b), the total maximum displacement calculated in continuum model in RS2 and Plaxis 2D software are 7.3mm and 7.5mm within a margin of error of 2%.

(a) RS2 Fully Bonded Element (Joint shear box is checked for discontinuum model)

(b) RS2 Tieback (Joint shear box is checked for discontinuum model)

(c) Plaxis 2D cable bolts (fully bonded)

(d) Plaxis 2D Embedded Beam - default Interface Properties

(e) Plaxis 2D Embedded Beam - Interface factor set to value of 100

Figure 6. Rock bolt properties.

With reference to analysis results shown in Figure 7 (c), (d) and (e), the total maximum displacement calculated in discontinuum model in RS2 and UDEC software are 9 to 15mm. The higher displacement in discontinuum model are due to block sliding comparing to continuum model

The larger displacements in UDEC compared to RS2 can be attributed to the inherent differences in the modelling approaches and algorithms of the two software packages. UDEC represents the rock mass as discrete blocks with explicit consideration of block rotations and large displacements along discontinuities. This approach allows for detailed modelling of complex behaviours. RS2, on the other hand, employs a discontinuum approach using Goodman, R.E., et al (1968) joint elements, which may not capture certain complexities to the same degree as UDEC.

5.2 Axial (tension) force

With reference to analysis results shown in Figure 8 (a), (b), (c) and (d) the axial force induced in the rock bolts in continuum model both in RS2 and Plaxis 2D software are similar with exception when embedded beam elements are modelled using default interface stiffness factors.

With reference to analysis results shown in Figure 8 (e), (f) and (g) the axial force induced in the rock bolts in discontinuum model both in RS2 and UDEC software are similar with exception when fully bonded rock bolt types are considered in RS2 discontinuum model.

In the comparison between continuum analysis and discontinuum analysis, it is generally observed that the former yields lower axial force in the bolts. This disparity arises because continuum analysis fails to account for the additional axial force resulting from the joint bolt shear displacement interaction.

6 CONCLUSION AND RECOMMENDATION

Based on this parametric study following conclusion are drawn:

1. Regardless of software type if the input parameters and modelling assumptions are similar the output results can be similar.

(a) RS2 Continuum Model; Total Maximum Displacement 7.3mm

(b) Plaxis 2D Continuum Model; Total Maximum Displacement 7.5mm

(c) RS2 Discontinuum Model (fully bonded rock bolt type); Total Maximum Displacement 10mm

(d) RS2 Discontinuum Model (Tie-back Rock Bolt Type); Total Displacement 9mm

(e) UDEC Discontinuum Model; Total Maximum Displacement 15mm

Figure 7. Tunnel total maximum displacement.

2. Beware of the default input parameters and limitation of the software and shall not be overlooked for simplification.
3. The higher strain development in rock bolts in discontinuum model due to joint interaction resulted higher bolt forces compare to continuum model.
4. Fully bonded conditions are achieved for the rock bolts in Plaxis 2D embedded beam rock bolt type by overwriting default interface stiffness factors.
5. UDEC cable elements have shown rock bolt force distribution behaviour similar to tieback rock bolt type option of RS2 software.

Based on this parametric study following recommendations are made for consistent rock bolt design result in numerical analysis using RS2, Plaxis 2D and UDEC software.

1. To get results within close approximation to Continuum model of RS2 fully bonded rock bolt type in Plaxis 2D Continuum model, rock bolts shall be modelled either as Cable bolt element or embedded beam element using interface stiffness factors as 100.
2. To get results within close approximation to Discontinuum model of UDEC cable element type in RS2 Discontinuum model, rock bolts shall be modelled using Tieback bolt type.

(a) RS2 Continuum Model – Fully Bonded Bolt
Maximum Axial Force – 45kN

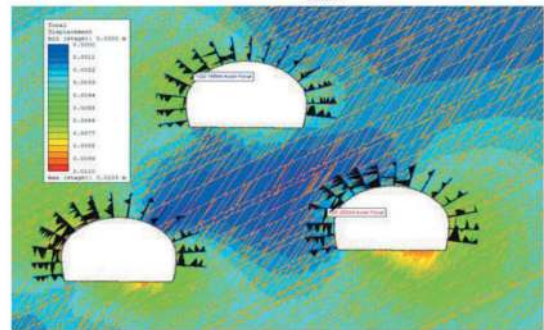

(b) Plaxis 2D Continuum Model – Cable Bolt
Maximum Axial Force – 45kN

(c) Plaxis 2D Continuum Model – Embedded Beam with default interface Properties; Maximum Axial Force – 25kN

(d) Plaxis 2D Continuum Model – Embedded Beam with interface factor equal to 100; Maximum Axial Force – 45kN

(e) RS2 Discontinuum Model – Fully Bonded Bolt Type
Maximum Axial Force – 126kN

(f) UDEC Discontinuum Model – Cable Element
Maximum Axial Force – 245kN

(g) RS2 Discontinuum Model – Tieback Rock Bolt Type
Maximum Axial Force – 245kN

Figure 8. Maximum rock bolt axial force.

The effect of a frictional interface in a preliminary yielding support for a deep tunnel

Lorenzo Batocchioni*, Valeria González & Salvatore Miliziano

La Sapienza University of Rome, Rome, Italy

ABSTRACT: The increasing demand for fast interconnections in modern society leads to the construction of tunnels, bringing with it the necessity to overcome difficult conditions. When deep tunnels are excavated in poor ground, squeezing conditions occur and the design must follow the *yielding principle*. To this aim, special elasto-plastic elements embedded in the temporary support can be employed. The presence of the elasto-plastic elements radically modifies the interaction mechanisms making necessary the use of numerical analyses. Therefore, in this paper a numerical model of a vertical section of a circular tunnel with deformable preliminary lining are developed to study the soil-lining interaction. Through a parametric analysis, special attention is paid to the role of the interface mechanical behaviour between the structure and the ground by varying the interface's friction angle.

Keywords: Tunnelling, Yielding principle, Soil-lining interaction, interface shear strength, Squeezing conditions, Numerical modelling

1 INTRODUCTION

Nowadays our society needs more and more fast link between big cities. For this aim tunnelling became more challenging with the crossing of deeper rock mass with difficult conditions. Not only for environmental reasons, but also for limiting corners and high slopes that reduce the efficiency of the track. In Italy the three main tunnels under construction (Brenner Base Tunnel, Turin Lyon and Terzo Valico del Giovi) are long more than 150km and cost more than 15bn€.

When deep tunnels cross poor grounds the so-called *squeezing conditions* happens, this leads to huge risks for the construction project, high times, and elevated costs (Hoek, 2001). Typically, these conditions are related to rock masses that show a marked rheological behaviour. Furthermore, in conventional tunnelling, extremely high convergence and overload of the preliminary lining can be experienced. The best way to challenge these difficulties is to design the preliminary support following the *yielding principle* (Kovári, 1998). In opposition to the *resistance principle*, where the support consists of a rigid element with a bearing capacity able to resist the rock load limiting the convergence; in the *yielding principle* the support has to be able to deform (Figure 1).

Therefore, allowing the ground deformations by so doing, reducing the stress field in the lining structure.

Such yielding support is obtained by inserting in the classic concept, usually made of steel ribs and

Figure 1. Load displacement curve of a yielding support.

a concrete shell, deformable elements. These have the purpose of permitting the convergence to develop when reaching the designed load level. The deformation can be mainly in the radial or in the circumferential direction (Cantiene & Anagnostou, 2009). The former consists in the construction of a compressible layer between the inner rigid support and the excavation boundary. Whereas in the latter the support deforms with the ground, then the tunnel circumference shrinks. This is possible through the relative displacements of different parts of the support itself (sliding, or TH, steel ribs) or the yielding of specific elasto-plastic elements (EPE, some examples are the LSC or the hiDCon) (Figure 2). In this case the support axial load

*Corresponding author: lorenzo.batocchioni@uniroma1.it

is respectively controlled by the frictional shear stress of the sliding elements and the yielding strength of the EPE. The insertion of punctual deformable elements is the solution most utilised nowadays; hence, this paper is going to focus on the regarding technology.

Figure 2. Two examples of elasto-plastic elements: hiDCon (left) and LSC (right).

There is limited literature on the design of yielding support in deep tunneling under squeezing conditions. Radončić et al. (2009) and Moritz (2011) assessed the Convergence Confinement Method (CCM) to yielding lining in order to estimate convergence values. Similarly, Wu et al. (2022) conducted a comprehensive study on concrete EPE, introducing a new characteristic curve for deformable supports. On the other hand, Yang et al. (2022) investigated concrete damage and proposed a numerical model to simulate the yielding support with EPE embedded in the concrete. Nevertheless, the study of the soil-lining interaction (SLI) in the presence of a yielding support has not been widely studied, leaving a notable gap between yielding and rigid support research. Specifically, there is a lack of study on the interface's role between soil and lining, a key-element of the interaction mechanism, and therefore of the whole tunnel behavior. Differently for a stiff support concept, many authors have introduced closed-form solutions and numerical approaches for the study of the interface's influence (Penzien & Wu, 1998; Song et al., 2018). These are well-known for the simplifications undertaken by analyzing two extreme cases: full-slip conditions, i.e., no tangential shear force at the interface, and infinite bond strength at the soil-structure interface; both representing an idealization of the real contact between soil and tunnel support.

Therefore, the aim of this work is to extend the lining knowledge and concept to the *yielding principle*, thus seeking to fill the existent gap. Our work (Batocchioni et al., 2023 a, b) was driven by the embedment of high deformable steel elements (hiDSte) in the steel ribs, which work along deformable concrete elements in the shotcrete (such as the hiDCon) as a coupled system, as shown in Figure 3a. Thus, the investigation focuses on embedding 8 EPE in the steel ribs (Figure 3b), studying the SLI using firstly analytical methods and secondly, numerical ones.

Indeed, it is believed that the numerical approach is crucial for yielding support design due to the simplifications that limit the analytical approach. With this vision and aiming for a deeper understanding,

Figure 3. a) hiDSte and hiDCon as a coupled system, and b) vertical cross-section of tunnel lining with 8 EPE embedded in the steel ribs.

this paper focuses on the influence of the interface between soil and structure. Motivated by the radical change in both the cinematic and stress field distribution on the interaction mechanisms. This change is due to the introduction of the EPE in the temporary lining, which leads to strong and punctual deformation near the elements. The methodology is developed following the numerical approach, carrying out a parametric analysis regarding the friction angle of the soil-lining contact. The importance of carrying out parametric analyses with numerical computations has been widely proven by many authors (Kovári et al., 1976). The numerical model is based on a vertical section of a circular conventional tunnel, where simplified hypotheses are taken into consideration regarding the geometry, the constitutive model, and the initial stress field. The primary objective of this research is to study how by varying the shear strength of the interface, the SLI modifies.

2 METHODOLOGY

In this paper 2D numerical analyses that model a temporary support following the *yielding principle*, have been developed with the aim of studying the peculiar SLI and more in particular, the interface's influence on it. The methodology is in line with the one used at Batocchioni et al. (2023 a,b), but with a deeper focus on the shear strength of the interface using the N-M interaction diagram representation. The analysis has been developed through the FDM code FLAC2D (Itasca, 2011). The model represents one quarter of the tunnel thanks to the symmetry planes (Figure 4). The mesh is composed of 4876 elements.

At the boundary, tensional constraints have been applied. Whereas cinematic constraints, preventing normal displacements, have been applied on the two internal boundaries with the direction radial at the tunnel. The initial stress field is isotropic. The ground has been modelled with parameters typical of a rock mass, with an elastic perfectly plastic behaviour, assumed to be isotropic (Table 1). Considering the depth of the tunnel and the poor ground, the ratio between the uniaxial compressive strength (f_c) and the initial stress field (p_o) has been chosen to be extremely low (≈ 0.06) (Anagnostou & Kovári, 1993; Ramoni & Anagnostou, 2010).

Figure 4. Numerical grid.

Table 1. Parameters used in the analyses.

	Rock mass	Steel ribs	EPE	Interface
Young's modulus, E (MPa)	1000	210000	177	
Area, A (m ²)		106	106	
moment of inertia, I (cm ⁴)		11.26	11.26	
Yielding stress, S_y (MPa)		275	138	
Plastic moment, M_y (MPa*m)		-	0	
Angle of friction, φ (°)	30			0 to 45
Cohesion, c (kPa)	100			0
Dilatancy, ψ (°)	0			
Tunnel radius, r (m)	5			
Initial stress field, p_0 (kPa)	6000			
Coefficient of earth pressure at rest, K_0 (-)	1			

Thus, leading to squeezing conditions. Despite that the numerical analyses do not consider the time effect connected to the rheological behaviour. This is a consequence of the following assumption: the time scale related to the creep phenomenon is much bigger than the excavation one. By so doing, the excavation phase and the creep phase can be modelled separately. The focus on this paper is only on the first, considering that the aim is to understand the SLI mechanism. Furthermore, the creep effect can be considered by simply reducing the rock mass strength parameters that simulates long-term conditions (Lombardi, 1975).

The excavation phase has been simulated with the well-known relaxation method, assuming an installation corresponding to a relaxation factor of 70%. The preliminary support has been modelled with one HEB240 steel rib per meter. For the sake of

simplicity, with a conservative hypothesis, the concrete has been neglected. Therefore, assuming it has the sole function of transferring the load from the ground to the steel ribs, the lasts become the only load-bearing elements. The lining has been modelled with beam elastic perfectly plastic elements, with values of the Young's modulus (E) and the compressive yielding stress (S_y) higher in the steel ribs and lower in the EPE. Furthermore, in order to make the yielding elements behave as a hinge, their plastic moment has been assumed to be null. That is a reasonable simplification, for the EPE's negligible capacity of withstanding bending moments in front of the steel ribs' one. The other geometric parameters, the area (A) and the moment of inertia (I), do not defer between the steel ribs and the EPE. This last simplification can be considered reasonable too, bearing in mind that: (1) the effect of the beam elements' axial stiffness (EA) is negligible if compared to the deformations that occur in the yielding state and (2) the EPE's bending stiffness (EI) is negligible, due to their null plastic moment. The lining interaction with the soil is considered through an interface characterized by infinite compressive strength (elastic behaviour) and shear elastic-plastic behaviour with frictional Mohr-Coulomb shear strength. A parametric analysis was conducted by varying the values of the interface's frictional angle. In order to evaluate the Ultimate Limit State (ULS) mobilization of temporary support, the results are reported on N-M diagram together with ULS domain.

The accuracy of the numerical results has been guaranteed by the relatively high density and dimensions of the mesh and by the high convergence criterion set in FLAC (*sratio*). Particularly, the mesh is 20 times the tunnel radius and the *sratio* is 10^{-5} . Furthermore, the accuracy of the analyses has been controlled verifying the achievement of stationary conditions with the calculation steps of the most important variables of the interaction problem. Furthermore, the accuracy of the numerical model has been verified comparing the value of the axial load in the lining with the one obtained by the analytical methodology based on Convergence-Confinement Method (CCM).

3 RESULTS

The inserting of the EPE in the preliminary support of a deep tunnel in *squeezing conditions* reduces the loads acting on the structural elements. Moreover, the design of a preliminary support following the *yielding principle* in extremely severe conditions, may results the only effective solution to manage in-situ stress field that can reach several MPa.

Figure 5 shows the Ground Reaction Curve (GRC) and the Support Reaction Curve (SRC) of both rigid (red line) and yielding (continuous line) linings.

The latter was obtained with 8 EPE inserted in the support. The rigid lining reaches its structural capacity in axial compression when the rock load reaches

Figure 5. Characteristic curves of a rigid lining (red line) and a yielding lining (black line).

about 700 kPa and collapses for occurrence of buckling phenomenon. The yielding lining, vice versa, thanks to the EPE, reached the equilibrium after a convergence of about 18 cm, with the steel ribs that remain in elastic conditions. Therefore, this simplified analytical interaction model highlights that the stress field in the HEB240, thanks to the EPE, remains below its bearing capacity.

The CCM has been also used as a reference for validating the numerical model, both with and without the EPE installed. Figure 6 shows that the values of the lining axial load obtained by the CCM, and the numerical model's ones are coincident. Here both models (rigid and yielding) have a smooth interface considering that the CCM is not able to consider an interface with shear strength. Furthermore, as it will be possible to see more in detail later, this figure clearly shows that the introduction of the EPE, also with a smooth interface, lead to important values of bending moment. One can then assume that the CCM can be considered as a simple pre-design tool to define the characteristics and the number of the EPE. But it is not possible to use it as a complete design instrument.

Figure 6. N-M interaction diagram for smooth soil-lining contact.

From a kinematic point of view, the rigid lining tends to contract homothetically, congruent with the surrounding ground (Figure 7, red arrows). On the other hand, consequently to the local deformation of the EPE, the steel rib between two EPE tends to move as a rigid body in a radial direction (watching from the midpoint of the beam, Figure 7, black arrows). However, the soil tends to have a homothetical contraction, thus leading to a peculiar SLI with 2 main consequences. By comparing in Figure 8 only the rigid lining (continuous lines) and the yielding lining with smooth interface (lines with symbols) it can be said: 1) with the yielding support the normal stress at the interface (σ_n) tends to concentrate near the extremities of the rigid part of the lining, as a sort of arch effect; 2) the normal stress transmitted by the ground to the lining is decisively lower than the rigid case. Considering instead also the effect of the interface shear strength (dashed lines) 2 further considerations can be done: 3) the relative displacements between soil and lining lead to important shear stress (τ) at the interface and 4) the normal load tends to grow again in the midpoint of the beam where the relative displacements soil-lining is zero for symmetry.

Figure 7. Kinematic interaction mechanism of rigid (red) and yielding (black) lining.

As a consequence of the contact stress distribution, the axial load notably decreases and, in the meantime, great shear load and bending moment values arise (Figure 9). More in detail, if comparing the behaviour of a rigid lining with a yielding lining with smooth interface, in the latter: 5) the axial load (N) is limited by the yielding stress of the EPE and 6) bending moment (M) develops for the normal stress peaks. While, if considering again the effect of the shear strength interface: 7) the axial load tends to increase in the midpoint of the beam for the shear stress that arises at the interface, whereas 8) the normal stress

Figure 8. Interface variables: normal (σ_n) and shear (τ) stresses.

Figure 9. Structural variables: axial load (N), and bending moment (M).

concentration at the beam midpoint has a beneficial effect mitigating the bending moment values.

In line with the previous assumptions, i.e. with the rising value of the interface's friction angle, the maximum axial load increases and the maximum bending moment decreases, the authors find very interesting and useful to represent this trend on the N-M interaction diagram (Figure 10).

This graph clearly shows that the results fit in a linear relationship with a higher gradient than the one of the HEB240 N-M interaction domain. This means that as the friction angle of the contact between soil and lining increases, the severity of load acting on the support tends to reduce (structural beneficial effect). Furthermore, the parametric analysis shows that with the increment of the interface's friction angle, the EPE's axial closure reduces.

Figure 10. N-M interaction diagram with increasing interface's friction angle (ϕ from 0° to 45°).

In short, the friction of the contact between soil and lining can be seen as a dissipative device that helps the soil-lining system to support high load.

4 CONCLUSIONS

In the design of preliminary support, followed by the *yielding principle* in *squeezing conditions*, for the extreme rock loads, can be necessary the application of elasto-plastic elements embedded in the lining. These allow the development of the required convergence for sufficiently reducing the load acting on the lining.

In this paper specific 2D parametric numerical analyses have been developed with the aim of studying the soil-lining interaction mechanisms. Particular attention was given to the effects of the interface between soil and lining. The main outcomes can be summarised as follows:

- the insertion of the elasto-plastic elements in the rigid lining leads to an increase of the convergence with an important decrease of the axial load and the emergence of not negligible bending moment;
- the ability of the interface to develop a frictional strength has a beneficial effect on the behaviour of the support system;
- in the design of a yielding lining is of utmost importance the development of numerical analyses, whereas analytical simplified models, such as the Convergence-Confinement Method, should be used as a preliminary tool for preliminary design.

The results obtained by this work provide some relevant insight on the soil-lining interaction of the preliminary support following the *yielding principle*. These are useful to highlight the peculiar aspects of the interaction mechanism both from a kinematic and a static point of view and correctly develops the project.

ABSTRACT: This study proposes an effective FEM methodology for the analysis of the structural behaviour and performance of special tunnel lining concrete segment equipped with inflatable O-ring sealing devices, used to limit any potential water inflow within the annular gap. All relevant loading and boundary conditions are evaluated, both those expected during construction phases and during design life of the tunnel. Particular attention is given to the, not so frequently discussed, transient phase of the ring exiting the TBM tailshield and O-ring hose sequential inflation. In this scenario the ring is mainly supported by friction at circumferential joints and TBM rams forces.

The case study of a Double-Shield TBM adopting bi-component grout as backfilling material for the annular gap is presented. Within this framework the analysed rock tunnel has a maximum overburden of 130 m and segment equipped with O-ring sealing devices are installed every 200 rings.

Keywords: Segmental lining construction phases, FEM structural analysis, inflatable O-ring, water barrier

1 INTRODUCTION

Precast concrete segments are the standard technique for shielded TBM final lining and are object of accurate studies and numerical analysis in the design phase. In recent years the number of load cases analysed has increased in many countries, to inquire the lining behaviour under new and more detailed loading conditions.

This study presents the numerical calculation approach developed for the structural dimensioning of a special tunnel lining ring equipped with inflatable O-ring sealing.

After an introduction to this technique and construction sequences, the numerical model, its special load cases, and relevant results in terms of stresses are presented.

2 CHARACTERISTICS OF O-RING TUNNEL LINING

In recent projects, precast elements of segmental tunnel lining fit several cast in-situ accessories to

limit any further on-site drilling. A special, and rather uncommon, type of equipment is the inflatable O-ring sealing installed at the extrados of segments (Figure 1).

Figure 1. 3D view of segmental tunnel lining equipped with inflatable O-ring sealing system.

*Corresponding author: mbazzani@systra.com

2.1 O-ring sealing equipment for precast segments

2.1.1 Fields of application

The inflatable O-ring is a technical solution applied in the tunnel industry mainly for two purposes:

- Radial loading transfer: Hoses or bags installed at the extrados of steel ribs or segmental tunnel lining (in case of pea gravel backfilling) are inflated to transfer radial loading from the sound rock to the supporting structure and to guarantee their effective confinement.
- Longitudinal compartmentalization of fluids: Hoses or bags installed on break-in/out devices or at the extrados of segmental tunnel lining to create a barrier against the flow of liquids (grout, groundwater).

This paper presents the O-ring sealing solution applied to precast tunnel segments with the aim of providing a physical water barrier in the annular gap, additional to the bi-component grout injection.

2.1.2 Adaptation of formwork and reinforcement

To fulfil its scope without compromising the ring-building operations and the TBM advance, the inflatable bag is housed in a recess obtained at the extrados of the segments by inserting a plastic box in the formworks (Figure 3a).

This recess develops in the circumferential direction at the centre of the ring, locally reducing the thickness of the segments of about 5 cm. To avoid the interference with EPDM gasket, the recess is interrupted at 10 cm from the longitudinal joints. The shape of the inflated bag is studied to guarantee the water barrier over this concrete arch of 10+10 cm at the joint location. Not to affect the durability of the final lining, the steel reinforcement cages are shaped to guarantee the minimum concrete cover around the sealing system (Figure 3b).

2.1.3 Accessories for O-ring device

The plastic box adopted for creating the recess and housing the inflatable bag is completed with some accessories:

- Protection sheet on the top of the inflatable bag, to prevent any damages of the sealing system during prefabrication and transient stages.
- Hydro-swelling stripes to prevent water inflow at the interface between the plastic box and the concrete.
- Special socket accessible by the intrados of the segment, to perform the inflation of the O-ring device by cement grout injection (Figure 3).

2.2 Construction sequence of the O-ring tunnel lining

The peculiarities of ring assembly inside the shield and of tunnel lining completion are presented in this section. This study considers the Double-Shield mode for the TBM.

2.2.1 Ring-building phase

After removing the protection layer, segments are ready to be installed. The ring-building procedure is the same of standard rings. Particular attention must be paid to avoid bumps and to limit misalignments. The spearbolts at longitudinal joint must be installed and fastened.

2.2.2 Ring exiting the tailshield

As TBM advances, the O-ring deflates and swipes outside the shield without colliding with tail brushes (Figure 4a).

Figure 2. Insertion of O-ring box inside formworks and reinforcement cage (source: Optimas).

Figure 3. Detail of O-ring sealing system injection socket.

Backfilling injection is stopped on the standard ring before the O-ring guaranteeing an empty annular gap, necessary for the sealing bag inflation.

2.2.3 O-ring inflation

Once the O-ring has completely exited the tailshield, the TBM advancement is stopped, and the O-ring inflation can start (Figure 4b).

First, the inflatable bags are filled with a controlled-pressure cement grout injection (< 3 bar) performed segment by-segment, starting from the invert up to the crown.

Once the complete O-ring has been partially filled with cement grout, a second round of injection is performed to ensure the complete bag extension and the

radial loading of the O-ring. The pressure is limited to 5 bar to avoid local overloading on the tunnel lining. Spear-bolts at longitudinal joints guarantee sufficient shear resistance to sustain punctual loads produced by localized injection pressures.

2.2.4 Completion of annular gap backfilling

After the minimum required curing of the cement grout inside the inflatable bags, the TBM advance can restart, and, in parallel with it, the concurrent backfilling injection performed through the tailshield. This operation must be performed avoiding excessive injection pressure (Figure 4c).

To seal the annular gap all around the O-ring and to provide a regular lateral support, secondary backfilling injections are performed upstream and eventually downstream of the inflated water barrier (Figure 4d).

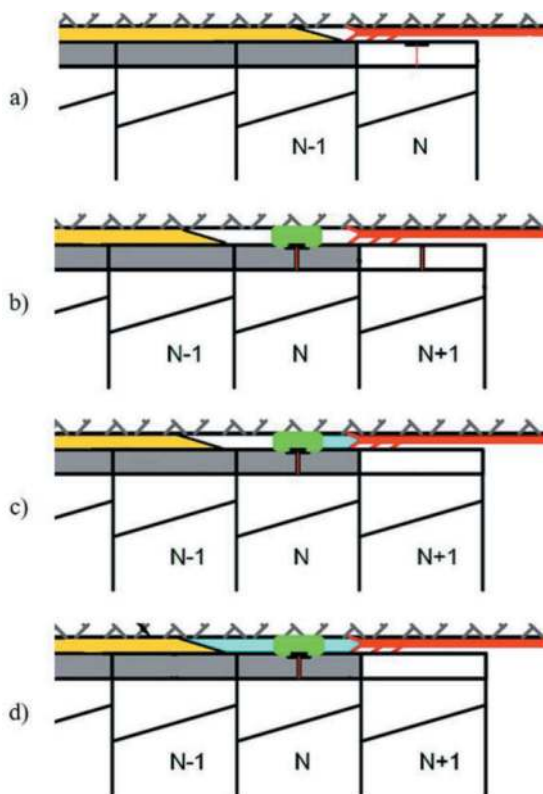

Figure 4. O-ring building and injection phases.

3 STRUCTURAL MODELLING OF O-RING TUNNEL LINING

A numerical study has been performed to simulate the structural behaviour of segments equipped with O-ring sealing devices.

A 3D FE model (Figure 5) has been developed using the software Strand7 (produced and distributed by Strand7 Ltd, Australia). A portion of the tunnel with a length equal to four consecutive rings (each made up of six segments) is implemented. The segments are modelled using 2D plate elements whose main characteristics are described hereafter:

- Dimensions: 0.14 x 0.15 m
- Thickness: 0.3 m
- Thickness at O-ring recess: 0.245 m (green)
- N° of plate elements per ring: 1728.

To consider the actual geometry of the tunnel, each ring is rotated of 30° compared to the previous one. The material behaviour of concrete has been considered as linear elastic.

Figure 5. Overview of the adopted 3D model.

3.1 Longitudinal joint behaviour assumptions

Particular attention has been given to the modelling of longitudinal joints; the dimensions of the contact are 185mm x 1650mm (Figure 6).

Figure 6. Contact area at longitudinal joints.

The surface of longitudinal joints is modelled adopting *point contact elements* with high axial stiffness acting only when subjected to compressive stresses. As shown in Figure 7, each *contact element* (red) is connected to the ring element *plate* by means of a series of *rigid links* (cyan).

The stiffness for each contact element in the joint has been considered as follows:

- Young's modulus of concrete: $E_{cm}=39941$ MPa
- Area of contact zone: $A=3.05 \times 105 \text{mm}^2$
- N° of joint links: $n_1 = 13$
- N° of elements per joint link: $n_c = 18$
- Reference length: $L = 300$ mm

Figure 7. Detail of longitudinal joints modelling.

The reference length (L) has been set equal to thickness of the segmental lining. The overall stiffness of the longitudinal joint has been estimated as:

$$k_{TOT} = \frac{E_{cm}A}{L}$$

Hence, the specific stiffness for each contact element:

$$k_{i,FEM} = \frac{k_{TOT}}{n_l \cdot n_c}$$

3.2 Circumferential joint behaviour assumptions

The contact zone between adjacent rings is characterized by the presence of five packers made of PP plastic material. Packers are modelled as *connection elements* whose behaviour has been defined considering the following parameters:

- Packer length: $b_p=450\text{mm}$
- Packer height: $h_p=170\text{mm}$
- Packer thickness $t_p=2\text{mm}$
- Area of each packer: $A=7.65 \times 10^4 \text{mm}^2$
- Young's modulus of packer: $E=200 \text{MPa}$
- N° of packers per joint $n_p=5$

The overall axial and tangential stiffness for each packer has been set equal to:

$$k_{p,Axial} = E_m \cdot A_p / t_p$$

$$k_{p,Tang} = 0.4 \cdot k_{p,Axial}$$

Considering $n^{\circ}=5$ packer for each contact area, the overall coupling stiffness for each ring corresponds to:

$$K_{Axial} = n_{Segm} \cdot n_p \cdot k_{p,Axial}$$

$$K_{Tang} = n_{Segm} \cdot n_p \cdot k_{p,Tang}$$

From these values, the stiffness of each connection element included in the model has been defined dividing the stiffness of the ring joint contact area by the number of elements connecting one ring to the adjacent one ($n_{cp} = 120$ - Figure 8).

Figure 8. Connection element for friction coupling at ring joint.

3.3 Connector behaviour assumptions

Longitudinal connectors between rings have been modelled using *connection elements* (Figure 9).

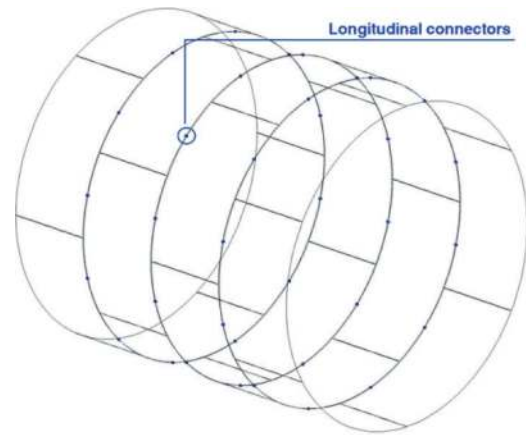

Figure 9. Connection element for longitudinal connectors.

To define the actual behaviour of longitudinal connectors, the *connection elements* have been provided with the constitutive law (shear force-displacement and pull-out force-displacement) provided by the connector supplier.

3.4 Boundary conditions

The rock-structure interaction has been considered by means of spring acting perpendicularly and tangentially to the lining surface. Radial springs have been considered with a non-linear behaviour, working only when in compression. Tangential bedding is coupled to radial one and they both deactivate simultaneously as the interface of the lining develops inwards displacement.

The stiffness of boundary springs has been evaluated in relation with rock and backfilling elastic modulus.

When bicomponent as backfilling material is applied, an extended approach is used based on a layered ground model. With this approach the annular gap and the surrounding ground are treated as an individual equivalent layer.

$$k_R = \frac{1}{\frac{d_{ag}}{E_{s,ag}} + \frac{d_{rm}}{E_{s,rm}}}$$

$$k_T = 0.4 \times k_{r,3h}$$

Where:

- k_R : radial bedding modulus [MPa/m]
- k_T : tangential bedding modulus [MPa/m]
- d_{ag} : average width of the annular gap [m]
- d_{rm} : influence depth of the rock mass [m]
- $E_{s,ag}$: constrained modulus of backfilled material [MPa]
- $E_{s,rm}$: constrained modulus of the rock mass [MPa]

According to bicomponent grout supplier, the following E-modulus – time law has been considered for the definition of the E values at the relevant time stages considered in the design of segments.

Figure 10. E-modulus-time law for bicomponent grout.

4 DESIGN SCENARIOS FOR O-RING TUNNEL LINING

O-ring tunnel segments follow a different installation procedure compared to the standard ones and the main differences are due to inflation sequence of the O-ring system. In fact, to allow proper expansion of the inflation bag, continuous injection of the bicomponent through the TBM shield must be temporarily stopped. In the time interval between stopping injection through the shield, and O-ring inflation, the O-ring is not supported by the rock mass as the annular gap is not filled.

The following paragraphs describe what are the boundary conditions and load assumptions considered to properly evaluate the expected structural behaviour of the O-ring segments at early stages.

It is noted that once the annular backfilling completion occurs, the behaviour of O-ring segments is

practically comparable to the one expected for standard segments. The recess hosting the inflatable sealing shall in any case be considered when design verifications are carried out.

4.1 External loads

The design load and boundary conditions expected to occur during O-ring installation, mainly due to the TBM operational special sequence, are accompanied together with loads referred to the external environment in which the tunnel will be executed.

Here is a summary of the remaining external loads that have been considered for the design of the O-ring segments.

[G1] Self Weight

The self-weight of the structure is automatically applied by the software based on:

- Volume of elements
- Specific weight of concrete $\gamma_C=25\text{kN/m}^3$

[G2] Bi component

This load considers the weight of the bicomponent grout that will be injected within the annular gap between the tunnel ring and the external rock mass. This load is defined assuming:

- Specific weight of grout $\gamma_G=12.6\text{kN/m}^3$
- Annular gap thickness: $t=0.19\text{m}$

The bicomponent self-wight has been applied as a vertical distributed load (Figure 11), varying linearly from a maximum value at the key of the ring, to a null value at level of tunnel longitudinal axis.

Figure 11. Bicomponent weight application.

[G3] Rock Wedge collapse

To simulate the effects of the geotechnical load expected in the region where the O-ring segments will be installed, it is assumed the weight of a triangular shaped rock wedge with a height equal to the

excavation diameter. The pressure due to wedge collapse has been calculated considering a specific weight of the rock equal to $\gamma_R=27\text{kN/m}^3$. The load has been applied to the FE model (Figure 12) throughout a distributed pressure with a triangular shape that has its peak at the key section in a way to generate a vertical force that is equal to the weight of the design rock wedge ($F=973\text{ kN}$).

Figure 12. Rock wedge load calculation and application.

[Q01/a] Temperature Load

Winter and summer characteristic temperature loads have been defined considering two scenarios, both in permanent and transient conditions, varying the temperature of the rock mass between the values $T_{\text{Rock}} = +4 - +12^\circ\text{C}$.

To define both uniform and variable temperature load, the initial value that defines the temperature of segments during installation has been set equal to $T_0 = +10^\circ\text{C}$.

The temperature of the internal environment has been set instead equal to:

Figure 13. Temperature load.

4.2 Ring exiting the tailshield

Once the O-ring segment is about to exit the TBM shield, bi-component grout injection is stopped. At this stage, the annular gap is effectively filled only at the rings that precedes the O-ring. Most likely, also part of the annular gap at O-ring will be filled with grout, but on the safety side, it has been chosen to neglect the eventual partial bedding that will generate at O-ring.

Hence, the following boundary conditions has been considered:

- Radial and tangential bedding at the two segments that precede the O-ring segment.
- Bedding stiffness is defined assuming the E modulus of the bi-component grout at $t=3\text{hr}$, $E(t=3\text{h})=50\text{MPa}$. The associated stiffness is computed by implementing the formulation shown in §4.4.

Also TBM rams forces are considered by means of a distributed pressure acting at the ring joint of ring installed after O-ring segments still placed within TBM shield.

The value of this pressure is defined assuming that the TBM thrust is operating in double shield mode $F_{\text{Nom,DS}} = 8\text{ MN}$.

Within this configuration (Figure 14), in addition to the structural self-weight, the possibility of a rock wedge acting right above the O-ring ring and the previously installed one is considered, while the bicomponent self-weight has been simulated as acting only on the rings that precedes the O-ring.

$$p = \frac{F_{\text{Nom,DS}}}{t \cdot Cr_f} = 1.32\text{ MPa}$$

Figure 14. Overview of O-ring segments exiting TBM shield.

4.3 O-ring inflation

Once the O-ring segments have exited the TBM shield, the sealing device inflation takes place. In this stage the boundary conditions and the restrains applied to the model remain unvaried compared to the previous stage.

In addition to the boundary conditions and loads described in the previous paragraph, a radial pressure of 3bar is applied to the lower half of the ring to simulate the first step of the sealing device inflation.

The radial pressure is applied only to the central portion of the ring (Figure 15), where the sealing device will be located ($\approx 300\text{mm}$).

Figure 15. O-ring inflation 1st step.

The second step of the inflation sequence is modelled with a pressure applied to the entire area, all along the ring circumference, occupied by the sealing device ($\approx 300\text{mm}$), and the value is set equal to 5bar.

Also in this second and final step of the inflation sequence, the boundary conditions as well as the external loads remain unvaried compared to the ones illustrated in the previous paragraph.

Figure 16. O-ring inflation 2nd step.

4.4 Asymmetric water load during service phase

Due to the water flow-limiting behaviour of the O-ring sealing device, it may occur that the water

pressure acting at one side of the O-ring segment may differ from the value acting at the opposite side. Hence, this eventuality has been simulated by applying a differential water pressure to the FE model. The value of the differential water load has been estimated considering the maximum overburden level variation Δz that has been encountered within the distance at which to consecutive O-ring segments will be installed. The load is applied to the model considering the water pressure associated with the recorded overburden variation $w = \Delta z \times \gamma_w$ on the elements that precedes the sealing device, while no load is applied to the remaining portion of the model.

Figure 17. Asymmetric water load in service phase.

5 STRESS STATE IN O-RING TUNNEL LINING

Aim of this section is to describe what are the results obtained from the performed FE analysis.

It is noted that the scenario related to the O-ring exiting from the tailshield represents the decisive one with regards to the design amount of reinforcement. This is mainly due to the lack of confinement that occurs on the ring due to the void located within the annular gap. While on one side, the flexural request is very similar to the one registered in standard segments where radial bedding is active, the axial force registered within the ring is significantly lower, leading to a higher demand of reinforcement aimed at fulfilling all relevant sectional verifications.

The following Figure 18 and Figure 19 show the recorded contour of internal forces. It is noted that, due to the presence of the recess hosting the O-ring sealing, reinforcement design and verifications are carried out also with regards to the longitudinal direction (parallel to tunnel axis).

Once the inflation of sealing device takes place, when the inflation pressure (5bar) is acting on the entire ring, a significant increase of flexural demand is recorded in the longitudinal direction (yy) at the crown area, due to simultaneous presence of the inflation pressure and the rock wedge load.

These scenarios referred to the early stages during the ring installation phase are the decisive ones with

Figure 18. Contours of bending moment when O-ring segments exit the tailshield.

xx: circumferential direction.

yy: longitudinal direction.

Figure 19. Contours of bending moment at the final step of the O-ring sealing inflation.

xx: circumferential direction.

yy: longitudinal direction.

regards to the reinforcement amount O-ring segments need to be provided with. The FE analysis results and the design verifications that have been carried out show that the critical section is in the key segment.

The M-N interaction domains shown in Figure 20 and Figure 21 referred to the O-ring section show the ULS verifications for the most critical investigated scenario.

The decisive case with regards to circumferential reinforcement is referred to the exit from the TBM shield. Once the inflation of the sealing device starts, the progressive increase of axial forces shifts the design M-N values towards the centre of the section M-N interaction domain, identifying a less demanding scenario. It is also observed that after the annular gap backfilling completion, mainly due to the stiffer support given by the surrounding environment, the recorded internal forces are again less demanding compared to the very early stages after ring assembly. The verification of the O-ring key section in ULS condition are shown in Figure 20, referring to circumferential direction ($N_{xx} - M_{xx}$).

With regards to the longitudinal direction (*yy*), the decisive scenario is recorded during the last inflation step, when the 5bar pressure is acting on the entire ring. The verification of the O-ring key section in ULS condition are shown in Figure 21, referring to circumferential direction ($N_{yy} - M_{yy}$).

Figure 20. Verification of circumferential reinforcement.

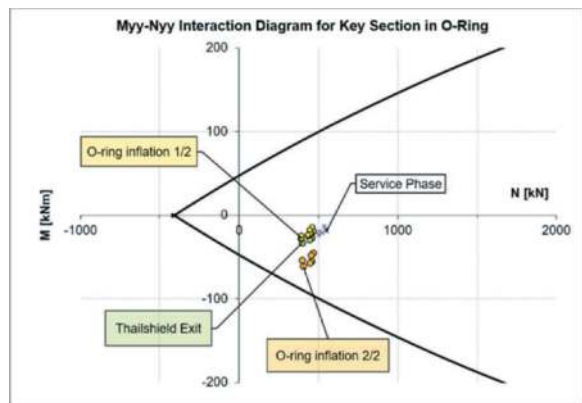

Figure 21. Verification of longitudinal reinforcement.

6 CONCLUSIONS

This article proposes a numerical modelling approach able to simulate the stress state acting within O-ring segments, which are assembled in a double shielded TBM.

Loads and constrain configurations have been implemented in the FEM model thanks to a meticulous study of the design scenarios, especially referring to the assembly sequences of rings equipped with O-ring type hydraulic sealing system.

The outcomes of the analyses show how these configurations are significantly critical and, in some cases, even dimensioning with regards to the design reinforcement.

The mechanism, functioning and installation of reinforced ribs of shotcrete in Norwegian Method of Tunnelling (NMT)

Rajinder Bhasin* & Mahdi Shabanimashcool

Norwegian Geotechnical Institute, Oslo, Norway

ABSTRACT: One of the key components of rock support in the Norwegian Method of Tunnelling (NMT) is the application of reinforced ribs of shotcrete (RRS) in tunnels. This basically comprises of six rebars with a center to center spacing of 10 cm mounted to rock bolts along the tunnel periphery and covered with sprayed concrete. During the last 25 years or so RRS has in many cases been installed in Norwegian tunnels instead of the in situ cast concrete arches (CCA) and heavy steel ribs. CCA was the common rock support in extremely and exceptionally poor rock masses when the rock mass quality Q was very low. RRS is in shape and support capacity similar to sprayed lattice girders but is more flexible in application because RRS is not prefabricated. In most cases RRS has been installed without any analysis of the support pressure or calculations of its capacity. RRS is considered to function as an active support which is in intimate contact with the rock mass and held in place through closely spaced rock bolts at 1m c/c spacing. It is envisaged that the bolts holding the RRS do not have any effect on load, shear force and bending moment distribution in RRS and that they only guarantee full contact of RRS with the rock mass. Thus, RRS functions as a liner element and behaves like a beam element which is in contact with the rock mass. This paper attempts to explain the mechanism of RRS and describe in detail its functioning & installation as a flexible rock support system. Some experimental and numerical results from literature on the behaviour of RRS are highlighted.

Keywords: Rock Support, Shotcrete, Reinforced Ribs of Shotcrete, Norwegian Tunnelling Method

1 INTRODUCTION

The Norwegian Method of Tunnelling (NMT) is a well-known underground construction technique that effectively minimizes the use of concrete and thereby contributes to reducing the production of CO₂ (Barton, 2017). NMT is emphasised by its single shell characteristics and differs from the conventional double shell New Austrian Tunnelling Method (NATM). In Norway alone more than 7000 kilometres of tunnels including hydropower, road and rail tunnels have been constructed using Norwegian Tunnelling Technology. The NMT method is considered safe, cost-effective & time saving. In addition to Norway, this tunnelling technology has been successfully adopted in various parts of the world including Korea, India and Sweden. This paper describes in general the design and installation of rock support according to NMT Principles. Emphasis is placed on reinforced ribs of shotcrete (RRS) which has revolutionized the installation of rock support in weak rock masses. RRS has for all practical purposes replaced cast concrete arches (CCA) and steel ribs in incompetent rock masses where the rock mass quality 'Q' characterised with the Q-system of rock mass classification is very poor to exceptionally poor (Barton et al, 1974, NGI 2017).

2 DOCUMENTATION AND OBSERVATIONS DURING UNDERGROUND EXCAVATION IN NMT

During underground excavation in Norwegian tunnels, it is very important to have a close visual inspection of the rock surface in the whole tunnel periphery before the rock is covered by sprayed concrete (NPRA, 2020). In addition to the visual observations, hammering with a scaling rod or a hammer will give important indications of deterioration of unstable rock giving particular sounds. Small cracks, invisible from the invert, can be observed with a closer look. It is important to have access to the face and crown by utilizing lifting equipment especially designed for this purpose. Rock mass stability is influenced by several parameters, but the following three factors are the most important as described in the Q-system of rock mass classification (see for e.g. NGI, 2017):

- Degree of jointing (block size): RQD/Jn
- Joint friction: Jr/Ja
- Stress: Jw/SRF

In hard rocks, deformations usually occur as shear displacements along joints. The friction along the joints will therefore be significant for rock mass

*Corresponding author: rkb@ngi.no

stability. Joint friction is dependent on joint roughness as well as thickness and type of mineral fillings. Very rough joints, joints with no filling or joints with only a thin, hard mineral filling will be favorable for stability. On the other hand, smooth joint surfaces and/or a thick filling of soft minerals will result in low friction and poor stability. In soft rocks where deformation is less dependent of joints, the joint friction factor is less significant.

The vertical stress in a rock mass commonly depends on the depth below the surface. However, tectonic stresses and anisotropic stresses due to topography can be more influential in some areas. This also applies for residual stresses inherent in some rock masses. Stability of the underground excavation will generally depend on the stress magnitude in relation to the rock strength. Moderate stresses are usually favorable for stability, and low stresses are often unfavorable. In rock masses intersected by zones of weak mineral fillings such as clay or crushed rock, the stress situation may vary considerably within relatively small areas. Experience from tunnel projects in Norway has shown that if the magnitude of the major principal stress approaches about 1/5 of the compressive strength of the rock, spalling (strain bursting) may occur (NPRA, 2020). When tangential stresses exceed the magnitude of the rock compressive strength, squeezing may occur. In other words, the anisotropy of the rock mass plays an important role when designing rock support.

2.1 Application of Q-system to determine rock support

Q-value and the six appurtenant parameter values give a description of the rock mass. Based on documented case histories a relation between the Q-value and the permanent support is found which can be used as a guide for the design of support in new underground projects. In addition to the rock mass quality (the Q-value) two other factors are decisive for the support design in underground openings and caverns. These factors are the safety requirements and the dimensions, i.e., the span or height of the underground opening. Generally, there will be an increasing need for support with increasing span and increasing wall height.

Safety requirements will depend on the use (purpose) of the excavation. A road tunnel or an underground powerhouse will need a higher level of safety than a water tunnel or a temporary excavation in a mine. To express safety requirements, a factor called ESR (Excavation Support Ratio) is used (Barton et al, 1974, NGI, 2017). A low ESR value indicates the need for a high level of safety while higher ESR values indicate that a lower level of safety requirement. The safety requirements and building traditions in each country may lead to different ESR-values than those given in a table in the Q-system.

The Q-value and the Equivalent dimension will be decisive for the permanent support design. In the support design chart shown in Figure 1, the Q-values are plotted along the horizontal axis and the Equivalent dimension along the vertical axis on the left-hand side. The support chart gives an average of the empirical data from examined cases. For a given combination of Q-value and Equivalent dimension, a given type of support has been used and the support chart has been divided into areas according to type of support. Note that the chart is not divided into definite support classes but shown as a continuous scale both for bolt spacing and thickness of sprayed concrete.

As the support chart is based on empirical data, it is able to function as a guideline for the design of permanent support in underground openings and caverns. The support chart indicates what type of support is used in terms of the center to center spacing for rock bolts and the thickness of sprayed concrete (shotcrete). It also indicates the energy absorption of the fibre reinforced sprayed concrete, as well as the bolt length and design of reinforced ribs of sprayed concrete. Support recommendations given in the chart are general. In especially difficult cases, an increase in the amount or type of support may be relevant.

The thickness of the sprayed concrete increases towards decreasing Q-values and increasing spans, and lines are drawn in the support chart indicating thicknesses. For positions between these lines the thicknesses will have an intermediate value. If deformation occurs, for instance caused by high stresses, reinforced concrete should be used in all categories.

Figure 1. Rock mass quality Q related to the rock support requirements (NGI, 2017).

The length of the rock bolts depends on the span or wall height of the underground opening and to some degree on the rock mass quality. Recommendations for bolt lengths are given on the right-hand side of the diagram, but some evaluation is necessary. In unfavorable joint geometry, longer bolts than recommended in the diagram will be necessary, and there is also a general need for increasing bolt length by decreasing Q-value.

3 ROCK SUPPORT IN TUNNELS USING RRS

As mentioned in the previous section, rock support with reinforced ribs of sprayed shotcrete (RRS) arches has in many cases replaced the more traditional full cast concrete arches (CCA). This solution saves both time and costs. Reinforced ribs of shotcrete (RRS) must always be combined with bolts that are distributed throughout the arch. Normally, the distance between the installed bolts in the arch should be about 1.5 meters. The bolts should be long enough to be included as part of the rock support system. Figure 2 shows the principle of construction of RRS.

Figure 2. Principal of construction of RRS (NGI, 2017).

An important prerequisite for using RRS is proper workmanship and good quality control. When the sprayed concrete arches are subjected to heavy loads, the reinforcement will begin to act gradually as the deformations increase. The reinforcement in the arches should prevent further deformation. It is therefore important that the number of rebars in each section of RRS and the thickness and width of the sprayed arches are dimensioned in relation to the expected load on rock support. Normally, Ø20 mm rebars are used as they can be shaped according to the tunnel profile.

3.1 Installation of RRS

To ensure the best possible arch effect, the tunnel profile should be levelled with sprayed shotcrete. In poor rock conditions where RRS is to be installed, the theoretical profile is usually over excavated by around 30-60cm compared to the normally excavated profile. If necessary, scaling of rock is performed in a very careful manner. Normally a first layer of fibre reinforced shotcrete is sprayed up to a thickness of about 15-25 cm depending upon the rock mass quality followed by spraying a second layer of shotcrete without fibres to make the surface even for installation of rebars for RRS. The sprayed section must be at least 70 cm wide to accommodate the six rebars that shall be installed. In Norway it has been most common to use 6 pieces of 20 mm diameter rebars in each arch, mounted with crossbars of 40 cm to 60 cm (see Figure 2).

A crossbar is attached to the radial bolts, for example by drilling holes in the crossbar that is threaded onto the bolt and fastened with a screw and nut. The reinforcement is thus clamped behind the crosspiece, which can advantageously have notches or grooves for the rebar. Jointing of the rebars

should be carried out with overlap behind the transverse irons. Figure 3 shows the installation of RRS near the face of a tunnel in the North of Norway. Note that the face of the tunnel is supported by shotcrete and bolts due to poor rock mass quality.

Figure 3. RRS installed close to the face of a tunnel where the tunnel face is also supported by bolts & shotcrete.

A fused construction of sprayed concrete arches can be constructed for increasing the capacity of RRS by mounting several rebars in several layers, increasing the thickness of the arcs and reducing the distance between the arches (NPRA, 2020). A third layer of shotcrete is then sprayed

without the fibres to cover the reinforcement. The total thickness of shotcrete including the second and third layer is approximately 30 cm.

Figure 4. Mounting of rebars in several layers (double RRS) and radial bolts (Adapted from NPRA, 2020).

Figure 5 Shows the pipe umbrella roof system which was erected in a tunnel before installation of double RRS (see Figure 4) in very poor rock masses in the North of Norway. The pipe umbrella (12-15 meter in length) was implemented as pre-support to increase the stability of the tunnel and to decrease the risk of surface subsidence induced by tunnelling in the prevalent weak rock masses (disintegrated rock) at the section. The pipe roofing system consisted of 114 mm diameter pipes with a 3 m overlap. The working face of this tunnel was supported by supported by 32 mm dia. and 12 m long bolts which were sheared off after every excavation sequence and fastened with new bolt plates. The spacing of the RRS is about 1.5m along the length of the tunnel.

Figure 5. Pipe roofing prior to the installation of double RRS.

4 FUNCTIONING OF RRS

It is widely believed that RRS functions as an active support and is not passive in nature. This is due to the fact that RRS is in intimate contact with the rock mass and held in place through closely spaced rock bolts at 1.0-1.5m c/c spacing. It is envisaged that the bolts do not have any effect on load, shear force and bending moment distribution in RRS, they only guarantee full contact of RRS and rock mass. Keeping the above facts in mind, RRS will function as a liner element in this situation. This means that it will behave like a beam element which is in contact with the rock mass.

In most of the cases where RRS has been installed, it has served the purpose of supporting the rock mass. However, the exact bearing capacity and the behaviour of RRS under various loading conditions is still not well understood. Although RRS has been instrumented in a number of tunnels (see Figure6) to obtain information on the axial forces and strains in the rebars, the gathered data shows insignificant stresses and strains in RRS. This may be due to the fact that the instrumented sections did not have high overburden or that the rock support was overdesigned meaning that RRS was not necessary.

Figure 6. Instrumentation of RRS (photo: NGI).

Another reason why small loads and strains are recorded during instrumentation can be due to the fact that the location of rebars in RRS may not be appropriately located in the existing design cross-section (see Figure 2). It may be noticed that in the current design of RRS, as shown in Figure 2 the rebars are located in the outer side of the whole section comprising of the liner element. It is possible that this reinforcement should be placed in both the inner and outer part for better functioning. This issue has recently been investigated by researchers in South Korea which is described in the section underneath.

4 EXPERIMENTAL AND NUMERICAL STUDIES

Various researchers (e.g. Yu et al, 2016) have carried out experimental and numerical studies on studying the behaviour of RRS. Their results have indicated that placing the reinforcement bars at the bottom of the cross-section has no significant effect on improving the load-carrying capacity compared to a beam made of fibre reinforced shotcrete only.

The researchers performed numerical experiments on various types of shotcrete liners (see Figure 7). Prior to performing numerical analysis, they validated their numerical model with experiments results. The numerical model was implemented by OpenSees, which was developed by University of California to simulate the seismic response of structural and geotechnical systems.

In the numerical experiments it was shown that the peak load of the section B was slightly higher than that of A by approximately 1.5%. This means that reinforcing the rebar at the bottom of the cross-section has no significant effect on improving the load-carrying capacity. Compared with the post-peak load-displacements values, it is found that the supporting effect of C is superior to other cross sections.

Their overall results indicated that behaviors of the shotcrete lining based on the configuration of reinforcements show a significant difference. The maximum load-carrying capacity of the liner with doubly reinforced cross-section increases by

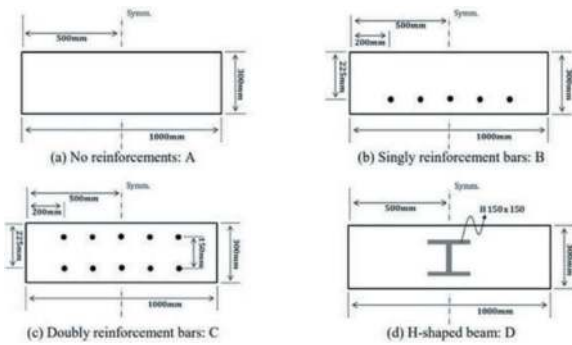

Figure 7. Cross-section of shotcrete liners, A: shotcrete only, B: singly reinforced bars, C: doubly reinforced bars, and D: H-shaped support (Yu et al, 2016).

10.21% when compared with the liner without reinforcements. Beyond the peak load, all the cases shown in could resist load softening (see Figure 8). Among them, however, the doubly reinforced cross-section shows the most supporting effects (in particular for the post-peak region) while the singly reinforced cross-section has almost no improvement. From the results of load-displacement curves, steel rebar type could be used as an alternative the previous steel reinforcement types such as H-shaped beam and lattice girder.

Figure 8. Load-displacement response of shotcrete with and without reinforcement (Yu et al, 2016).

What's important to remember is that the design of the structure is based on having the steel in the right place. Incorrect reinforcing steel placement can and has led to serious concrete structural failures. For example, lowering the top bars or raising the bottom bars by $\frac{1}{2}$ inch more than that specified in a 6-inch-deep slab could reduce its load-carrying capacity by 20%.

Steel reinforcing bars and welded wire reinforcement should be positioned in the upper third of the slab thickness because shrinkage and temperature cracks originate at the surface of the slab. Cracks are wider at the surface and narrow with depth.

5 CONCLUSIONS

This paper has described one of the key components of the Norwegian Method of Tunnelling (NMT), which is the application of Reinforced Ribs of Shotcrete (RRS) as rock support in tunnels. RRS has practically replaced cost expensive cast concrete arches (CCA) and steel ribs as rock support in tunnels. One major advantage of RRS is that the reinforced ribs are in close contact with the rock mass and there is no gap or shadows formed between the final lining and the rock mass. This helps to avoid unwanted differential deformations around the periphery of the tunnel that may occur due to potential gaps between the final lining and the rock mass. Pre-spraying of shotcrete for immediate support helps to retain the self-bearing capacity or the inherent strength of the rock mass. In the cases where RRS are used, it is important to first utilise fibre reinforced sprayed concrete (Sfr) before applying a second smoothing layer of shotcrete without fibres. A guideline for use of RRS in relation to Q-values and equivalent dimension of the underground opening is given in the support chart of the Q-system (NGI, 2017).

ACKNOWLEDGMENTS

The authors acknowledge the support and literature utilised from the Norwegian Public Roads Administration (NPRA) and the Norwegian Tunnelling Society (NFF) for preparing this manuscript. The authors are also thankful to their colleague Dr. Pål Drevland Jacobsen for making arrangement for the tunnel site visit where double RRS were erected.

Shotcrete structural behaviours as tunnel support in hard jointed rocks – Swedish state of the art

Yanting Chang*

Geton Consulting LTD, Stockholm, Sweden

Christian Höök

Sweco Sweden LTD, Gothenburg, Sweden

ABSTRACT: Shotcrete has been used as a tunnel support element in Sweden since 1960's. Intensive research work and engineering practise have been conducted. This paper presents the “state of the art” regarding the understanding of shotcrete structural behaviours, design guidelines and application requirements for underground engineering in Sweden.

Keywords: Shotcrete, Tunnel support, Structural behaviours, Jointed rocks

1 INTRODUCTION

Shotcrete has been used as tunnel support element in Sweden since 1960's and steel fibre reinforced shotcrete was introduced in the beginning of 1980's. Since 1980's comprehensive research works have been conducted to enhance the understanding of the shotcrete support mechanisms for jointed rocks. These studies have been aimed on shotcrete properties, mixing procedures, interactions between rock and shotcrete, long term durability, fire resistance etc. Based on the results of the research work, design guidelines and performance requirements including materials, mixing procedures, on-site testing, quality controls etc. have been developed for underground engineering structures.

This paper will present the major research results on shotcrete structural behaviours as well as the state of the art regarding design guidelines and requirements of shotcrete applications in Sweden.

2 SHOTCRETE STRUCTURAL BEHAVIOUR

Hard jointed rock conditions are often encountered in Sweden for constructions of underground structures, where rock blocks or loosening rock pieces are of major concerns. The load-bearing mechanism of a shotcrete layer applied to rock blocks has been studied, for example by Holmgren (1979, 1985) with punch load tests as shown in Figure 1. Three stages

of support effects of a shotcrete layer under a punch load were identified (see Figure 2):

- Adhesion resistance,
- Bending resistance, and
- Membrane resistance.

Figure 1. Set-up of the punch load test (after Holmgren, 1979).

The conducted studies in Sweden have resulted in the following significant findings:

- Shotcrete layers applied to jointed rock conditions have distinguished behaviours compared to shotcrete linings in soft rock conditions. For instance, adhesion between rock and shotcrete has essential importance for the shotcrete support functions in hard jointed rock conditions. As

*Corresponding author: yanting.chang@geton.se

Figure 2. Failure modes of shotcrete subjected to block load (after Holmgren, 1979).

shown in Figure 2, the adhesion determines the maximum bearing capacity of the shotcrete layer,

- Steel fibres mixed in shotcrete have significant effects for bending and membrane resistances. Steel fibres will increase the residual flexural strength of shotcrete, making it ductile, which is essential for avoiding sudden failure of shotcrete,
- Hardening time of shotcrete shall be considered in rock excavation planning. If rock excavations resume short after shotcreting, the risk for damages in shotcrete because of early loadings will be relatively high (Chang, 1992, 1994; Ansell, 2019).
- Unevenness /irregularities of tunnel surfaces do not have adverse effects on the overall bearing capacities of shotcrete. In contrast, the unevenness /irregularities would enhance the overall bending capacity of shotcrete.

More details of the above findings are briefly presented as follows.

2.1 Adhesion between rock and shotcrete

Investigations of the adhesions for different rock types have been conducted during 1970's and 80'. The typical results for different rock types are shown in Table 1 (Hahn, 1983).

The investigation results show that the adhesion has significant variations depending largely on

- Rock types,
- Cleaning/washing of rock surfaces before shotcreting,
- Water leakages from rock surfaces,

Table 1. Typical results of adhesion with different rock types.

Rock Type	Grain size	Bond strength (MPa)	
		Smooth surface	Rough surface
Shale	Very fine grained	0.24	0.28
Lime stone-marlstone	Middle grained	1.49	1.89
Marble	Fine grained	1.38	1.52
Granite	Middle grained	1.04	1.40
Granite	Fine-middle grained	1.48	1.71

- Composition of shotcrete mixtures,
- Performance of shotcreting, e.g. angels and distances to rock surfaces.

The investigation results led to on-site quality controls by adhesion tests which are included in contractual documents for construction of underground structures.

2.2 Steel fibres in shotcrete

For investigating the effects of steel fibres, laboratory bending tests have been conducted and results show that the shotcrete bearing capacities in bending are largely dependent on the contents of steel fibres, see Figure 3. It is understandable that low fibre contents would cause low bending capacities, while too high fibre contents would lead to unsatisfactory bending the shotcrete mixtures, consequently poor bending capacities as well.

Figure 3. Steel fibre content and shotcrete bending capacity.

To ensure the required bearing capacities in underground structures, construction contractual documents include the clauses that pre-testing of flexural strengths shall be performed with different shotcrete mixtures and fibre contents. The approved shotcrete recipe including fibre contents shall not be

changed during construction phases without approval by the client.

2.3 Effects of shotcrete hardening

After shotcreting the shotcrete will be subjected to so called hardening process, i.e. the stiffness, strength and adhesion are increasing with time. Typical data collected from other countries for compressive strength and adhesion are shown in Figure 4 (Chang, 1994) and Figure 5 (Ansell, 2019). The factors to the strength variations are cement qualities, additive types and amounts, temperatures etc for the sample preparations.

Figure 4. Development of compressive strength with time (based on data from literatures, Chang, 1994).

Figure 5. Development of adhesion strength with time (Ansell, 2019).

Blasting is the common method for rock excavations in Sweden and often performed nearby young shotcrete. Studies have been conducted to increase the knowledge on how the shotcrete is affected by the vibrations from blasting (Ansell, 2019).

These time-dependency phenomena have been taken into consideration in construction contractual documents. Under certain critical conditions, maximum allowed vibrations from blasting are specified, or mechanical excavation methods e.g. wire cutting or drill/ split are required.

2.4 Effects of unevenness of rock surfaces

All the theoretical calculation models for shotcrete layers are based on ideal dimensions and geometries. Questions have been raised about how the excavated tunnel surfaces with unevenness/irregularities affect the bearing capacity of shotcrete. Studies have been conducted to investigate the issues by laboratory model testing and numerical models (Chang, 1994; Chang et al 1995; Nilsson, 2003). The set-up of the laboratory models is shown in Figure 6.

Figure 6. Set-up of the test model (Chang, 1994).

The major findings from the studies are:

- The unevenness/irregularities of the tunnel surface do not have significant adverse effects on the overall behaviour of the rock-shotcrete interactions. In contrast, the overall bearing capacity of shotcrete in bending is enhanced by the unevenness/irregularities of the tunnel surfaces,
- Observations from the model tests show that the apexes are the weak points of the shotcrete so that cracks often occur first at the apexes. It should be noticed that local cracks in the shotcrete are unfavorable to shotcrete durability. Therefore, bolts should be placed at the apexes to enhance the bond between shotcrete and the rock surface (see Figure 7). This could be achieved by site engineers purposely locating the positions of the bolts at the apexes of the tunnel surface.
- Placing more shotcrete at the recess may reduce local stress concentrations. However, covering over-breaks with shotcrete is very costly and has no significant improvement of shotcrete bearing capacity. It is more important to ensure that the shotcrete layer has sufficient thickness covering the apexes,

Figure 7. Suggested placement of rock bolts (Chang, 1994).

- The fact that the unevenness and irregularities of tunnel surfaces would cause local cracking in shotcrete reveal the importance of the residual strength of shotcrete for reducing risks of progressive tunnel failures. This also show the importance of the steel fibres in shotcrete.

3 DESIGN OF SHOTCRETE SUPPORT

Rock supports for underground structures in Sweden are divided into two categories:

- Typical rock supports,
- Special rock supports.

Typical rock supports apply for the following conditions:

- Tunnel span is less than 20 m,
- Rock cover/overburden is larger than 1/2 of tunnel span,
- Normal stress conditions, e.g. tunnel depth is less than 100m,
- Rock quality expressed by Q-index > 1,
- No buildings or structures that could be affected by the underground structure,
- Normal hydrogeological conditions where risks for high water leakage are judged being low.

Special rock supports and excavation methods are regularly adopted for conditions such as low rock covers, weakness zones with poor rock or high risk for considerable water leakages.

Design guidelines of rock supports for underground structures have been developed by the Swedish Transport Administration (Trafikverket, 2019), based on the engineering experiences and research results during the past decades. The simplified design process is shown in Figure 8. It would be distinguished that the employment of the observational method is an essential part of the rock support design process to be able to manage the uncertainties regarding rock mass properties, geological features such as fracture systems and hydrogeological conditions etc. The on-site observations include geological mappings (obligatory), identifying potential instable rock blocks (obligatory), deformation monitoring, stress monitoring, notices of water leakages etc. It is

also worth to notice that risk management is involved throughout the whole process.

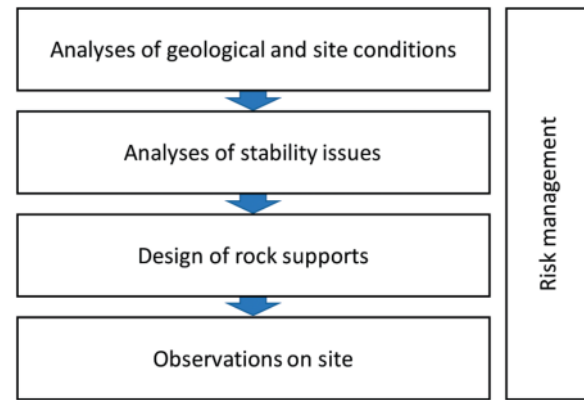

Figure 8. Simplified design process of rock supports (based on Trafikverket, 2019).

Geological conditions are investigated and commonly described in geological reports. Rock mass classifications are often carried out by using Q-index and RMR. One of the advantages with Q-index method is that rock supports can be estimated empirically, see Figure 9. Such empirical estimations are, however, often considered being on the safe side, which means that safety margins could be high, especially for hard jointed rock conditions. Another shortcoming of the empirical approaches is the lack of understanding for the interaction mechanisms between the shotcrete, bolts and rock mass.

Figure 9. Estimation of rock supports based on Q-index (NGI, 2015).

For the jointed rock conditions in Sweden, the rock support design is, therefore, generally based on the design situations as given as follows.

- Conditions with good adhesion
- Conditions with no adhesion
- Weakness zones with or without swelling materials.

For these design situations, the support mechanisms of shotcrete are different. The design

methodology for the above conditions is briefly described as follows.

3.1 Shotcrete support with good adhesion

For jointed rock conditions with acceptable adhesion between rock and shotcrete, rock blocks could be stabilised by shotcrete combined with spot bolting. The bearing capacity of the shotcrete is determined by (Trafikverket, 2019):

$$B = \sigma_{adh} \cdot d \cdot L$$

Where, B is shotcrete bearing capacity (kN); σ_{adh} is adhesion (kPa); d is bearing width (m); L is circumference of the block base (m), see also Figure 10.

Please note that the bearing width d is dependent on the thickness of shotcrete and can be determined by Table 2.

Figure 10. Design model for shotcrete support with adhesion (modified after Trafikverket, 2019).

Table 2. Shotcrete thickness and bearing width (Stille et al 1988).

Shotcrete thickness, t_c (mm)	Bearing width, d (mm)
40	25
60	30
80	35

During the design phases, the block sizes could be estimated by statistical analyses of geological data, e.g. joint spacing and persistence.

During construction phases, geological mapping is obligatory in Sweden and rock blocks can be identified by the geologists. Spot bolting is performed when necessary.

3.2 Shotcrete support without adhesion

For conditions where adhesion between rock and shotcrete is judged being inefficient, shotcrete layer will be designed with consideration of interactions with rock bolts. The bending capacity at the first crack is considered as the origin of the bearing

resistance of the shotcrete. The design model is shown in Figure 11.

Figure 11. Design model for shotcrete support without adhesion (modified after Fredriksson, 1995).

The bending capacity of the shotcrete can be determined by

$$M_b = f_{max} \cdot t_c^2 / 6$$

Where M_b is the bending capacity (kN-m/m); f_{max} is the flexural strength at first crack (kPa); t_c is shotcrete thickness (m).

The bending moments in the shotcrete depend on the loads from the rock block and bolt spacing. An estimation of the maximum bending moment in shotcrete can be done by Figure 12.

Figure 12. The maximum bending moment vs bolt spacing (modified after Fredriksson, 1995).

The design criterion is that the bending capacity M_b shall be higher than the bending moment cause by the rock block.

3.3 Shotcrete support for weakness zones

Weakness zones are often encountered, even in the hard and jointed rock conditions. The support of weakness zones is often a combination of shotcrete together with rock bolts. The design model for rock support is shown in Figure 13.

The loads from the weakness zone can consist of two parts, see Figure 13:

Figure 13. Support of weakness zone with shotcrete and bolts (modified after Holmgren, 1992).

- Weight of the losing material from the zone, W
- Swelling pressure from swelling minerals, P_{swell} .

The bending moment in the shotcrete can be determined by the theory of critical failure lines (Holmgren, 1992):

$$m = q \frac{S - 2e}{4} \cdot \frac{S + 2e}{4}$$

where m is the bending moment in shotcrete (kN-m/m); S is the bolt spacing (m); e is the distance from the bolts to the zone (m), q is the distributed load (kPa/m) on the shotcrete and is determined by

$$q = P_{swell} + W/b.$$

The bearing capacity of shotcrete determined by the formular in the previous section needs to be higher the bending moment given above.

4 MATERIAL AND SITE PERFORMANCE REQUIREMENTS

The following general material requirements apply for shotcrete support in underground structures, i.e. road and railway tunnels:

- Cement quality is chosen based groundwater chemical conditions, exposure classes and technical life length etc,
- Maximum aggregate size < 4 mm,
- Technical life length 120 years,
- Adhesion to rock > 0,5 MPa for normal rock conditions,
- Compressive strength >30 MPa,
- Steel fibres shall be used if no other types specified, fibre contents are regulated by the following requirements,
 - Maximum flexural strength 4 MPa in pure bending tests,
 - Residual flexural strength 3 MPa at 2 mm deflection in pure bending tests,

- Mixing components of shotcrete including water/cement ratio, aggregates, accelerators etc shall be approved by pre-testing and shall not be changed after approval.

For testing the shotcrete mechanical properties, the Euro codes SS-EN 14488-1:2005, SS-EN 14488-3:2006 and SS-EN 12504-1 are used.

The major requirements on shotcreting performance are given as follows:

- Shotcreting shall be performed by trained and certified personal,
- Shotcreting shall be performed with wet spraying methods,
- Shotcrete shall not be applied on rock surfaces with temperature below 5° C,
- Rock surface shall be cleaned by pressured water before shotcreting,
- Shotcreting shall only be performed after geological mapping.

5 CONCLUSIONS

Shotcrete has been successfully used in Sweden for underground structures for decades. The research work during the past decades have played important roles in understanding the support mechanisms using shotcrete in typical Swedish rock conditions. Design methods and guidelines have been developed based on the research work and practical experiences. Design of rock supports by considering the adhesions between rock and shotcrete is one of the significant characteristics of the Swedish method.

To reduce the environmental impacts caused by civil constructions, efforts are being made upon innovations of new materials and technologies for rock excavations and supports.

Study on the influence of cracks on mechanical behaviors of tunnel lining of high speed railway with a speed of 400 km/h

Peng Chen & Kai Liu

China Railway Southwest Research Institute Co., Ltd., Chengdu, China

Congwen Yan

China Railway Siyuan Survey and Design Institute Group Co., Ltd., Wuhan, China

ABSTRACT: In view of the current research status that most studies have not considered the influence of crack distribution patterns on lining structural stress, the ABAQUS finite element software and CDP model are used to study the influence laws of single crack, mesh cracks and radial cracks on the stress characteristics of high-speed railway tunnel lining structure. The main conclusions are as follows: (1) When the cracks are located at the crown, the influence on structural stress is the most obvious, and the crown cracks have the greatest influence on the tensile damage degree and deformation of the structure, and have little influence on the compressive bearing capacity of the structure; (2) Single longitudinal crack has the most obvious influence on the structural stress, and the tensile damage degree induced by non-penetrating cracks is positively correlated with the length and depth of cracks; (3) The tensile damage degree induced by mesh cracks is positively correlated with the length and width of crack distribution; (4) The tensile damage degree induced by radial cracks is negatively correlated with the area of regional center, and positively correlated with the number and length of cracks; (5) The larger the depth and range of cracks, the more obvious the increase of structural deformation. The 12m long and 0.9H deep longitudinal cracks on the vault can cause structural deformation to increase by more than 5 %.

Keywords: High-speed railway tunnel, Running speed of 400 km/h, Plastic damage, Cracks, Mechanical behaviour

1 INTRODUCTION

With the increase of operating mileage and life of high-speed railway tunnels, lining cracks often occurred, which have had different impacts on the safety and durability of tunnel structures^[1-3]. At present, China's high-speed railway tunnel at a speed of 400km/h is still in the research stage. With the speed boost of China railways, the requirements for tunnel section is higher and also the mechanical behaviors of tunnel structure become more complicated. As if the construction defects cause the lining cracks, it will bring more and more troubles to the safe operation of tunnels and so the research works on the structure mechanical behaviors of cracked linings are carried out in urgent need. For the high-speed railway tunnels at speed of 350km/h and below, the domestic and foreign experts have already commenced some corresponding research works^[4-6]..

Taking the Beijing metro project as an example and based on the theory of concrete elastic-plastic damage, Xuan Liu^[7] conducted the mechanical analysis of cracked linings. The analysis results show that the influence of vault crack is remarkable and the crack depth has the most significant impacts on the safety of lining structure.

Yujun Zhang^[8] adopted the plane finite element model and the fracture mechanics theory to calculate and analyze the stability of different cracks at the secondary lining of tunnel. The main conclusions show that the depth and number of cracks have greater influence on the stability of cracks and fewer influence on crack width.

Yihong Zhang^[9] established a cracked structure by using the finite element models and the contact elements, analyzed the changing law of the strength factors at the crack tip of lining with the crack characteristic parameters. The main conclusions show that the depth of lining crack has the most significant impacts on the safety of lining structure.

In summary, domestic and foreign experts have done extensive research works on the mechanical characteristics of cracked lining in tunnel and achieved the conclusions that the depth and number of cracks have had significant impacts on the stability of cracks. However, at present, most of the research works focus on the ordinary speed railway tunnel only and not yet consider the impacts of crack distribution patterns such as reticulated or radial cracks on the mechanical characteristics of lining structure. Therefore, this paper adopts ABAQUS finite element software and the concrete plastic damage model to study the impacts of different cracks such as single crack, reticulated crack or radial crack on the mechanical behaviors of lining structure of single or double line high-speed railway tunnels at a speed of 400km/h. It will provide a reference for the subsequent operation and maintenance decision of cracked lining in high-speed railway tunnel at a speed of 400km/h.

2 CONCRETE ELASTIC-PLASTIC DAMAGE MODEL

2.1 Concrete damaged plasticity variable

In order to describe the nonlinear mechanical behaviors of sensitive materials to damage like concrete under loading, this paper adopts the concrete damaged plasticity model (CDP model) in ABAQUS software to carry out research works [10, 11]. In the process of adoption, two assumptions are made as follows: ① the failure mode of concrete is assumed to be crushing or tensile cracking; ② concrete damage is assumed to be isotropic. Therefore, the plastic damage factor d is adopted to represent the reduction of material elastic modulus E due to damage and the plastic evolution equation is shown in equation (1).

$$\begin{cases} E = (1 - d)E_0 \\ (1 - d) = (1 - s_t d_c)(1 - s_c d_t) \end{cases} \quad (1)$$

Where, E_0 is the initial elastic modulus; s_t and s_c represent the state functions of tensile stress and compressive stress of concrete, respectively; d_t and d_c represent uni-axial tensile damage factor and uni-axial compressive damage factor, respectively.

2.2 Stress-strain relationship and damage evolution equation of concrete

In this paper, the stress-strain relationship of concrete in Code for Design of Concrete Structures (GB50010-2010) is recommended (as shown in Figures 1 and 2). Based on the assumption of strain equivalence, the damage evolution equation of concrete is obtained with reference to the research results of Zhenhai Guo [12].

Figure 1. Uni-axial tensile stress-strain relationship of concrete.

Figure 2. Uni-axial compressive stress-strain relationship of concrete.

According to the geometric relationships in Figures 1 and 2, the concrete damage evolution equation with taking the concrete elastic modulus E as the damage variable is obtained and shown in Equation (2).

$$d_k = \frac{(1 - \beta_k)\varepsilon_k^{in}E_0}{(1 - \beta_k)\varepsilon_k^{in}E_0 - \sigma_k} \quad (2)$$

Where, d_k represents the plasticity damage factor; k represents the damage type, $k=t$ represents the pull-induced damage, $k=c$ represents the compression-induced damage; ε_k^{in} represents the concrete inelastic strain; σ_k represents the value of concrete stress; $\beta_k = \varepsilon_k^{pl} / \varepsilon_k^{in}$ is the ratio of plastic strain vs. inelastic strain, while the 0.5~0.95 is taken under tension and the 0.35~0.7 is taken under compression; ε_k^{pl} is the plastic strain.

3 CALCULATION MODELS AND CONDITIONS

3.1 Calculation model

The finite element software ABAQUS is used to build a “load-structure” model and to study the mechanical behaviors of high-speed railway tunnel at a speed of 400km/h under the influences of different cracks. The longitudinal length of lining is 12m. The lining structure is simulated by C3D8R element and

the foundation spring is simulated by T3D2 element. According to the “Code for the Design of Railway Tunnels” (TB10003-2016), the vertical load of the single line tunnel within surrounding rocks of Class IV is 86.940kPa, the double line tunnel is 112.153kPa and the lateral pressure coefficient is 0.25. The load-bearing ratio of secondary lining within surrounding rocks of Class IV is 50%. The calculation model is shown in Figure 3. The cracks of lining are simulated by means of contact surface. Meanwhile, it is considered that the cracks do not transfer tensile stress and shear stress, but transfer compressive stress.

Figure 3. Finite element calculation model.

3.2 Physical and mechanical parameters of materials

According to the “Code for the Design of Railway Tunnels” (TB10003-2016), the parameter for the elastic foundation within surrounding rocks of Class IV is 350MPa/m. The concrete material is C35 and the standard values of tensile and compressive strengths are selected as the representative values of concrete strength. The physical and mechanical parameters are shown in Table 1. The bi-axial compressive strength is 1.16 times as much as the uni-axial compressive strength.

Table 1. Physical and mechanical parameters of concrete.

Class	$\gamma(\text{kN/m}^3)$	ν	$E_0(\text{GPa})$	$f_{tk}(\text{MPa})$	$f_{ck}(\text{MPa})$
C35	23	0.2	31.5	2.20	23.4

In Table 1, γ , ν , E_0 , f_{tk} and f_{ck} represent the concrete’s weight, Poisson’s ratio, initial elastic modulus, standard value of tensile strength and standard value of compressive strength, respectively.

3.3 Calculation conditions

In order to systematically explore the influences of single longitudinal crack, reticulated crack and radial crack on the mechanical behaviors of lining structure, the prepared calculation conditions are shown in Tables 2-4. Where, H represents the design thickness of lining structure.

Table 2. Calculation condition of single crack.

The Serial Numbers of Conditions	The angle between crack and tunnel alignment ($^\circ$)	Length of crack (m)	Depth of Crack (m)	Locations	Remarks
1	/	/	/	/	No-crack
2~16	0	1, 3, 6, 9, 12	$0.1H, 0.5H, 0.9H$	Vault	/
17~18	30, 45	6	$0.5H$	Vault	/
19~27	0	6	$0.1H, 0.5H, 0.9H$	Haunch, Side wall, Foot of the wall	/
28~30	0	12	$0.9H$	Haunch, Side wall, Foot of the wall	/

Table 3. Calculation condition of reticulated cracks.

The Serial Numbers of Conditions	Length of reticulated cracks(m)	Width of reticulated cracks(m)	Crack spacing (cm)	Locations	Remarks
1	/	/	/	/	No-crack
2~4	0.5, 1, 1.5	0.5			
5~7	0.5, 1, 1.5	1	25	Vault	The depth is $0.5H$
8~10	0.5, 1, 1.5	1.5			

Table 4. Calculation condition of radial cracks.

The Serial Numbers of Conditions	The area of radical cracks(m ²)	The numbers of cracks	Length of cracks(m)	Locations	Remarks
1	/	/	/	/	No-crack
2~4	0.25, 1, 4	3	3	Vault	
5~7	0.25, 1, 4	5	3	Vault	The depth is
8~11	0.25	3, 5	4.5, 6	Vault	0.5H

4 ANALYSIS OF THE INFLUENCES OF CRACKS ON MECHANICAL BEHAVIORS IN SINGLE-LINE TUNNEL

4.1 Single crack

4.1.1 Different locations

The calculated results of single longitudinal crack conditions 1, 9, 20, 24 and 28 were selected separately for comparative analysis, so as to demonstrate the effects of crack locations on structure mechanical behaviors. The calculated results are shown in Table 5.

Table 5. Calculation results of single cracks at different locations.

conditions	Locations	S _{1max} (MPa)	S _{3max} (MPa)	Tensile damage	U ₁ (mm)	U ₂ (mm)
1	/	1.726	5.408	0.000	1.252	4.933
9	Vault	2.398	5.418	0.735	1.278	5.081
20	Haunch	1.726	5.408	0.000	1.253	4.934
24	Side wall	1.726	5.409	0.000	1.252	4.933
28	Foot of the wall	1.726	5.466	0.000	1.252	4.933

Where, S_{1max} and S_{3max} represent the maximum values of the first and third principal stresses of lining structure, respectively. U₁ represents the maximum value of unilateral horizontal convergence of lining structure and U₂ represents the maximum value of vertical displacement at vault.

As shown in Table 5, when the single longitudinal crack appears at vault, haunch, side wall or foot of the wall, the compression-induced damage degree of lining structure is 0 and the maximum value of the third principal stress is 5.408MPa~5.466MPa, which is far less than the design value of compressive strength of concrete C35. When the single longitudinal crack appears at vault, the Tensile damage degree of lining structure is 0.735 and the maximum value of the first principal stress of lining structure is 2.398MPa, which increases by 38.9% and the deformation of the structure increases slightly, compared with the no-crack condition. When the single longitudinal crack

appears at haunch, side wall or foot of the wall, the Tensile damage factor of lining structure is 0 and the maximum value of the first principal stress of lining structure is 1.726MPa, which is the same as the no-crack condition. Therefore, the single longitudinal crack at vault has more significant influences on tensile properties of the structure, fewer influences on the compressive behaviors and slightly influences on the deformation, while the cracks in other locations hardly influence the mechanical behaviors of lining structure. As a result, the subsequent research will focus on the influence rules of the cracks at vault on tensile properties and deformation of lining structure.

4.1.2 Depth and length of crack

The influences of the depth and length of single longitudinal crack on mechanical behaviors of lining structure are analyzed by taking the calculated results of the Tensile damage degree, the unilateral horizontal displacement value of lining structure and the vertical displacement value of vault under conditions 2-16, as shown in Figures 4-6.

Figure 4. Tensile damage degree of lining structure with single longitudinal cracks.

As shown in Figure 4, when the crack does not penetrate through the primary lining (the length is less than 12m), the Tensile damage degree of the crack is positively correlated with the length and depth of crack, and the maximum Tensile damage degree is up to 0.910 with the increase of the length and depth of crack. When the crack penetrates through the primary lining (the length is 12m), the Tensile damage factor of the lining structure decreases

with the release of strain energy at the tip of lining crack. From the perspective of quantitative value, when the crack length is greater than 3m, the crack length does not have significant influences on the Tensile damage degree of lining structure, and the expansion of the crack is mainly controlled by crack depth.

Due to space limitation, only the calculation results of pull-induced damage under conditions 11, 12 and 13, respectively are introduced in this paper, as shown in Figure 5.

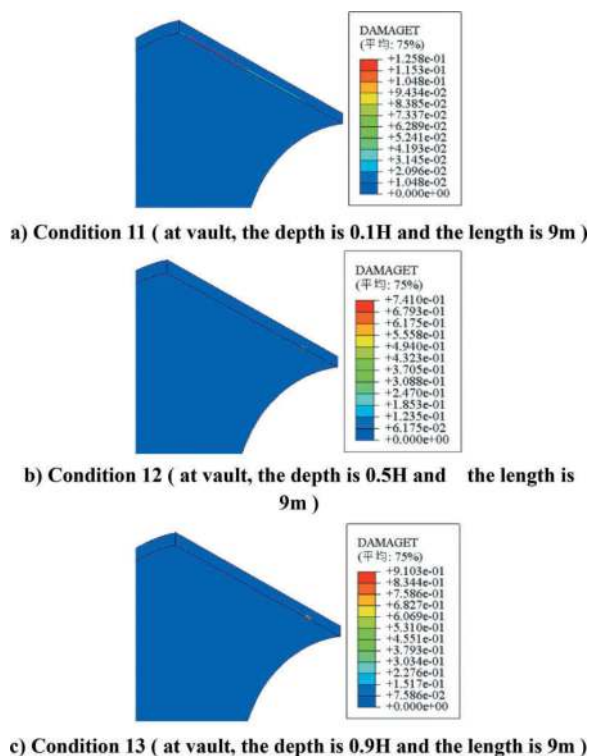

Figure 5. Tensile damage degree of vault with single crack.

As shown in Figure 5, when the crack depth is 0.1H, the crack expands along the direction of depth. When the crack depth is 0.5H and 0.9H, the crack expands along the direction of length. Therefore, the Tensile damage degree of lining structure is positively correlated with the crack depth. When the crack occurs shallowly, the crack expands along the direction of depth, and when the crack depth reaches a certain degree, the crack expands along the direction of length. Except for the condition of 12m-long crack, the variation trends of other cracks are identical to that of the 9m-long crack.

The calculation results of the maximum unilateral horizontal convergence of lining structure and the maximum settlement of vault under conditions 2-16 are shown in Figures 6 and 7.

Figure 6. Maximum unilateral horizontal convergence of lining structure with single longitudinal crack.

Figure 7. Maximum vertical displacement of vault with single longitudinal crack.

As shown in Figures 6 and 7, the maximum unilateral horizontal convergence of lining structure and the maximum vertical displacement of vault increase with increasing of the length and depth of cracks. When the crack length is 12m and the crack depth is 0.9H, the maximum horizontal displacement and the maximum vertical displacement of lining structure are 1.306mm and 5.190mm, respectively, which increased by 4.31% and 5.21%, compared with the no-crack condition.

4.1.3 Crack strike angle

The calculation results of conditions 9, 16 and 17 are selected, respectively to analyze the influences of different crack strike angles on the mechanical behaviors of lining structure. The calculation results of displacement behavior values of lining structure are shown in Figure 8.

The variation law of the maximum displacement along with the crack strike angle is shown in Figure 9. When the depth of the 6m-long crack at vault is 0.5H, the maximum displacement value slightly decreases with increasing of the crack longitudinal angle. When the angle reaches 30° and 45°, the vertical displacement decreases by 1.6% and 2.2%, and the horizontal displacement decreases by 1.2% and 2.0%, respectively.

Figure 8. Displacements of lining structure under different crack strike angles.

According to the calculation results, when the crack strike angle reaches 30° and 45°, the Tensile damage degree of lining structure is 0. As shown in Figure 8, the influences of crack strike angles of 30° and 45° on lining deformation is less than that of longitudinal cracks, in which the unilateral horizontal convergence of lining structure decreases by 1.2% and 2.0%, and the vertical displacement of vault decreases by 1.6% and 2.2%, respectively. The larger the crack strike angle is, the smaller its influence on lining structure becomes.

4.2 Reticulated crack

The calculation results of the Tensile damage degree, the maximum unilateral horizontal convergence of lining structure and the maximum vertical displacement of vault under reticulated crack conditions of 1-10 are shown in Figures 9-11.

Figure 9. Tensile damage degree of lining structure with reticulated cracks.

Figure 10. Maximum unilateral horizontal convergence of lining structure with reticulated cracks.

Figure 11. Maximum vault vertical displacement of lining structure with reticulated cracks.

As shown in Figure 9, the Tensile damage degree of lining structure increases with the extension of the varying ranges of length and width of reticulated crack. When the length and width of reticulated crack are greater than 100cm, the maximum Tensile damage factor of lining structure will rapidly rise above 0.85, indicating that the crack has a development trend and propagates along with the alignment of tunnel.

As shown in Figures 10 and 11, the maximum horizontal convergence of lining structure and the maximum vertical displacement of vault are positively correlated with the length and width of reticulated cracks. When the length and width of reticulated crack increase up to 150cm, the maximum horizontal convergence of lining structure and the maximum vertical displacement of vault are 1.266mm and 5.015mm, which increase by 1.12% and 1.66%, compared with the no-crack condition. It indicates that the lining stiffness decreases accordingly.

4.3 Radial crack

4.3.1 The area and number of crack central zone

The calculation results of radial crack conditions 1 to 7 are selected, respectively to analyze the influences of the area of radial crack central zone and the number of cracks on the mechanical behaviors of lining structure. The calculation results are shown in Figures 12-14.

Figure 12. Tensile damage degree of lining structure with radial cracks of different areas.

Figure 13. Maximum unilateral horizontal convergence of lining structure with radial cracks of different areas.

Figure 14. Maximum vault vertical displacement of lining structure with radial cracks of different areas.

As shown in Figure12, when the radiating area of crack ranges from 0 m² to 1 m², the pull-induced damage degree of lining structure decreases with increasing of the area of crack central zone; when the area of radial crack central zone is 0.25m², the pull-induced damage degree of lining structure is 0.869; when the area of radial crack central zone is above 1m², the pull-induced damage degree of lining structure is 0.078. It shows that the larger the area of radial crack central zone becomes, the less the possibility of crack propagation is.

As shown in Figures 13 and 14, the maximum unilateral horizontal convergence of lining structure and the maximum vertical displacement of vault decrease with increasing of the area of radial crack central zone and increase with rising of the number of cracks. When the number of cracks is 5 and the area of radial crack central zone is 0.25m², the maximum horizontal convergence of lining structure and the maximum vertical displacement of vault are 1.270mm and 5.030mm, which increase by 1.44% and 1.97%, compared with the no-crack condition. Thus, the lining stiffness is most significantly declined under this condition.

4.3.2 The length and number of cracks

The calculation results of the radial crack conditions 1, 2, 5 and 8~11 are selected respectively to analyze the influences of the degree of

radial crack, the number of cracks on mechanical behaviors of lining structure and the calculation results are shown in Figures 15-17

Figure 15. Tensile damage degree of lining structure with radial cracks of different lengths.

Figure 16. Maximum unilateral horizontal convergence of lining structure with radial cracks of different lengths.

Figure 17. Maximum vertical displacement of vault with radial cracks of different lengths.

As shown in Figure15, the Tensile damage degree of lining increases with increasing of the number and length of radial cracks. When the length of crack is 6m long and its number is 5, the Tensile damage degree of lining structure is 0.897.

As shown in Figures 16 and 17, the maximum unilateral horizontal convergence of lining structure and the maximum vertical displacement of vault are positively correlated with the length and number of radial cracks. When the length of radial crack is 6m and its number is 5, the maximum unilateral horizontal convergence of lining structure and the maximum vertical displacement of vault are 1.282mm and 5.069mm, which increase by 2.40% and 2.76%, compared with the no-crack condition. It indicates that the lining stiffness decreases accordingly.

5 ANALYSIS OF THE INFLUENCES OF CRACK ON MECHANICAL BEHAVIORS OF DOUBLE-LINE TUNNEL

According to the analysis results of the influences of the crack on mechanical behaviors of double-line tunnel, the influence rule of each behavior parameter of single crack, reticulated crack and radial crack on the Tensile damage degree of lining structure, the maximum unilateral horizontal convergence of lining structure and the maximum vertical displacement of vault are consistent with those of single-line tunnel, but the degrees of influence are varying from each other. Only the calculation results of the most unfavorable conditions under each working condition are given, as shown in Table 6 to Figure 8.

As shown in Table 6, for single crack, under the most unfavorable working conditions of the depth and length of crack, the Tensile damage degree of lining structure is 0.947, and the maximum unilateral horizontal displacement of lining structure and the maximum vertical displacement of vault are 2.603mm and 9.660mm, which increase by 1.28% and 2.34%, compared with the no-crack condition. For the working condition of the most unfavorable crack strike angle, the Tensile damage degree of lining structure is 0.939, and the maximum unilateral horizontal displacement of lining structure and the maximum vertical displacement of vault are 2.593mm and 9.610mm, which increase by 0.89% and 1.81%, compared with the no-crack condition.

For the reticulated crack, the Tensile damage degree of lining structure is 0.979 under the condition of the most unfavorable length and width of crack, and the maximum unilateral horizontal displacement of lining structure and the maximum vertical displacement of vault are 2.582mm and 9.543mm, which increase by 0.47% and 1.10%, compared with the no-crack condition.

For the radial crack, under the most unfavorable conditions of the area and number of crack central zone, the Tensile damage degree of lining structure is 0.937, and the maximum unilateral horizontal

displacement of lining structure and the maximum vertical displacement of vault are 2.593mm and 9.603mm, which increase by 0.89% and 1.74%, compared with the no-crack condition. Under the most unfavorable conditions of the length and number of cracks, the Tensile damage degree of lining structure is 0.950, and the maximum unilateral horizontal displacement of lining structure and the maximum vertical displacement of vault are 2.593mm and 9.603mm, which increase by 1.28% and 2.27%, compared with the no-crack condition.

The comparison with the single-line tunnel suggests the most unfavorable condition for all kinds of cracks, i.e., the Tensile damage degree of lining structure in double-line tunnel is generally greater than that of single-line tunnel, while the maximum unilateral horizontal displacement of lining structure and the maximum vertical displacement of the vault is smaller than that of single-line tunnel, indicating when the vault in single-line tunnel is cracked, the lining stiffness decreases more obviously than that of double-line tunnel, and when the vault in double-line tunnel is cracked, the crack propagates more easily than that of single-line tunnel.

6 CONCLUSIONS AND SUGGESTIONS

In this paper, a numerical simulation study is carried out on the influence rule of lining structure mechanical behaviors under the actions of single crack, reticulated crack and radial crack in the high-speed railway tunnel with a speed of 400km/h, or the single-line and double-line tunnels within Class IV surrounding rocks and plain concrete. The main conclusions are as follows:

- (1) The influence of vault cracks on mechanical behaviors of lining structure is much greater than that of cracks at other locations. When the vault is cracked, the Tensile damage degree and deformation of lining structure will be affected, but the compression bearing behaviors of lining structure will be less affected.

Table 6. The most unfavorable situations of the influences of crack on mechanical behaviors of double-line tunnel.

Types of cracks	Influential factors	d_t	U_1 (mm)	U_2 (mm)	Remarks
No-crack	/	0	2.570	9.439	/
Single crack	Depth, length of crack	0.947	2.603	9.660	Length is 9m, depth is $0.9H$, strike angle is 0°
	Crack strike angle	0.939	2.593	9.610	Length is 6m, depth is $0.5H$, strike angle is 0°
Reticulated crack	Length, width of crack	0.979	2.582	9.543	Length is 150cm, width is 150cm
	The area and number of crack central zone	0.937	2.593	9.603	The area of crack central zone is 0.25m^2 . the number of crack is 5, the length of crack is 3m
Radial crack	Length, number of crack	0.950	2.603	9.653	The area of crack central zone is 0.25m^2 , the number of crack is 5, the length of crack is 6m

- (2) The calculation results of the influences of cracks on lining structure in single-line and double-line tunnels show that the cracks at vault in single-line tunnel have more significant influences on lining stiffness, while the cracks at vault in double-line tunnel propagate more easily than that of single-line tunnel.
- (3) The longitudinal crack has the most significant influences on the mechanical behaviors of lining structure; When the length of crack does not penetrate through the primary lining, the Tensile damage degree of lining structure increases with increasing of the length and depth of crack. When the length of crack is 9m and its depth is 0.9H, the Tensile damage degrees of lining structure in single-line or double-line tunnels are 0.910 and 0.947, respectively. When the length of crack is more than 3m, its extensibility is mainly controlled by the depth of crack. When the depth of crack is shallow (such as 0.1H), it mainly propagates along the direction of crack depth, and when the depth of crack reaches a certain degree (such as more than 0.5H), it mainly propagates along the direction of crack length.
- (4) The Tensile damage degree of reticulated crack is positively correlated with the length and width of crack. When both the length and width of reticulated crack are 150cm, the Tensile damage degree of lining structure in single-line and double-line tunnels is 0.949 and 0.979, respectively, it develops longitudinally along the tunnel.
- (5) The pull-induced damage degree of radial crack is negatively correlated with the area of crack central zone, and positively correlated with the number of cracks and the length of cracks. When the area of crack central zone is 0.25m^2 , the number of cracks is 5, and the length of cracks is 6m, the pull-induced damage degree of lining structure in single-line and double-line tunnels are 0.897 and 0.950, respectively.
- (6) The greater the crack depth is, the wider the distribution range is and the more significant the influences on lining stiffness becomes. When the length of single crack is 12m and the depth is 0.9H, the maximum unilateral horizontal convergence of lining structure and the maximum vertical displacement of vault increase by 4.31% and 5.21%, respectively. When the depth of crack is 0.5H, the maximum unilateral horizontal convergence of lining structure and the maximum vertical displacement of vault increase less than 2.5% under the actions of all kinds of cracks.

In this paper, the influences of single crack, reticulated crack and radial crack on the mechanical

behaviors of lining structure in single-line and double-line high-speed railway tunnels are studied and some study results are certainly achieved. However, there are still two shortcomings: one is that the influence rule of crack width on the mechanical behaviors of lining structure has not yet been considered; the other is that the study achievements about the influence rule of cracks on mechanical behaviors of lining structure has been inclined to be qualitative, and the quantitative study has not yet been fully realized. Therefore, the next study will further improve the integrity of indicators and the quantification of study results.

Design and verification of shear key support system for segmental lining openings at cross passages using non-linear finite element model

Jin Thai Chong*

Pini, Sydney, Australia

ABSTRACT: This paper presents the design and verification of a shear key support system for tunnel segmental lining openings at cross passages. During the construction of cross passages, temporary support is required to ensure the continuous transfer of hoop load within the segmental lining rings and maintain stability. Shear keys, along with other shear-transfer mechanisms, have been adopted as an alternative to traditional steel frames and lintel beams. The shear key system typically consists of steel circular hollow sections that are infilled with high-strength grout and installed at circumferential joints surrounding the openings. A non-linear finite element model is employed to determine the load transfer capacity of the shear key, analyze stresses in the adjacent segments, and verify the ultimate and service capacity of the system. The paper aims to present the efficiency and limitations of the shear key support system and promote the adoption of innovative support systems for cross passage construction, thereby contributing to the reliability and safety of tunnel structures.

Keywords: shear key support system, cross passages opening, temporary support, safety in design

1 INTRODUCTION

Cross passages are essential structures that facilitate not only maintenance and operational efficiency but also serve as crucial safety passage, providing emergency access, ventilation, and evacuation routes. However, constructing these passages poses technical and safety related challenges, especially when ensuring the stability of the tunnel lining around the openings during cross passage construction. Traditionally, steel frames and lintel beams have been used to provide temporary support during the construction of cross passages. While these methods have proven effective over the years, they often come with their own set of challenges, including increased costs, extended construction durations, safety issues related to the handling of heavy steel elements and potential disruptions to ongoing tunnelling operations. In recent years, the shear key system with combination of segment-embedded high performance bicone dowels has been adopted in several projects offering a promising alternative to traditional support methods. Comprising of steel circular hollow or reinforced cored sections filled with high-strength grout and positioned at circumferential joints around the openings, the shear key system promises to be an alternative that ensures the continuous transfer of hoop load within the tunnel lining

rings, maintaining stability during cross passage construction. This paper seeks to present the design, verification, application, advantages, and limitations of the shear key support system. Furthermore, this paper recommends the design and verification processes with recognized standards, providing a comprehensive overview of the shear key system in the context of modern tunnel construction.

2 SHEAR KEY SYSTEM OVERVIEW

The excavation of the cross passages will require creating an opening in the segmental lining by removal of segments or cutting and removing portions thereof. Doing so breaks the continuous transfer of hoop load in the lining and requires a secondary thrust transfer system be installed to maintain stability in the system. Intercepting and transferring this hoop load away from the opening and into the adjacent rings is the key to creating a stable opening in a segmental lining. Aside from being designed to resist and transfer the forces within the cut rings to the adjacent rings, the support system must also limit deformations in the segmental liner to an acceptable level. For soft ground conditions, such as in clays or sands, high hoop loads may be expected on the tunnel lining. The traditional way to address the

*Corresponding author: jin.chong@pini.group

design of the openings under these high load conditions is to include a heavy propping system, often in the form of steel ring beams, vertical props, lintel beam, or combinations thereof. For openings where the loading is less than full overburden, or which are self-supporting, the propping system can be reduced or potentially eliminated with the application of shear key system with combination of segment-embedded high performance bicone dowels as shown in Figure 1.

Figure 1. Illustration of bicone dowels and shear key system in circumferential joint.

The shear key system is typically comprised of cored hole reinforced with Steel Circular Hollow Sections (CHS) or vertical and spiral steel bars inside a cored hole. The core is infilled with high-strength grout, enhancing its bond with the surrounding concrete, and ensuring the effective transfer of stresses. The system is strategically positioned around the cross-passage openings between the ring-to-ring joint to ensure a uniform force distribution around the opening. According to research (Vladislav Mihaylov and Zenz, 2019), in comparison with plastic bicones dowel, the slip-free and stiff construction of shear keys means that the shear resistance can be mobilised without previous deformation, making it suitable for tunnels with expected high hoop load. Noteworthy applications include their use in cross passages in Aked Tunnel (Della Valle, Salas Monge and Savin, 2014), Wienerwald Tunnel, Perschling Tunnel and Pfänder Tunnel projects (Walter, Vladislav Mihaylov and Wagner, 2019). The use of shear keys has also been proposed for Follo Line as described by Ring and Johannes Gollegger (2019). The design principle of shear key system has also been referred to by Gehwolf et al. (2016).

3 DESIGN OF THE SHEAR KEY SYSTEM

This section describes the various considerations and recommendations that inform the shear key system design using CHS as shown in Figure 2.

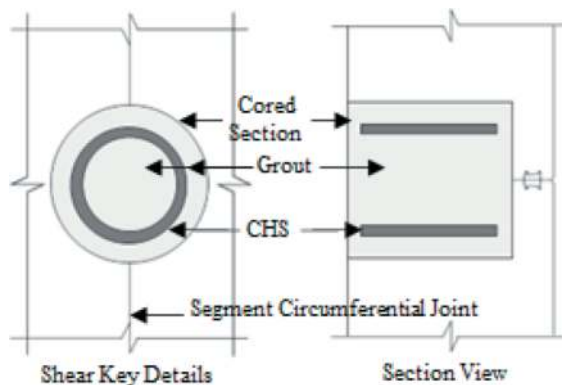

Figure 2. Shear key details.

3.1 Sizing the Circular Hollow Section (CHS)

The diameter of the CHS should align proportionally with the segment thickness. Generally, the CHS diameter could range between 0.5 to 0.75 times the segment thickness. This approach ensures that the CHS effectively carries shear loads while maintaining the segment's structural integrity. The CHS ought to possess an appropriate wall thickness to resist shear forces and bending moments. A thicker wall boosts shear resistance but also increases weight and cost. Selecting the steel grade for the CHS depends on anticipated loads and the desired safety factor. CHS sizing should facilitate easy installation, and it's crucial to ensure that sufficient grouting can envelop the CHS when placed in the cored hole. Additionally, the CHS should be positioned without hindrance to other structural elements such as reinforcement bars, dowels, or gaskets. This might involve adjustments to the CHS size or placement for compatibility.

3.2 Cored hole size

The cored hole diameter should be marginally larger than the CHS diameter to ensure a precise fit. Typically, an additional 40-50mm clearance around the CHS diameter is recommended. This allowance accommodates potential slight deviations during installation and provides space for grouting. The gap between the CHS and the cored hole facilitates the application of high-strength grout. This grout not only secures the CHS in position but also facilitates load transfer between the CHS and the adjacent concrete. It's essential to ensure that the gap is adequately wide for effective grouting while maintaining a strong bond between the CHS and the concrete.

3.3 Depth of the shear key

In practice, the depth usually spans from 0.5 to 0.6 times the segment thickness. This approach guarantees that the shear key engages a substantial part of the segment, effectively transferring the shear loads. A deeper shear key yields a broader surface for load transfer, dispersing shear stresses over a larger section

of the shear key. While deeper shear keys enhance load transfer, it's imperative to ensure that depth doesn't compromise the segment's structural integrity. A minimum concrete cover at the base of the shear key must be retained to sustain the segment's strength and durability in line with the project specific requirements.

3.4 Spacing between two shear keys

The spacing between shear keys is essential for effective load transfer. Typically, the center-to-center vertical spacing might range from 2 to 3 times the CHS diameter. Adequate spacing ensures even load distribution and reduces the risk of stress concentrations between adjacent shear keys. An FEA or truss model described by Gehwolf et al. (2016) as shown in Figure 3 can help to verify the chosen spacing and stress distribution, ensuring effective load transfer without causing stress concentrations or cracking of the concrete lining.

3.5 Proposed design steps

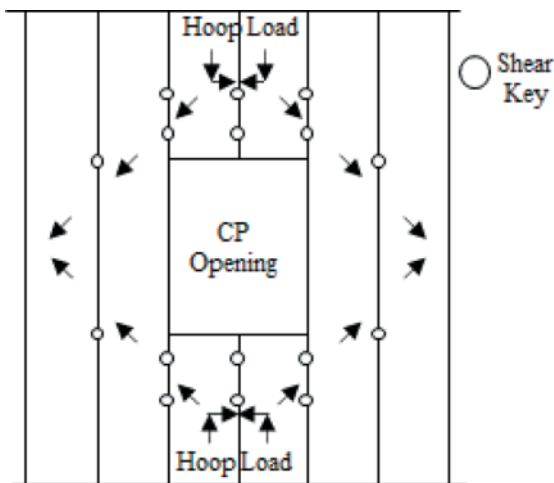

Figure 3. Shear key hoop load redistribution around the cross passage opening based on truss model.

The design and verification of the shear key system necessitate an integrated design approach, leveraging advanced computational tools and methodologies as summarized in the design and verification steps below.

1. Determine project requirements
 - Evaluate the need for a shear key system based on project specifications and requirements.
 - Assess the geological conditions and soil or rock stress near the intended cross passage location.
2. Determine optimum shear key arrangement
 - Analyse the segmental lining's structural behaviour and estimate complete lining hoop load.

- Decide on the number of shear keys required around the cross passage opening considering the opening dimension and affected segment rings.
 - Consider the symmetrical arrangement around the cross passage opening using simplified truss model (Gehwolf et al., 2016).
 - Ensure positions avoid existing segment dowels, longitudinal segment joints, segment reinforcement (if any), and does not intersect the circumferential joint gasket.
 - Decide on the size of steel for the circular hollow sections (CHS) based on segment thickness, cored hole size, and the type of high-strength grout for infilling.
3. Verify Shear Key System Capacity on a single joint (2D Analysis)
 - Setup 2D axis symmetrical model of concrete with the proposed cored hole, CHS size, shear key spacing on a single joint.
 - Incorporate material properties, boundary conditions and anticipated hoop load to mobilize the shear key.
 - Evaluate the stresses developed on the concrete segment and the grout.
 - If stresses are excessive, return to Step 2. If not, proceed to Step 4.
 4. Verify Overall System Capacity (3D Analysis)
 - Setup 3D FE Model of the tunnel lining with opening considering any segment bicone dowels and shear key with spring elements according to their actual position in the circumferential joint.
 - Simulate ground springs and impose loadings.
 - Assess the concrete segment's capacity to withstand all load cases and combinations.
 - Ensure that the shear forces are within the shear capacity of the shear key.
 5. Refinement (if necessary)
 - If the design does not meet the requirements, return to the "Determine project requirements" or "Determine optimum shear key arrangement" steps and make necessary adjustments.
 6. Finalize Design
 7. Implementation & Monitoring
 - Monitor the performance of the shear key system during and after construction by verifying the expected ring deformation during lining opening and cross passage excavation against expected deformation informed by design.

4 CASE STUDY

4.1 General description

This case study involved partial removal of segments on two consecutive rings of a metro tunnel to give an

overview of the integrated design approach combining the 2D finite element and the 3D modelling techniques for design of tunnel opening with shear key system.

4.2 Lining geometry

The example described here concerns the construction of cross passage for connection between twin bored tunnels. The tunnel was excavated by an open-faced double shield TBM which allows safe installation of a universal segmental lining ring formed by 6 +0 precast pieces of steel fibre reinforced concrete (SFRC) segments. Each segment is provided with an all-round seal by elastomeric compression gasket which prevents groundwater entering the tunnel. The tunnel lining has an outer diameter of 6,690mm and an inner diameter of 6,170mm. The ring has been standardized to 1.7m wide. The thickness of lining is 260mm with a 28-day concrete strength of 50MPa. Table 1 shows the details of geometric characteristics of the precast concrete segmental lining.

Table 1. Geometric characteristics of the precast segmental lining.

Parameter	Value
Internal diameter	6,170mm
Lining thickness	260mm
No. of segment per ring	6+0
Ring width	1,700mm
Concrete strength	50 MPa
Ring connections	3 bicone dowels per segment

The opening on the lining was sized to provide a 5.2m high and 3.4m wide clear passageway for connection to the cross passage. This required partial removal of segments from two consecutive rings. The section of the tunnel where the opening to be formed is embedded in sandstone formation, with a total ground cover of approximately 50m above the tunnel crown.

4.3 Shear key system description

Openings have been designed considering the maximum expected ground loads from the segmental lining design, allowing for load relaxation arising from deformation of the opening rings. Zero groundwater pressure is assumed due to the installed temporary drainage and low permeability of the ground strata.

Combination of embedded bicone dowels and shear keys were adopted as cross passage opening support systems to accommodate both standard cross passages and cross passage with sump opening during temporary stage. The construction methodology assumed as part of analysis is that at each of

the identified cross passage opening location, the steel pipe is installed inside 250mm diameter cored holes that are 150mm deep within the 260mm thick segment. The proposed 168 CHS (Grade 275) is installed and then grouted into the cored holes using non-shrink 60MPa grout. The cored hole location does not intersect the circle joint gasket so that water tightness of the ring is maintained in the long term.

The numbers and locations of the shear keys proposed are designed to allow optimum stress redistribution. There are total of 12 numbers of shear keys, 6 above the opening, and 6 below the opening. The shear key positions have been based on the avoidance of the existing bicone dowels as well as the longitudinal segment joints.

According to research (Walter, Vladislav Mihaylov and Wagner, 2019), it is expected that plastic bicone dowels to undergo a certain deformation in order to activate their effective shear resistance. Hence, when two or more load transfer elements are used, it is important to assess the load distribution to the relevant elements depending on the stiffness distribution. To address this, a 2D finite element model was used to verify and determine the load transfer mechanisms of the proposed shear key system across a joint, considering the anticipated lining hoop load. The shear key stiffness is then calibrated and adopted in the 3D model to assess the overall effect of opening to the segmental lining with the bicone dowel elements and ring to ring contact stiffness engaged. These models were crucial in studying load transfer mechanisms and assessing the capacity of the opened and adjacent rings to withstand force concentrations.

4.4 2D Analysis

Due to the complex load transfer system, a 2D non-linear finite element model using Strand7 has been utilised to determine the load transfer capacity of the shear key and to determine the stress concentrations, potential points of failure, and the overall behaviour of the shear key system. This model has also been used to check the load distribution between the 2 shear keys.

Material properties, such as material stress-strain curves, elasticity modulus, Poisson's ratio, and yield strength, are defined for concrete and grout materials for the compressive (crushing) and tensile (cracking) behaviour of the concrete material. These models have been run for both the service limit state (SLS) case to determine crack widths and the ultimate limit state (ULS) case to confirm the loading is within structural capacity. Different scenarios of axial forces due to earth pressures, groundwater pressures, and other external loads acting on the tunnel lining are applied on the plate element as edge pressures. For the 2D model, the curved segments were simplified as straight segments, considering that the straight segment will lead to conservative results as all shear load goes into the shear key whereas for

a curved segment model, some compressive load would be resisted by the boundary support on the external face of the segment. Only one half of the segment was modelled on each side of the shear key, and symmetric boundary conditions were provided on the plane of symmetry.

Figure 4. Shear key 2D modelling arrangement.

The segment-segment contact surface was modelled as frictionless, with a coefficient of friction set to zero. This assumption is consistent with research by Vladislav Mihaylov and Zenz (2019) to ensure that shear forces are exclusively transferred via the shear keys, eliminating any potential shear transfer through friction through segment-segment contact. The contact interface between the segments and the shear key system was defined using parameters from Eurocode 2. Based on a “very smooth” contact, a coefficient of friction of 0.5 was adopted for this interface, reflecting the inherent frictional resistance between the shear key and the segment.

Figure 5. Concrete principal tensile stress (σ_{11}).

Design verification for both, concrete and grout elements, at ULS is done by checking the Major Principal (σ_{11}) stresses against the factored tensile

design strength and Minor Principal (σ_{22}) stresses against the factored compressive design strength as calculated in accordance with relevant concrete design code or local standard. The design is considered adequate at ULS if the concrete stress does not exceed the design compressive or tensile strength. For the case study, the factored tensile design strength is taken as 3.33MPa for Grade 50 concrete, and 4MPa for the Grade 60 grout considering a material factor of 1.5. An example of a concrete segment principal tensile stress plot is shown in Figure 5, showing stress concentration at the bottom shear key region, as anticipated. At SLS, the concrete or grout is verified against the limiting tensile strain at cracking considering the project specific crack width limit. For this case study, tensile strain at crack width limit of 0.3mm gives 0.002 for the grout and 0.0012 for the segment. These are approximate values, and the actual tensile strength and modulus of elasticity can vary based on the specific mix design. It is recommended to refer to material test results or relevant local standards when available.

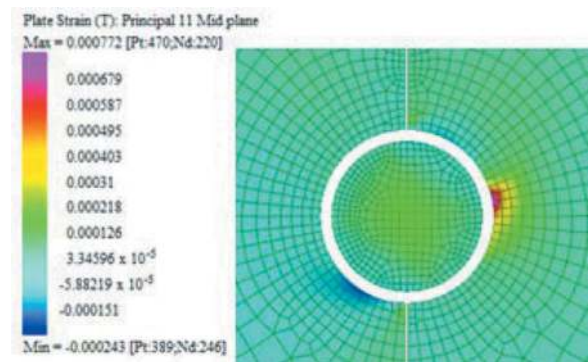

Figure 6. Grout and concrete principal strain (ϵ_{11}).

An example of a grout and concrete principal strain plot is shown in Figure 6. The study shows that the lower shear key, which is closer to the opening, carries 20 to 30% more shear load than the higher shear key. The analysis demonstrates that the first cracks appear in the concrete section near the bottom shear key closest to the opening. Tensile strains also indicate cracks in the middle part of the inner grout and in the outer grout. In the corners, strains show significantly higher values, indicating the gradual crushing failure of the segment as the applied hoop loads increase.

4.5 3D Analysis

The 3D model was then created to replicate the tunnel lining. Eight (8) monolithic rings comprised of a grid of quadrilateral shell elements have been considered in the analysis, which includes two (2) cut rings and three (3) adjacent rings either side. Radial

joints are considered by reducing the bending stiffness according to the Muir wood's formula (Wood, 1975). The ground medium was represented by radial springs. The stiffness of the radial springs was calculated using the linear load deformation relationship according to Duddeck & Erdmann (1985). Ground springs under tension were ignored and therefore no 'pulling' reaction was imposed on the segmental lining. The 3D model incorporated the opened and the adjacent fully enclosed rings in the temporary stage, without considering any support from the cross passage lining and the collar. Connection elements are used to simulate the behaviour of bicone dowels and shear keys with axial and shear stiffness. These connections are connected with compression only springs to allow separation to occur and to allow joint rotation. The magnitude of the shear force transferred by the shear elements is highly dependent on the stiffness of the shear key. While the non-linear modelled bicone dowels stiffness is typically determined from the shear force vs. displacement from the supplier's product data sheet, estimating the shear stiffness of a composite element like a shear key without a direct laboratory shear test can be a complex effort. The behaviour of a grouted CHS subjected to shear can be conceptually simplified to understand its shear strength and behaviour by isolating it into its individual components: the steel CHS and the grout. The shear strength of the steel can be derived from the steel's yield strength. Similarly, the shear strength of the grout often correlates with its compressive strength. For a fully bonded interface between steel and grout, a common assumption in grouted sections is that the combined shear strength of the composite can be conceptualized as a weighted average based on the area of each component. Displacement or deformation in shear is then related to the shear strain. For a given shear force, the induced shear stress on the grouted CHS can then be estimated. Using the relation between shear stress and shear strain, the displacement can be estimated by integrating the shear strain over the depth of the section. While these analytical models present an initial approach to understanding the behaviour, their limitations remain in simplifying complex interactions and potential non-linearities. As such, the use of these models is recommended in conjunction with experimental validation or advanced finite element simulations to ensure comprehensive insights, as recommended by Gehwolf et al. (2016). With the shear stiffness of the shear key calibrated, verification of the lining is performed considering load combinations and factors of safety in accordance with the national codes and standards. The design loads were applied directly on the tunnel lining under different load combinations. The resulting internal forces and moments from the 3D model were used to undertake the structural assessment for the lining and shear keys design.

Figure 7. 3D Model hoop load distribution and deformation.

Figure 8. 3D Model shear forces of shear keys.

Figure 7 shows the full 3D model which was used for the design of the opening at the temporary stage during the cross-passage construction. The factored design load couples acting on the lining are checked against the Moment-Axial force envelope. In terms of serviceability, it is required that the ovalization produced under working loads be sufficiently relevant local standards, typically maximum distortion ratio of 2% and cracking, if any, be controlled with maximum crack width not exceeding the tolerable limits specified by the project requirement. The shear forces of each individual shear key are extracted from 3D models and verified against the total shear capacity of a shear key as shown in Figure 8.

The total shear capacity of the grouted CHS can be taken as the sum of the shear capacities of the steel and the grout assuming a perfect bond and interaction between the steel and the grout. Depending on the quality of the bond, the actual combined shear capacity might be less than the sum of the individual capacities. Hence, it is recommended to apply appropriate material factors based on relevant design codes or standards.

5 CONCLUSIONS

While FEM provides a detailed insight for the shear key system design and verification, it comes with

inherent assumptions, such as linear material behaviour in certain regions or simplifications in geometry. Recognizing and addressing these limitations is crucial for a holistic understanding of the results. Incorporating FEM into the design and analysis of the shear key system offers a detailed, comprehensive understanding of its behavior under various conditions. This method, combined with real-world validation and alignment with recognized standards, ensures that the system is both safe and efficient, meeting the demands of modern tunnel construction.

ABSTRACT: Concrete plays a key-role in tunnelling where it constitutes the final lining and represents one of the elements, which contributes to define the wideness of the opening in respect to the rock-mass behaviour. Concrete has a high carbon footprint, mainly due to the calcination reactions and the energy required for the production process, with a CO₂ emission of approximately 0,7 tons for Portland cement ton. International standards and regulation on sustainability and circular economy (CE) goals require the reduction of the carbon footprint to avoid increased prices rising and reach the carbon neutrality in 2050. Today, ready mixed High-Performance Fiber Reinforced Self Compacting Concrete (HPFRSCC) can be industrially available at the excavation face, ensuring a high degree of compactness and fully meet these needs. Its use is more environmental sustainable thanks to the use of low CO₂ cements and the substitution of part of the natural aggregates with recycled ones, recoverable from muck. HPFRSCC can reach strength up to 85-120 MPa, thus allowing a reduction in the thickness of the final lining, and consequently a reduced excavation diameter and of all the connected works. Here, we present a case history of a tunnel with 10 m of diameter where the classic 60 cm of final lining at 30-35 MPa had been replaced by HPFRSCC at 85 MPa, leads to a significant reduction of the diameter ensuring a higher durability and fire resistance. That implies a reduction in the volume to be excavated, with substantial costs-saving due to less time consuming and costly activities. For this goal, the focus of concrete qualification should switch from the concept of fixed mix to a product defined by its mechanical, durability and compatibility performances. The use of HPFRSCC for final lining increases tunnel durability, fire-resistance, and its environmental and financial sustainability and improve circular economy.

Keywords: Tunnelling, Concrete, Environment compatibility, Economic sustainability, Fibre reinforcement

1 INTRODUCTION

Tunnelling is a very expensive economic activity, a recent study of the EU Commission (EU, 2018a) fixed at about 35⁺/₋₁₂ M€/km the cost of tunnelling, even if today it can also reach 40 M€/km. Most of the cost (50%) is for excavation work, lining weight at about 5% (WPI, 2012). Despite the diameter of the tunnel, it is interesting to consider the costs by m³, which for conventional tunnel is about 230 €/m³ and for base-tunnel around 330 €/m³; the use of TBM can

reduce this number by 1/3. Any topic that can reduce the excavation volume, and the muck, ensuring safety, technologies and loading gauge represents a significant chance for achieving costs reduction.

The thickness of the final lining, made in concrete, represents one of the elements that contribute to define the wideness of the excavation open in respect to the rock-mass behaviour saving the clear-section requirements.

Concrete has a high carbon footprint, which is mainly due to the calcination reactions and the

*Corresponding author: coli@unifi.it

energy required for the production process of the cement, with approximately 0.7 tons of CO₂ emission for ton of Portland cement.

In an economic balance, the environmental costs have to be also considered, and in particular the CO₂ emission that for concrete is planned to be drastically reduce for reaching the carbon neutrality in 2050 (Federbeton, 2020).

International standards and regulation on compatibility and circular economy (CE) goals require the reduction of the carbon footprint to avoid increased prices rising and reach the carbon neutrality in 2050.

The High Performance Fibres Reinforced Self Compacting Concrete (HPFRSCC) can give a response to this need.

2 THE HPFRSCC

Self-Compacting Concrete (SCC) can reach very high performance and durability.

The advanced formulation of the SCC is particularly open to the use of low-clinker cements, innovative additions, industrial by-products, recycled aggregates, including tunnelling muck; its formulation is based on a significant volume of cement +filler paste, which allows for very high fluidity with very low water/cement ratios.

SCC can be environmentally friendly, economical, very durable, successfully used in many types of construction. It can also enable for daring and innovative designs, both from a structural and architectural point of view.

The potential of ultra-performance and sustainable SCC is enormous. However, the use of large quantities of alternative materials and recycled aggregates (including those from muck) requires an adaptive formulation with expert use of admixtures, which must be ensured only by the competence of a qualified industrial manufacturer. This entails a fully performance-based prescription/control model, no longer based on compositional indications.

In an evolved vision, one should not look at the recipe of the concrete, but at the performance and properties that it guarantees. That implies a qualification process centred on the performance offered by a product with a proprietary and modifiable formulation, rather than on its fixed recipe.

This does not conflict with European standards, which provide for concrete with guaranteed performance (without recipe declaration), nor does it conflict with the qualification concept of Eurocode 7, which only provides for preliminary verification of the product's ability to satisfy the required performance. But above all, this fits perfectly with the natural approach of the specifier, who can focus on the pure performance necessary for the success of the project.

The addition of steel, carbon, basalt, or glass fibres can give considerable toughness to SCC, thus ensuring a new and important performance: ductility. The fibres, distributed homogeneously in the

concrete mass, create a dense network of reinforcing elements capable of reducing post-cracking deformations (with hardening behaviour) and increasing fire resistance and durability.

To-day, ready-mixed High-Performance Fibre Reinforced Self Compacting Concrete (HPFRSCC) can be industrially prepared at the concrete batching plants on the construction site, and transported by concrete mixer trucks directly to the excavation face, thanks to the possibility of extending the workability maintenance time as desired by means the use of dedicated additives.

Ready-mixed HPFRSCC can reach strength over 100 MPa, thus allowing a reduction in the thickness of the final lining, and consequently a reduced excavation open and a gain in times and costs of all the connected works, allowing a more efficient work-cycle, with less equipment and labour.

Regarding the checks during construction, these can be limited to regular testing of the properties and performances guaranteed by the product, without any need to verify its compositional characteristics, for which it is often necessary to adopt rather questionable verification methods.

In tunnelling, the use of a low carbon footprint HPFRSCC, fosters the environmental compatibility (lower CO₂ emissions per m³ of tunnel) of the entire work, increase the durability (longer operating life) and reduces the excavation sections (less m³ = less earth work and less muck), being so cost-effective.

Furthermore, the possibility to use larger quantities of muck as aggregates (even fine ones and with low technical quality) implies less costs for muck transport and disposal, and less costs for supplying aggregates.

3 CASE HISTORY

In order to verify in the field the contribute that the use of HPFRSCC can give in reducing the final lining thickness, ensuring the same safety, and therefore gaining in the excavation open and all the others factors connected, some case history have been analysed. For having a comparison two cases, named A and B, have been analysed for a 12 m span highway tunnel with full face excavation by drill and blast methods.

Case history A refers to the excavation of a tunnel in a geological formation constituted by a Granitoids unit with a tunnel overburden of 600; case history B is related to the excavation in a complex sequence of conglomerates, sandstones and mudstones with an overburden of 800 m.

The adopted requirements for the lining of the tunnel (Figures 1–3) are as follows: (1) fully grouted rockbolts to stabilize the tunnel and a temporary lining made of fibre reinforced sprayed concrete 15 cm thick, for case A (section type Ab1) and steel ribs, spacing 1.0, embedded in shotcrete 25 cm thick, for case B (section type B0), sufficient to stabilize the tunnel during construction and until the

final lining is placed; (2) a drainage layer consisting of porous geotextile fabric, connected to drainage pipes in the final tunnel invert (3) a waterproof membrane to prevent water entering into the space behind the final concrete lining; (4) a cast in place concrete lining and invert capable of resisting loads imposed by the surrounding rock mass for both short and long term operation of the tunnel.

Figure 1. Tunnel excavation section type Ab1.

Figure 2. Tunnel excavation section type B0.

On the basis of geotechnical investigation and geomechanical characterization, the geomechanical parameters adopted for the numerical models have been defined (Table 1).

To analyse the positive effect of the use of HPFRSCC, in the dimensioning the tunnel lining support, some numerical plane strain analyses have been carried out using the 2D finite element programme Phase2 (©Rocscience, 1998 - 2001).

The numerical models implemented (Figure 4) non – linear, Mohr – Coulomb plasticity with a graded mesh of 6 – nodes triangular solid materials elements, and Timoshenko - beam elements with an elastic concrete material model.

To simulate the stress relief and 3D arching effects during excavation, a relaxation factor is applied to the

rock mass in order to simulate the rock deformation prior to advance and installation of the lining at each excavation step (Vlachopoulos et al., 2009). This was realized through the stiffness reduction method, i.e. the rock within excavation zone is assigned lower elastic parameters (Young's modulus, Poisson's ratio) and the ground is allowed to deform to a new equilibrium before the lining installation.

The final step after the excavation and stabilization of the full tunnel profile is the installation of a final lining (Figure 5).

For both the section type, Ab1 and B0, the invert and vault final lining is made of cast concrete, respectively of 0.70 m and 0.60 m thick; the strength concrete class is C35/45, that is a cylinder characteristic strength equal to 28 MPa and a cube characteristic strength equal to 45 MPa.

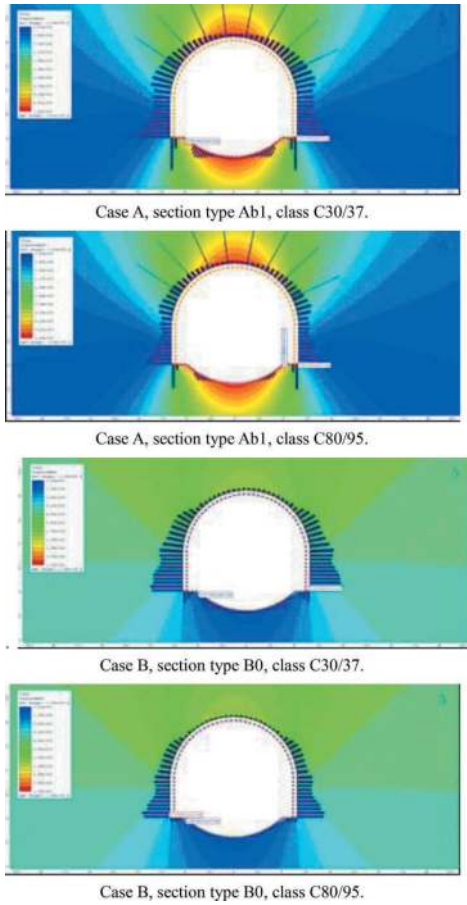

Figure 5. FEM results for the analysed configurations.

An additional numerical analysis has been carried out, for each section type, adopting HPFRSCC, characterized by a strength class C80/95, to evaluate the thickness reduction of the invert and vault final lining.

The results for the concrete strength properties C35/45 and C80/90 are presented in form of capacity limit curves, utilizing the support capacity diagrams proposed by Hoek et al. (2008), Kaiser (1985) and Sauer et al. (1994), (Figg.Figures 6–9).

For our purposes it is very important to have numerically verified the real technical feasibility of the premises.

4 DISCUSSION

From the analysis it results that the adoption of a HPFRSCC, with a value of the characteristic

cylinder compressive strength equal to 80 MPa and a value of the characteristic cube compressive strength equal to 95 MPa, allow to halve the thickness of the final lining from 0.70 m to 0.35 m, for the invert, and from 0.6 to 0.3 m, for the vault.

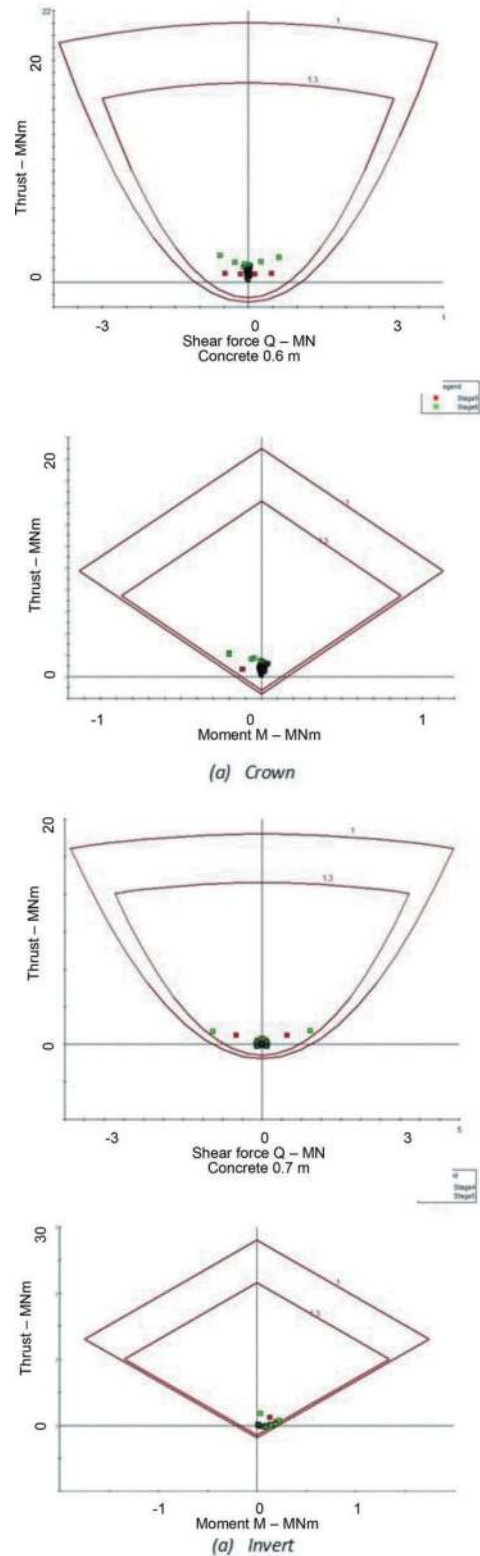

Figure 6. Case A (section type Ab1), FEM numerical analysis results, capacity limit curves/interaction diagrams for the final lining with a strength class equal to C30/37.

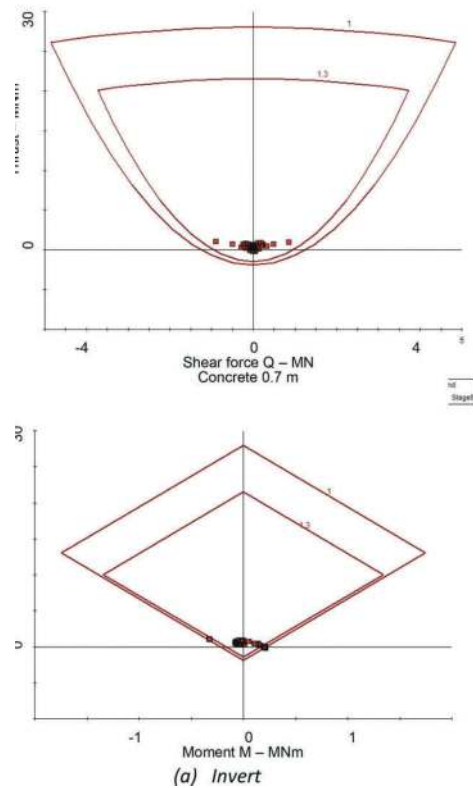

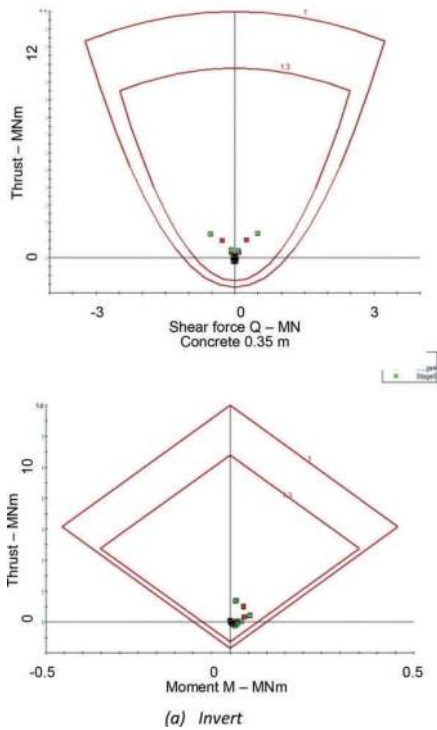

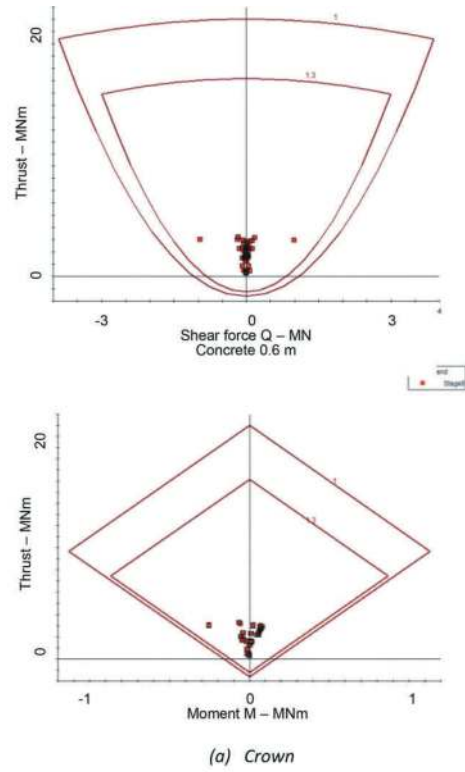

Figure 7. Case A (section type Ab1), FEM numerical analysis results, capacity limit curves/interaction diagrams for the final lining with a strength class equal to C80/95.

As stated in the introduction, a normal tunnels costs about 230 €/m^3 excavated, of which about 50% = 115 €/m^3 is for the excavation work and about 5% = 12 €/m^3 is for the lining.

From the above analysis it appears clear that the cost of the lining can be halved up to 6 €/m^3 .

Figure 8. Case B (section type B0), FEM numerical analysis results, capacity limit curves/interaction diagrams for the final lining with a strength class equal to C30/37.

By the use of HPFRSCC, the excavation span, maintaining the clear open required, can be reduced by 35 cm in the invert and 30 cm in the vault, which corresponds to gain about 20 m^3 of excavation

Figure 9. Case B (section type B0), FEM numerical analysis results, capacity limit curves/interaction diagrams for the final lining with a strength class equal to C80/95.

material for 1 m of a tunnel (= minus 20% from 113 m³ to 90 m³).

That corresponds into saving about 3,000 € for one m of tunnel (= minus 20%, from 13,000 €/m down to 10,350), or 3 M€ for km of a tunnel.

This solution is not only economic advantageous, but also environmentally friendly and compatible because reduces:

- the CO₂ emission related with cement furniture,
- the quantity of much produced and to be put on disposal,
- the trucks travels in need for supplying concrete and mucking, with the connected CO₂ emission and others pollutions,
- the conservation interventions,
- the total time to be planned for the execution,
- the final costs.

And increases:

- the production process,
- the lining resistance.
- the reuse of the muck in the same tunnel for concrete,
- the durability of the tunnel,
- the environmental compatibility of a design,
- the economic sustainability of a project.

HPFRSCC can easily substitute the use of reinforced concrete in tunnelling, largely boosting works and saving CO₂ emission that is estimated at about 1.85 ton of CO₂ for 1 ton of steel.

On more, instead that steel or carbon fibres it can be used basalt, or glass fibres, so farther reducing the carbon foot print.

5 DO NO SIGNIFICANT HARM – CIRCULAR ECONOMY

Considering EU funds, the REG. (EU) 2020/852 defines the criteria for determining whether an economic activity qualifies as environmentally sustainable for the purposes of establishing the degree to which an investment is environmentally sustainable, which is one of the conditions for eligibility of financing with EU funds and financial products. Two of the environmental objectives (art.9) is the transition to circular economy and climate change adaption. Having this type of sustainability criteria will contribute to steer the flow of capital towards sustainable investments; identify steps that financial institutions and supervisors should take to protect the financial system from sustainability risks (EU, 2018b).

With regards to the carbon footprint balance of a project, the use HPFRSCC lowers the CO₂ emissions decreasing: transport and concrete quantities.

Additionally, the use of HPFRSCC should help in increasing the energy efficiency by the use of less energy and less waste. Filling then some of the eligibility criteria for financing a project nowadays.

6 CONSIDERATIONS

The use of Fibres Reinforced Concrete began at the end of the 20th century (RILEM, 2003), and now is mature for a widespread use in tunnelling.

Because a tunnel project iter last up to 20 years it is now time to move design into the use of the HPFRSCC in order to have tunnelling on run by the half of this century, when the carbon neutrality must be reached.

That also help in elongating the Life Cycle Assessment (LCA) and having the Environmental Product Declaration (EPD) document as by EN 15804:2012+A1(ITB 2015).

Experiences in this way for saving CO₂ emissions, with the goal of contributing substantially in reaching carbon neutrality, have been already done for the segments of TBM tunnel (De Rivaz, 2022) and this goals is in the target of some Drill & Blast tunnel projects (Robinson, 2023; Holter et al., 2023), also coupled with sprayed waterproofing.

The use of HPFRSCC brings benefits in terms of costs reduction and increasing the necessary financial sustainability for the purposes of financing a specific underground investment project, and the application of sound and tested HPFRSCC can contribute in the fulfilling of sustainability criteria according to IFIs recommendations.

In order to mobilize additional funds and unlock investments resulting in the private sector playing a larger role in the financing projects of this type and the achievement of the Sustainable Development Goals (SDGs), a diversification of construction products compatible with standards should be a priority.

7 CONCLUSIONS

The focus of this paper is to present, on the base of a case history, the real possibility of the use in tunnelling of the HPFRSCC, so saving times, costs and impacts while improves financial sustainability. Technology is ready, letting the HPFRSCC easily available at the tunnel face by concrete-mixer trucks with precast HPFRSCC (Figure10). The requirement for a performance-based model, is in compliance with EU technical codes and rules, and, furthermore, EU environmental requirements are targeted.

As summary, we have that for a Drill & Blast tunnel the use of HPFRSCC can reduce the total cost of the tunnel by about 10% (from 230 €/m³ to 200 €/m³) plus all the others connected savings as above quickly outlined. On this base, we can roughly estimate a total reduction of the tunnel cost from 230 €/m³ down to 180 €/m³ (= minus 20%) that for a classical tunnel the required section of about 113 m² now reduces to 90 m².

For a tunnel of 10 km, these numbers lowers the cost from around 260 M€ to 160 M€, so largely increasing financeability and environmental compatibility for a tunnelling project.

Therefore, the use of HPFRSCC can contribute in the success of an underground project by:

Figure 10. Furniture of the HPFRSCC at the tunnel face, ready-to-use, by means of concrete-mixer truck, is today possible.

- contributing to have a higher ratio Benefits/Costs (BCR),
- contributing to have a reduced carbon footprint balance. These two points are nowadays key for supporting a sustainable development of an underground infrastructure.

The main output from the case history here presented is that the HPFRSCC is a challenge for tunnelling of the 21th century and its use must be the target of all the tunnel projects on run.

Structural and sustainability requirement with high performance fibre reinforced precast segment carbon counting example

Benoit de Rivaz*

NV Bekaert SA, Zwevegem, Belgium

ABSTRACT: Saving cost, reduced production time, improved handling, crack control and long-term durability, together with sustainability and carbon footprint reduction have driven the use of steel fiber as the predominant reinforcement for precast concrete segments worldwide the last 30 years. One of the aspects that are boosting the use of FRC in segmental linings is the introduction of guidelines for the design of FRC. In 2013, the fib presented the Model Code 2010 in which a specific part related to FRC is inserted. This document has sparked great interest in the tunnelling community and several documents consider Model Code 2010 as a reference. For this reason, fib Task Group 1.4 “Tunnels” decided to create Working Party 1.4.1 on “Tunnels in Fibre-Reinforced Concrete”. The Working Party prepared the present fib bulletin 83 with the aim to support designer, clients and construction companies in introducing FRC in segmental lining tunnels referring to the indication of Model Code 2010. This paper will introduce the process to validate the material properties used for the design process according to fib bulletin 83 being considered as the reference basis for the design of FRC segmental lining and some recent detail carbon counting from international recent project.

Keywords: High performance steel fibre low carbon lining

1 INTRODUCTION

Underground space plays a vital role in sustainable urban planning as it provides a solution to the limited surface area available. In terms of transportation, underground networks enable efficient and rapid mass transit, helping alleviate congestion and reduce carbon emissions. Moreover, underground space is essential for the infrastructure required to sustain cities, such as dense networks of pipes for delivering fresh water and sewers for wastewater treatment. Additionally, it accommodates the extensive network of cables and service stations necessary for modern communication systems. By utilizing underground space, cities can optimize their resource management and minimize their environmental impact, contributing to a more sustainable urban future.

For a sustainable use of structural concrete, environmental and mechanical performances of concrete structures must have the same importance. By means of sufficiently high mechanical performances, the structural safety of a construction is ensured. In a tunnelling project, it is generally considered that 60% to 70% of embodied carbon is contained in the concrete linings of the shafts and tunnels. It is

paramount, therefore that the tunnelling industry does its utmost to significantly reduce or eliminate its use of cement in all applications – segmental linings, in-situ linings, sprayed concrete, and annulus grouts. This is the reason why a great challenge for the coming years will be develop solution for low carbon lining. Mechanical excavated tunnels (tunnels excavated with a TBM – Tunnel Boring Machine) are more and more used in Civil Engineering. In these tunnels, the lining is made assembling precast segments used by the TBM as reacting elements in the excavation process. The use of Fibre-Reinforced Concrete (FRC) allows to reduce or eliminate the traditional reinforcement in the precast segment production. Over the last twenty years, the use of this technology has increased.

The use of Fibre Reinforced Concrete (FRC) allows several advantages, compared with traditional steel mesh or steel bar reinforcement according to fib bulletin 83 and all main recommendation published as:

Cracking control during construction phases.

- Higher impact resistance
- Durability advantages at final stage
- Reduction of costs

*Corresponding author: Benoit.DeRivaz@bekaert.com

- Sustainability advantages
- Boosting of the production process

Recent project has demonstrated that structural ductility, durability, and sustainability are going hand to hand. This holistic approach will be clearly a new booster for FRC tunnel lining. This paper will provide the start of the art on this issue, the key design principal and detail recent cases studies showing impact in carbon calculation saving in France, Middle East, and Australia.

2 SUSTAINABILITY & STRUCTURAL REQUIREMENT

For a sustainable use of structural concrete, environmental and mechanical performances of concrete structures must have the same importance. By means of sufficiently high mechanical performances, the structural safety of a construction is ensured. At the same time, a low environmental impact guarantees a sustainable development, which is, in accordance with the definition by the Brundtland Commission of the United Nations, a “development that “meets the needs of the present without compromising the ability of future generations to meet their own needs” (Brundtland Commission, 1987). FRC acts on the tensile behaviour of cracked concrete and imparts ductility to a fragile material. FRC’s excellent properties which overcome cracking as well as its improved durability over reinforced concrete are why we continue to develop that material and explain its economic success. The Life Cycle Assessment (LCA) is a methodology for assessing environmental im-pacts associated with all the stages of the life cycle of a product or process. It quantifies a material impact on the environment over its entire existence, from extraction of the raw materials required for its production up to its end of life. This approach, combined with research into a low-carbon solution, will give new momentum to FRC.

3 BASIC FRC BEHAVIOUR

A minimum tensile (strength) strength > 2200 MPa is recommended for final lining application considering the performance required and concrete classes. The hooked ends ensure the desired fiber pull-out. This is the mechanism that generates the renowned concrete ductility and post-crack strength.

The tensile strength of a steel fiber has to increase in parallel with the strength of its anchorage. Only in this way can the fiber resist the forces acting upon it. Otherwise, it would snap, causing the concrete to become brittle. On the other hand, a stronger wire cannot be fully utilized with an ordinary anchor design. Therefore, the tensile strength of a fiber has to be perfectly aligned with its anchorage system and its diameter.

Wire ductility and concrete ductility are two different aspects. Dramix® 4D steel fibers create

concrete ductility by the slow deformation of the hook during the pull-out process, and not by the ductility of the wire itself. The network provides by the fibre get a fundamental importance. Recommended diameter is 0.75mm and l/D= 80 to ensure a network > 10km/m³ with 40kg/m³. This network will play a key role in cracking control, structural ductility and allow low dispersion in the result.

Table 1. Influence of the l/D ratio on the network effect.

l/D	80/60	65/60	45/50
Length (mm)	60	60	50
Diameter (mm)	0.75	0.90	1.05
Aspect Ratio	80	65	45
Network (m/kg)	276	200	147

4 DESIGN PRINCIPAL

Model Code 2010 is the most comprehensive code on concrete structures. It covers their complete life cycle from conceptual design, dimensioning, construction, and conservation through to dismantlement. It is edited by fib Model Code 2010 was produced through the exceptional efforts of participants in 44 countries from five continents. The fib bulletin 83 document aims to support designers, contractors and clients with guidance for the use of steel fibre-reinforced concrete, known as FRC, in precast segmental lining tunnels constructed using tunnel boring machines (TBMs) The document is intended to complement the fib Model Code 2010 (MC2010), which presents a section on the design of FRC, with the Model Code 2010 being considered as the reference basis for the design of FRC segmental lining.

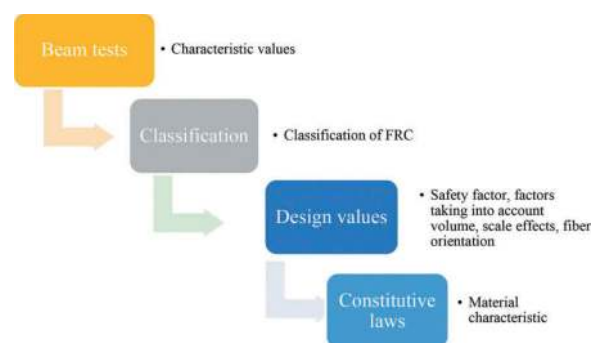

Figure 1. Illustrates the design process involved, from beam tests, classification, design values, and constitutive laws.

The tensile behaviour of the materials was characterized by performing bending tests on a notched beam. The tests were performed according to the EN 14651 European code, which is the reference standard for the CE label of steel and for ISO certification.

The compressive strength of the materials was measured by a testing cube with a side of 150 mm. For every cast made to produce every single segment, three beams were produced. In agreement with EN 14651, nominal strengths corresponding to four different crack mouth opening displacement (CMOD), namely 0.5, 1.5, 2.5 and 3.5 mm, were evaluated.

Figure 2 and 3 shows a typical result of the beam tests considering 40KG fibre type Dramix® 4D 80/60BGP with significant strength values. FL is peak force, f_{R1} and f_{R3} are the stresses related to CMODs equal to 0.5 and 2.5 mm respectively. These values are the reference ones for final lining design performed according to the fib Model Code 2010 prescriptions.

Figure 2. Curve Load -deflection of the beam bending tests according to EN 14651 (Roma University Report).

	f_L [Mpa]	f_{R1} [MPa]	f_{R2} [MPa]	f_{R3} [MPa]	f_{R4} [MPa]
Beam_01	4.68	6.70	7.86	7.69	7.47
Beam_02	4.90	6.28	8.49	8.20	7.58
Beam_03	4.78	6.45	8.41	8.42	8.04
Beam_04	5.15	6.56	9.04	8.64	7.44
Beam_05	5.72	7.33	8.95	8.75	8.19

Beam_07	5.63	7.75	10.2	8.99	8.54
Beam_08	4.60	6.28	8.16	9.25	8.40
Beam_09	5.43	6.18	8.03	8.50	8.33
Average	5.10	6.64	8.64	8.63	8.05
Characteristic	4.30	5.58	7.26	7.65	7.19

Figure 3. Results of the beam bending tests according to EN 14651 mean and characteristic value (Roma University Report).

To dimension a steel fiber-reinforced concrete segment, a reference test methodology needs to be adopted for the characterization of performance. In addition to the mechanical performance, various properties of the FRC can be specified.

Since brittleness must be avoided in structural behavior, fiber reinforcement can be used as substitution (even partially) of conventional reinforcement (at ULS), only if both the following relationships are fulfilled:

$$f_{R1k}/f_{Lk} > 0.4$$

$$f_{R3k}/f_{R1k} > 0.5$$

Where f_{Lk} is the characteristic value of the nominal strength, corresponding to the peak load (or the highest load value in the interval 0 – 0.05 mm),

determined from the EN 14651 beam test. It is recommended to realize 12 beams per dosage and concrete mix formula.

If fibres are used as the only reinforcement for final lining, hardening post-crack behaviour at section level (beam test) allow immediately:

- Cracking control at SLS
- Structural ductility (ULS)

The Figure 3 shows the typical expected result considering FRC only as reinforcement. The performance class according to Model Code 2010 in this example is C40/50 5e FRC material, which means,

$$f_{R1k} > 5 \text{MPa.}$$

$$f_{R3k}/f_{R1k} > 1.3.$$

Indeed, materials with f_{R1k} ranging from 4.0 MPa mini to 6.0 MPa are commonly used for precast tunnel segments without any bar reinforcement, combined with a f_{R3k}/f_{R1k} ratio in the ranges $1.1 < f_{R3k}/f_{R1k} < 1.3$ or $1.3 < f_{R3k}/f_{R1k} <$ (class d and e respectively, according to the Model Code 2010 definition).

5 LOW CARBON PRECAST SEGMENTS CASE STUDIES

5.1 Grand Paris

The use of steel to replace all or a part of conventional reinforcement has been demonstrated to lower the embodied CO₂ of the segmental lining. While it is possible to significantly reduce the embodied CO₂ of a concrete mixture for segment production by replacing a portion of its cement content with alternative cementitious materials, there is little or no difference between the cementitious blends and contents required to produce fiber reinforced or conventionally reinforced concrete segments for tunnel linings.

Figure 6 shows an example reduction in CO₂ emissions on a project made possible by modification of the concrete and further reduction by being able to replace the rebar with steel fibers in a dosage that satisfied all the design requirements. On a - per pound (kg) basis the embodied CO₂ of conventional rebar and steel fibers is assumed the same. This is a generalization assuming the wire rod that the fiber is produced from, and the rebar have similar % recycled material content and similar steel production methods. In a precast segment the reduction in carbon footprint is due to the steel fibers being more efficient in reinforcing the element. In this example the elimination the combination of the right binder and steels fibre could conduct to a reduction 70%.

The recent project for the Grand Paris Linea 16.1 has shown the following:

- From the saving in the ratio of fibers compared with steel reinforcement bars, leading to

a significant reduction in CO2 emissions during transportation. If we compare 85kg/m³ for steel reinforcement bars with the 40kg/m³ for fibers, we get a saving on materials of more than 50%.

- By the benefit of better optimized loading for the fibers. 22 big bags of 1,100/kg per truck = 24.2 tons per load for the delivery of the fibers in comparison with 60 equivalent segments per truck = 17.85 T for the delivery of the concrete reinforcement bars.
- From the small diameter of the fibers which helps to further limit toxic emissions from the primary steel industry, due to primary coils which do not exceed 1 mm of wire diameter. The drawing technology is low emission.
- Fewer trucks on the road and optimized waste management in a large city like Paris is an important element to take into account. From an ecological point of view, the carbon balance is therefore very positive. In this respect, Bekaert has recently obtained its EPD (Environmental Product Declaration) Type III ITB certificate number 215/2021.
- The concrete chosen for the Line 16 Lot 1 fibre reinforced segments has a low carbon footprint of 170kg CO₂ equivalent/m³ and reduces the carbon weight of the steel in the segments by

Figure 4. Project jobsite Grand Paris - Photo Credit Eiffage Génie Civil.

90kg equivalent CO₂/m³ or nearly 11,000 tons equivalent CO₂ per 10km.

In terms of concrete, there will be a before and after Grand Paris Express. Until now, to design the segments, we used reinforced concrete, that is to say concrete poured around cages of massive metal reinforcements.

The graph hereunder illustrates the main impact gain in term of carbon emission for typical Pre-cast segment ring used for a Metro tunnel.

Figure 5. Typical Metro project, precast segment carbon emission counting.

This example (Figure 5) is based on the following assumption:

- Using a CEM III vs CEM I improves the CO₂ score significantly.
- As we use 60% less reinforcement (100kg rebar vs 40 kg Dramix®) and also average rebar EPD is higher than Dramix® EPD, we end up with this difference with reinforcement
- Using FRC allows thickness reduction by 2cm mini which results in additional savings in concrete.
- Thickness 38 cm

5.2 Middle East Journey

A paper by consultant COWI Denmark entitled 'Consultant's view of durable and sustainable concrete tunnel constructions in the Middle East' WTC 2018 Dubai provides this example how much CO₂ emission saving was reached by replacing traditional concrete and steel-reinforced with steel fiber reinforcement and adding GBBS/FA to the concrete mix provides an example of reduction of concrete and further reduction by being able to replace the rebar with steel fibres in a dosage that satisfied all the design requirements.

This project as Doha Metro Green line has been designed with FRC using Dramix® fibre based on MC2010 to meet some specific condition:

- Very high chloride content: 10,000 - 50,000 mg/l
- High sulphate content: 100 - 5,500 mg/l
- High soil temperature: 28 - 32°C

Figure 6. Evolution of Precast segment lining (Cowi/C. Edvarsen publication WTC 2018).

Main advantages

- Increased resistance to chloride-induced corrosion
- Eliminated risk of stray current-induced corrosion
- Easier production/handling
- Simplified segment precasting process

This return of experience in Middle East demonstrates that by using FRC increased resistance to chloride-induced corrosion and reduced carbon footprint. Durability and sustainability go hand in hand.

5.3 The Montreal Metro Blue Line Extension Project

The Montreal Metro Blue Line Extension Project consists of construction of 6 kilometres of tunnel, as well as five new underground stations. This represents a good example as well showing that durability and sustainability goes hand to hand. Indeed, the reduction in segment thickness achieved with fibers can be primarily attributed to the concrete cover requirements of 60-75 mm on both intrados and extrados rebar to ensure the durability against corrosion when designing according to Canadian code CSA A23.1:19 (2019). In contrast, when subjected to chloride exposure, corrosion in steel fiber reinforced concrete is limited to just a few millimeters from the surface, and nonetheless, does not lead to spalling cracks and is not regarded as a durability issue. CO2 savings in the segments is realized by replacing rebar with steel fibers as the quantity of steel required is 50% less per m3 of concrete with fibers. (40 kg/m3 vs 80 kg/m3) Additionally, the CO2 equivalent factor for rebar is reported to be 1.85 vs 0.88 for fibers. The fiber reinforced segments can be reduced in thickness due to no requirement for cover like rebar. This quantity of concrete savings also lowers the carbon footprint.

The owners' design engineer, AECOM, as part of a commitment to integrating sustainability best practices, performed a study utilizing the Envision framework to evaluate alternatives to achieve a most sustainable infrastructure project. Based on the results of this study the TBM bored tunnel sections will be lined with steel fiber reinforced precast concrete segments using low-carbon Supplementary Cementitious Materials (SCM) concrete.

In the TBM tunnel sections lined with pre-cast concrete segments, high performance Dramix® steel fiber 4D80/60BGP with a dosage of 40 kg/m3 is designed as standalone reinforcement.

See below table summarizing the results of the evaluation showing a reduction in total CO2 equivalent by nearly 50% using SFRC with an optimized SCM concrete mix design:

Mix Design Components	CO ₂ e Factor	Baseline Reinforced Concrete Mixture (OPC)			Moderate SCM Concrete Mixture with Fiber		
		Mass (kg/m ³)	CO ₂ e (kg/m ³)	% Replacement by Mass	Mass (kg/m ³)	CO ₂ e (kg/m ³)	% Replacement by Mass

5.4 The Forrestfield airport link

“The Forrestfield airport link is a “design and construct” type of project; it will deliver an 8.5 km extension of the existing PTA urban rail network in Perth, Western Australia, connecting the Midland Line, just past Bayswater Station, to Forrestfield. The twin-bored tunnels will travel underneath the Swan River, Tonkin Highway and Perth Airport. The project will include three new stations; Redcliffe Station (located under-ground in Redcliffe), Airport Central Station (located underground at Perth Airport to service both domestic and international terminals) and Forrestfield Station. The tunnel excavation diameter is 7,100 mm; the segmental lining has an inside diameter of 6,170 mm, and thickness of segment is 300 mm with an average length of 1,600 mm”.

The segmental lining was designed to meet the project's concrete requirements of 120-year service life with a minimum water/binder ratio of 0.35. This article draws its attention to the specific concrete mix design from the design up to the construction phases of the precast segmental linings.

Several trials were performed with cast concrete beams according to standard BS EN 14651 (single trial was made with #9 concrete beams) with 35 kg/

The characteristic values of these results were more than the serviceability state 5.08 MPa at CMOD1 and 5.28 MPa at CMOD3. The results have confirmed the assumptions for the quantity reduction and the mix with 35 kg/m³ of Dramix® 4D 80/60BGP steel fibres content was adopted in project works.

Carbon Counting

6 EPD CERTIFICATE

An Environmental Product Declaration (EPD) is a document that transparently communicates the key environmental performance indicators of a product over its lifetime.

A third-party verification ensures that data relating to environmental aspects of Dramix® has been validated by an external organization.

This declaration is the Type III Environmental Product Declaration (EPD) based on EN 15804:2012+A1 and verified according to ISO 14025 by an external auditor. It contains the information on the impacts of the declared construction materials on the environment. Their aspects were verified by the independent body according to ISO 14025. Basically, a comparison or evaluation of EPD data is possible only if all the compared data were created according to EN 15804:2012+A1.

The environmental impact of Dramix® product (cradle to gate with options) is largely dependent on the energy intensive production of steel (half product) on which the manufacturer has only a limited influence. The carbon impact of steel production (Wire Rods) in the product stage A1 is as high as 85%. The impact of the production line largely depends on the amount of electricity consumed by manufacturing plant (0.34 kWh/kg of product). There are no significant emissions or environmental impacts in the A3 production processes alone (partly gas combustion). The production process itself does not have significant environmental impacts in the life cycle.

7 CONCLUSION

There has been a trend the last years that concrete tunnel linings have increased material consumption, cost, and environmental loads. Nowadays develop

and/or improve tunnel construction methodology to choose the optimal tunnel lining, including environmental footprint and cost-effectiveness. Create required knowledge to produce final lining to meet new large infra-structure projects with modern demands to functionality incl. 100-year service life and environmental impact.

The use of steel fibre reinforced concrete will highly participate to meet low carbon lining by concrete consumption and steel reinforcement saving. If ductility and durability have been the key words the last 40 years, the sustainability will be the key driver for further FRC lining development in the coming years.

Indeed, new generation of binder combined with FRC allow new achievement:

- Provide excellent long-term durability performance exceeding that of Portland cement-based concretes.
- Excellent long-term durability performance exceeding that of Portland cement-based concretes. Extremely low embodied carbon footprint compared to conventional concretes on Portland cements.
- Compared to reinforced concrete, fiber-reinforced concrete notably represents savings of around 5,000 tons of steel for 10 kilometers of tunnels (Typical Metro Tunnel).

We all believe that tunnels should use smart and sustainable construction materials. The future of tunnelling is choosing these materials today. High Performance steel fibre could play an important role in this final lining sustainable journey.

Research on reinforcement measures for soft plastic loess tunnel base

Qihua Deng*

Faculty of Architecture, Civil and Transportation Engineering, Beijing University of Technology, Beijing, China
China Railway 22 Bureau Group Co., Ltd., Beijing, China

ABSTRACT: The loess strata has characteristics such as collapsibility and structural sensitivity. Constructing tunnels in this formation can easily lead to excessive deformation of the initial supporting structures, especially causing cracking and heave disasters at the invert position, which affects the safety during both the construction and operation periods. This article firstly analyzes the physical properties of soft plastic loess through indoor experiments. Secondly, specific reinforcement schemes are proposed based on the sleeve valve tube grouting reinforcement mechanism. Finally, the morphology, moisture content, strength, and range of influence of loess after grouting are analyzed through on-site monitoring data and core sampling analysis. The results indicate that the plasticity index and liquidity index of the loess samples are 12 and 0.55, respectively, with an average liquidity index greater than 0.50, indicating that the loess samples are in a soft-plastic state; The sleeve valve tube grouting reinforcement technique can effectively reduce the permeability and moisture content of the loess formation, as well as improve its unconfined compressive strength; The influence of the grouting process on the stress in the surrounding soil gradually decreases from near to far, and the maximum influence radius in the horizontal direction is 8.03 meters.

Keywords: Tunnelling, Soft plastic loess, Grouting reinforcement, Monitoring measurement

1 INTRODUCTION

Tunnels are an important means of transportation construction. With the increase in the number of tunnels, it is inevitable to encounter complex and adverse strata (Fu et al., 2022; Li et al., 2023), among which the loess strata has obvious structure, strong permeability, collapsibility, development of vertical joints, and other characteristics (Wei and Zhu, 2021; Zhang et al., 2018), which may cause construction risks such as water leakage, large deformation, falling blocks, and collapse in tunnel construction in this stratum, especially the risk of sudden instability caused by collapsibility (Liang et al., 2016). In addition, the disaster characteristics of loess may also lead to cracking and uplift of the arch structure, which will affect the later safe operation of the tunnel project (Liu et al., 2017).

During the construction of most loess tunnels, waterfall erosion, lateral erosion, headward erosion (Li et al., 2020), will occur due to surface water infiltration or groundwater erosion, which will lead to the decrease of surrounding rock strength, large deformation, loess collapse and other problems (Cheng et al., 2017; Sun et al., 2021), eventually leading to cracking and uplift disasters in the inverted arch. Based on the analysis of 27 loess

tunnels, Sun (Sun et al., 2021) believes that the infiltration of surface water into the surrounding rock through joints and fissures will increase the water content of the loess and reduce the strength of the surrounding rock. The tunnel support structure bears more load, resulting in uplift and cracking disasters in the inverted arch. As the water content continues to increase, a saturated zone is formed at the bottom plate, which in turn affects the overall displacement of the tunnel (Li et al., 2022), and in severe cases will lead to tunnel collapse (Yan et al., 2022). Based on the deterioration mechanism of mechanical properties of loess surrounding rock under the action of surface water, Liu (Liu and Lai, 2020) used a multi-point independent loading test system for tunnel lining to analyze the deformation and cracking of lining structure. It was found that the development order of cracks in lining structure was type I initial cracks, L-type middle cracks and Y-type late cracks, and the types of cracks in lining were mostly concentrated in L-type. Li (Li et al., 2019) analyzed the stress state of the tunnel structure through a large-area immersion test on site. The results show that as the water content of the loess surrounding rock near the tunnel lining structure gradually increases, the inverted arch begins to produce upward

*Corresponding author: dqh18635489278@163.com

displacement. Therefore, a reinforcement method that can reduce the water content of loess and improve the overall strength of the stratum is needed. The grouting reinforcement method is to inject the solidified slurry into the stratum through a certain pressure and expand through the cracks in the soil to improve the overall physical and mechanical properties of the stratum (Lee et al., 2020). Grouting properties and grouting range are also different due to different formation conditions and actual construction control requirements (Wu et al., 2020). There is a loess fine grouting reinforcement scheme based on improving the physical and mechanical parameters of the slurry (Yang et al., 2020). Numerical manifold method is also used to simulate the whole process of grouting reinforcement, so as to analyze the influence of grouting reinforcement technology on the deformation of surrounding rock of deep tunnel caused by excavation (Xu et al., 2021). Some scholars analyzed the influence range of sleeve valve tube grouting reinforcement technology on improving the strength of surrounding rock of weak tunnel face by means of numerical simulation (Liu et al., 2019). At present, the research on sleeve valve tube grouting reinforcement technology mainly focuses on its slurry composition, casing material ratio, etc., and there are relatively few studies on the influence of reinforcement soil in the grouting process. In addition, most of the research methods used are laboratory tests and numerical simulations, while the loess strata are more sensitive to the structure, and field tests are needed to better reflect the grouting reinforcement effect.

In summary, this paper first analyzes the physical properties of soft plastic loess. Secondly, based on the grouting reinforcement mechanism of sleeve valve tube, a specific reinforcement scheme is proposed. Finally, the shape, water content, strength and grouting influence range of loess after grouting were analyzed by field monitoring data and core sampling. The research results of this paper have good theoretical significance and application value for the grouting reinforcement technology of loess tunnel basement.

2 PROJECT PROFILE

The total length of Shanggecun tunnel on Yinxi high-speed railway (Ganning section) is 6782.45 m (DK 207 + 517.55 ~ DK 214 + 300), the buried depth is 5.5 ~ 102 m, the length of grade IV surrounding rock is 2560 m, and the length of grade V surrounding rock is 4222.45 m. The tunnel position and profile are shown in Figure 1. The strata in the tunnel site area are mainly Quaternary Middle Pleistocene aeolian clay loess, mainly hard plastic, and vertical joints are developed. Some sections of the tunnel body pass through the shallow buried slow slope, hard plastic loess and groundwater affected section, which has high construction risk and high safety risk. According to the drilling data

and the survey of wells in the tableland, the groundwater level in the loess tableland is about 50 ~ 70m, and the thickness of the aquifer is 10 ~ 30m in the exploration depth. The area of loess tableland where the tunnel passes through is complete and open, and the groundwater occurrence condition in the center of loess tableland is relatively good, and the water level is shallow. In the deep section of the valley, the discharge conditions of surface water and groundwater are better, and the occurrence conditions of groundwater are relatively poor.

Figure 1. Tunnel location and geological profile.

3 DAMAGE STATUS

In the excavation process of Shanggecun Tunnel of Yinxi Railway (Ganning Section), the surface of the primary support structure is wet, and the phenomenon of water seepage (leakage) is more serious, which is dripping or linear outflow. The local section flows out in the form of strands along the tube roof drilling, and the arch foot is softened seriously. Settlement occurs at the vault, and cracking and uplift disasters occur at the inverted arch. After on-site investigation, the inverted arch parts of the DK210 + 600 ~ DK211 + 700 section of the tunnel have different degrees of cracking and uplift, as shown in Figure 2. The maximum crack width is 30 mm. At the same time, there is a more serious arch uplift disaster, and the amount of uplift is up to 30 cm. The inverted arch parts of the other sections have different degrees of cracking and uplift disasters. The cracks in the inverted arch are basically longitudinal cracks. In addition, the vault of the tunnel also has different degrees of subsidence.

Figure 2. Tunnel location and geological profile.

4 PHYSICAL PROPERTIES OF SOFT PLASTIC LOESS

In order to reduce the disturbance to the undisturbed soil sample, the sample was sealed by the plastic film immediately after the sampling of the surrounding rock of the loess in the field, and then the sample was wrapped by the shock absorption foam, and sent to the laboratory within 24 hours. The indoor geotechnical tests such as density test, moisture content test and boundary moisture content test were carried out. The physical and mechanical parameters of the loess sample were obtained by statistical analysis as shown in Figure 3. In this experiment, the liquid limit and plastic limit of soil were measured by the combined measurement method of liquid and plastic limit. It can be seen from Figure 3 that the maximum water content of loess samples is 26.9 %, and the average water content is 26.1 %. The range of natural density is 1.94 ~ 1.98 g/cm³, and the average natural density is 1.96 g/cm³. The range of natural void ratio is 0.73 ~ 0.77, and the average natural void ratio is 0.75. The saturation of the sample is high, ranging from 91.90 % to 97.6 %, and the average saturation is 94.5 %. According to the average values of liquid limit and plastic limit of loess samples are 31.5 % and 19.5 % respectively, the plasticity index and liquid index can be calculated to be 12 and 0.55 respectively. The average liquid index is greater than 0.50, indicating that the loess sample is in a soft plastic state.

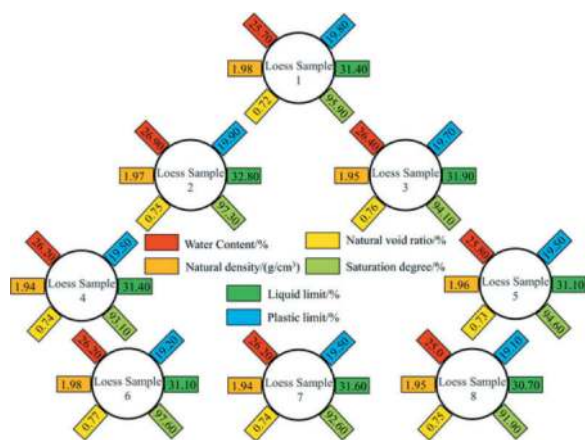

Figure 3. Tunnel location and geological profile.

5 SLEEVE VALVE TUBE GROUTING REINFORCEMENT MEASURES

5.1 Reinforcement mechanism

Splitting grouting is a dynamic grouting process in which the soil is compacted first and then split. It is grouted while the soil is split, so that the slurry can enter the soil after splitting and expand the reinforcement area. Sleeve valve tube grouting technology is an effective and economical soft soil foundation reinforcement method based on splitting grouting. First of all,

the slurry enters the soil through the small hole on the sleeve valve tube, and produces a squeezing effect on the soil with a lower pressure. Secondly, with the continuous injection of slurry, the pressure of soil is increasing, and the squeezing effect of slurry on soil is gradually transformed into splitting effect. Finally, the slurry can flow in a wide range through the cracks in the soil after splitting, so as to complete the overall reinforcement of the foundation. The particles and pores of loess are small and dense. At the same time, the loess foundation also has collapsible characteristics. Therefore, when dealing with the soft plastic loess of the tunnel base, a simple, easy to implement, small space and economical soft foundation treatment method is usually needed. The sleeve valve tube grouting has the advantages of pre-buried casing, staggered peak construction and controlled grouting, which is very suitable for the treatment of loess foundation.

5.2 Strengthening schemes

The construction steps of sleeve valve tube grouting technology to reinforce the soft plastic loess tunnel base mainly include pre-embedded casing, drilling pressure tube, grouting and hole sealing treatment.

5.2.1 Pre-embedded casing tube

In the process of tunnel excavation, in order to prevent the collapse of surrounding rock, maintain the three-dimensional stress state of surrounding rock, and give full play to the self-bearing capacity of surrounding rock, it is necessary to construct the initial support structure in time. In this project, the initial support structure adopts the construction scheme of combining I-steel frame and shotcrete. The sleeve valve tube grouting needs to follow the excavation construction of the inverted arch. The construction period is long, which is not conducive to the timely closure of the initial support into a ring, and the risk is large. Therefore, $\Phi 133$ mm casing tube is reserved in the inverted arch and the filling layer. After the embedded casing tube is completed, the inverted arch and the filling surface can be poured. In the pouring process, it is necessary to protect the upper mouth of the casing tube to avoid the concrete falling into the casing tube and increase the difficulty of later drilling.

5.2.2 Bore hole

After the pouring of the inverted arch surface and the filling surface is completed, after the site is leveled, the drilling rig enters the field to drill in the reserved casing tube and drill to the design depth. The drilling position generally lags behind the construction of the secondary lining by 40 ~ 60 m. After the drilling is completed, the auxiliary drilling rig is used to press the plastic sleeve valve tube. Finally, according to the field test, the appropriate ratio of the casing material injection tube is determined, and the sleeve valve tube is sealed with the casing material.

5.2.3 Grouting and hole sealing treatment

After the backfilling of the inverted arch is completed and reaches the required strength, and the hole is sealed, the base sleeve valve tube grouting reinforcement is conducted. The grouting reinforcement profile is shown in Figure 4, with a transverse reinforcement range equal to the excavation width of the inverted arch and a vertical reinforcement range of 13 meters below the inverted arch. The grout holes are arranged in an equilateral triangle with sides of 1.5×1.5 meters, and the grout dispersion radius is 0.9 meters (as shown in Figure 5). The grouting material consists of P.O42.5 ordinary cement single liquid slurry mixed with a certain proportion of HPC admixture, with an admixture dosage of 15-20%, and a water-cement ratio of the slurry is 0.8:1. $\Phi 76$ mm steel sleeve valve tubes (with a thickness of 5 mm) are used for retrogressive grouting. Retrogressive layered grouting is achieved through the insertion of grouting core pipes and the use of grout plugs (layered length of 1-1.5 meters). When the grout plug is pressurized to 2.0 MPa with a hand pump, grouting begins. When the grouting process reaches a certain degree, the grouting is considered complete, and grouting can be carried out for other sleeve valve tubes. After grouting is completed, the floating slurry and loose debris inside the steel pipes should be promptly removed, and then filled and compacted with HoJa-53F micro-expansion grouting compound.

Figure 4. Grouting reinforcement range profile diagram.

5.3 Result analysis

5.3.1 Core morphology

After the completion of base grouting, a more intuitive analysis of the effectiveness of grouting can be achieved through core sampling from drilling (Mu et al., 2023). Therefore, after using sleeve valve tube grouting to reinforce the soft plastic loess at the base of Shangge Village Tunnel, core

Figure 5. Grouting reinforcement diffusion range illustration.

samples were taken from the reinforced area to evaluate the application effect of sleeve valve tube grouting technology on soft plastic loess through the analysis of loess core samples. The morphology of loess core samples and drill holes before and after grouting is shown in Figure 6. Before grouting, a large amount of groundwater quickly infiltrated into the drill hole, indicating a high permeability of the soil. In addition, the surface of the loess core sample was water-rich, difficult to shape, and exhibited obvious characteristics of soft plastic loess. After the implementation of sleeve valve tube grouting reinforcement, there was no visible water in the drill hole, indicating a decrease in permeability compared to before grouting. Furthermore, there was no apparent water-rich morphology on the surface of the loess core sample, and the core sample exhibited better formation. Additionally, after grouting, cement mortar was observed in the cracks of the core sample, and compaction was observed in the cross-section, indicating good fracturing capability of sleeve valve tube grouting, which can effectively strengthen the soft plastic loess in a larger area of tunnel foundation. Therefore, the sleeve valve tube grouting reinforcement technology can reduce the permeability of soft plastic loess.

Figure 6. Loess core sample and borehole formations.

5.3.2 Moisture content of core sample

From the drilling and core sampling conducted before and after the grouting reinforcement, the water content of the yellow loess samples in the DK210+700, DK210+720, DK210+740, DK210+760, DK210+780, and DK210+800 sections was measured through laboratory experiments, as shown in Figure 7. Prior to grouting reinforcement, the DK210+800 section had the highest water content in the yellow loess, reaching 34.4%. The DK210+700 section had the lowest water content, at 27.4%. The average water content of the six sections of yellow loess was 30.55%. After grouting reinforcement, under the splitting action of the grout, the soil mass was compacted, and pore water began to be expelled outward. The cracks in the soil mass were filled with grout, sealing off the groundwater supply lines. The water content of the yellow loess in all six sections showed varying degrees of decrease. Among them, the DK210+800 section had the highest reduction in water content, decreasing from 34.4% to 18.6%. The DK210+760 section had the smallest decrease, only about 1/5. The average water content of the six sections of yellow loess was 20.75%. Therefore, it indicates that sleeve valve grouting technology can effectively reduce the water content of soft plastic yellow loess.

Figure 7. The water content of loess core sample.

5.3.3 Core strength

Before and after the grouting reinforcement, core samples were taken from the DK210+740 section by drilling. The core sampling range was 3.5 meters below the crown base. The 3.5-meter yellow loess core sample was divided into six sections, and each section was prepared into a cylindrical specimen with a diameter of 4.0 cm and a height of 8.0 cm for unconfined compressive strength testing. The steps for unconfined compressive strength testing were carried out according to the “Standard for Geotechnical Testing Methods”(GB/T 50123-2019, 2019). The unconfined compressive strength of the yellow

loess core samples before and after grouting reinforcement is shown in Figure 8. Prior to grouting reinforcement, the maximum unconfined compressive strength within the range of 0-3.5 meters below the crown base in the DK210+740 section was 0.41 MPa. After grouting reinforcement, the unconfined compressive strength of the base yellow loess increased to varying degrees, with the highest increase being 0.16 MPa. Compared to the unreinforced state, the average unconfined compressive strength of the entire formation increased by 31.18% after reinforcement. Therefore, sleeve valve grouting technology can improve the strength of soft plastic yellow loess, reduce the load on tunnel support structures, and reduce the risk of deformation and cracking in support structures.

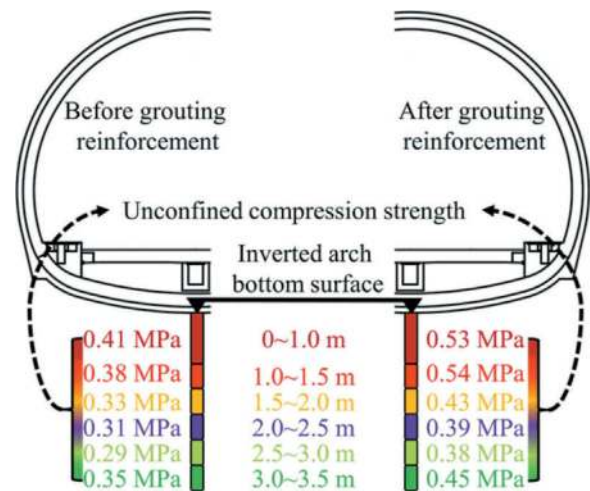

Figure 8. Unconfined compressive strength of loess core sample.

5.3.4 Grouting influence range

The advantage of sleeve valve grouting technology lies in its wide applicability, as it allows for continuous high-pressure fracturing grouting, enabling the formation of a large area of interconnected solidified grout within the soil. Therefore, the range of fracturing effects generated by sleeve valve grouting is crucial for reinforcing yellow loess formations. In this study, monitoring holes with pre-embedded soil pressure cells were set up around the grouting holes to monitor the stress increment in the soil during grouting. The arrangement of the monitoring holes is shown in Figure 9. Four monitoring holes were set up at distances from the grouting hole, with monitoring hole No.1 located at a distance of 1.5 m, monitoring hole No.2 at a distance of 4.0 m, and monitoring holes No.3 and No.4 at distances of 6.0 m and 7.5 m respectively. Each monitoring hole was equipped with a soil pressure cell at depths of 0 m, 2 m, and 4 m.

According to the data recorded by the soil pressure cells in the four monitoring holes, the stress increments in the soil at different depths during drilling or sleeve valve grouting can be obtained, as

Figure 9. Layout schematic of monitoring stations.

shown in Figure 10. When the ungrouted borehole is formed, the yellow loess formation is in an undisturbed state, and the stress increments in each monitoring hole are all 0 kPa. After the grouting hole is drilled, in monitoring hole No.1, the stress increment in the soil increases from 21.31 kPa to 30.79 kPa with increasing depth; in monitoring hole No.2, the stress in the soil increases with increasing depth, reaching a maximum increment of 3.59 kPa; in monitoring hole No.3, the stress increment in the soil decreases with increasing depth, decreasing from 4.18 kPa to 1.24 kPa; in monitoring hole No.4, the stress increment in the soil decreases with increasing depth and reaches a minimum of only 0.2 kPa at a depth of 4 m. The stress increments in the soil in the four monitoring holes show two different trends with increasing depth. In monitoring holes No.1 and No.2, as the depth increases, the soil structure becomes stronger and the connection between the yellow loess particles becomes tighter, resulting in higher stress increments in the soil due to the drilling action. In monitoring holes No.3 and No.4, as the depth increases, more cracks appear in the soil, and the sensitivity to external forces decreases. When sleeve valve grouting is carried out after drilling, the stress increments in the soil in all monitoring holes decrease with increasing depth. The stress increment in monitoring hole No.1 decreases from 181.49 kPa to 81.93 kPa, in monitoring hole No.2 from 78.55 kPa to 35.19 kPa, in monitoring hole No.3 from 39.74 kPa to 22.48 kPa, and in monitoring hole No.4 from 31.86 kPa to 21.68 kPa. Sleeve valve grouting technology produces fracturing effects in the surrounding soil when grouting vertically, and then injects grout into the fractures to form grout veins. The grouting pressure is no longer simply transmitted vertically or horizontally but is transmitted along the weak structural planes of the soil that are subject to fracturing. In addition, as the distance between the monitoring hole and the grouting hole increases, the stress increment in the soil gradually decreases. Therefore, during sleeve valve grouting, the closer the monitoring hole is to the grouting hole, the more pronounced the fracturing effect will be.

Figure 10. Stress increment of soil under sleeve valve tube grouting.

Based on the data recorded by the soil pressure cells after grouting, the influence range of horizontal grouting can be analyzed, as shown in Figure 11. Under different burial depths, the horizontal stress increments caused by grouting show a certain linear variation. By fitting the data, the following regression equations are obtained:

$$\sigma_0 = 202.88 - 25.26H_0 \quad R^2 = 0.91 \quad (1)$$

$$\sigma_2 = 135.80 - 15.96H_2 \quad R^2 = 0.96 \quad (2)$$

$$\sigma_4 = 88.40 - 10.12H_4 \quad R^2 = 0.86 \quad (3)$$

In the equation, " σ_0 " represents the soil stress increment at a burial depth of 0 m (kPa), " σ_2 " represents the soil stress increment at a burial depth of 2 m (kPa), " σ_4 " represents the soil stress increment at a burial depth of 4 m (kPa), " H_0 " represents the horizontal distance at a burial depth of 0 m (m), " H_2 " represents the horizontal distance at a burial depth of 2 m (m), and " H_4 " represents the horizontal distance at a burial depth of 4 m (m).

From the regression equations (1), (2), and (3), it can be inferred that the horizontal influence range of the grouting hole at burial depths of 0 m, 2 m, and 4 m is 8.03 m, 8.50 m, and 8.73 m, respectively. Therefore, considering the worst-case scenario, the horizontal influence radius of the grouting hole is 8.03 m.

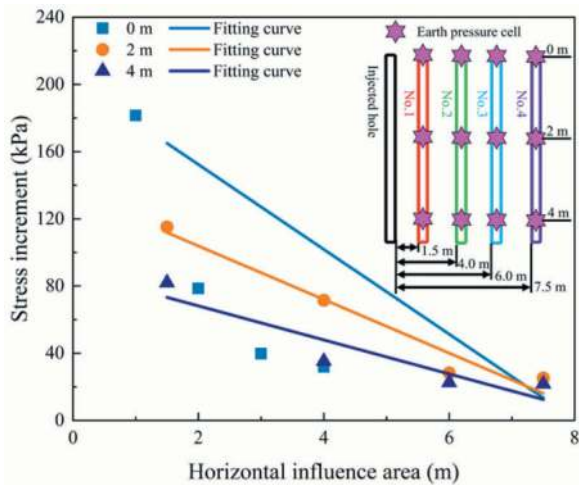

Figure 11. Influence range of horizontal grouting.

Through drilling core sampling before and after grouting with sleeve valve in the yellow loess layer, the morphology, water content, strength, and range of influence of the core samples were analyzed. The results show that the grouting reinforcement technology with sleeve valve can effectively reduce the water content of the yellow loess layer and improve the overall strength of the formation.

6 CONCLUSIONS

- (1) Based on indoor experiments, the maximum water content of the loess sample is 26.9%, with an average water content of 26.1%. The natural density ranges from 1.94 to 1.98 g/cm³. The range of natural porosity is 0.73-0.77. The average values of liquid limit and plastic limit are 31.5% and 19.5% respectively. The plasticity index and liquidity index are 12 and 0.55 respectively. The loess sample is in a soft plastic state.
- (2) After grouting reinforcement with sleeve valve tubes, the cracks in the loess formation are reduced, reducing the permeability of the soft plastic loess. The average water content is effectively controlled, decreasing from 30.55% to 20.75%. The unconfined compressive strength has been strengthened to some extent, with a maximum increase of 0.16 MPa.
- (3) When grouting causes splitting in the soil, the stress in the surrounding soil near the grout begins to increase. The stress increment gradually decreases as the distance from the grout hole increases. The horizontal distance between the grout holes has an influencing radius of 8.03 m. These findings are important for evaluating the effectiveness of grouting reinforcement and determining grouting construction parameters.

ABSTRACT: In this paper, an explicit analytical formula is proposed for analyzing the failure history of a segment joint with inclined bolts as connecting element under high loading levels. By analyzing the full-scale test results, we have developed a non-linear interface model for the segment joint. Based on three assumptions, an explicit formula is derived using analytical methods. The explicit analytical expression consists of variables that have specific physical meaning. This allows us to determine the main factors that influence the rotation and ultimate bearing capacity of the segment joint, as well as the relationship between the mechanical behavior of the segment joint and these influencing factors. The mechanical behavior of the segment joint under high loading levels can be accurately described by the analytical formula. It is shown that: (1) The failure history of segment joints is subdivided into three stages: linear rotation, joint opening, and joint yielding; (2) The ultimate bearing capacity of segment joint is related to the axial force of segment joint, concrete compressive strength, joint dimensions; (3) For segment joint with inclined bolts, the ultimate bearing capacity of segment joint calculated by the analytical solution is in good agreement with that of the full-scale test performed for shielded tunnels, such as Shanghai Yangtze River Tunnel. For joint with curved steel bolts, a correction method for the formula of ultimate bearing capacity is presented.

Keywords: segmental lining, segment joint, interface model, analytical formula

1 INTRODUCTION

Segmental tunnel lining is typically a prefabricated concrete structure composed of flat or box -type segments, with circumferential joints between rings and radial joints between segments. The mechanical behavior of radial joints (segment joints) has a significant impact on the deformation, internal force, failure behavior, and ultimate bearing capacity of the segmental lining as previously shown (Blom., 2002).

In the last 30 years, there has been a large amount of research on the mechanical behavior of segment joints. Several simplified models have been developed to describe their mechanical behavior, including the elastic-hinge (rotation spring) model as previously shown (ITA., 2000; GB 50157), beam model as previously shown (Cheng., 2010), contact algorithm model as previously shown (Su and He., 2007; He et al., 2005), and joint element model as previously shown (Molins and Arnau., 2011; Arnau and Molins., 2011; Zhu et al., 2000; Zhu et al., 2006). In the widely used

rotation-spring model for segmental joints, the stress distribution and state at the contact surface between segments cannot be analyzed. This model is primarily used for elastic calculation, such as determining the deformation in service state of the lining system. The contact algorithm can be used to examine the opening and yielding state of a segment joint. However, the computation process and convergence checking based on the Finite Element Method (FEM) is cumbersome and costing-time.

In the field of lining failure behavior, the non-linearity of the segment joint is a vital factor for describing the failure history of the lining system as previously shown (Blom., 2002). To describe the mechanical behavior of segment joints under high loading level, the analytical formula for the non-linear interface model of the segment joint is proposed and verified according to the measured data from the full-scale tests on segment joints conducted in China, and the FEM simulation on the segment joints in following

2 CONFIGURATION OF SEGMENT JOINT AND ITS NON-LINEAR INTERFACE MODEL

The connecting elements, such as curved steel bolts, reusable inclined steel bolts and straight steel bolts, are typically utilized in plain joints as previously shown (Liu and Hou., 1991). The study focuses on the segment joint connected by inclined steel bolts, as depicted in Figure 1.

Figure 1. Segment joint with inclined steel bolt.

This type of connecting bolt is used in some crossing-river tunnels, such as the Shanghai Yangtze River Tunnel, the Nanjing Yangtze River Tunnel, the Shiziyang Ocean Tunnel, the Botlek Railway Tunnel in Netherlands, and metro section tunnels, such as, Nanjing Metro Line No. 10. There is no packing material between segment joints, resulting in the direct contact between the concrete segments in these joints.

The segment joint with the curved steel bolt is widely used in metro tunnels in China, as shown in Figure 2.

Figure 2. Segment joint with curved steel bolt.

To deal with the influence of the inclined steel bolts used in the 2nd Heinenoord tunnel, a series of full-scale tests were performed in Netherland as previously shown (Blom., 2002). Based on the tests results, it is concluded that the effect of inclined steel bolts on the rotation behavior and ultimate bearing capacity of segment joint is negligible. Therefore, the effect of inclined bolts can be disregarded in the failure history of segment joint as previously shown (Dong and Xie., 2013). For this type of segment joint, a non-linear interface element model can be applied, as indicated in Figure 3. The contact surface between segments is simulated using a surface spring with a non-tension gap element as previously shown (Arnau and Molins., 2011).

Figure 3. Non-linear interface model for segment joint.

3 ANALYTICAL SOLUTION TO THE NON-LINEAR MODEL OF THE SEGMENT JOINT

The non-linear model in Figure 3 can be solved using numerical methods, such as iteration methods or the FEM method. One of the disadvantages of the numerical method is that some important information about the mechanical properties of the segment joint is omitted, such as the essential dependence of the ultimate bearing capacity (UBC) on the parameters. In this study, certain assumptions are made on the non-linear model in order to derive explicit analytical expressions. According to the explicit formula, the failure characteristics of segment joints under high loading level and their causal factors, as well as the mapping relationships between the failure behavior and causal factors, could be understood more thoroughly and described more concisely.

3.1 Assumptions on segment joint

The coordinate system used in this paper is shown in Figure 3. Point O is the origin of coordinate system. The length of joint OA is L_{seg} , and h represents the height of segment joint. The line CD and EF represents the contact surface between segments.

Fundamental assumptions relating to the flexure of joint are as follows:

- (1) Planar contact interface: the cross-section of the joint contact surface remains planar during joint rotation.
- (2) No-tension between contact surfaces of joint: the normal stress at the contact surface is 0 when joint opening.
- (3) Linear distribution of the normal stress between contact surfaces

Based on the aforementioned assumptions (3), the nonlinear stress distribution between contact interfaces, as shown in Figure 4, can be simplified.

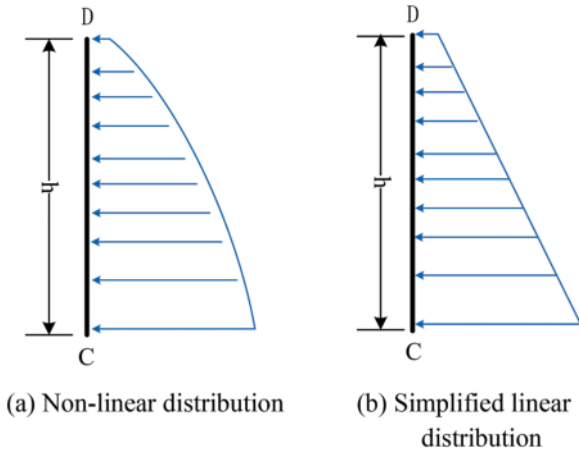

Figure 4. Distribution of normal contact stress.

It means that the contact normal stress on the interface surface CD and EF depends on the normal displacement and the constant k , as follows:

$$p = k \cdot d(y) \quad (1)$$

Where, p is the stress at y ; $d(y)$ is the displacement at y ; k is the normal contact stiffness of the contact surface. The value of k can be determined using the method proposed by Dong as previously shown (Dong and Xie., 2013).

3.2 Stage I: Linear rotation of segment joint

At stage I of linear rotation, the maximum normal stress p resulting from the bending moment M is less than the normal stress induced by the axial force N :

$$p \leq \sigma_N = \frac{N}{A} = \frac{N}{bh} \quad (2)$$

Where, σ_N is the compression stress induced by axial force N ; A represents the area of the segment joint, while b and h refer to the width and height of joint, respectively.

The rotation can be calculated according to the aforementioned assumption (1) and (3).

The rotation of section (OA) θ_{OA} resulting from the bending of beam OA is:

$$\theta_{OA} = \int_0^x \frac{1}{\rho} dx = \int_0^x \frac{M}{EI} dx = \frac{ML_{seg}}{EI} \quad (3)$$

Where, E is the Young's elastic modulus; I is the moment of inertia of area of segment joint; M is the bending moment applied to the segment joint.

The rotation between contact surface CD and EF resulted by the compression of surface spring is calculated as follows:

$$\theta_{AB} = \frac{M}{k \int_0^h b \cdot y^2 dy} = \frac{M}{k \cdot I} \quad (4)$$

The total rotation of segment joint θ_{joint} is:

$$\theta_{joint} = \theta_{OA} + \theta_{AB} = \frac{M}{kI} + \frac{ML_{seg}}{EI} \quad (5)$$

At the linear rotation stage I, the total normal stress can be considered as a direct superposition of the stresses generated by the axial force and bending moment respectively. The critical moment of joint opening can be calculated on according to Eq. (6)

$$M \leq M_t = \frac{N \cdot h}{6} \quad (6)$$

Where, M_t is the critical moment of joint opening.

3.3 Stage II: Joint opening

When the bending moment M continues to increase, and when $M > M_t$, according to the aforementioned assumption (2), the contact surfaces between joints start to separate. The distribution of the total normal stress in contact surface is shown in Figure 5.

Figure 5. Distribution of contact stress at Stage II.

Where, h_0 is the effective height of the joint, which refers to the height of the joint's compression region. The normal stress in tension region is assumed to 0, according to the assumption (2).

Based on the normal stress distribution as shown in Figure 5, the equilibrium equations for internal force and bending moment can be obtained as follows:

$$N = \frac{pbh_0}{2} \quad (7)$$

$$M = N \cdot \left(\frac{h}{2} - \frac{h_0}{3} \right) \quad (8)$$

From Eq. (8):

$$h_0 = 3 \cdot \left(\frac{h}{2} - \frac{M}{N} \right) \quad (9)$$

The rotation θ_{AB} resulting from the surface spring is calculated as follows:

$$\theta_{AB} = \frac{2N}{9kb\left(\frac{h}{2} - \frac{M}{N}\right)^2} \quad (10)$$

The total rotation of segment joint at Stage II is:

$$\theta_{joint} = \frac{2N}{9kb\left(\frac{h}{2} - \frac{M}{N}\right)^2} + \frac{ML_{seg}}{EI} \quad (11)$$

3.4 Stage III: Joint yielding

With the increase of moment M , the effective height h_0 of the joint gradually decreases, while the stress p at the outer side gradually increases. When the stress p reaches the compressive strength f_c of the concrete, i.e.

$$p_{max} = f_c \quad (12)$$

Where, f_c is the compressive strength of the segment concrete.

Then, the concrete begins to yield, and if moment M continues to increase, the yielding range at the interface surface gradually extends from the outer side to the inside. Assuming that the joint concrete is perfectly elastic-plastic material, the critical moment of joint yielding M_c , can be obtained as follows:

$$M_c = N\left(\frac{h}{2} - \frac{2N}{3bf_c}\right) \quad (13)$$

Where, M_c is the critical moment of joint yielding.

When M increases to satisfy $M > M_c$, the joint cross-section rotation and the corresponding normal stress distribution are shown in Figure 6. In this figure, h_1 is the yielding height of joint, and h_0 is the effective height of the segment joint.

Figure 6. Distribution of contact stress at Stage III.

The ultimate bearing capacity of segment joint M_{lim} is:

$$M_{lim} = \frac{-3N^2 + 3Nhf_c b}{6f_c b} \quad (14)$$

Where, M_{lim} is the ultimate bearing capacity (UBC) of segment joint.

The rotation caused by the surface spring at stage III is as follows:

$$\theta_{AB} = \frac{d}{h_0 - h_1} = \frac{f_c}{k(h_0 - h_1)} \quad (15)$$

The total rotation at stage III is:

$$\theta_{joint} = \frac{f_c}{k(h_0 - h_1)} + \frac{ML_{seg}}{EI} \quad (16)$$

Summarizing the Eqs. (5), (11), (16) gives:

$$\theta_{joint} = \begin{cases} \frac{M}{kI} + \frac{ML_{seg}}{EI} & M \leq M_t \\ \frac{2N}{9kb\left(\frac{h}{2} - \frac{M}{N}\right)^2} + \frac{ML_{seg}}{EI} & M_t < M \leq M_c \\ \frac{f_c}{k(h_0 - h_1)} + \frac{ML_{seg}}{EI} & M_c < M \leq M_{lim} \end{cases} \quad (17)$$

Figure 7. Joint dimensions (Unit: mm).

The length of segment joint is small, typically measured in millimeters, in engineering practice. Hence, the part of joint rotation $ML_{seg}/(EI)$ caused by the beam bending can be neglected. Moreover, when the external moment imposed on joint $M > M_c$ and the joint is in Stage III, the segment joint rapidly loses its bearing capacity. In other words, the failure history in Stage III is shorter. Therefore, the Eq. 17 can be simplified as follows:

$$\theta_{joint} = \left\{ \begin{array}{l} \frac{M}{kI} \\ \frac{2N}{9kb\left(\frac{h}{2} - \frac{M}{N}\right)^2} \end{array} \right. \quad \begin{cases} M \leq M_t \\ M_t < M \leq M_c \end{cases} \quad (18)$$

The analytical solutions of Eqs. 18 and 14 for the failure history and ultimate bearing capacity of joint with the inclined steel bolt are verified against some full-scale tests in China in the following manner.

4 VERIFICATION OF ANALYTICAL FORMULA FOR THE NON-LINEAR INTERFACE MODEL OF JOINT

4.1 Case 1: Shanghai Yangtze river tunnel

The outer diameter and inner diameter of segmental lining are 15,000mm, 13,700mm, respectively. The height of the segment is 650mm and the width is 2000mm. The concrete strength is C60. The configuration of the segment joint is as shown in Figure 7 as previously shown (Chen et al., 2010). And the loading scheme is illustrated as shown in Figure 8.

The horizontal loading device is divided into axial force and longitudinal force. Eight 400-tons jacks are used to apply axial force, and the loading center is located on the centerline of the contact surface of the joint. The longitudinal force F is applied using pre-stressing ties. There are two vertical loading points, each located 700mm away from the centerline of the joint. Through a loading distribution beam, two 400-ton jacks are used to apply a line load to the segment, simulating the ground and water pressure, surcharge, and other loads.

Two loading cases include an axial force of N 1893 $\text{kN}\cdot\text{m}^{-1}$ for case 1 and 3333 $\text{kN}\cdot\text{m}^{-1}$ for case 2. In the loading process, the axial force is first applied to the transverse end of the segment and kept constant. Then, a vertical force 100 kN is applied per step in 10 steps.

Figure 8. Schematic of loading methods.

Based on the dimensions and material, the ultimate bearing capacity of segment joint used in Shanghai Yangzi river tunnel can be calculated on according to Eq.14 and compared with that of the full-scale test, as shown in Table 1.

It can be seen that the ultimate bearing capacity calculated by the analytical solution agree well with that of the full-scale test, and the maximum error is less than 10%.

Based on the Eq. 18, the moment-rotation curve can be calculated and compared with the test results, as shown in Figure 9.

Table 1. Error of analytical solution.

Loading case	Axial force /kN/ring	M_{lim} (test) /kN·m/ring	M_{lim} (Eq.14) /kN·m/ring	Error /%
Case 1	3786	790	758.8	3.95
Case 2	6666	1300	1211.3	6.82

(a) Case 1 (Axial force 3786 kN/ring)

(b) Case 2 (Axial force 6666 kN/ring)

Figure 9. Rotation in joint, analytical results compared to experimental data.

As can be seen in Figure 9, the calculated joint rotation curves for two cases are in good agreement with those of the full-scale test.

4.2 Case 2: Nanjing Yangtze river tunnel

The dimensions and properties of the Nanjing Yangtze river tunnel is shown in Table 2.

The configuration of the segment joints is as shown in Figure 10.

The loading mode of the full-scale test on the mechanical performance of the segment joint subjected to the bending moment is shown in Figure 11. The axial force is the uniaxial compression load N , and the

Table 2. Parameters of the Nanjing Yangtze river tunnel.

Parameter	Value	Unit
Outer diameter	14.5	m
Inner diameter	13.3	m
Segment height	0.6	m
Segment width	2.0	m
Concrete compression strength	C60	
Number of segments per ring	9+keystone	
Connecting element	3 inclined bolts	
bolts grade	6.8 grade M36	

bending moment is $M = F \cdot a$, as shown in Figure 11 as previously shown (Liu et al., 2015; He et al., 2011)

Figure 10. Joint dimensions (Unit: mm).

Figure 11. Schematic overview of loading method.

Hydraulic jacks are used as loading equipment. The horizontal axial force is generated by two 1500 kN jacks. The maximum axial force in the model test is 3000 kN, corresponding to a prototype value of 9000 kN; The bending moment is generated by two 1500kN jacks, and the maximum bending moment in the model test is 933.75 kN·m, corresponding to a prototype value of 2801 kN·m. The capacity of jacks meets the requirements of the failure test on segmental joint.

Based on the internal forces in segmental lining of the Nanjing Yangtze River Tunnel, the axial force is applied from 3000kN to 8000kN, increasing by 1000kN per level. The loading procedure is as follows: first, a lower level horizontal load is applied, and then the vertical load is applied to produce the bending moment. The bending moment is applied gradually until the joint opening reaches approximately 2mm. Subsequently, the vertical loads are released. After the horizontal loads are increased to a higher level, the bending moment is applied again. According

to Eq.18 and the properties of the full-scale test, the $M-\theta$ curves are calculated at axial force $N = 6049$ kN, 7038 kN, 8027 kN. These curves are then compared to the $M-\theta$ curve of the full-scale test, as shown in Figure 12.

(a) Case 1 (Axial force 6049 kN/ring)

(b) Case 2 (Axial force 7038 kN/ring)

(c) Case 3 (Axial force 8027 kN/ring)

Figure 12. Rotation in joint, analytical results compared to experimental data.

As can be seen in Figure 12, the agreement between the calculated curves and the test curves on the Nanjing Yangtze River Tunnel is excellent.

For the three cases of the Nanjing Yangtze River Tunnel, the ultimate bearing capacity can be predicted more accurately using the aforementioned Eq. 14. The error rates are shown in Table 3

Table 3. Error of the analytical solution.

Loading case	Axial force/kN/ring	M_{lim} (test) /kN·m/ring	M_{lim} (Eq.14) /kN·m/ring	Error /%
1	6049	1063.3	1096.2	3.09
2	7038	1166.2	1230.2	5.49
3	8027	1264.6	1351.6	6.88

As shown in Table 3, the maximum error in the joint UBC is less than 7%.

4.3 Case 3: Shenzhen metro tunnel

The curved steel bolts are used as connecting element in the segmental lining of tunnel located in Liyumen-Qianhaiwan section of Shenzhen Metro Line No.1. The outer diameter, inner diameter, and width of the lining system are 6m, 5.4m, 1.5m, respectively. The concrete strength grade of the segment is C50. Segments are connected with M24 curved steel bolts (with a mechanical performance grade of 8.8).

To address the diseases caused by neighboring construction, a full-scale test of a single ring is performed. There are 24 loading points (total number of jacks is 24×2 jacks) in the horizontal direction, and these 24 horizontal loading points are divided into 3 groups. The maximum load that can be supplied by a single jack is 1000kN, and the maximum stroke of a single jack is 300mm.

Lu as previously shown (Lu., 2019) utilized finite element software to simulate the loading history of the full-scale test. The comparison between the finite element calculation results and the full-scale test is illustrated in Figure 13.

Figure 13. Convergence deformation at the springline, FEM results compared to the test data.

From the comparison, it can be observed that the numerical calculation of the FEM model closely matches the data from the full-scale test. It is evident that the simulation model of the segment joint can accurately simulate the mechanical behavior of the segment joint in the full-scale test.

Meanwhile, Lu as previously shown (Lu., 2019) used a FEM model of the segment joint to analyze the mechanical behavior of the joint under axial forces of 1000, 1500, and 1700 kN/ring, respectively.

Using Eq. 18 to analyze the FEM model by Lu, the moment-rotation curve is calculated and verified against the FEM results, as shown in Figure 14.

(a) Case 1 (Axial force 1000 kN/ring)

(b) Case 2 (Axial force 1500 kN/ring)

(c) Case 3 (Axial force 1700 kN/ring)

Figure 14. Rotation in joint, analytical results compared to experimental data.

From Figures 14(b) and (c), the calculated values for Case 2 and Case 3 are well-fitted to the simulation results, and the errors are shown in Table 4 for a rotation angle of 0.05 radians.

Table 4. Error of the analytical solution.

Loading case	Axial force/kN/ring	M_{lim} (FEM) / kN·m/ring	M_{lim} (Eq.14) / kN·m/ring	Error (%)
1	1000	170.6	122.7	28.1
2	1500	186.4	175	6.11
3	1700	199.5	195	2.26

However, there is a significant difference between the calculated value of case 1 and the simulation results. This is due to the significant impact of the preload of the curved steel bolt at low axial forces. Therefore, the influence of the preloading generated by the curved bolts should be considered when the axial force is at lower levels. The solution is to multiply the axial forces by a correction factor greater than 1.0 when using the analytical model presented in this paper. And when the loaded axial force is at higher level, the preloading force becomes of minor importance, and the analytical solution model presented in this paper can be applied directly. After using the correction factor 1.4, the simulation results for case 1 are compared with the calculated values as shown in Figure 15.

Figure 15. Rotation in joint, analytical results compared to experimental data.

As can be seen in Figure 15, the agreement for case 1 is very good after applying the correction factor. When the rotation angle is 0.05rad, the ultimate bearing capacity corresponding to the analytical model is 164.9 kN.m/ring, and the numerical model result is 170.6 kN.m/ring. The error in the ultimate bearing capacity is 3.34%.

5 CONCLUSION

- (1) In failure history of a segment joint subjected to incremental moment with constant axial force, the mechanical behavior can be divided into three stages: linear rotation, joint opening, and joint yielding. When the bending moment exceeds the critical opening moment, the segment joint undergoes nonlinear opening and rotation. When the bending moment exceeds the critical yielding moment, the segment joint will enter Stage III and rapidly approach to its ultimate bearing state. The failure behavior and root cause of segment joints can be accurately described and interpreted by the analytical solution to the interface model presented in this paper.
- (2) The explicit analytical equations for the ultimate bearing capacity of the segment joint are derived. According to the equation, the ultimate bearing capacity of the segment joint depends on several variables that have specific physical meaning. These variables include the axial force applied to the segment joint, the compressive strength of the concrete, and the dimensions of the joint. The formula can be used to predict the ultimate bearing capacity of segment joints.
- (3) The analytical equations for the ultimate bearing capacity and $M-\theta$ curves have been validated using full-scale tests on segment joint with inclined steel bolts in the Shanghai Yangtze River Tunnel, and the Nanjing Yangtze River Tunnel. It demonstrates that, for the segment joint with inclined bolts, the analytical solution to interface model can accurately describe the mechanical behavior of the segment joints throughout the failure history. When neglecting the inclined bolt, the errors in the joint capacity in the Shanghai Yangtze River Tunnel are 3.95% and 6.82%, respectively. In the Nanjing Yangtze River Tunnel, the error are 3.09 %, 5.49 % and 6.88 %, respectively.
- (4) The numerical model of a segment joint based on a full-scale test of a single ring with curved steel bolts, is selected as a case to verify the analytical solution. It demonstrates that, for the segment joint with curved steel bolts and at a loading level with higher axial force, the errors in the ultimate bearing capacity between the analytical solution and the FEM results are 6.11% and 2.26%, respectively. In the case of a segment joint subjected to a low axial force, the influence of the preloading caused by the curved bolts cannot be disregarded, and an adjustment factor for axial force can be incorporated into the analytical solution. After applying a correction factor of 1.4, the discrepancy between the adjusted analytical solution and

the numerical calculation is 3.34%. It shows that the analytical solution developed based on the segment joints with inclined steel bolts can be applied to the segment joints with curved steel bolts.

ABSTRACT: London Power Tunnels (LPT) Phase 2 is a new purpose-built cable tunnel system which will replace the existing buried cable network in the south of London. This £1 billion National Grid scheme comprises 32.5km of 3m internal diameter deep underground tunnels and 8 shafts which will help keep Londoners connected to safe and reliable electricity supplies. The tunnels extend from Wimbledon in the West to Crayford in the East, reaching depths of up to 60m below ground level. At the New Cross site, a pair of circular shafts 41m and 36m deep, 15m and 10.5m diameter respectively, will receive cables from Circuits 1 and 2 of the new network of cable tunnels, whilst also providing permanent access and ventilation to the tunnels. Previous use of the site as a gas works has left a legacy of highly variable Made Ground to considerable depths, buried obstructions and ground contamination which required extensive remediation works. The paper will consider the design of the shaft linings, for which a system of secant piles, contiguous piles and underpinned precast concrete segmental linings, combined with fissure grouting of the Chalk, was chosen to cope with the challenging groundwater conditions. The design of the shaft linings was carried out using PLAXIS 3D numerical modelling with a three-dimensional zoned ground model based on ground investigation findings. The advanced analysis enabled a more sustainable and economical design to be produced than would have been possible with a uniform ground model. The interaction between adjacent shafts was also studied, which helped confirm that the contractor's proposed construction sequencing would be acceptable.

1 INTRODUCTION

London Power Tunnels (LPT) Phase 2 is a new purpose-built cable tunnel system which will replace the existing buried cable network in the south of London. This £1 billion National Grid scheme comprises 32.5km of 3m diameter deep underground tunnels and 8 shafts which will help keep Londoners connected to safe and reliable electricity supplies. Two new cable circuits will replace the existing 275kV Wimbledon to New Cross and New Cross to Hurst cable circuits. The new tunnels extend from Wimbledon in the West to Crayford in the East, constructed by tunnel boring machines (TBMs) in 5 tunnel drives with a precast concrete segmental

lining and reaching depths of up to 60m below ground level. Shaft diameters vary between 9m and 15m depending on the requirements at each shaft location and are constructed by a variety of techniques including caisson sinking and underpinning with precast concrete segmental lining, sprayed concrete lining and secant piling. The shafts will later be covered by headhouses to provide access and ventilation for the tunnels. The scheme is currently under construction and due to be completed in 2027. HOCHTIEF-MURPHY Joint Venture are contracted to deliver the Package 2 Tunnels & Shafts and Package 5 Headhouses & M&E contracts on the scheme, and appointed AECOM as permanent works design partner.

*Corresponding author: joseph.ellis@aecom.com

The New Cross shafts site is located approximately 2km South of the River Thames, in the London Borough of Southwark. Works at the site comprise a pair of circular shafts 15m and 10.5m (reduced from 15m) in internal diameter, which serve as launch and service shafts for two Tunnel Boring Machines (TBMs) tunnelling towards King’s Avenue in the West and Eltham in the East. The West shaft extends to a depth of 41m to top of base slab, allowing space for the High Angle Conveyor (HAC) to remove spoil from the shaft during tunnelling, while the East shaft is shallower at 36m depth. The shafts are connected by a Sprayed Concrete Lining (SCL) adit approximately 15m long, which serves as an access route between shafts during construction and in the permanent case.

2 SITE BACKGROUND

The New Cross shafts site is part of the former Old Kent Road gas works, opened in 1833 by the South Metropolitan Gas Company. At its largest in the late 1800s, the gas works included 13 gas holders, covering a total of 36 acres. Since its closure in 1953, the land has been gradually re-developed for commercial use, including a large waste management facility and an existing National Grid substation. Today, only the Grade II listed gas holder No. 13 remains, which is located adjacent to the scheme site.

The scheme site occupies the footprint of three of these gas holders. While the above-ground structures have now been demolished, the below-ground legacy of the site is still very much present. This includes the buried gas holder foundations, significant depths of Made Ground and contaminated soils, all of which pose a risk to shaft construction at the site.

Figure 2. Enabling works cofferdam showing gasholder footprint prior to casting the protective capping slab (JSM Group, 2020).

2.1 Enabling works

The proposed location for the shafts was directly between two of the decommissioned gas holders. Whilst this was one of the few possibilities on a very constrained site, it resulted in very little clearance between the shafts and the existing gas holder foundations. This increased the risk of striking buried obstructions or releasing contamination during the sinking of the shafts. In order to mitigate this risk, an extensive programme of investigative and remedial works was carried out prior to construction by the enabling works contractor, JSM Group.

The enabling works included the excavation of a large cofferdam 48m long by 22m wide by 5m deep encompassing the footprint of the two shafts and part

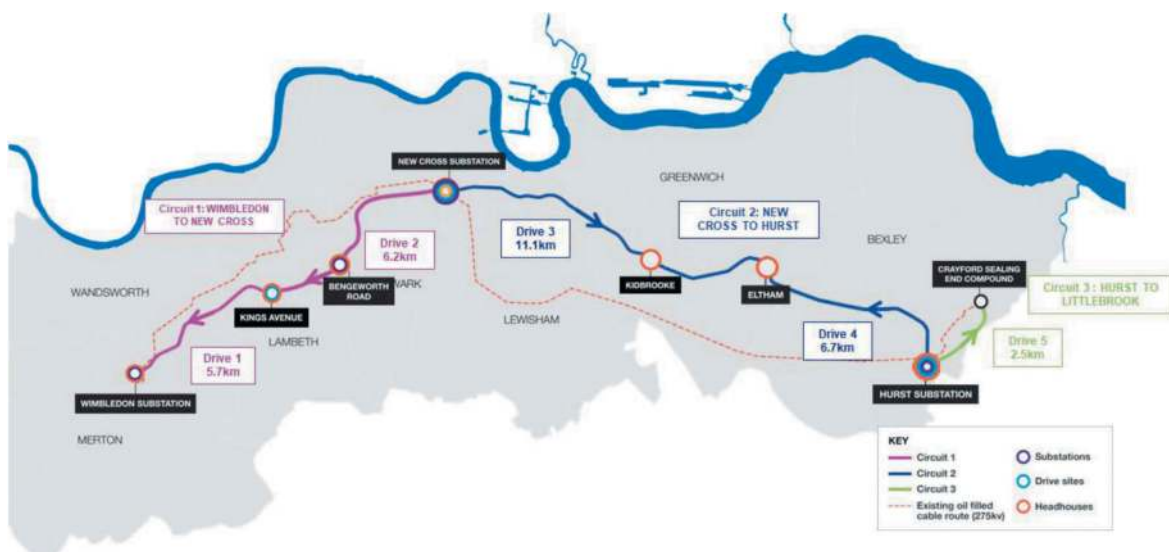

Figure 1. Tunnel route map showing the location of the New Cross Substation site.

of the footprint of one of the gas holders. During the works, the gas holder foundations were demolished down to the bottom level of the excavation, and the remaining foundations capped to contain any contaminated material. The capping consisted of a 300 mm thick concrete blinding layer, a Bentotex 30 geosynthetic clay liner and a 300mm thick concrete protection layer. The position of the remaining foundations was surveyed, which helped inform the choice of shaft position and diameter adopted in the detailed design stage. A number of boreholes were also drilled from the base of the excavation to provide a better understanding of the ground stratigraphy.

Upon completion of the remedial works, the cofferdam was initially backfilled with Class 2B and 2C site-won material (dry cohesive material and stony cohesive material). However, inclement weather conditions necessitated a switch to imported Type 1 granular fill material for the final layers of the backfill.

2.2 Ground conditions

The bedrock geology of the site comprises Thanet Sand Formation and Upper Chalk Formation, overlain by a combination of River Terrace Deposits and Made Ground to varying depths.

Such was the complexity of the ground stratigraphy due to historic activity, the site was divided into four different ground model zones for the purposes of the shaft design:

- i. Zone 1: Area within the enabling works cofferdam but outside of the footprint of the area associated with the construction and backfill of the gasholder foundations.
- ii. Zone 2: Area within the enabling works cofferdam and inside the footprint of the area associated with the construction and backfill of the gasholder foundations.
- iii. Zone 3: Area outside the enabling works cofferdam and outside the footprint of the area associated with construction and backfill of the gasholder foundations
- iv. Zone 4: Area outside the enabling works cofferdam but inside the footprint of the area associated with construction and backfill of the gasholder foundations.

The stratigraphy for each of these zones is summarised in Table 1, and the zoned areas illustrated in Figure 3.

Characteristic geotechnical parameters for each material are presented in Table 2. Limited ground investigation data was available for the Chalk, and therefore parameters were derived with reference to the guidance in CIRIA Report C574 (CIRIA, 2002) for the grade C2 to B2 material typically encountered at the site. The parameters have been derived such that the Chalk is represented as a continuum, as opposed to a material that is controlled by discrete discontinuities. Allowance was also made for creep of the Chalk, by adopting a 50% reduction in the long-term Young's modulus after Barthes et al (1994).

Table 1. Ground stratigraphy.

Strata	Depth of upper surface (m bgl)	Thickness (m)
Zone 1		
Engineered Fill	0.0	4.6
River Terrace Deposits	4.6	2.1
Thanet Formation	6.7	6.7
Upper Chalk	13.4	>30
Zone 2		
Engineered Fill	0.0	4.6
Made Ground	4.6	7.5
Made Ground – Puddle Clay	12.1	1.4
Upper Chalk	13.5	>30
Zone 3		
Made Ground	0.0	2.4 to 5.3
River Terrace Deposits	2.4 to 5.3	2.0 to 5.2
Thanet Formation	5.0 to 8.1	2.3 to 4.4
Upper Chalk	10 to 14.9	>30
Zone 4		
Made Ground	0.0	9.7 to 14.3
Upper Chalk	13.4	>33

Figure 3. Ground stratigraphy zoning showing approximate position of shafts between the gas holders.

2.3 Groundwater conditions

Groundwater was found to be present in all strata at the site and was considered to be in hydraulic continuity between the upper aquifer (River Terrace Deposits) and lower aquifer (Thanet Sand and Chalk). Previous groundwater monitoring also identified perched groundwater within the Made Ground. Groundwater flow within the River Terrace Deposits and Thanet is facilitated by high intergranular permeability of these strata. Within the Chalk, intergranular permeability is lower and forms a much smaller proportion of the flow. Groundwater flow is instead facilitated by a network of fractures providing high secondary permeability.

2. ST = Short-term, LT = Long-term

3 SHAFT DESIGN DEVELOPMENT

3.1 Temporary ground support

In order to manage the challenges of poor ground conditions, high groundwater pressures, spatial constraints between the existing gasholders and contamination risk during the construction phase, a solution was developed combining three components;

- i. Secant piles and capping beam
- ii. Contiguous piles
- iii. Fissure grouting of the Chalk

The secant and contiguous piles were temporary in their function but remain incorporated in the works in the long-term. These three ‘temporary’ components worked together to enable the construction of a precast concrete segmental lining which provides permanent ground support and watertightness for the 120-year design life of each shaft. The segmental lining was excavated and constructed in 1m advances by underpinning, and therefore a robust solution that ensured the stability of the exposed soil face and the safety of the workforce was required.

For the shallower part of the shaft, up to 17m below ground level (bgl), where the ground was at greatest risk of instability, a secant piled wall was constructed, made up of 880mm diameter piles in a hard/firm arrangement. The primary function of the secant pile wall was to reduce groundwater infiltration, and therefore pile spacing was based on the maximum spacing needed to maintain contact between primary and secondary piles at the toe, including allowance for positioning and verticality tolerances. Typically, a secant pile wall also provides structural support to the ground and would require a closer pile spacing to ensure sufficiently large overlap between piles such that the contact stress does not exceed the concrete strength. However, given the use of precast segmental lining which was intended to act as the structural lining, this was not required at New Cross.

Below the secant piled wall, the bore of the secondary (‘male’) piles was extended to form a contiguous pile wall between 17 and 30m bgl. The contiguous piles were designed to act in conjunction with fissure grouting of the Chalk to reduce groundwater flows into the shaft. By incorporating contiguous piles, it was predicted that the average permeability of the ground surrounding the shaft would be reduced by an order of magnitude more than could be achieved with fissure grouting alone. The piles were installed by Murphy Ground Engineering using two rotary drill rigs to meet the schedule. Full depth temporary segmental casing was used both for soil support and to ensure the piles were drilled to an accuracy of 1:200 or better. At all times a positive water head was maintained within the casing.

Fissure grouting was performed by Spie Batignolles Fondations UK from the ground surface by drilling through the unreinforced primary piles. The grouting was carried out in two phases using Stage separated TaMs also known as MPSP (Multiple Packer Sleeved Pipe). The first phase was to drill and grout to a depth of up to 48m, both to grout between the contiguous piles on either side and provide the grout curtain below the piles. First phase grouting was carried out through every fourth primary pile and then through every second primary pile. The results of the first phase of grouting were then analysed to determine if the second phase, which was to drill through every first and third primary pile, would be to the toe level of the contiguous piles or would need to be taken to the same

Figure 4. New Cross West Shaft 3D BIM model.

depth as the first phase. From this analysis it was considered prudent to drill and grout full depth at only four locations. On completion of the works and based on a 10% packer testing criterion the specified performance of $100\% < 5 \times 10^{-6}$ m/s and $95\% < 1 \times 10^{-6}$ m/s was shown to have been achieved.

3.2 Permanent shaft lining

The permanent shaft linings are comprised of a number of rings of precast concrete steel fibre reinforced segments supplied by FPMcCann. Each ring in the West shaft comprises 16 no. 350mm thick segments, whilst in the East shaft 14 no. 300mm thick segments make up each ring. The use of an off-the-shelf product brought with it benefits of tried and tested design details, whilst also ensuring that lead times were minimised.

The construction of the lining commenced at the top of the shaft, with the first ring being secured to the shaft capping beam with 400mm long dowels. The first ring was used as a shutter for the casting of the capping beam, which made it possible to install the dowels from the extrados face of the ring prior to casting the capping beam. The next advance of approx. 1.5m depth was then excavated and the following ring fixed to the rings above with vertical through-bolts integrated in the segment casting. Any void between each segment ring and the soil or secant piled wall was then filled with a cementitious grout to ensure that full frictional resistance would be mobilised at this interface.

EPDM gaskets fixed to the radial and circumferential joints ensure the watertightness of the shaft in the long-term.

3.3 Tunnel portals

Two openings were constructed in each of the shaft linings to provide a permanent access route between shafts and to facilitate the launch of the two TBMs. Two steel universal column sections ('needles'), with sizes up to 305x305x198, were fixed into the shaft segmental lining either side of each opening to enable the construction of the portals and SCL chambers. The needles provided a means for hoop force in the segmental lining to be transferred between segment rings through shear in the steel and carried over the crown and invert of the opening. Octagonal openings were formed in the segmental lining by stitch drilling, from which the excavation and spraying of the SCL chambers was undertaken. A reinforced concrete permanent portal was then cast around the openings to encapsulate the temporary needles and provide permanent ground support and water-tightness in the long-term.

3.4 Base slab

A cylindrical reinforced concrete base slab 2.0m and 1.5m thick was constructed in the West and East shaft, respectively. The base slabs feature a shear key extending beyond the extrados of the shaft segmental lining which provides additional resistance against uplift failure. Pressure relief wells were included in the base slabs to reduce groundwater pressures beneath the slab during construction, when the mass concrete infill necessary to resist uplift failure of the shaft had not yet been cast. The base slabs were designed to resist a nominal heave pressure of 10% of the effective overburden stress.

4 NUMERICAL ANALYSIS – MODEL DEFINITION

Design of the shaft was undertaken using advanced geotechnical finite element modelling in PLAXIS 2D and 3D. This approach made it possible to study a number of different aspects of the shaft design, including:

- Effects of the construction of each shaft on the adjacent shaft.
- Design forces occurring in the precast segmental lining and secant/contiguous piles.
- Design forces occurring in the shaft capping beam.
- Base heave pressures
- Shaft displacement

4.1 Constitutive soil models

The Mohr Coulomb constitutive model was adopted for all materials in the analysis. Whilst this constitutive model has various shortcomings, for instance it does not consider strain dependency of stiffness, it was considered the most appropriate model given the limited quantity of ground investigation data available.

All materials at the site are granular in nature and are therefore considered to exist in a drained state. This is with the exception of the Chalk within the fissure grouted zone which was assigned Undrained (A) parameters (strength and stiffness specified in terms of effective parameters, c' and ϕ) to simulate the short term stability ('stand up time') of vertical excavations.

Figure 5. Cut-away view of PLAXIS 3D numerical model.

4.2 Groundwater pressures

All strata in the model were assigned a steady-state pore water pressure profile based on the maximum predicted groundwater level during the construction period, which was approximately 4m below ground level.

The effect of the fissure grouting of the was studied by first undertaking a SEEP/W analysis, in which the target permeability and width of the grouted zone was input to generate a prediction of the steady-state pore water pressures around the shaft. The output from SEEP/W formed the basis for the pore water pressures defined in PLAXIS, which were approximated by a gradient increasing from zero at the exposed shaft wall to the full hydrostatic pressure at a distance of 4m from the excavation face.

4.3 Structural element properties

The simulation of each structural element in the PLAXIS numerical model is described in the following sections. The construction of the SCL launch/connection adits and portals was not included in the model. Given the higher Young's modulus of the Chalk at this level, the construction of these adits was not anticipated to have significant effects on the shaft as a whole and hence these elements were designed using separate local numerical models.

4.3.1 Secant piles

The secant piled wall was modelled using linear elastic plate elements with equivalent properties to C32/40 grade concrete. Soil-structure interaction

was defined with interface elements which limit the degree of shear force transmitted to two thirds of the soil strength.

According to L.Zdravkovic et al. (2005), any retaining wall is unlikely to be a continuous membrane along its perimeter, as it is made from number of vertical elements that are not fully connected in this direction. It is likely there will be joints between the piles and any vertical deviation of individual piles will also reduce the contact area between piles. This is particularly true at New Cross, where the wider pile spacing is likely to result in a small contact area between piles and a relatively low hoop-direction axial stiffness.

Two cases were therefore considered depending on which element the outputs would be used to design:

- i. For secant pile design, the hoop direction stiffness of the plate element representing the piles was set to zero. This had the effect of maximising the bending moment in the vertical plane to give the most onerous case for the pile reinforcement design. The vertical stiffness considered only the reinforced secondary piles, as only these piles would be capable of resisting bending.
- ii. For capping beam designs, the hoop-direction stiffness of the secant pile wall was modelled based on the calculated contact area between piles, assuming no deviation due to construction tolerances. This ensured that the share of hoop force between the secant piles and capping beam was realistic.

4.3.2 Precast segmental lining

The segmental lining was defined by linear elastic volume elements with stiffness properties equivalent to C45/55 concrete. Circumferential joints between rings were modelled explicitly using interface elements with a friction coefficient of 0.5. Radial joints were modelled using a reduced hoop direction bending stiffness after Muir Wood (1975).

4.3.3 Base slab

The base slab was modelled with linear elastic volume elements with interface elements to simulate the soil-structure interaction. It was found that the high stiffnesses of the base slab and the Chalk on which it was founded resulted in inaccuracies in the predicted contact stresses of the slab on the soil. More realistic results were obtained by adopting a reduced concrete stiffness during the base slab construction phase, which was then increased to the full value in subsequent construction phases.

4.4 Construction sequence

The construction of the shaft was modelled stage-by-stage in the numerical model. The key phases of the construction sequence are outlined in Table 3.

5 NUMERICAL ANALYSIS – RESULTS

5.1 Shaft interaction

One of the factors in choosing to adopt a three dimensional numerical analysis was the need to assess whether the construction of one shaft had an influence on the other. Displacements and total normal stresses on the West shaft lining were extracted for construction phases before and after the construction of the East shaft, as presented in Figures 6 and 7. Results are extracted at the point on the shaft closest to the adjacent shaft.

Change in horizontal total stress was predicted to be negligible, whilst change in displacement was predicted to be no more than 1mm.

Table 3. Construction sequence.

N°	Phase Name	Description
1	Initial phase	K_0 procedure to establish initial soil pressures. Maximum K_0 conditions applied.
2	Apply 75kPa surcharge	75kPa surcharge at ground surface representing construction loading
3	Construct secant piles	Activation of plate elements representing the secant piles
4	Construct capping beam	Cropping of piles, construction of capping beam and placing of backfill on top.
5	Underpinning	Excavate within secant piles in 1.5m advances and construct segmental lining by underpinning. When excavation enters the Chalk, apply pore pressure gradient at sides of excavation to represent fissure grouting.
6	Excavate and cast base slab	Excavate, install drainage blanket, blinding and cast base slab, represented with volume elements
7	Restore full hydrostatic pressure	Restore groundwater pressure in zone of fissure grouting
8	East shaft construction	Repeat steps 1 – 7 for East shaft
9	Cast mass concrete infill	Casting of C16/20 mass concrete infill to raise shaft invert levels to final tunnel invert level.

5.2 Secant pile design forces

The results of the PLAXIS 3D numerical modelling indicated that the forces occurring in the secant pile wall were heavily dependent on the ground stratigraphy in the immediate vicinity. As illustrated in Figure 6, the difference in strength and stiffness between the Made Ground and Chalk in Zone 2 created a ‘fixed toe’ condition which produced bending moments almost double those in Zone 1. For the purposes of pile design, the shafts were therefore divided into two regions

Figure 6. Displacement of West shaft lining before and after construction of the East shaft.

around their circumference – an area of low bending moment influenced by the Zone 1 ground conditions and an area of much higher bending moment influenced by the Zone 2 ground conditions. These regions formed the basis for the design of the secant piles with two different reinforcement typologies.

Agreement between the PLAXIS 2D and 3D models was found to be very good. This made it possible to streamline the process of designing the secant piles by using the 3D model to inform the extent of each type of reinforcement, and then using the 2D models within each zone to further refine the analysis. Within the 2D models, the sensitivity of the analysis to factors such as upper and lower bound secant pile hoop stiffness and the properties of the interface elements between the secant piles and segmental lining was studied.

6 CONCLUSIONS

The design and analysis of two deep circular shafts at the London Power Tunnels Phase 2 New Cross site has been carried out using the PLAXIS 2D and 3D numerical modelling packages. The analysis indicated that proposed design was feasible, and this was confirmed by successful construction of the design with minimal change to the overall concept.

The analysis was used to study the potential interaction between shafts with respect to stresses and displacements, which was found to be negligible. This can be attributed to the adoption of a secant piled wall for ground support, which minimised the relaxation of horizontal soil stress occurring between shafts during excavation. Additionally, compared to

Figure 7. Horizontal total stress acting on West shaft lining before and after construction of the East shaft.

the poor ground conditions in adjacent areas of the site, the ground between the shafts was comprised predominantly of virgin soil of relatively high strength and stiffness.

The outputs of the analysis have also been used to locally refine the pile reinforcement according to the varying ground conditions around the shaft perimeter. In doing this, a 25% reduction in steel reinforcement was achieved, as well as associated reductions in embodied carbon emissions.

The results highlight the importance of extensive ground investigation for shaft sites, particularly on brownfield sites with a long history of previous use. Localised areas of poor ground were found to have significant influence on the structural forces occurring in the shaft linings.

Comparative analysis of simplified solutions for the radial joint behaviour of segmental tunnel linings with finite element numerical modelling

Amin Emadi*

Senior Associate Engineer Tunnels, Sydney, Australia

Alexandre RA Gomes*

Chief Technical Principal Tunnels and Underground Works, Sydney, Australia

ABSTRACT: Tunnel segmental linings are composed by several individual precast concrete segments that are connected to each other through radial (longitudinal) and circumferential joints. The structural behaviour of the joints is an important aspect in the structural analysis of tunnel segmental linings. Because joints have more degrees of freedom and a reduced contact area with respect to the standard precast concrete segment thickness, stress concentration occur at the contact zones making them particular areas of concern regarding potential damage and failure. Currently, for typical load cases, the structural design of segmental tunnel linings is often based on simplified 2D rigid ring models with an equivalent reduced inertia (Muir-Wood model) to account for the presence of radial joints. However, for less standard and more asymmetric load and/or bedding conditions, a more detailed analysis of the lining behaviour is required to assess controlling failure mechanisms. This includes the explicit modelling of the radial joints in numerical models and the incorporation of consecutive rings and circumferential joints. Specifically for the radial joints, simplified methods such as Janssen or Bloom's approach based on torsional springs have been proposed. This paper presents a comparative analysis of these simplified methods used to model the radial joint behaviour with the results of a Finite Element Method (FEM) utilising a Concrete Damage Plasticity model (CDPM) which allow for a more detailed modelling of the concrete behaviour, including tensile and compressive damage initiations and evolutions, stiffness degradation and the material nonlinearity. Results indicate that the proposed simplified solutions are suitable for predicting maximum bending moments, but they may not accurately predict crack occurrence or verify serviceability requirements in case of significant joint rotation.

1 INTRODUCTION

Precast concrete segmental linings are interconnected by radial and circumferential joints, which play a critical role in the lining's structural behaviour. Understanding the behaviour of joints is essential for ensuring the stability and integrity of tunnel structures. Analytical approaches provide simplified solutions for assessing the behaviour of radial joints in segmental tunnel linings.

Jassen (1983) conducted a study on the performance of joints between adjacent parts of bridges. Building upon this work, Bloom et al. (2002) further refined the relationships by considering elastic-perfectly plastic behaviours for concrete. Tvede-Jensen et al. (2017) introduced the concept of the block compressive force of concrete as a parabola and made additional

assumptions to enhance the existing relationships. The forementioned analytical approaches have been widely adopted by designers in various projects. The Japanese Society of Civil Engineering (JSCE) (2016) and the German Tunnelling Committee (ITA-AITES) (DAUB) (2013) have established specifications that utilize analytical approaches, specifically through use of beam spring models, to assess and verify the behaviour of radial joints.

Teachavorasinskun and Chub-uppakarn (2010) found that segmental joints have a significant influence on tunnel lining behaviour. They proposed a simplified method for evaluating the moment-carrying capacity of segmental tunnel liners using calibrated parameters from a true-scale model test. The study showed that jointed linings carry smaller maximum bending moments compared to non-jointed linings. This

*Corresponding author: amin.emadi@smec.com; alexandre.gomes@smec.com

reduction in bending moment, known as the moment reduction factor, can be determined based on angular joint stiffness and the number of lining segments.

Arnaud and Molins (2011) utilized finite element analysis and experimental models to investigate stress distribution and displacement patterns within radial joints, providing valuable insights into their structural response. Yuelang et al. (2017) showed the mechanical behaviour of segmental joints is influenced by joint section details, loading conditions, and contact conditions between adjacent segments. The study's findings indicate that even a minor initial gap of 2 mm between segments has a notable impact on joint stiffness.

Full-scale tests and numerical analysis have been carried out to study the bending stiffness, joint opening variation, and failure characteristics of segmental joint structures for under-river shield tunnels by Williams (1982). Results show that the bending stiffness and joint opening behave significantly non-linearly, and concrete cracking and bolt breaking have been detected in the tests.

Caratelli et al. (2018) examined the behaviour of flat radial joints without connectors through full-scale experimental tests on fibre reinforced concrete elements. Tests involved inducing joint openings to simulate scenarios of high levels of ovalization of the lining. Results revealed the impact of concrete crushing and bursting phenomena on the joints.

X. Li et al. (2015) investigated the behaviour of longitudinal joints in shield tunnel operation. This research provides valuable insights and a progressive model for understanding and designing longitudinal joints in operational tunnels, considering factors like axial stress, bolt force, and concrete condition.

This paper presents a comparative analysis of these simplified methods used to model the radial joint behaviour with the results of a Finite Element Method (FEM) utilising a Concrete Damage Plasticity model (CDPM) which allow for a more detailed modelling of the concrete behaviour, including tensile and compressive damage initiations and evolutions, stiffness degradation and the material nonlinearity. Results from this comparison provide insights on the range of applicability of simplified methods for the structural analysis of segmental linings.

2 CDPM MATERIAL MODEL AND VERIFICATION

The CDPM finite element analysis (FEM), is used to simulate the behavior of the concrete. The stress-strain curve of the concrete assumed in the CDPM (FEM) model is shown in Figure 1. In the case of uniaxial tension, the stress-strain relationship in concrete follows a linear elastic pattern until it reaches the failure stress value σ_t . At this point, micro-cracking initiates within the material. Beyond the failure stress, the presence of micro-cracks is macroscopically represented by a softening stress-strain response, leading to localized strain within the concrete structure. When subject

to uniaxial compression, the concrete's response remains linear until reaching the initial yield value σ_{c0} . In the plastic regime, the response typically exhibits stress hardening, followed by strain softening beyond the ultimate stress σ_{cu} . While this representation is somewhat simplified, it captures the primary characteristics of concrete's response.

Figure 1. CDPM (FEM) - stress-strain diagram of concrete considering nonlinear behaviour in compression and tension.

The strain softening branch of the stress-strain curve is associated with the degradation of elastic stiffness, which is characterized by two damage variables: dt and dc . These variables range from zero to one and represent the degree of damage. The initial (undamaged) elastic stiffness of the material is denoted as E_0 , while ϵ_c^{pl} , ϵ_t^{pl} , ϵ_c^{in} and ϵ_t^{in} represent the values of compressive plastic strain, tensile plastic strain, compressive inelastic strain, and tensile inelastic strain, respectively.

Liu et al. (2017) performed a comprehensive study on the behavior of joints in segmental tunnels using a full-scale ring test, as shown in Figure 2. Tested rings' outer and inner diameter were 6.2 m and 5.5 m, respectively. The segment thickness was 0.35 m, composed by C50 Concrete.

Figure 2. Segment layout of tested rings. (Liu et al., 2017).

For verification purpose, a radial joint at 348.75° was selected to exhibit joint closing behavior. Figure 3 illustrates the geometry of the model with the generated mesh.

Figure 3. Geometry of the radial joint and finite element modelling using shell element (cpe4) meshing.

To assess the accuracy of the CPDM (FEM) model analysis to predict segment damage, the experiment by of Liu et al. 2017 was modelled in this study. For that, an axial load of 1400 kN was applied and the radial joint subjected to incremental joint rotation, until concrete failure was observed. Experimental results showed spalling of the segment extrados at the radial joint of the middle ring (see Figure 4).

Figure 4. Ultimate failure state of tested segment (Liu et al., 2017).

A similar behaviour was observed, in the CPDM (FEM) model, as indicated by the damage index of 0.9 shown in Figure 5, indicating concrete damage. This damage has the potential to propagate from the joint and extend beyond the segment's thickness along its surface, in alignment with the experimental findings.

Figure 5. The damage Index in CDP FEM.

3 RADIAL JOINT MODELLING

3.1 Geometry and material properties

To compare the behaviour of the radial joint in the analytical approach with the CPDM (FEM) analysis, two adjacent segments were modelled, as shown in Figure 6.

Figure 6. The geometry of the model and radial joint.

The thickness of the segments is 420mm and the radial joint contact area is 340mm. Parameters used in the model are presented in the table 1.

Table 1. Concrete properties for the CPDM analysis.

Density (kg/m ³)	E (GPa)	Poisson ratio	compressive strength (MPa)	f _{bo} / f _{co}	K
2500	35.5	0.15	40	1.16	0.67

3.2 Radial joint rotation

In the analytical approach, the initial position of the joint is considered on the circular circumference at the ring radius. The deformation of the segment structure is calculated by analyzing the ring structure under the loads imposed on the tunnel. Assuming a change in shape from a circle to an ellipse and

Table 2. Equations for the radial joint in the analytical approach (Groeneweg, 2007).

	Closed	Opened	Plastic behavior
Rotation	$\phi = \frac{12M}{b\ell^2 E_c}$	$\phi = \frac{8N}{9b\ell E_c' \left(\frac{2M}{N\ell} - 1\right)}$	$\phi_{1,2} = \frac{\left(6N \pm \sqrt{21 N^2 + 30Mf_c' b - 15N\ell f_c' b}\right) \ell f_c'^2 b}{6(-2Mf_c' b + \ell N f_c' b + N^2) E_c'}$
Rotational stiffness	$c_r = \frac{b\ell^2 E_c'}{12}$	$c_r = \frac{9b\ell E_c' M \left(\frac{2M}{N\ell} - 1\right)^2}{8N}$	$c_{r1,2} = \frac{6(-2Mf_c' b + \ell N f_c' b + N^2) M E_c'}{\left(6N \pm \sqrt{21 N^2 + 30Mf_c' b - 15N\ell f_c' b}\right) \ell f_c'^2 b}$
Maximum strain	$\epsilon_{\max} = \frac{\phi}{2} + \frac{N}{E_c' b \ell}$	$\epsilon_{\max} = \frac{-3\phi}{2} \left(\frac{2M}{N\ell} - 1\right)$	$\epsilon_{\max} = \frac{f_c' \ell b + 2N E_c' \phi}{2E_c' f_c' \ell b}$
Maximum bending moment	n/a	$M_{\max} = N \frac{\ell}{2}$	$M_{\max} = N \frac{\ell}{2} + \frac{N^2}{2f_c' b}$

Where: ℓ = Height and width of the contact area, M = Bending moment, N = Normal ring axial load, b = width, E_c = module of elasticity, f_c' = compressive strength of concrete, ϕ = Rotation in the joint, and C_r = rotational stiffness.

writing compatibility equations, the radial displacement of the joint is calculated. Table 2 provides a summary of the equations governing the rotational stiffness and reactions for all three situations in the analytical approach for closed joints, opened joints and concrete behaving plastic in joints (Groeneweg, 2007).

In the analytical approach, the contact length is determined by the rotation of two adjacent segments around a point. It is assumed that this rotation does not affect the normal ring axial load. Figure 7 illustrates the rotation of the joint obtained from the analytical approach equations considering two different normal ring axial load equivalent to 10%, and 70% of the sectional compressive capacity which is equal to $f_c' \times A$ where A is the gross area of the section.

The assumed geometry and material properties are identical to those used in the CPDM (FEM), as mentioned in section 3. The sectional compressive capacity is 1680 kN at 10%, increasing to 11,760 kN at 70% of the sectional compressive capacity. The simplified analytical approach fails to capture the fact that the two segments are not only rotating but also pushing against each other.

Figure 7. Radial joint opening in analytical approach and segments pushing against each other - CPDM (FEM model).

In the CPDM (FEM) model, the same axial loads as those assigned in the analytical approach are applied and the behavior of the joint is assessed for the gradual increase in the rotation of the two segments. The loading scheme of the model is shown in Figure 8.

Figure 8. Modelling of the rotation on radial joint.

A “hard contact” is generated as the two surfaces are compressed against each other. In the CPDM (FEM) model, the concept of “hard contact” is employed to define the interaction property in the normal direction of the adjacent segments. This modeling approach allows for the representation of the separation between two surfaces (Figure 9). It is worth noting that in the CPDM (FEM) model, the position of the normal force on the joint may vary due to rotation. Furthermore, the magnitude of the axial stress on the joint can be affected by both the modeling of the hard contact and by the anticipated rotation, which closely resembles practical conditions.

4 RESULT AND DISCUSSION

4.1 Moment- rotation

According to the analytical approach, as the flexural moment increases, the joint experiences three states:

Figure 9. Separation between two surfaces at the radial joint.

(1) opening, (2) concrete yielding, and (3) concrete crushing.

Table 3 presents the corresponding rotations for each of these states, as derived from the analytical approach.

Table 3. Rotations (mrad) for Various Joint States.

Joint states	Axial load (kN)	
	N=1680	N=11760
Joint opens	0.28	1.96
Concrete yields	10.9	1.55
Concrete fails	53.4	7.62

Figure 10 Illustrates the relationship between the bending moment and the radial joint rotation for different axial loads for both the analytical and the numerical models. Initially, when the joint is still closed, bending moments rapidly increase with rotation. As the joint starts to open, bending moment increases at a slower rate. In the third stage, concrete plastification occur, causing additional reduction in the rate of increase of the bending moment with rotation.

Figure 10. Bending moment – radial joint rotation relation: comparison between numerical and analytical models for various axial forces.

Based on Figure 10, the analytical approach shows good prediction capability with respect to maximum bending moments. However, there are some differences in the results between the two

methods. The numerical method exhibits a slightly earlier transition from elastic to plastic behaviour compared to the analytical approach. This can be attributed to two factors. Firstly, the numerical analysis considers the effects of adjacent segments (hard contact approach), which results in forces being applied to the joint surface from the moment segment rotation initiates. This causes deformations to enter the non-elastic region more rapidly due to a reduced contact area. Secondly, the CPDM (FEM) considered in the numerical method provides a more accurate representation of nonlinear concrete behaviour, whereas the analytical approach assumes an elastic-perfectly plastic behaviour model.

It should be noted that due to the nonlinear behaviour and crack growth within the section, finite element models exhibit less rotational stiffness compared to the theoretical approach.

In the CPDM (FEM) model, the analysis may terminate or fail to converge due to the occurrence of tensile cracks. In contrast, the analytical approach does not impose a defined rotation limit, as the crack occurrence cannot be assessed in the analytical approach.

4.2 Bursting stress

Another significant finding is the comparison of bursting stress. Figure 11 illustrates a comparison between the bursting stress obtained from CPDM (FEM) analysis and the analytical approach, revealing a high level of accuracy in the analytical predictions, which is slightly on the conservative side. It is important to mention that in the CPDM (FEM) model, the evaluation of bursting stress is conducted at the location of the internal point load at joint, which dynamically changes with joint rotation. This implies that the bursting stress aligns well with the analytical approach at the specific point being compared. However, some discrepancies are observed if the evaluation is conducted for a section located closer to the outer side of the segment, as explained in the section 4.3.

Figure 11. Bursting stress. comparison between numerical and analytical models.

It can be observed in both methods that the rotation of the Radial joint leads to the formation of tensile

cracks in the concrete. The mentioned observation is consistent with the findings presented in the next section regarding the expansion of tensile cracks at the stress concentration point within the contact zone. Despite both methods predicting the occurrence of cracks in the segment, the analytical method estimates the maximum tensile stress to happen at a distance of 190 mm from the edge of the segment, whereas the finite element method calculates the maximum tensile stress at a closer distance of 132 mm.

Figure 12. Occurrence of first crack for the model with axial load $n = 11760$ kn at $m = 324.45$ kn·m and $rot = 1.38$ mrad.

4.3 Crack occurrence

Cracking in concrete occurs when the tensile strain exceeds approximately 0.00011. In CPDM (FEM) analysis, concrete cracks are observed when the tensional damage index reaches around 0.1. Figure 12 illustrates the damage index at the onset of the first crack for the model subjected to an axial load of 11760 kN.

Based on Figure 12 and in comparison, to Table 3, it is evident that the occurrence of the first crack takes place at a significantly lower rotation than the threshold rotation determined by the analytical approach in Table 3.

Figure 13 Demonstrates a damage index of 0.9, indicating substantial damage, when the moment M reaches 201 kN·m for the section under an axial load of 1680 kN. Similarly, in Figure 14, a damage index of 0.9 is observed when the moment M reaches 808 kN·m for the section under an axial load of 11760 kN.

As shown in Figures 13 and 14, it is important consider the concentration of tensile stress within the segment, as they can lead to cracking and spalling of the segment, starting at the joint and extending beyond a distance greater than the thickness of the segment along its length.

While a satisfactory compliance between the CPDM (FEM) model and analytical approach is observed when evaluating the bursting stress at the section underneath the point load, a comprehensive comparison of the entire section reveals that the analytical method has limitations in predicting tensile stresses and induced cracks, whereas these phenomena can

Figure 13. Damage index in cpdm for $m = 200$ kn·m in the model with $n = 1680$ kn.

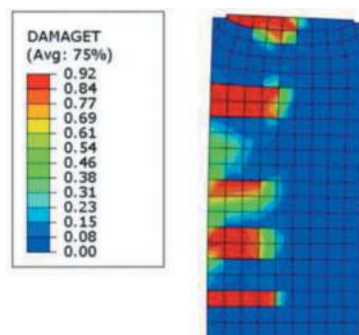

Figure 14. Damage index in cpdm for $m = 808$ kn·m in the model with $n = 11760$ kn.

be properly captured through the CPDM (FEM) model.

5 CONCLUSIONS

This paper presents a comparative analysis of the simplified analytical methods used to model the radial joint behaviour with the results of a Finite Element Method (FEM) using a Concrete Damage Plasticity Model (CDPM), which allow for a more detailed modelling of the concrete behaviour, including tensile and compressive damage initiation and evolution, stiffness degradation and the material nonlinearity. Results suggest that:

1. Both the CPDM (FEM) model and the analytical approach exhibit comparable and consistent bending rotation behaviour. This indicates that the analytical approach can be used with an acceptable level of accuracy.
2. Bursting forces induced by an equivalent concentrated load acting on the joint are similar for both the CPDM (FEM) model and the analytical approach.
3. The sole reliance on the analytical approach is insufficient for predicting crack occurrence beyond a certain magnitude of joint rotation.

Results underscore the importance of using numerical detailed modelling (such as CPDM FEM model) to assess cracking behaviour when large joint rotations are anticipated.

4. The region affected by tension crack has the potential to extend beyond the joint and expand over a distance greater than the thickness of the segment along its length.

While the analytical approach is often sufficiently accurate for practical use, it is important to establish the rotation limit beyond which the analytical approach's predictive accuracy in determining crack occurrence becomes inadequate. This limit may vary depending on factors such as material properties, geometry, and specific project constraints, including rotation resulting from building imperfections or structural deformations.

ABSTRACT: Uma Oya Multipurpose Development Project constructed in Sri Lanka. This project involves two Roller Concrete Core (RCC) dams, drill and blast link tunnel which connected two dams, 15.4 km mechanized headrace tunnel for transferring water to the top of a 618 m deep pressure shaft, underground powerhouse and turbine chamber and tailrace tunnel. During the boring in headrace tunnel, TBM faced a mud zone. The support for this system was concrete segment installation. Geotechnical studies confirm the clay and mud zone are surrounding this section. According to design of headrace tunnel as a pressurized water conveyance, another steel lining have been designed for this section.

Keywords: Uma Oya Project, Headrace Tunnel, Mechanized Tunnelling, Support, Mud Zone, Steel Lining

1 INTRODUCTION

The Uma Oya Multipurpose Development Project (UOMDP) is a water transfer, hydropower and irrigation project. The project extends partly into Badulla and Monaragala districts in the Uva province.

Bandarawela is the largest settlement within the project area, located halfway between the upstream and downstream ends of the scheme. The project will transfer long term an annual average water quantity of 145 MCM for irrigation purposes and will develop a head of more than 700 m for the generation of electricity in an underground power plant with a rated capacity of 120 MW.

Main Features of the Project:

- Two storage reservoirs at Puhulpola and Dyraaba in Welimada area
- Link or conveyance tunnel between the two reservoirs to transfer water from Puhulpola to Dyraaba reservoir
- Headrace tunnel to convey water from Dyraaba reservoirs to the power house

- Vertical pressure shaft at the end of the headrace tunnel and a surge shaft
- Underground power house and switchyard at Karandagolla
- Tailrace tunnel to convey water from the power house to downstream irrigation works

The salient features of the headrace tunnel (HRT):

- Elevation at intake (invert) - 960 m.a.s.l.
- Total Length - 15.4 km
- Tunnel slope - 0.01 and 0.002
- Excavation method – Double Shield Tunnel Boring Machine (DS-TBM)
- Excavation diameter - 4.3 m
- Design discharge - 19.5 m³/s
- Flow conditions - Pressure flow

2 HEADRACE TUNNEL SUPPORT

This paper aims to review the steel lining support installation in headrace tunnel in Uma Oya Multipurpose Development Project. The excavation of the

*Corresponding author: ata.rahbar.f@gmail.com; a_noorzad@sbu.ac.ir; yuvaraju56@gmail.com; rejith.neduvakkattu@gmail.com

15.4 km long headrace tunnel started in March 2014 and breakthrough was on 2nd of October 2019. Two Double shield TBMs were used to mine the HRT to increase tunnel excavation advance rate and provide for higher quality tunnel lining. Headrace tunnel boring firstly started from the outlet side driving upwards and later 2nd TBM re-assembled from tail-race tunnel and started boring from HRT intake driving downwards (Rahbar et al., 2016).

There are design features separating this tunnel from other similar cases. First, this tunnel is a pressure tunnel, meaning that it will operate under hydraulic pressure in excess of 20 bars at the intake location with water up to 200 m water column. Second unique feature of HRT in the present project is various adverse geological conditions including hard abrasive rocks, undetected faults containing high pressure water and mud, as well as possibility of encountering karst.

Four different ground support types (TBM) have been selected for the HRT based on the anticipated ground conditions (Figure 1). They include the following:

- TBM 1: No support (invert segment only)
- TBM 2: Spot bolts where required (with invert segment)
- TBM 3: Systematic bolt pattern (with invert segment)
- TBM 4: Full ring segmental lining

Figure 1. Support in headrace tunnel.

Support type installation was based on the geological condition of the boring rock and for this reason, all the times there was a geologist with each shift on the TBM to check and control the face rock geological condition. After each stroke advance of TBM, the rock face geologically mapped and monitored through the cutter head manhole. Then the supervisors decided to install the full ring or shift from the full ring to invert only, or shotcrete and rock bolt support or reverse versa.

On December 24, 2014 during the upward boring from the outlet, a first significant water ingress occurred at the chainage 11+160 of the tunnel and the tunnel support type changed to the full ring. By the advance of boring, TBM faced to a completely weathered crushed zone and later mud zone which mixed with water ingress, flowed into the tunnel through the segmental lining holes. The chainage of the headrace tunnel in this section from the outlet to intake is CH. 12+287 to CH. 12+225, i.e. 62 m of

headrace tunnel. Same as the other full ring area, pea gravel and grouting injection for this section have been examined which was not completely successful. Because the headrace tunnel is pressurized tunnel, and this zone contain mud and clay, finally it has been decided to design and install the steel lining support.

Ground water ingress was one of the great talented activities in headrace tunnel of Uma Oya project and achieved the lots of lessons learned from the deep underground geological condition in Sri Lanka (Rahbar et al., 2017, 2019 and 2022).

3 MUD ZONE SUPPORT DESIGN

Design indicates to use the S460 steel plates in 9.5 m-length/2 m-wide/30 mm-thickness. The design parameters were for:

- 3 m internal dimension,
- 14 bar internal pressure, and
- 20 bar external pressure.

According to the progress plan and the design specifications, 10 m out of 62 m design, revised for concrete lining from the waterway (means CH. 12+287 to CH. 12+225). The steel lining installed on the other remaining parts of the crushed mud zone.

During the feasibility studies, there were some faults and crushed zones recognized in the headrace tunnel trace. Consequently, the designer has considered headrace tunnel alignment including three curves in 750 m radius and two slopes which is 1% for 9 km of tunnel from the intake and the remaining parts of the tunnel slope is 0.2 %.

First alignment bend starts from CH. 12+326 with 112 m length. So, the mud zone is located in the headrace tunnel bend area. According to the tunnelling surveying as-built and regarding the curve of tunnel, steel lining design in this section includes three bends.

The designed space between the steel lining and primary installed concrete segment is 30 cm which should be used for SCC back filling. Furthermore, a reducer as well as a final ring has been designed at the end of the steel lining. To conclude this section, total sums of the steel lining parts are as the following from CH. 12 + 235 to 12+287:

- 10 straight strakes which have been welded by two numbers of 2 m rolled pipes
- Three bend strake which have been welded of two no. of 2 m rolled and level adjusted pipes to prepare bend
- One reducer assembled in four parts in 1.1 m as a part of the steel transition and four parts welded at site
- One final ring assembled in two parts in 0.4 m as another part of the steel transition

The reducer and the final ring installed after the CH. 12+287. The other side of the support is the

concrete lining from CH. 12+235 to 12+225 and the concrete transition constructed from CH. 12+224.40 to 12+225 (Figure 2).

Figure 2. Steel Lining – Longitudinal section.

4 PROCESS AND CLASSIFICATION

The steel lining preparation in the rolling factory is as:

- Cutting the plates in the required length
- Rolling the plates
- Fit-up will be done to prepare the pipe for welding
- Welding the joint
- Back grinding and NDT will be followed
- Back welding
- NDT tests on the welded joints as QC protocols
- Grinding and repairs the welded joints, as required
- Repeat the NDT tests on the welded joints as QC protocol
- Fit-up two-welded pipes to each other to make one strake and above mentioned procedures will be followed for finalizing the strake
- Sand blast of each strake
- Painting in four layers by Hempel (1st- Hempadur Avant Guard Zinc, 2nd- Hempadur MIO, 3rd- Hempel's Brown and 4th- Hempel's Black)
- Boring holes for back filling in 11 cm diameter, will be welded, NDT and painting

The process of the rolling and welding is illustrated in Figures 3 and 4.

5 STEEL LINING INSTALLATION

As the welding and painting completed in the rolling factory, transporting the strakes needed a special trailer/flat car, which has been fabricated in the job site for this matter according to the heaviest load and maximum dimensions (Figure 5). During the transportation, some rolling wheels fixed on the steel lining to avoid any damage on the strakes.

Figure 3. Rolling the steel plates for steel lining support.

Figure 4. Welding process in rolling factory.

Due to the space limitation inside the tunnel, in addition to more than 3 km distance from the headrace tunnel portal, before starting the transportation all the steel segments assembled in the rolling factory (Figure 6). Moreover, the back strip belts fixed and welded on the joints.

For this reason, firstly all the rails, segmental inlays and booster jet fans removed from the tunnel. Later another jet fan installed near to the portal for blowing the air to the steel lining area. After delivery of all steel segments, welding of strakes inside the headrace tunnel started, and consequently it was required the dry condition for the process. In this section of the headrace tunnel the cumulative water leakage is 300 l/s. Therefore, before transporting the steel segments and starting the concrete lining, all

Figure 5. Special trailer.

Figure 6. Assembled steel lining.

the required water pumping and drainage systems delivered to the area and installed in the upstream of the steel lining section. Such that the procedure of the steel lining installation inside the headrace tunnel continued as below:

- Remove all the rails
- Remove jet fans
- Remove ventilation ducts
- Invert cleaning of the path
- Transport of all the pumps, pipes, connections and electrical drives
- Make a sump in the upstream
- Transport the steel segments

- Fit up the steel segments
- Installation of dewatering pipes and connect to the pumps
- Welding the strakes joints
- In parallel, start of the concrete lining
- NDT tests on the welded joints as QC protocols
- Grinding and repairs of welded joints, as required
- Repeat the NDT tests on the welded joints as QC protocol
- Painting
- Remove all the dewatering pipes
- Remove the sump
- Remove the pumps
- Cleaning the section

It should be noted that four numbers of 132 kW - 225 l/s water pumps (three active and one standby pumps) installed in the sump for dewatering while two pumps active simultaneously to fully dry the section with two lines of 16 inch poly ethylene pipes in 80 m length. The pipe lines installed in height of 1.5 m in the middle of the steel lining to proceed the welding and other activities (Figure 7). In all the shifts, one electrician was working in the sump area to looking after the pumps and operation.

6 WELDING METHOD

Type of filler used flux-core arc welding (FCAW), which is widely used in construction because of its portability and high welding speed. It is a flexible welding method, suitable for all welding positions, provided the welder uses the right filler material and flux composition.

- Process and classification of welding in rolling factory is:
- Process: FCAW
- Filler shielding gas: CO₂
- Filler: ESAB 13.23, MG-51T, ESAB-81-Ni1-H4

Process and classification of welding inside the headrace tunnel is:

- Process: FCAW
- Filler shielding gas: CO₂
- Filler: ESAB-81-Ni1-H4

7 STEEL LINING BACK FILLING

By completion of the steel lining welding and painting, back filling of the steel lining started through the designed holes in the steel lining. The diameter of this holes is 11 cm and seven holes bored in 8 m zig-zag spacing of steel lining strake. Also every 8 m a bulkhead fixed behind the steel lining for better solution in back filling (Figure 8).

Self-compacting concrete (SCC) mainly because of its self-compacting characteristics and strength. SCC is a highly flowable, non-segregating, special

Figure 7. Dewatering sump and lines.

concrete type that can settle into formworks, and encapsulates, heavily reinforced, narrow, and deep sections by means of its own weight. Mixing the class of SCC-30 concrete with non-tilting drum mixer inside the steel lining location.

After completion of the back filling, the caps welded and after QC tests, all the gaps and welded as well as damaged parts painted to the final layer.

During the preparation, transport, fit up, grinding, welding, QC tests, painting and demobilization from steel lining area, HSE officer was there to control the situation and the impacts. As welders using the gas and CO₂ cylinders in small and narrow area under 2 lines of 16 inches pipes and supports. So, control of the PPE and the ventilation situation was very high requested and essential. For these reasons the First Aid boxes and all required extinguishers are keep in the working places as well as sump area.

8 CONCLUSION

Headrace tunnel of Uma Oya Multipurpose Development Project faced lots of the challenges during the construction from boring in very hard and abrasive rocks to the fractured and mud zone. This paper has

Figure 8. Back filling holes.

been focused on the steel lining design and execution in 62 m critically mud zone. During the mechanized excavation, concrete segmental lining installed in this section. Later exploratory drillings evidences that mud surrounded this section and as this tunnel would be a pressurized tunnel as well as the internal pressure in this section would be more than 10 bar, the consultant has reviewed the design and the second support based on the combination of the steel lining and concrete lining has been proposed. The steel lining details are summarized as below:

- 10 strakes in 4 m (jointing 2 pipes),
- Three bends in 4 m (jointing 2 pipes),
- One reducer,
- One final ring,
- Six welding machine,
- 350 litres of paints,

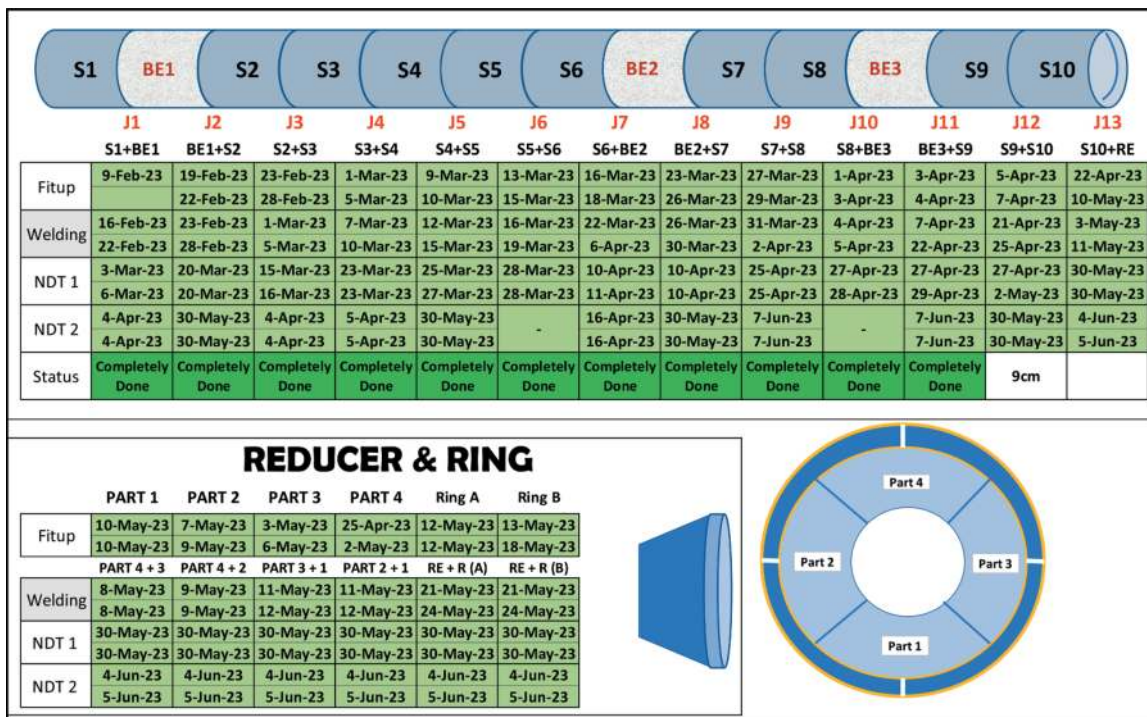

Figure 9. Steel lining time schedule.

- 60 litres of thinner,
- 1,500 m² area painted,
- 300 m NDT tests including 150 m UT and 150 m MT/PT in rolling factory,
- 140 m NDT tests including 150 m UT and 150 m MT/PT inside headrace tunnel.

After completion of the steel lining installation, fit up, welding and QC controls, back filling of the steel lining completed through the indicated holes. Final stage was to welding, NDT tests, any repair and painting this hole's caps. Delivery of first segment started on February 9, 2023 and the last NDT tests done on June 5, 2023 (Figure 9).

Durability of two-component backfill grout: An experimental study

Marta Di Felice & Anita Di Giulio*

GEEG, Geotechnical and Environmental Engineering Group, Rome, Italy

Nicola Valiante

Webuild S.p.A., Rozzano, Italy

ABSTRACT: Two-component grout is widely used in mechanized tunnelling to fill the annular gap behind the segmental lining. Besides the numerous advantages of this technology, it is well known that this type of mortar is subject to rapid degradation processes when exposed to air, even for short periods of time. This is not a concern under normal operating conditions, i.e. underground and often below the water table, but it may be detrimental to the quality of the backfilling in case part of the grout is temporarily exposed to air during the construction phases. In lack of dedicated standards, the purpose of this work is to share a laboratory experience on a topic that has not been fully addressed in the literature. The research activity presented in this paper was specifically designed to evaluate the effect of exposure to air and dry soil on a high-performance two-component mortar. The experimental study entailed the execution of visual inspections, UCS tests and mineralogical analyses on small and full-scale specimens subjected to specific exposure environments for an observation period of six months. The results show that, depending on the imposed conditions, there is a certain degree of decay of the mechanical properties but that they remain above those required by technical specifications.

Keywords: Tunnelling, TBM, Backfilling, Two-component grout, Laboratory test, Durability

1 INTRODUCTION

In TBM tunnelling, the use of two-component grout as backfilling material for the annular gap behind the segmental lining is experiencing a great diffusion, encouraging further technical and scientific research on this topic. Several studies, among which Thewes and Budach (2009), Pelizza et al. (2010), Antunes (2012), Youn and Breitenbücher (2014), Mähner and Hausmann (2017) and Todaro et al. (2022), dealt with the mechanical characterization and the standardization of testing procedure for this material. On the other hand, there is little published knowledge on the long-term behaviour of two-component grout under site conditions as well as in the laboratory. Only recently a comprehensive work by Peila et al. (2015) provided some case histories and laboratory experience. Furthermore, on-site quality checks are generally not made public.

The long-term behaviour of the backfill as a component of the support system of the tunnel together with the lining is important not only in terms of safety and costs, but also to improve sustainability. Hence, its durability should be considered since the design phase.

Laboratory testing of two-component grout usually refers to standards made for concrete and single component mortars (for example UNI EN 11417-1:2012, UNI EN 13057, UNI EN 13295), which cannot be fully applied when the material is exposed to aggressive environments. The exposure conditions of the backfilling in fact are not comparable to those of the structural concrete and also several of those tests entail oven drying, which has proven to be detrimental for the integrity of the two-component grout.

For the backfilling grout, usually working in confined environments and below the water table, the exposure to aggressive environments during the tunnel life may be related to the characteristics of the groundwater (i.e. acid, rich of chlorides, sulphates) or to particular construction phases, during which the grout can be subjected to drying or low temperatures. In this context, it seems appropriate to define the experimental activity according to the conditions and needs of the specific project.

With the goal of sharing a laboratory experience focused on the long-term behaviour of the backfill, this work presents the study of the durability of the backfill grout carried out for the Inclined Pressure Shaft of Snowy 2.0 Project, carefully approached

*Corresponding author: anita.digiulio@geeg.it

starting from the design phase due to the special features of the backfilling required for this very challenging project (De Carli et. al (2022) and Di Giulio et al. (2023)).

The performance requirements were:

- unit weight $>20 \text{ kN/m}^3$ or porosity $<50\%$
- Unconfined Compressive Strength $\text{UCS} \geq 15\text{--}20 \text{ MPa}$
- Young modulus $E \geq 3.0\text{--}5.0 \text{ GPa}$
- Decay of $\text{UCS} \& E < 20\%$ after 10^6 loading/unloading cycles

The selection of a mix design able to meet these targets and its mechanical characterization was followed by a further experimental activity aimed at assessing the grout durability under specific site conditions; in fact, the project schedule involves a construction phase during which the drainages that cross both the lining and the backfill will be operational. These drainages will be necessary to discharge the external hydraulic load acting on the lining in a phase in which the tunnel will be dry but will probably put the backfill in contact with air for a few months. The object of the study was to verify if the two-component grout could withstand, without damage, this temporary phase.

2 MATERIALS AND METHODS

Two-component backfill grout consists of two fluids: a component A (binder, bentonite, water and a retarding agent) and a component B (accelerating additive, usually sodium silicate), which produce a gel within seconds from the moment they are mixed. The materials used and the mixing process significantly affect the behaviour of the grout, therefore, in the laboratory, particular attention was paid to the supply of the actual materials from the jobsite and to the mixing system, that was designed to simulate as closely as possible the injection system of the TBM. The durability of the grout was considered at an early design stage, with constraints on the binder and the filler to be used and on the porosity to be achieved.

The mix design reported in Table 1 (Di Giulio et al. 2023) was obtained after a trial phase aimed at finding a proper balance between the characteristics of the fresh and hardened grout, i.e. achieving high-performances while maintaining the component A fluid and stable enough to be pumped. The special features of this mix design with respect to common practice (Thewes and Budach 2009) are the use of a composite slag/cement binder, the low water/binder ratio (0.85), the reduced amount of bentonite, and, most importantly, the introduction of a superplasticizer to improve the workability and of a filler (silica flour) to impart structure. The component B was sodium silicate, which dosage is about 11% of the total weight of 1m^3 of grout.

Table 1. Mix design.

Binder (kg/m^3)	608
Filler (kg/m^3)	339
Water (kg/m^3)	518
Bentonite (kg/m^3)	2.8
Retarder (kg/m^3)	11.3
Superplasticizer (kg/m^3)	3.6
Accelerator (kg/m^3)	176

A series of laboratory tests was performed to measure the properties of the component A (viscosity at the Marsh' cone, density, gel time) and to verify the performance requirements on the hardened grout (unit weight, porosity, Unconfined Compressive Strength and elastic moduli). The unit weight and porosity were 16.5 kN/m^3 and 35% , respectively; the average UCS of the mortar was 36 MPa after 28 days and the average value of the Young's modulus was 10 GPa .

2.1 Experimental program

As already pointed out, the experimentation could not follow the existing standards for durability testing due to the peculiar features of two-component grout, so the study was carried out with a site-specific approach, dealing with expected conditions that could be detrimental for the grout integrity and performance on the long-term.

The experimentation lasted six months and consisted in the execution of UCS tests on samples cured in different environments, and in the preparation of a full-scale sample simulating the grout around a drainage hole, subjected to visual inspections, UCS tests and mineralogical analyses.

2.1.1 Curing at controlled humidity

The effect of a prolonged exposure to air was investigated on prismatic specimens, cured in water at constant temperature for about four months before the beginning of the tests. The samples were sealed in paraffin leaving free one of the bases, as shown in Figure 1, and then were kept at $25 \text{ }^\circ\text{C}$ in containers with relative humidity equal to 50% , 90% and 98% .

Temperature and humidity were monitored by a thermometer and a hygrometer for the entire test duration. After a first inspection, executed after two months of exposure, it was decided to continue the observation up to six months, exposing other samples (now six months old) to the worst conditions, i.e. 50% relative humidity. At the end of the fixed period of exposure the samples were subjected to visual inspection and UCS tests.

2.1.2 Full-scale set-up: Simulation of the drainage hole

A specific test set-up, illustrated in Figure 2, was developed with the aim of studying in the laboratory the potential degradation of the portion of grout surrounding the drains.

Figure 1. Prismatic specimen sealed in wax.

Figure 2. Scheme of the set-up for the simulation of the drainage.

A 40x40x18 cm block of grout was prepared leaving a PVC pipe (80 mm external diameter) in the centre. The grout was poured directly on a layer of sand, simulating the contact between backfill and rock mass, while the impermeable lining was simulated by a top layer made of wax. The casting of this full-scale sample (Figure 3) was the most challenging task of the experimentation, requiring the laboratory team to build a new system able to pour about 40 L of mixture in a continuous flow under 1 bar of pressure, which was much more complex than the system previously used and already discussed in De Carli et. al (2022).

After 40 days of curing in sealed conditions, the PVC pipe was extracted and replaced with a smaller slotted pipe, leaving a gap of about 2 mm between the hole wall and the external surface of the drain. The system thus made was then kept at a temperature of 25 °C and relative humidity, hr , of 70% for six months, during which visual inspection and UCS tests were performed at regular intervals.

Figure 3. Pictures of the full-scale set-up.

The value of relative humidity equal 70% was selected as the minimum among the available environmental measurements taken in another tunnel of the jobsite.

3 RESULTS

3.1 Prismatic samples in unconfined environment

As illustrated in Figure 4, which shows longitudinal sections of sawn prisms, the samples presented a dry/discolored external layer, while the inside appeared fresh.

Figure 4. Pictures of sections of samples sawn after exposure to air at different values of relative humidity, from the left: 50%, 90% and 98%.

The extent of the discolouration, localized at the exposed faces, is greater in the specimens exposed to lower humidity values ($hr=50\%$), as could be expected. Beside the external discoloring, the exposure at $hr=50\%$ produced the formation of cracks propagating from the free base inwards.

The results of the UCS tests carried out on cubic samples sawn from the prisms are presented in Table 2 and Figure 5. It can be observed that the UCS of the control sample (cured in water for the same period) is about 36 MPa, congruent with the average UCS at 28 days of this mix, and that after two months of exposure all samples provided results comparable or above this value, in the range 34-45 MPa.

The thickness of the altered layer after two months was about 2 mm, but this did not translate in a deterioration of the performance, even for the samples kept at the lowest humidity.

Table 2. Results of UCS tests after exposure to air at hr=50%.

Curing conditions	Time of exposure (months)	Total age of samples (months)	UCS (MPa)
Standard	0	6	35.7
hr=50%	2	6	39.3*
hr=50%	2	6	45.2
hr=90%	2	6	33.8
hr=90%	2	6	40.6
hr=98%	2	6	43.6
hr=50%	6	12	51.6
hr=50%	6	12	29.7*
hr=50%	6	12	44.3
hr=50%	6	12	27.7*
hr=50%	6	12	42.5

*Sample including the exposed surface

Figure 5. Results of UCS tests after two and six months of exposure to air at relative humidity = 50%.

As anticipated, once seen the cracks proceeding from the exposed face of the samples cured at hr=50%, it was decided to extend the observation period up to six months. The extent of the altered layer grew, producing measurable damages to the strength of the cubic samples containing the exposed surface; in fact, as it can be noted from Table 2 and Figure 5, the UCS values measured on the external portion of the prisms (28 and 30 MPa) are lower than the UCS measured on the internal portion of the same specimens (42-52 MPa).

A picture taken after the UCS test of a cubic sample containing the exposed face is shown in Figure 6. It's worth noting that the test was conducted putting the altered surface parallel to the vertical axis in order to have regular surfaces on which apply the load. Of course, this could have an influence on the results.

3.2 Full-scale sample with drainage crossing

The block of grout was inspected after one, three and six months of exposure to air at 25 °C and humidity 70%.

Figure 6. Broken sample with an exposed surface.

Figure 7 shows the microscopic enlargements of the portion of grout immediately around the drainage hole, taken at the first and last visual inspections.

Figure 7. Enlargements of the layer of grout exposed to air within the drainage, after 1 month (above) and 6 months (below).

The boundary between altered and “fresh” grout can be easily spotted by colour, so it was possible to measure its progress over the time. After one month, the thickness of the altered layer was less than 1 mm, about 0.2 – 0.5 mm, after 3 months it was about 3-4 mm, after six months it was between 4 and 6 mm.

During the first and last inspection, portion of the block near the drainage hole were sawn to obtain cubic samples for UCS tests. The results are reported in Table 4 and Figure 8.

Table 3. UCS tests on samples retrieved from the block.

Time of exposure (months)	Density (Mg/m3)	UCS (MPa)
1	1.66	36.7
1	1.70	29.5
1	1.64	28.1
6	1.68	29.9
6	1.68	22.3
6	1.59	26.2
6	1.70	28.6

Figure 8. UCS values after 1 and 6 months of exposure.

The measured UCS values, even if always higher than the threshold of 20 MPa set by performance requirements, are generally below the average UCS expected for this mix design at 28 days. This difference may be due to the preparation of the block, which entailed the injection of a huge volume of grout in a single step and a dry, even if sealed, curing. These conditions made the formation of joints and small defects in the block practically unavoidable. Also, the presence of these joints made quite difficult the preparation of cubic samples from the block (from which the modest number of tests that could be executed).

The result show that a reduction of strength due to the exposure to air can be detected comparing the UCS values obtained at different inspections. In fact, after six months of exposure, the samples closer to the hole had an average UCS of 26 MPa, about 17% lower than that of the samples taken close to the hole after one month (31 MPa). Also, visual inspection allowed to observe that the failure of these samples occurred along pre-existing surfaces, while samples retrieved beyond a layer of about 10 cm from the drainage hole provided higher UCS values and appeared fresh after the tests, as shown in Figure 9.

Figure 9. Pictures of samples retrieved from the full-scale block. On the left a sample taken far from the drainage hole, on the right one taken close to it.

3.3 Mineralogical analyses

Portions of the block were subjected to mineralogical (DRX - X-ray diffraction) and petrographic analyses to understand the process of alteration that the grout experiences when exposed to air.

Table 4 synthesizes the results of DRX analyses carried out at three and six months on altered and fresh portions of grout.

Table 4. Results of mineralogical analyses.

Phases	3 months		6 months	
	Fresh	Altered	Fresh	Altered
Quartz	27	27	27	26
Calcite	8	9	10	10
Gypsum	1	1	1	1
Vatherite	-	24	-	23
Aragonite	-	4	-	2
Etringite	3	-	3	-
Smectite	-	-	-	-
Alite/belite	0	-	2	-
Portlandite	-	-	-	-
Amorphous	60	35-40	57	38

It can be noted that the recognized phases are practically the same, with a significant part of the samples composed by not-crystalline phases and quartz (the filler), compounds contained by the clinker as gypsum, calcium silicates (alite/belite) and other hydration products. The altered layer contains more vaterite, a meta-stable form of calcite, at the expenses of the amorphous phase.

Figure 10. Detail of the passage between altered and fresh grout (yellow line). The porosity is shown in the red circles.

The petrographic study highlights the separation between the white and dark layers already observed at a macroscopic level, sometimes gradual and sometimes neat, the latter associated with a higher porosity. The porosity consists mainly of spherical voids presumably due to air entrapped during mixing, but also from narrow cracks probably due to shrinkage (Figure 10).

The altered portion is characterized by a predominantly micritic matrix typical of carbonation due to reaction with the CO₂ in the air.

4 CONCLUSIONS

The study here presented was carried out to investigate the long-term behaviour of the backfilling grout of the IPS of the Snowy 2.0 project, following

a site-specific approach. The experimentation was aimed at evaluating the effects of the exposure to air and low humidity on two-component grout. The experimental activity was developed to simulate specific and severe environmental conditions, in lack of dedicated standards, and involved prismatic samples as well as a full-scale set-up, simulating a portion of grout around a drainage hole.

At the end of an observation period of six months, the following conclusions can be drawn:

- the alteration that the two-component grout undergoes when exposed to air at low humidity is caused by carbonation phenomena and, in this high-performance mix, proceeds from the external surface inwards at an average rate less than 1 mm/month measured on the full scale sample;
- cubic samples obtained from sealed prisms with one free face in contact with air, at relative humidity equal to 50%, provided UCS values in the range 42-52 MPa measured far from the exposed surface, and lower values (28 and 30 MPa) when containing the altered layer;
- in the full-scale sample, the alteration proceeding from the exposed surface (4-6 mm) and the formation of cracks due to the casting procedure, volume of the block and dry curing, produced a reduction of the strength in the layer of grout immediately surrounding the hole. This reduction was observed comparing average UCS values obtained after one and six months of exposure, which are about 31 and 26 MPa, respectively;
- in the full-scale sample, the grout resulted substantially unaffected, in terms of strength and aspect, beyond a layer of about 10 cm from the exposed surface.

Tangential resistance between primary and secondary lining with PVC waterproofing sheet membrane

Luigi Forlingieri
Arup, Milan, Italy

Carmen Hu & Mirko Morosi*
Arup, London, UK

Angelica Zanichelli
Arup, Milan, Italy

ABSTRACT: Urban areas have continuing growing demand for mobility, and as such a great interest is being taken in underground construction. Sprayed Concrete Lining (SCL) is a well-established method for large diameter tunnel construction throughout the UK and the world, sometimes referred to as NATM (New Austrian Tunneling Method). A SCL tunnel usually consists of a primary and a secondary lining. The primary lining is often adopted to support the ground loading during construction, usually assuming full degradation in long term condition. Subsequently, a drainage layer or waterproofing layer will be installed depending on the type of tunnel. The secondary lining will be constructed in the final stage. Depending on the groundwater table and permeability of the ground, tunnel watertightness becomes one of the most critical aspects of tunnel design. When a waterproofing membrane is required, a specific “sandwich” configuration between the primary and secondary lining is used. The common approach is to neglect any of the tangential frictional resistance provided at the interface between the waterproofing sheet membrane and the permanent lining due to its smoothness and a number of factors which could influence the predicted behaviour.

The tangential resistance is a product of the interaction between the primary lining, the loading conditions and the interface friction of the PVC membrane. This paper summarises the key findings of introducing a friction interface between the primary and secondary lining as part of the permanent lining design, thereby, leading to re-distribution of the stresses across the lining interface, and directly assessing the impact on the lining response, and an optimisation of the tunnel geometry. The application of friction interface is a complex interaction, and recommendations will be made in this paper to inform future designers of permanent linings.

Keywords: waterproof membrane, friction resistance, sprayed concrete lining, tangential spring

1 INTRODUCTION

Urban areas have continuing growing demand for mobility and, as such, there is great interest in underground space utilisation and underground construction. Sprayed Concrete Lining (SCL) is a well-established method for large diameter tunnel construction throughout the UK, sometimes referred to as NATM (New Austrian Tunneling Method). SCL is one of the most common methods of construction, due to its adaptability to different tunnel geometry/size and ground conditions.

A SCL tunnel usually consists of a primary and a secondary lining. The primary lining is often

adopted to support the ground loading during construction, usually assuming full degradation in long term condition. Subsequently, a drainage layer or waterproofing layer is installed depending on the type of tunnel. The secondary lining, generally cast in-situ, is constructed in the final stage.

Depending on the groundwater table and permeability of the ground, tunnel watertightness becomes one of the most critical aspects of tunnel design. When a waterproofing membrane is required, a specific “sandwich” configuration between the primary and secondary lining is used.

It is clear that friction resistance at the interface between the primary and secondary lining can impact

*Corresponding author: mirko.morosi@arup.com

the structural design of the secondary lining. With better understanding of the interface resistance, better design of the secondary lining there is the opportunity to optimise lining thickness and reinforcement.

2 OBJECTIVE

The general approach is to neglect any of the friction resistance provided at the interface between the waterproofing sheet membrane and the secondary lining due to its smoothness and the difficulties in the definition of all the factors that are needed to predict the correct behaviour.

Although the benefit of introducing friction resistance is clear, this value is extremely difficult to define and depends, amongst others, on factors such as the undulation (roughness) of the primary lining, installation method, gaps due to concrete shrinkage and the presence of infill grouting between the waterproofing membrane and the secondary lining.

The paper aims to define the impact of friction resistance at the interface on the global behaviour (e.g. internal stresses, lining deformation) of the secondary lining, and provide an insight for secondary lining design which is more representative of the actual behaviour.

In this paper, different loading conditions and friction coefficients between primary and secondary lining are considered to evaluate the variability of the lining system.

3 NUMERICAL MODELLING

3.1 Geometry

A typical lining layout is modelled using numerical software LS-DYNA. A 2D view of the plane strain model is shown in Figure 1. A thin portion of the lining – 0.5m deep with 4 volume mesh elements in the depth of the lining is modelled.

The external height of the tunnel is 11.40m, and it is 12.87m wide at the springline. The primary lining

Figure 1. 2D view of the geometry of the tunnel.

thickness is modelled as 375mm. The secondary lining is 350mm thick, whereas the invert is modelled with a variable thickness (max. 1560mm).

3.2 Tunnel lining interface

Figure 2. Detailed interface between primary and secondary lining.

The concrete linings and the soil are modelled with solid 3D constant stress elements defined by 8 nodes, called solid elements in LS-DYNA. A typical mesh of 0.2x0.2m is used for the soil, while approximately 0.1x0.1m mesh is used for the linings, to have 3 elements with a total 0.5m out-of-plane thickness.

The interaction between the soil and the primary lining and between the primary and secondary linings are modelled in LS-DYNA with a penalty based contact elements (*AUTOMATIC_SURFACE_TO_SURFACE), in which numerical springs are defined at the linings interface to prevent penetration of one of the linings into the other. Whenever a slave node attempts to penetrate the master surface, a reaction force is generated. The magnitude of the force acting at the slave node is proportional to the penetration depth achieved by the slave nodes and to the lowest stiffness of the two mediums in contact. Reaction forces at the master surface side are generated by equilibrium. Both normal (F_N) and friction penalty forces (F_f) are generated, with the latter assigned as $F_f = m \times F_N$, where m is the friction coefficient.

Different friction coefficients are set between primary and secondary lining, to investigate the effects of this parameter to the response of the system.

In absence of dedicated lab tests, a value of the friction coefficient between primary and secondary linings of 0.15 is adopted in the base model, assuming the following shear friction values for each interface:

- Primary lining (rough) to geotextile of 0.6
- Geotextile to PVC membrane of 0.25
- PVC membrane to secondary lining (smooth) of 0.45.

The friction coefficient at the tunnel crown is always set to 0.0, under the assumption that the secondary lining would settle under its-own self-weight due to gravity.

The typical friction coefficient between soil and concrete is between 0.6 to 1.0. An average value of 0.8 is adopted for all the models.

3.3 Materials

Concrete C32/40 and C40/50 properties are used for primary and secondary lining, respectively. The elastic modulus of the primary lining is reduced with respect to the value reported in the Eurocode to account for early strength development. The design values of compressive and tensile capacity used in the model are similar to typical design situation. Concrete mechanical properties are detailed in Table 1. The ground medium is modelled as linear elastic material, adopting the properties detailed in Table 2.

Table 1. Concrete elements properties.

Element	E_{cm} [GPa]	f_{ck} [MPa]	f_{cd} [MPa]	f_{ctd} [MPa]
Primary lining	17	32	18.13	1.41
Secondary lining	30	40	22.67	1.64

Table 2. Ground medium properties.

Element	ρ [kN/m ³]	E [MPa]	ν [-]
Soil	20	500	0.3

Concrete is modelled with a smeared crack model, implemented for the 8-node single integration point solid elements, based on the Ottosen plasticity model (*MAT_WINFRITH_CONCRETE). As it is a material model with solid elements, it allows the capture of in-plane/out-of-plane through thickness tension, compression, bending, shear as well as concrete cracking in tension, crushing in compression, tension stiffening and compression softening. This model considers the effects of confinement effect in the compressive strength calculation of concrete.

3.4 Boundary conditions

The model is built assuming a plane-strain condition. All the nodes are restrained in the Y direction and supported in the Z direction, both sides of the model are restrained in the X direction.

Initial vertical stresses are used to initialise the horizontal stresses on the soil, using *INITIAL_STRESS_DEPTH. For the main model, a factor k , which is defined as the ratio between the total horizontal stress and the total vertical stress ($\sigma_{hor}/\sigma_{vert}$), of 1.5 is used. Different k values are considered as sensitivities (see Section 3.6). In this study only symmetrical loading condition is considered.

3.5 Construction stages

The model is analysed in typical NATM construction sequences as described in Table 3.

Table 3. Construction stages.

Stage	Time (s)	Description
1 – Initial Phase	0	Initial stress application
2 – Primary Lining Installation	0 to 1	Primary lining activation with gravity loading at 0.5s.
3 – Secondary Lining Installation	1 to 1.5	Secondary lining installation
4 – Primary Lining Degradation	1.5 to 2	Primary lining degradation (*LOAD_STIFFEN_PART) 50% of its initial stiffness
5 – Final stage	2 to 2.5	End of Analysis

This model adopted a “creep” deformation (50% elastic modulus reduction) for the primary lining during its degradation, after which the applied loading resisted by this layer is partially transferred to the secondary lining.

The simulation of the applied loading is consistent with this modelling approach, where soil and water pressure are applied at the soil-to-primary lining interface in form of total stresses.

3.6 Models scenarios

To analyse the effects of friction between the primary and secondary lining in typical tunnel lining configuration, different models are created. These models differ in terms of parameters: k values and friction coefficient between primary and secondary lining.

Table 4. Models developed for the study.

Model name	k	μ (Primary to Secondary)
Base model (M1)	1.5	0.15
Model 2 (M2)	1	0.15
Model 3 (M3)	0.5	0.15
Model 4 (M4)	1.5	0.0
Model 5 (M5)	1.5	0.3
Model 6 (M6)	0.5	0.0

4 RESULTS

In the following sections, the key LS-DYNA model results are presented and discussed. The base model is the one described in detail in Section 3, whereas all the sensitivity analyses are carried out with different design parameters as described in Section 3.6, to investigate how different model inputs affect the tunnel lining behaviour in term of internal forces and deformed shape.

Model results are shown at six cross sections of interest, for both the primary and secondary lining. The locations of interest are indicated in Figure 3.

Figure 3. LS-DYNA model cross sections location.

4.1 Influence of stress initialisation ($k=1.5$ vs. $k=0.5$)

Before investigating the influence of the friction coefficient at the primary to secondary lining interface, preliminary findings from the comparison between different stress initialisation ($k=0.5$ vs. $k=1.0$ vs. $k=1.5$) are provided.

Figure 4 illustrates the deformed shapes of the primary lining for the three modelling scenarios at the end of Stage 5 ($t = 2.5$ s). It is evident that different k values leads to different deformed shapes and generates active and passive soil pressure at different locations around the lining. The secondary lining final deformation is the result of two contributions. The first contribution is the deformation occurring due to its own self-weight, and it develops during the secondary lining installation (Stage 3). The initial shape of the secondary lining is governed by the deflections occurred in the primary lining during Stage 1 and 2, that are functions of the k values, see Figure 4. Between 1.0s and 1.5s (Stage 3), the secondary lining deformation is driven by the gravity loading, and it is characterised by crown inward deformation with a gap created between the primary and secondary linings, side walls outward deflections and invert settlement (outward deflection). The second contribution of the secondary lining deformation occurs during Stage 4 (onset at 1.5s), and it is the result of the primary lining degradation. In this phase, a fraction of the soil stress applied at the soil-to-primary lining interface is transferred at the primary-to-secondary lining interface, as induced by the primary lining degradation. During Stage 4, a general inwards deformation of the two linings is observed. Larger deformations occur in the primary lining across the crown area due to the presence of the gap which was created during Stage 3. Inward deformations are captured at the side walls and invert, whereas only limited deformations are observed at the knees section of the lining, where the secondary lining invert slab constrains the primary lining deflection.

These behaviours are detailed in Figure 5, which shows the primary and secondary lining deflections at the end of the analysis (Stage 5), representing the deformations measured from Stage 3, see a) and b),

Figure 4. Primary lining deformed shape of the three models [m]: a) M1 ($k=1.5$), b) M2 ($k=1.0$) and c) M3 ($k=0.5$). Magnification factor = 1000.

Figure 5. Primary and secondary lining radial deflections [m] at end of Stage 5. Deflections relative to Stage 3 for a) $k=1.5$ (M1) vs. b) $k=0.5$ (M3). Deflections relative to Stage 4 for c) $k=1.5$ vs. d) $k=0.5$.

and the deformations measured from Stage 4, see c) and d), for $k=1.5$ and $k=0.5$, respectively. Positive deflections represent outward deflections, negative inward deflections.

Despite a significantly different initial deformed shapes, the numerical findings suggest that the lining deformation after the secondary lining installation is practically not influenced by the k value and consequent initial primary lining deflected shape, see a) vs. b) from Figure 5.

Table 5. Normal stress between soil and primary lining at $t=1.0s$ (& $t=2.5s$).

Model	Crown [kPa]	Shoulder [kPa]	Side W. [kPa]	Knee [kPa]	Invert [kPa]
M1	330 (300)	330 (310)	400 (380)	470 (510)	360 (330)
M3	135 (120)	220 (205)	350 (330)	300 (320)	170 (170)

Table 6. Normal stresses and stress ratio at primary lining to secondary lining interface at $t=2.5s$.

Model	Crown [kPa]	Shoulder [kPa]	Side W. [kPa]	Knee [kPa]	Invert [kPa]
M1	110 (110/ 260=)	120 (120/ 260=)	170 (170/ 260=)	260 (260/ 260=)	150 (150/ 260=)
Stress ratio	42%	46%	65%	100%	58%
M3	60 (60/ 160=)	75 (75/ 160=)	110 (110/ 160=)	160 (160/ 160=)	80 (80/ 160=)
Stress ratio	38%	47%	69%	100%	50%

These findings are also supported by the radial stress results provided by performed simulations.

Table 5 summarises the normal stresses at the interface between the soil and the primary lining, where the stresses are extracted at the beginning of Stage 3 ($t=1.0s$) and at the end of the analysis ($t=2.5s$). The latter values are detailed within parentheses. It can be observed how the soil pressure is almost constant throughout the analysis's stages, i.e. no significant increase of normal stress at $t=1.0s$ and $t=2.5s$.

Table 6 details the final normal stress build-up at the primary to secondary lining interface. Despite different magnitudes, by comparing the stress profile developed at the secondary lining profile for M1 and M3 ($k=1.5$ vs. $k=0.5$) it can be observed that for both models the largest stresses develop at the knee level.

Moreover, it can be noted that the ratio between the stress at knee level and the stress at the other locations of interest are similar between M1 and M3, see normalised stresses illustrated in Table 6.

These results show that the primary lining deformation is predominately influenced by the stress initialisation (k value), while the secondary lining deformation is not significantly affected by the primary lining pre-imposed deformation. However, the secondary lining internal forces are affected by the k value.

The correlation between the friction resistance and the force development in secondary lining is discussed in the following sections.

4.2 Influence of friction coefficients for $k=1.5$ models

This section details the comparison between Base Model (M1) and Models 4 (M4) and 5 (M5).

During the secondary lining gravity loading development (Stage 3), the secondary lining undergoes a vertical shortening (shortening of the crown-to-invert distance), whilst developing only very small outward deflections at the sidewalls. The analysis shows that the smaller the friction coefficient, the larger the secondary lining vertical shortening is. Up to this modelling stage, there is negligible influence of the friction coefficient to the secondary lining internal force development, except for the invert results, which show relatively smaller axial force with corresponding larger bending moment development for increasing friction coefficient. Possible interpretation of this mechanism is that a friction resistance partially reduces the axial force induced by gravity loading, while inducing internal bending moment due to friction tangential stresses developed at the lining interface.

More significant influence offered by the friction coefficient is shown at the following stage (Stage 4), triggered by the primary lining degradation, which unfold between 1.5s and 2.0s. Further evidence is that the larger vertical deflections occur for increasing friction coefficient, while larger vertical shortening is measured for decreasing friction coefficient, with maximum shortening observed for M5 ($\mu=0.0$). Larger horizontal shortening is also observed for smaller friction coefficient ($\mu=0.0$).

Figure 6 and Figure 7 show the development of axial force and bending moment at the crown and invert of the primary and secondary lining, while Figure 8 and Figure 9 show the development of axial force and bending moment at the side walls of the primary and secondary lining.¹

The key observation is the opposite trend for the secondary lining axial force developed at the crown and side walls, which increases with decreasing friction coefficient throughout Stage 4, whilst the secondary lining axial force at the invert increases with increasing friction coefficient. The same trend is observed for the bending moment at the invert level, not at the side wall, while negligible bending moments develops at the crown.

4.3 Influence of friction coefficients for $k=0.5$ models

This section details the comparison between Model 3 (M3) and Models 6 (M6).

During Stage 3 phase (1.0s to 1.5s), same trends observed for $k=1.5$ models (see 4.2) are here observed for $k=0.5$ (e.g. same friction coefficient influence on the axial force and bending moment

¹ Bending moment sign convention depends on the cut-section local axes: positive bending moments are associated to inwards deflection at the right-side wall and invert, while positive bending moments are associated to outwards deflection at the left-side wall and crown.

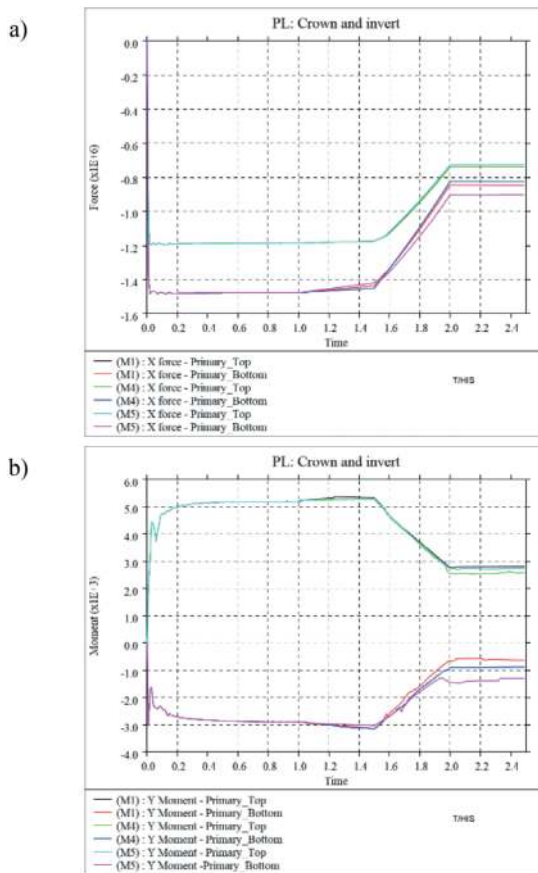

Figure 6. Comparison between M1 ($\mu=0.15$), M4 ($\mu=0.3$) and M5 ($\mu=0.0$): primary lining crown (top) and invert (bottom) a) axial force [N] and b) bending moment [Nm].

developing at the invert level). This is explained by observing that the lining deflections measured for $k=1.5$ and $k=0.5$ between 1.0s to 1.5s are essentially the same, see 4.1. Therefore, in the following, discussion is focused on the results from Stage 4.

In this stage, smaller internal forces variations are generated due to friction coefficient when compared with $k=1.5$ results. A possible interpretation is that smaller radial stresses are transferred to the secondary lining at the final stages (Stage 4 and Stage 5), see

Table 6, which in turn induce smaller friction stresses.

Regarding the influence of the friction coefficients at the side walls and invert, it shows a opposite trend of what observed for $k=1.5$ scenario.

Figure 10 and Figure 11 show the development of axial force and bending moment at the crown and invert of the primary and secondary lining. Figure 12 and Figure 13 show the development of axial force and bending moment at the side walls of the primary and secondary lining.

For $k=0.5$ models, with increasing friction coefficient results in an increase of the axial force at the secondary lining side walls, while at the invert level the larger axial secondary lining forces occur with the lower friction coefficient. The bending moment

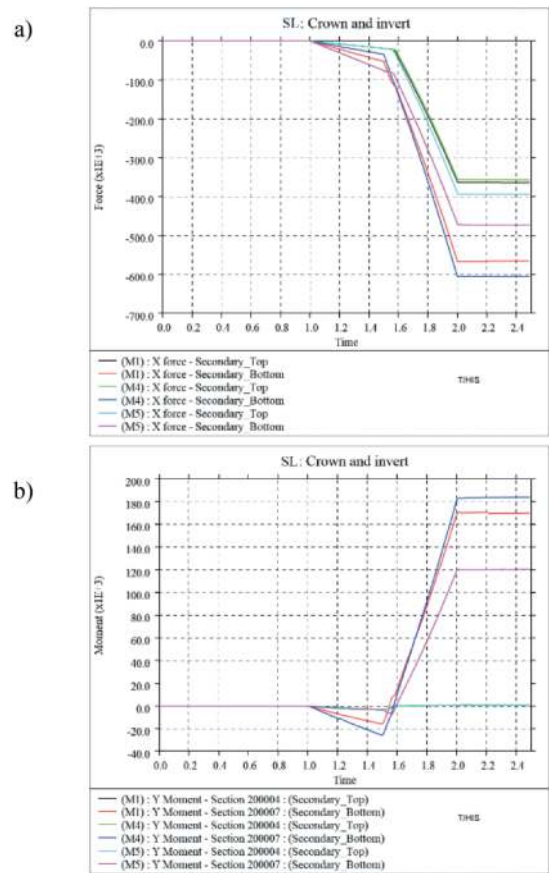

Figure 7. Comparison between M1 ($\mu=0.15$), M4 ($\mu=0.3$) and M5 ($\mu=0.0$): secondary lining crown (top) and invert (bottom) a) axial force [N] and b) bending moment [Nm].

development follows the same trend both for the invert and the side walls, as it was measured with opposite outcomes for $k=1.5$, see 4.2.

A possible interpretation of this trend is that an outward primary lining deformation prior to the secondary lining installation, as occurs at the side walls for $k=0.5$ and invert for $k=1.5$, might facilitate and enhance the bonding between the primary lining and the secondary lining at Stage 4, during which a general inward deflection of both linings has been observed.

At the crown sector, same dependence on the friction coefficient is confirmed for the axial force development, as shown by $k=1.5$ results, with larger secondary lining axial force measured for smaller friction coefficient.

Further considerations of observed response behaviour are provided as follows.

5 DISCUSSIONS

Performed analyses show that, while the tunnel deformation is primarily influenced by the initial primary lining deformation, which is driven by the stress initialisation (k factor), a more significant

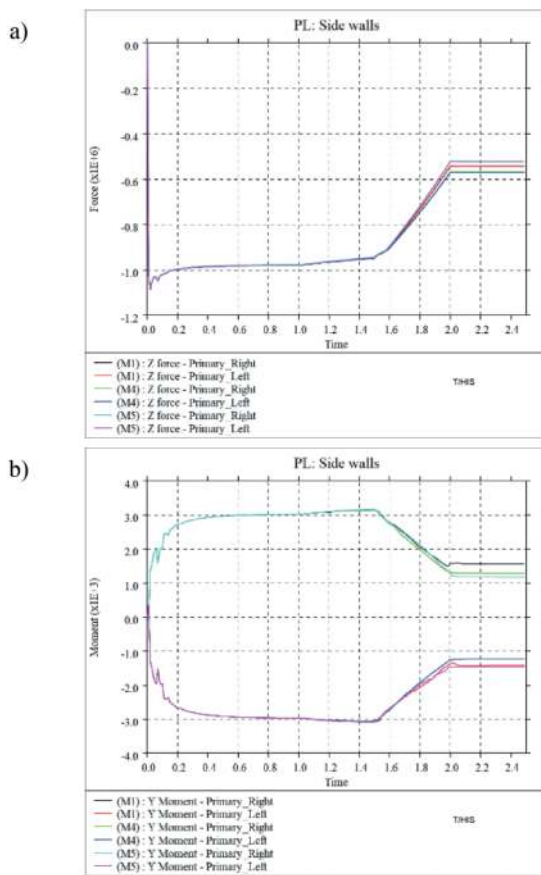

Figure 8. Comparison between M1 ($\mu=0.15$), M4 ($\mu=0.3$) and M5 ($\mu=0.0$): primary lining side walls a) axial force [N] and b) bending moment [Nm].

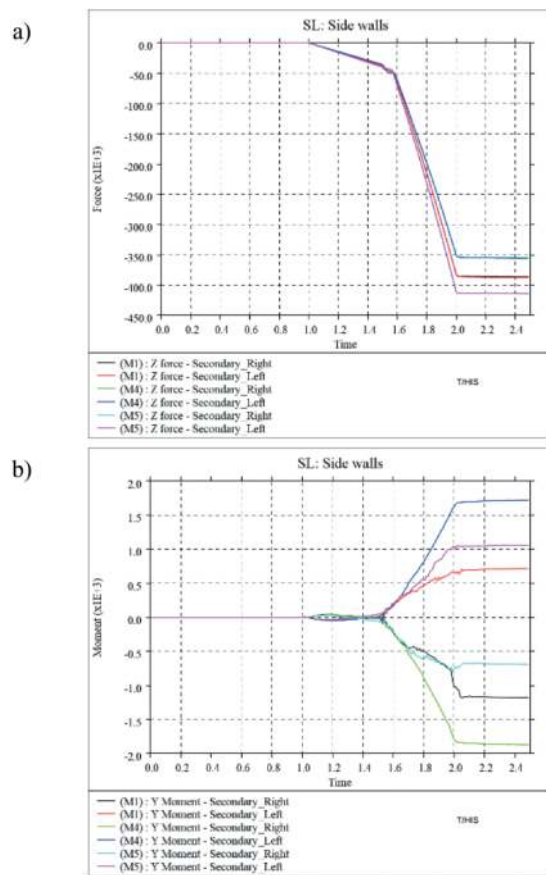

Figure 9. Comparison between M1 ($\mu=0.15$), M4 ($\mu=0.3$) and M5 ($\mu=0.0$): secondary lining side walls a) axial force [N] and b) bending moment [Nm].

internal force development at the secondary lining only starts with the primary lining degradation.

The secondary lining deformation is influenced by the friction stresses developed at the interface with the lining. These friction stresses are a result of normal stresses experienced by the lining and the relative tangential deformations between the lining and the contact surface.

Further additional complexity to this mechanism is the different combinations of primary and secondary lining curvatures, achieved prior to and during the final stage (Stage 4), in the same sectors.

The following analogies are found via developed numerical investigations:

1. Tunnel sectors where the largest axial force is measured in the primary lining at the end of Stage 2 (at side walls for $k=0.5$ and at invert for $k=1.5$) are the same sectors where the axial force and bending moment are larger with higher friction coefficient in the secondary lining at the end of Stage 5.
2. For the same section of linings (side walls for $k=0.5$ and invert for $k=1.5$) the largest compressive strain is developed at the primary lining. This is observed during the degradation stage.

3. The initial deformation of the side walls for $k=0.5$ and invert for $k=1.5$ is an outward deformation, where passive pressure of the surrounded soil is engaged. Larger axial compressive stresses are developed at the primary lining near face, as induced by outward curvature.
4. During the primary lining degradation, the line-of-thrust of the primary lining axial force moves towards the primary lining centreline, reflecting a decrease of the axial force eccentricity, both across side walls for $k=0.5$ and across the invert for $k=1.5$. In terms of deflections, in both sectors (side walls for $k=0.5$ and invert for $k=1.5$), the primary lining curvature reduces, while deforming towards the secondary lining.

On the contrary, for both $k=0.5$ and $k=1.5$, the axial force at the crown decreases with increasing friction coefficient. This response shows that it is not directly correlated to the friction coefficient for two reasons: firstly, following a conservative approach, no friction coefficient is assigned to the sector where a gap is generated due to secondary lining gravity deformations; secondly this gap is closing while the lining degradation occurs. Consistent with the observed trend, negligible bending moments develop

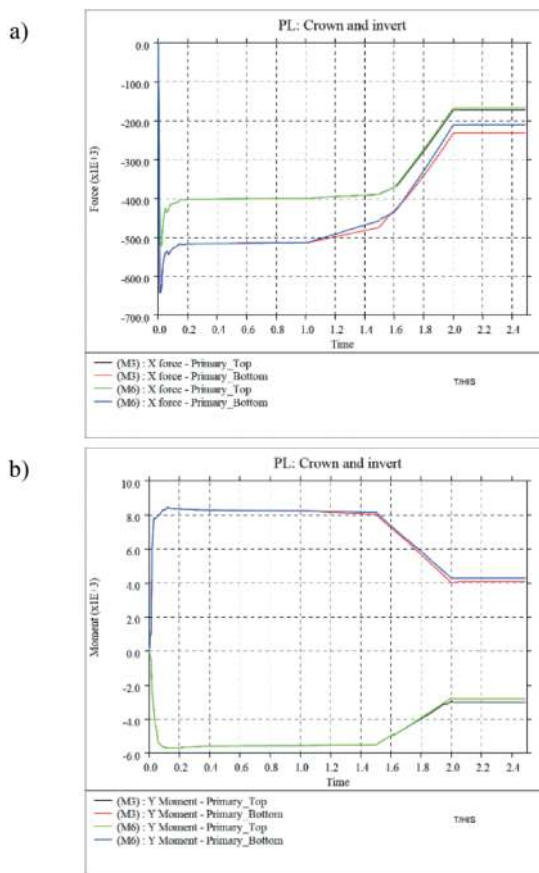

Figure 10. Comparison between M3 ($\mu=0.15$) and M6 ($\mu=0.0$): primary lining crown (top) and invert (bottom) a) axial force [N] and b) bending moment [Nm].

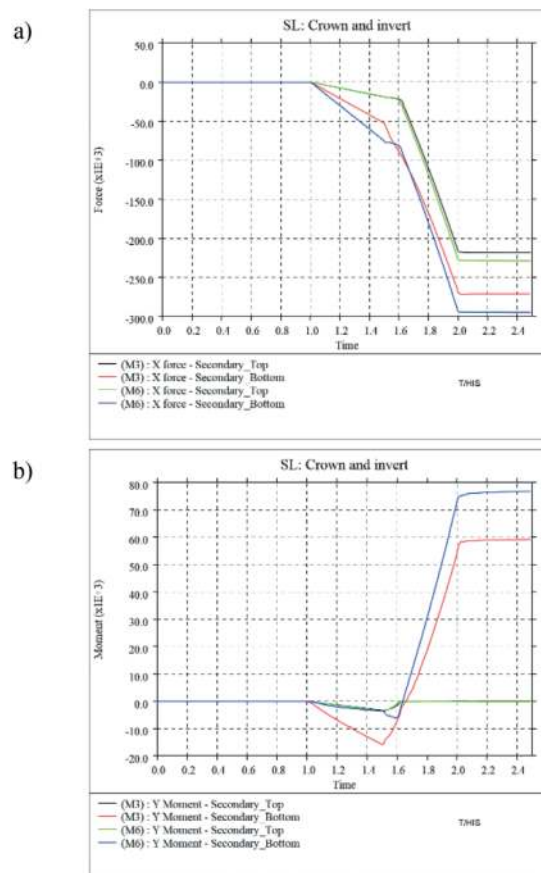

Figure 11. Comparison between M3 ($\mu=0.15$) and M6 ($\mu=0.0$): secondary lining crown (top) and invert (bottom) a) axial force [N] and b) bending moment [Nm].

across the secondary lining crown, which is indicative of an arch-type response.

Knee levels findings have been found to be an exception from what stated by analogies 2 & 4, for $k=0.5$ and for both $k=1.5$ and $k=0.5$, respectively. This can be explained by the lining geometry, with the secondary lining invert modelled with flat top-face. For this reason, the tunnel is highly restrained at the knee levels, therefore, the deformed shape is “locked-in”. This contributes to a different response behaviour at the tunnel knee levels, where our numerical investigations have shown the largest soil stress transfer to the secondary lining.

6 CONCLUSIONS

The objective of this research is to investigate different factors affecting the secondary lining response, with primary focus on the influence of the friction resistance. The magnitude of this friction resistance is shown to be one of the key factors influencing behaviour and stress distribution.

The following can be concluded based on the following assumptions:

- Total stress is applied at the soil to primary lining interface throughout the construction sequence, with no seepage considerations.
- Secondary lining with flat invert.
- Plain strain and symmetrical soil stress loading is applied.

For tunnel secondary lining design, it is often understood that neglecting the friction coefficient would have result in the largest axial forces with minimal bending moment, and therefore a conservative approach. However, this may not be the case based on our results comparing $k=1.5$ and $k=0.5$.

At the invert, for a $k=1.5$ scenario, increased axial forces and bending moment are expected to develop with an increase of friction, which is opposite, despite smaller variation, to what has been observed for $k=0.5$ scenario. The design of tunnel lining requires the consideration of variable axial force and its associated bending moment capacity; therefore, it is not always conservative approach of neglecting the friction coefficient. At the sidewalls, the analyses outcome proves the common approach of neglecting the friction coefficient being conservative for condition of $k=1.5$. Whereas it may be conservative for $k=0.5$ scenario, given the beneficial trend of the axial force

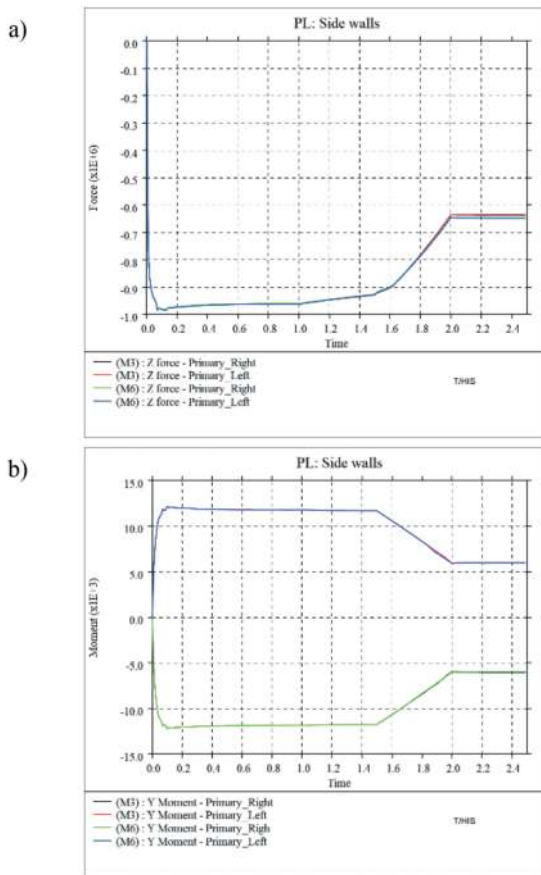

Figure 12. Comparison between M3 ($\mu=0.15$) and M6 ($\mu=0.0$): primary lining side walls a) axial force [N] and b) bending moment [Nm].

and minimum variations of the associated bending moment.

At the crown, the analyses outcome proves the common approach of neglecting the friction coefficient being always conservative, provided zero friction is adopted.

In conclusion, numerical findings show a not univocal interpretation of the impact of the friction coefficient, with its influence closely correlated with the stress initialisation (k values). Therefore, the application of the friction coefficient between the primary and secondary lining may not always be conservative.

ABSTRACT: The escalating annual extraction of materials from the Earth's crust, highlights the urgency for more sustainable construction practices. The construction industry is responsible for approximately 50-60% of global material consumption and 37% of CO₂ emissions. Embracing eco-friendly, low-carbon materials aligns with UN Sustainable Development Goals.

Tunnelling projects contribute to sustainable, long service-life infrastructure with minimal disruption. Projects like high-speed rails and metro/LRT lines provide low-emission transportation whereas hydro-power projects, provide more sustainable energy sources. However, the construction of such projects is still associated with substantial emissions.

The assessment of the environmental impact should start at the early stages of the design, and when selecting the optimal construction method, as this can potentially lead to significant reduction of carbon emissions. A collaboration among stakeholders is also fundamental. Overcoming challenges involves incentivizing eco-friendly practices from project inception. However, developing carbon-efficient designs often encounters obstacles in codes and standards.

As regards the materials, instead of setting unrealistic targets to eliminate steel and concrete, which are integral to underground construction, the use low emission materials and relying on local resources, recycling and reusing material from excavation should be promoted.

The most direct way to lower the carbon emissions is to reduce the actual required material quantities. The focus of this article is on how the use of advanced design tools and concepts can support this target. Case studies, such as the Eglinton Crosstown LRT in Toronto and Bank Station Capacity Upgrade in London, showcase the environmental benefits of such advanced design approaches.

Keywords: Tunnelling, Conventional Tunnelling, Finite Elements, Carbon Reduction

1 INTRODUCTION

The annual extraction of materials from the Earth's crust is on a continuous rise, with current projections reaching 186 billion tons by the year 2030—a staggering twofold increase from the 2015 levels (Sobek, 2022). A significant contributor to this surge is the construction industry, accounting for approximately 50-60% of global material consumption and contributing to 37% of total CO₂ emissions (Spyridis & Bergmeister, 2023). At the same time, the rapid pace of urbanization adds buildings equivalent in size to the

city of Paris every five days, heightening the sector's environmental impact.

Encouraging sustainable construction practices, prioritizing low-carbon concrete and eco-friendly materials aligns with broader sustainability goals outlined in the United Nations Sustainable Development Goals (<https://sdgs.un.org/goals>), particularly Goal 9 (Industry, Innovation, and Infrastructure) and Goal 13 (Climate Action). The UNEP's report, developed in collaboration with the Yale Center for Ecosystems + Architecture within the Global Alliance for Buildings and Construction, emphasizes the need for innovative cooperation models to decarbonize building materials

*Corresponding author: petr.salak@dr-sauer.com

(United Nations 2023). Three over-arching strategies are identified: i) avoiding unnecessary extraction and production, ii) transitioning to regenerative materials, and iii) enhancing the decarbonization of conventional materials. Implementing these strategies collectively holds the key to a more sustainable built environment, aligning with global climate objectives.

Tunnelling projects are providing infrastructure with long service life and minimum disruption to the environment. Projects like high-speed rails and metro/LRT lines not only aim to improve the quality of life but also mitigate environmental impacts by offering alternative, low-emission means of transportation. Similarly, hydro-power projects, where tunnelling plays a significant role, contribute to the generation of more sustainable forms of energy. However, tunnel construction is not innocent when it comes to associated emissions.

The environmental impact assessment and planning of tunnelling projects can commence as early as the feasibility and concept design stages, where strategic and influential decisions are made, such as the selection of the construction methods, followed by the detailed design phase, where support elements can be optimized through advanced and innovative design concepts. Engineers possess the necessary tools to significantly minimize the usage of concrete and steel.

2 OPTIMAL CONSTRUCTION METHOD SELECTION

Some of the largest infrastructure projects in urban environment involve metro or light rail transit systems, where tunnelling is used to create long, linear running tunnels and, in many instances underground stations. A recent example is the Crossrail project in London, featuring 21 km of twin running tunnels and the construction of 5 out of the 7 new underground stations using conventional tunnelling means. Underground construction can utilise various construction methods, in many cases predetermined in the project contracts.

While country-specific preferences exist, long running tunnel sections in uniform geological conditions are typically well-suited for tunnel boring machines (TBMs), which demonstrate impressive advance rates. On the other hand, tunnels in highly variable geology, significant overburden, numerous intersections, and changing geometries are better suited for excavation via conventional means. Running tunnels excavated via TBM nowadays feature a single-pass-lining compared to conventionally excavated tunnels that often involve a two-pass-lining, comprising an initial (temporary) shotcrete liner followed by cast-in-place final (permanent) liner. Combined/composite linings design approaches, where the initial tunnel lining also provides some permanent load-bearing

function, are becoming more common in conventional tunnelling, reducing the overall lining thickness and material quantities.

For the construction of underground stations in urban rail projects, the most common excavation techniques are cut-and-cover and conventional tunnelling. Although inherently different, both methods can create large underground spaces necessary for accommodating trains, platforms, vertical circulation, systems, and ventilation. From a structural point of view, a rectangular cut-and-cover box carries loads in bending and shear compared to a round or ovoid tunnel shape which carries loads predominantly in compression. This simple fact makes a big difference from a carbon footprint point of view as bending moments and shear forces often require thick wall and slab thicknesses with heavy reinforcement.

The Eglinton Crosstown LRT project in Toronto, Canada (Figure 1) provided an opportunity to compare fully designed cut-and-cover with mined stations. Steel and concrete quantities were assessed for excavation support, and the permanent liner for a typical station with platform and crossover sections. In this comparison, a cut-and-cover station required approximately eight times as much steel and one and a half times as much concrete for excavation and support, while for the permanent liner, it required about 19 times as much steel and one and a half times as much concrete compared to a mined station.

Achieving meaningful carbon reduction in any tunnelling project demands a comprehensive approach to lowering CO₂ emissions, the primary contributor to man-made global warming. In the instances of different construction methods mentioned above, the decision for the optimal method is typically driven by cost and schedule criteria, which may not always align with the method having the least environmental impact. Therefore, an optimal solution should consider environmental impact alongside cost and schedule considerations.

Figure 1. Underground station Cavern (Eglinton LRT project, Toronto).

3 A COLLABORATIVE APPROACH

Reducing construction emissions calls for an early involvement and collaboration of all relevant parties: the public, owners, designers, suppliers, and contractors. The current paradigm, where project owners award projects mainly on lowest price criteria, sets a basis where the designers produce fast and inefficient designs using simple analytical methods to align with cost considerations. The contractors naturally seek the fastest and lowest cost solution, which potentially contributes the highest environmental impact.

The current paradigm, where project owners award projects mainly on lowest price criteria, makes it likely more challenging to consider environmentally friendly solutions.

While the contractor undoubtedly plays a key role in reducing the carbon footprint of a tunnelling project, the owner and their designer must lay the groundwork from the onset of the project. The opportunities to reduce the carbon footprint of a tunnelling project during the design phase can be substantial and come at a comparatively small cost.

In essence, the necessity to reduce CO₂ emissions must become a fundamental project requirement incentivizing environmentally friendly practices. To design structures which are pushing the limits in efficiency, carbon reduction and constructability, the designer needs time to deploy advanced and innovative design techniques. The efforts and complexities on the design side will increase compared to the common practice to achieve these goals.

One reoccurring obstacle to the development of carbon efficient tunnel designs lies in prescribed codes and standards. The absence of dedicated structural design codes for tunnelling, particularly in conventional tunnelling, often compels owners and designers to resort to general structural building codes. These codes typically require minimum reinforcement quantities based on gross concrete area, leading to excessive quantities of rebar in cases such as tunnel or cavern inverts, where structurally such quantities may not be required. Choosing applicable project codes and standards wisely can have a significant impact on reducing the carbon footprint.

4 MATERIALS

Arguably, the two most important materials in underground construction are steel and concrete, each possessing unique characteristics such as durability, strength, ductility, that make them highly desirable for construction.

However, both materials come with a considerable environmental cost, demanding significant energy input and consequently contributing to a substantial carbon footprint. On average, one ton of steel emits approximately 1.85 tons of CO₂, while

one cubic meter of concrete emits about 0.35 tons of CO₂. To put these values in perspective, the steel industry alone contributes 8% of global CO₂ emissions and 23% of global energy consumption. In 2019, global cement production reached 4.1 billion tons, contributing to 6% of global CO₂ emissions and 7% of global energy consumption.

Despite ongoing efforts to reduce CO₂ emissions in the production of both materials, these remain significant and require substantial amounts of energy (approximately 55% of cement CO₂ emissions are process related).

In regular concrete, it is possible to reduce concrete emissions by adding fly ash, silica fume, slag, limestone, pozzolana, however, this is not as easy with sprayed concrete due to the fast strength gain requirements that makes the reduction or substitution of cement more complicated.

Fiber reinforced concrete or shotcrete is also common in tunnelling. Although fibres can provide significant time and safety benefits, their incorporation does not necessarily translate into reduced material quantities when compared to traditional rebar reinforcement. To illustrate, if a 5m inner diameter tunnel with 20cm lining is to be reinforced with either minimum rebar reinforcement 0.2% of the gross concrete area or with a nominal 30kg/m³ of steel fibres, rebar reinforcement results in 50kg of steel per tunnel meter while steel fibres in 100kg.

The carbon reduction in tunnelling requires therefore a more elaborate approach aided by advanced design, that focuses on reducing the overall size of excavation and support requirements (lining thickness, tunnel size, reinforcement quantities) or even using unreinforced linings where applicable. Furthermore, the use of low-emission materials, relying on local sources, recycling, and reusing of excavation materials are key elements in delivering environmentally friendly projects.

5 ADVANCED DESIGN

Design plays a crucial role in reducing steel and concrete quantities. Each ton of material saved through advanced design not only translates to a reduction in CO₂ emissions during production, transportation to the project site, and installation, and considering the full life cycle even during demolition and recycling. Nonetheless, as outlined in the previous sections, an appropriate project framework is required to incentivise, enable, or even force the designers to focus their efforts on material savings.

Few important aspects related to tunnelling are described in the following sections.

5.1 *Advanced material models/design methods*

Numerical analysis methods provide the most advanced means of simulation of engineering problems. In tunnelling, it is imperative to consider the

behaviour of both soil/rock medium, and of the tunnel support elements as well as the interaction between them. The selection of the appropriate constitutive model for geomaterials and concrete/steel is not straight forward. In many cases, advanced soil models are used in combination with linear elastic concrete models yielding unrealistic results. Another important aspect is the level of detail included in the numerical analysis, related to both the geometrical aspects as well as the staged construction. The effects of each of these parameters need to be optimized with regards to the objective of the analysis and the computational effort. Additionally, a model is only good if it can be interpreted. Therefore, the engineer is encouraged to rely on tools he is experienced with and can derive useful results from. As an example of advanced simulation, Figure 2 shows the calibration of the concrete damaged plasticity (CDP) model used in Abaqus against the ASTM C1550 flexural strength test. CDP is an advanced model for concrete, yet simple to define and interpret, which assumes tensile cracking and compressive crushing mechanisms, with the uniaxial compressive and tensile responses characterised by damaged plasticity (Lubliner et al 1989). Calibrating a concrete model such as CDP against experimental results provides greater confidence in the outcomes of the finite element (FE) analysis and supports optimised designs.

Figure 2. Top – Maximum principal strains at the bottom of a test panel at 2mm deflection (left – linear elastic and right CDP). Bottom – calibration of experimental results from round panels using the linear elastic (LE) and the CDP models.

5.2 Shape optimisation

The cross-section of a tunnel is one of the most influential factors affecting the performance under given loading conditions. Although the minimum size and the main geometrical aspects are typically related to the required spaceproofing envelope, this can be further optimized to provide the best fit to the exerted stresses. Gakis et al. (2019) assessed the performance of 7 separate cross-sections (Figure 3) with the same cross-sectional area of 50m² and variable height over width aspect ratio, in a probabilistic scenario varying

the main soil properties (elastic modulus, shear strength and K_0) as well as the elastic modulus of the lining. The study concluded that the optimization of the tunnel shape can provide notable savings in terms of lining design and increase the overall structural safety.

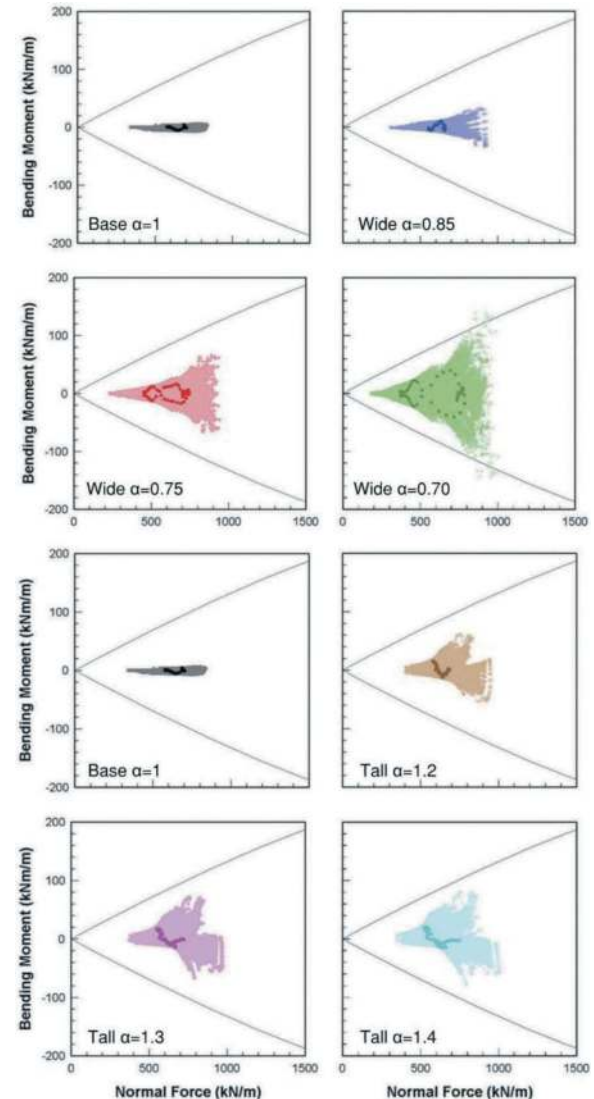

Figure 3. Interaction diagrams for the analysed sections with variable aspect ratio (α) of height over width (Gakis et al. 2019).

5.3 Openings

Multiple openings in tunnel linings are common in mined stations for the formation of tunnel intersections. These openings result in redistribution of the lining stresses that can potentially be carried by the existing tunnel support or may require additional measures such as the implementation of additional reinforcement or thicker concrete linings. To identify with confidence the capacity of the lining following an opening, it is important to use non-linear concrete models in 3D finite element analysis. Figure 4

illustrates the importance of using advanced models also for the tunnel lining (Gakis & Salak 2016). The use of the CDP model with careful examination of the post-peak behaviour, allowed the design of this complex intersection relying purely on steel fibre reinforced shotcrete, without any additional thickening or reinforcement.

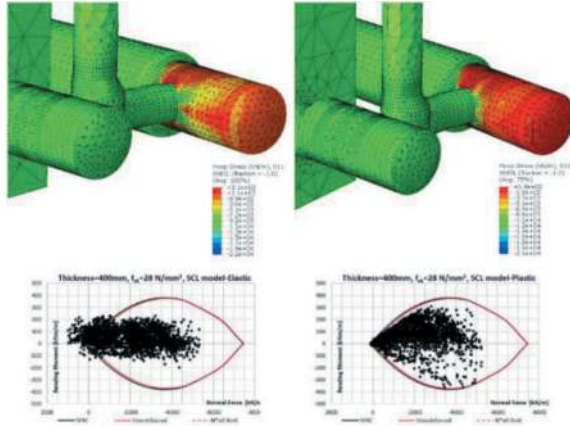

Figure 4. Hoop lining stresses and interaction diagrams of a linear elastic concrete model (left) compared to a concrete damaged plasticity model (right) (Gakis & Salak 2016).

5.4 Combined/composite linings

In various past projects, shotcrete linings have been assumed to be of insufficient quality to serve an extended service life due to the application of shotcrete with alkaline accelerators that reduce the long-term strength or due to inconsistent quality and poor compaction. This double shell approach, where initial and final linings are assumed to act independently, inevitably results in thicker overall linings and as such higher material quantities.

The load sharing in tunnel linings is however a reality, one that the designer must exploit in order to produce more economical and environmentally friendly designs. This is further supported by the advancements in shotcrete technology such as automated and mechanized spraying, improved mix designs, alkali-free accelerators, stringent quality control processes and improved profile control result in a product similar to a well compacted poured concrete.
