Keywords: TBM, scanning, survey, ring, wriggle, systemwide

1 INTRODUCTION

Bored tunnels normally consist of rings assembled from segments. See Figure 1. Bored tunnelling with a Tunnel Boring Machine (TBM) is a process that requires continuous geospatial information for both the machine and the rings as the tunnel is driven in order to optimize the accuracy of the tunnel alignment. Measurement of the rings for position and “attitude” (see below) is normally related to the so-called leading or trailing edges of the ring related to the direction of progress of the tunnelling.

Furthermore, tunnel segments that form the ring normally contain features such as bolt pockets, grout holes and unreinforced edges that are not suitable for drilling into during the later tunnel fit-out stage. In this case, there is an obvious tension between the segment positions and the planned layout of bracketry, bolts, and anchors to support the systems installed in the tunnel.

In both cases, the measurement of segment edges (a ring edge is formed from more than one segment edge) provides the required information. However,

despite the uniformity of the environment of a bored tunnel hitherto there has been no automated way of identifying and extracting segment edge positions from scan data to quickly and efficiently provide the information required. Therefore, it is still the case that these measurements are taken manually. This paper will elaborate on the needs for both the tunnel construction phase and the systemwide “fit-out” phase before describing the automated solution using state-of-the-art software that has now been formulated.

2 TUNNEL CONSTRUCTION GEOSPATIAL INFORMATION

The required geospatial information for the bored tunnel drive can be broken down as follows:

- (i) Checks on the tunnel guidance system by making comparisons of TBM position and attitude to guidance system outputs.
- (ii) Establishment of so-called “lead & look-up” of the last built ring in order to plan the arrangement of segments for the next built ring.

*Corresponding author: James.Douglas@Hexagon.com

Figure 1. Typical tunnel rings made up of segments.

For the position of both the TBM and rings, several (as well distributed as possible) measurements are taken around the inner lining and a best-fit centre (BFC) is calculated. This is known as a “wriggle” survey. The difference between the best-fit centre to the design tunnel centre (at the measured chainage) in terms of horizontal and vertical offsets from an alignment indicates the misalignment of the TBM or ring at that location. Often tunnel positional tolerances are aggregated to a radial value which is found by taking the square root of the squares of the horizontal and vertical offsets. Radial tolerances for metro tunnels might be as demanding as +/-50mm. TBM “steering” is achieved by varying ram extensions from the rear of the machine pushing off the last built ring. The rings then need to follow the direction of the TBM and a built-in taper on the segment length (in terms of direction of tunnel progress) is employed to make the rings change direction. See Figure 2.

Figure 2. Segment/Ring taper and effects on direction.

Figure 3. Typical in-tunnel services installed systemwide.

Rings are typically formed of a “key” segment plus two “shoulder” segments and then a number of “standard” segments. The pattern of segments in a ring is constant but the location of the key determines where the taper is. If the taper is at the bottom of the ring, then the top of the ring will be further forward in terms of the direction of progress and the rings will head down. If the taper is on the right-hand side of the ring, then the left-hand side is further forward, and the rings will turn right.

The rings “lead and look-up” (which shall be collectively called “attitude” for the purposes of this paper) are measured in millimetres over the diameter of the ring in the horizontal and vertical (plumb) axes. They indicate the difference of the ring in terms of attitude to the design alignment 3D trajectory of the tunnel. These figures are gathered along the leading edge of the last ring, often using combinations of empirical methods, such as a “plumb bob”, with chainage marks. They are used to assess which key location should be next utilised to keep the tunnel in good alignment.

3 SYSTEMWIDE INSTALLATION GEOSPATIAL INFORMATION

After the tunnel has been built it is typical for metros, railways, and other transport systems to require fit-out of the power, mechanical, electrical, and pumped systems that service the use of the tunnel.

For such usage, the in-tunnel installation is itself dimensionally critical. This is primarily to do with the kinematic envelope of the trains/vehicles using the tunnel.

Superelevation (cant) and curvature both affect the cross-sectional position of the vehicle and this in turn forces certain services such as power supply (via overhead catenary or power rail), signalling, and emergency walkway to move with the vehicle in order to interface properly.

Furthermore, the remainder of the services must always be kept clear of the kinematic envelope of the vehicle to avoid clashing and in fact, it is normal for an additional clearance factor to be applied for safety purposes. See Figure 3 for an example of systemwide installation.

4 HISTORY OF SCANNING AND MODELLING TUNNELS

Scanning operational bored tunnels for the purposes of providing clearance and asset inventory has been established for twenty years. The point cloud is sliced into profiles for clearance and the means of collecting bandwidths of data and extracting the most representative (or closest) point for placement in a profile for gauging calculations is already automated.

For CAD modelling on point cloud in a “virtual surveyor” mode, automated extraction of strings representing rails, power lines, continuous structural edges, and boundaries is also already established, although not always used. Feature recognition for vegetation and well-defined point features (e.g., signal aspects) is also available.

In 2004 the Channel Tunnel Rail Link (CTRL) in the UK for the High Speed One line between Paris and London elected to scan the running tunnels from St. Pancras station to Barking portal for the purposes of recording the handover of the tunnels from the civil contractor to systemwide and also to plan drilling for overhead line electrification (OHLE) anchors in the bored tunnel segments. One of the deliverables from the scanning was drilling plans with the guidance given relative to tunnel ring numbers and segment edges. See Figure 4.

Figure 4. High Speed One OHLE anchor drill plan.

These plans combined modelling of selected segments from the point cloud where they coincided with a planned OHLE position. The anchor position was calculated allowing for vehicle dimensions above the design rails (and incorporated cant and curvature). Where a clash between the drilling and a segment edge was identified a “rule book” of shifts, including potential “knock-on” shifts to adjacent installations, was referenced. In this way, using a trial-and-error process, (which was off the critical path to the site teams for installation,) the fit-out of the OHLE anchors without clashing with “no-drill” zones was resolved in the design office, albeit manually.

In 2015 the London Crossrail project decided to use dedicated semi-automated drilling machines for installing systemwide services in 40 Km of bored

tunnel. The installation required around 250,000 holes. In order to resolve the positioning of these holes in bored tunnel segments with “no-drill” zones a full mapping of the segmental lining was required. See Figure 5 for typical Crossrail no-drill zones.

Figure 5. Typical Crossrail no-drill zones in red.

With a full tender process premised on guaranteed delivery dates for information, as well as accuracies and cost, the “state of the art” for modelling the segments was established:

In the most innovative approach at the time, the scanned tunnel was “unwrapped”. This means it was projected to a 2D plan (the inner lining when rolled out is, for all intents and purposes, flat), and then the chain of segments for a ring was overlaid and matched manually by a CAD modeller. Once the linework was added to the model the tunnel was projected back from 2D to 3D space. Clearly, this was a significant improvement over drawing each segment edge manually (as per CTRL) but still involved a process that was repeated manually over 25,000 times for the 40 km (the rings being 1.6m long).

The final stages of the Crossrail systemwide drilling project involved the authors formulating algorithms for acceptable drilling patterns that satisfied both the frequency and density required to support the in-tunnel services whilst avoiding the no-drill zones in the segmental lining. Once patterns of drilling were finalised, they were exported to the drilling machines.

Crossrail’s drilling machine project was a qualified success: There were challenges with combining so many inputs. Systemwide design, segment edge location, drilling machine parameters, and tunnel geospatial control all had to be input to create guidance. On reflection, there was not enough emphasis on overlaying the finalised drilling patterns on models of the bored tunnel in order to help visualize errors and monitor machine progress. This was partly as a result of the contractual deliverables for the drilling algorithms “only” being tunnel drilling machine inputs which were defined in terms of angles from the zenith and chainage along the tunnel allocated to different drilling arms.

5 JUSTIFICATIONS FOR AUTOMATION OF EXTRACTION

The key cost element of the Crossrail drilling project was the amount of CAD modeller time dedicated to

manual extraction from point cloud data. Despite significant increases in productivity, this was still the same case as for the CTRL project which had been completed ten years earlier. For 40 Km, even when modelling at 20 rings per hour, with assistance from the 2D projection technique, it would require a dedicated modeller for nearly forty working weeks without a break to deliver the required model.

Secondly with Building Information Modelling an ever-greater stipulation for new build projects and existing infrastructure alike, the omission of accurate segment representation in final as-built models of bored tunnels is more and more difficult to justify. However, dedicating skilled CAD modellers to highly repetitive tasks for long periods causes obvious human resource problems.

Thirdly, the uniform nature of the pre-cast segments, in terms of mapping all the characteristics of the lining, lends itself to automated extraction of geospatial position and accurate representation in a CAD model without every feature of every segment being identified. i.e., the position of all bolt pockets and grout holes can be generated from the segment edge positioning by using a library of models for each segment type, attaching them in a “chain” that forms a ring, and matching the chain to the point cloud edges. The “redundancy” afforded in the pattern matching allows the automated extraction to be validated to a high degree of confidence.

Finally, the arrival of a centralised data storage approach to manipulating and processing point cloud has removed the hurdle associated with the amount of data required is considered too great for working efficiently in CAD modelling software. An example of centralised data storage is Leica Geosystems’ JetStream™ and their propriety “LGS” file format which reduces file sizes to 5x to 10x smaller than traditional point cloud storage. LGS allows instant loading and rendering of any sized project and when panning and zooming shows “all the points, all the time”.

6 A NEW AUTOMATED APPROACH: STAGE ONE

The first challenge with the automated mapping of the bored tunnel segments is the likely presence of significant amounts of in-tunnel equipment, temporary or otherwise, during the data collection stage.

To automatically remove all features from the point cloud, except the inner lining of the bored tunnel, it is necessary to find the best-fit centre of the tunnel rings as a wriggle survey at an interval for which interpolation does not undermine the required accuracy for this data of +/-5 mm. Typically for railway tunnels, this would require a best-fit centre extraction every 5m.

The process of creating a best-fit centre trajectory is as follows: Using the nominal tunnel diameter slices are taken perpendicular to a manually indicated start direction and centre for the tunnel (which is not required to be highly accurate, just “eyeballed”.)

Each successive slice is assessed for uniformity of radius. Oblique slices will generate an ellipse and will lead to further incrementation of direction at the same

Figure 6.1. Automated iterative process of finding the best-fit centre of the bored tunnel.

Figure 6.2. Oblique slices detected when the diameters or not equal.

Figure 6.3. Perpendicular slices detected when the diameters or equal, with a certain tolerance.

location until the slice is shown to be circular to the expected tolerances. See Figure 6.

Once the best-fit centre trajectory is found for the tunnel a clean-up of the objects inside the inner lining takes place using a radial “exclusion” which is just inside the “clear bore” for the tunnel.

7 A NEW AUTOMATED APPROACH: STAGE TWO

Segment extraction is possible via more than one automated route.

7.1 Detection using peaks

Once the as-built trajectory of the tunnel is established radials can be measured in a perpendicular plane from the trajectory line to the bored tunnel lining. Comparing distances for these radials over appropriate size areas allows the joints for the edges to be detected because at the joint the radial distances are greater than on the segment itself. See Figure 7.

There are three different edges to detect: The “radial” edge that forms part of the leading edge of a ring; the standard longitudinal edge between two segments on the same ring; and the “slanted” edge between the key segment and a shoulder segment on the same ring. Three similar algorithms are needed which slice in a focussed area in order to detect the edges to a resolution that is commensurate with the required accuracy of the segment edge representation in the CAD model (+/1cm). The angle of the slice varies based on the type of edge to detect.

When there is no edge in the slice the radial distances are all very close together in magnitude. If all the distances are ranked from low to high, there is a very high

Figure 7. Radial and longitudinal joints for segment edges.

peak frequency of the same value (c. 98% within a few mm on a well-aligned slice) which we shall call the “centre peak”. However when there is an edge inside the area a second “peak” appears for the gap/joint/recess created by the edge and the frequency occurrence of the “centre peak” drops significantly (c.78% on a well-aligned slice). See Figures 8.1, 8.2, 8.3, 8.4.

On this basis as many edges as can be found are extracted. The presence of in-tunnel “furniture”, perhaps including a first stage “floor” in the invert of the tunnel to assist in the passage of vehicles, plants, and machinery, means that not all edges for each ring can be seen by scanning. However, as the “chain” of segments in a ring is always the same not all edges need to be detected in order for the as-built position of all the segments to be determined sufficiently accurately. It can be seen that if either of the key segment slanted longitudinal edges is identified all the edges are resolved and additional detection creates redundancy. And if four standard segments are in the chain (as per High Speed Two (HS2) in the UK) then the detection of five successive straight longitudinal edges also resolves the position of the whole ring.

7.2 Detection using machine learning

Machine Learning is a type of artificial intelligence that allows computers to learn without being explicitly programmed. Instead, machine learning algorithms learn from data and improve their performance over time. That is: As they are exposed to more data, they become better at identifying patterns and making predictions.

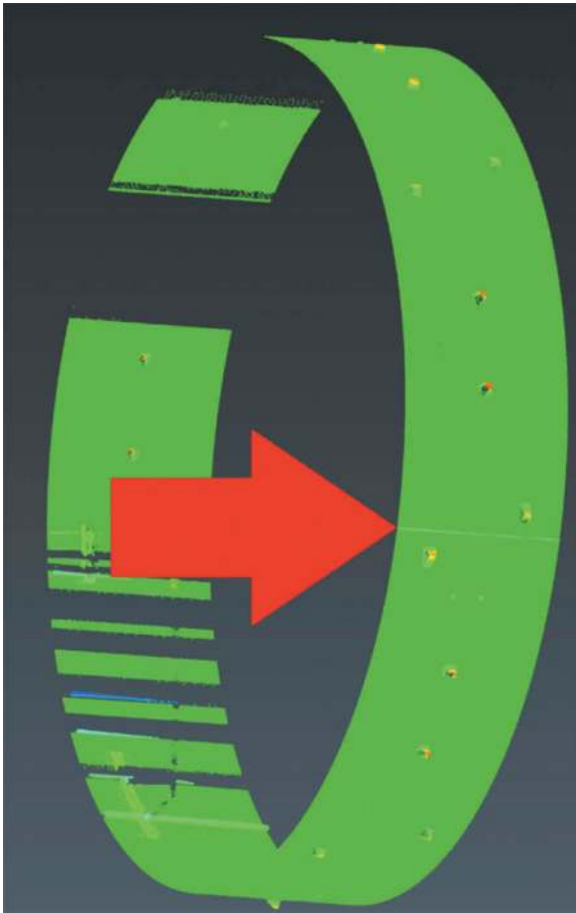

Figure 8.1. Area of interest for the demonstration.

Figure 8.2. View in the direction of the main axis of the areas that will be demonstrated.

It is important to remember, however, that machine learning algorithms are only as good as the data that they are trained on. If the data is biased or inaccurate, the algorithm will learn the wrong patterns and make inaccurate predictions.

PointNet++ is a deep learning algorithm used for semantic segmentation of unorganized lidar point clouds. Semantic segmentation aims to associate each point in a 3D point cloud with a class label, (for

Figure 8.3. Zone 1: 100% of the points are at the same distance from the centre.

Figure 8.4. Zone 2: A peak of 6% of the points is 0.027 m from the centre.

example bolt, grout hole, radial edge, or longitudinal edge,) with certain characteristics, by sampling, grouping, and then extracting to a new data set with fewer elements.

It is important to be aware of the computational costs and sensitivity to the quality of the input point cloud when using this algorithm.

Clearly in such a uniform environment as a segmentally lined tunnel using PointNet++ to detect segment edges and extract geospatial coordinates at their point ends has a high probability of success.

8 A NEW AUTOMATED APPROACH: STAGE THREE

With the segment edges now described by points with a registered geospatial coordinate they can be compared to the proposed systemwide design for fit-out. In-tunnel positioning is not best described by coordinates because eccentricities in the as-built tunnel position mean that the proposed positions might not intersect with the tunnel lining at all, sometimes missing by hundreds of millimetres.

Instead, positioning is by height above alignment on the sides of the tunnel and horizontal offset left or right of the alignment in the roof of the tunnel.

Ideally, drilling positions are resolved by combining the tunnel as a built position with projected radials from a fixed reference position for the vehicle whose vectors are transformed to coordinates with an origin at the best-fit centre of the tunnel. In this way the intersected position with the as-built tunnel is accurate. See Figure 9.

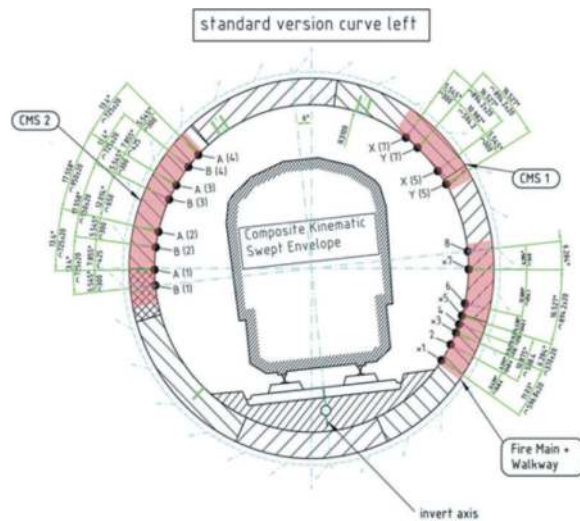

Figure 9. Example of in-tunnel fit-out relative to the vehicle and accommodating as-built position of tunnel lining.

To optimally combine the segment positions with the proposed systemwide layout it is best to consider both in terms of an angle from the zenith and a chainage along the tunnel. If this polar coordinate system is with an origin at the best-fit centre of the tunnel all radial distances will be the same. This completes the transformation of the datasets to a reference system best suited to this environment. See Figure 10.

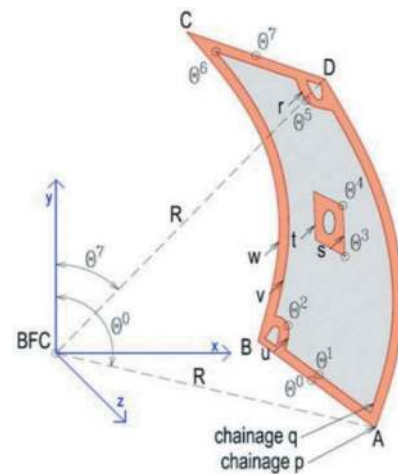

Figure 10. Coordinate system best suited for intersecting drilling patterns with bored tunnel lining.

For the systemwide installation layouts to be resolved in terms of compatibility with the segmental lining and the associated “no-drill” zones a “rule book” of allowable permutations and variations in the fixings is required. These are more than tolerances; they are a series of variables in the detailed design intended to accommodate all possible arrangements on site of segmental lining. It should be borne in mind that the phenomena of machine and ring roll, caused by forces acting on the TBM during excavation, and capable of introducing hundreds of millimetres of unintended rotation in the tunnel lining means that it is possible for longitudinal segment edges to be found at almost any location “around the clock” of the bored tunnel. In past projects, such rules have included the allowable maximum distances between anchors plus the provision of different fixing patterns for the same bracket by providing additional holes in the mounting. Once all the permutations and variations are ranked in order of preference a computer program is written to iterate the fit-out locations for each installation on the whole length of the tunnel. Iteration primarily seeks to find a position at the originally proposed chainage by moving the drilling up or down on the same bracket before considering changing the chainage location. This is because of the “knock-on” effect on adjacent locations in terms of respecting intervals for installation. To manage interval, change a nominal, acceptable “reduced” interval can be employed along with the option to increase the interval where necessary to accommodate changing of a location without any knock-on effects.

9 A NEW AUTOMATED APPROACH: STAGE FOUR

In the case of the Crossrail project, in addition to the “resolution” of the detailed design in terms of its

interface with the segmental lining, there was a need to produce guidance inputs for two bespoke drilling machines. The inputs consisted of chainage and a zenith angle. Because this influenced the output of the fit-out computer program there was a lack of emphasis on “transforming” the guidance data into lay-out “model” data in geospatial project coordinates that could be overlaid on the 3D model of the segment edges to provide comprehensible clash detection. This somewhat denied the most obvious check and balance on what was an easy-to-confuse general arrangement of tunnels where one section looked identical to any other.

In the interim eight years, the now relatively straightforward conversion of drilling data back to points intersecting with the as-built tunnel lining in a 3D model invites new technology such as Augmented Reality, plus automated clash detection between different models in commercially available software such as Cyclone 3DR, multiple opportunities for rapid, independent validation of the outputs ahead of drilling.

10 COST BENEFITS

In the context of systemwide installation for bored tunnels, there are two obvious cost benefits. The first is modelling time, where it is estimated that not less than one week per Km of the bored tunnel would be needed just for manually modelling the segmental lining. The second, less quantifiable benefit, assuming that the systemwide detailed design for layouts is resolved, and there are no clashes with no-drill zones on the segmental lining, is the elimination of delay on-site for the teams and machinery employed to install the bracketry and anchors.

Equally significant but less tangible benefits include the opportunity to refine the component design for in-tunnel fit-out so that remedial or reworks of the components themselves are eliminated. For example, an extra hole in a bracket might be all that is necessary for the component to be compatible with all found cases for the arrangement of the segments on a particular project.

An additional, less tangible, benefit is the completion of the modelling of bored tunnel segment edges for the asset BIM. Previously the modelling of bored tunnels has tended to be limited to best-fit ring representations alongside point clouds without classified features. This situation has denied the mass interrogation of the segmental lining for potential clashes with planned asset maintenance or upgrade operations.

11 CONCLUSIONS

Automated extraction of segment edge location from scan data is the next logical step in the evolution of managing geospatial data for bored tunnels.

The authors are confident it will be proven on the HS2 London-Birmingham high-speed rail project in a “post-processing” mode to optimise the system-wide installation and maximise the digitalisation of the engineering.

Automated extraction is really the only way in which as-built bored tunnels are likely to be analysed for the detail of the segment positions because manual modelling is still considered too slow and monotonous. The option for automated clean-up of tunnels is compelling for all users of the scan data. Furthermore, the extraction and analysis of segment positions are clearly going to optimise some high-risk site operations for systemwide installation in an environment with some extreme challenges in terms of access and logistics. The potential for costly delays in these operations without sufficient planning is very great indeed.

Finally, the automated recognition and extraction of segment edges, and therefore ring position and “attitude”, creates an exciting opportunity to use “sentinel” scanners and linked analysis in “near” real-time to export the required “ring by ring” build analysis to the TBM team at the front of the drive. Currently bored tunnel surveying and ring build assessments by engineers are still separate activities. Using a condensed version of stages one and two of the systemwide solution, focussed only on the ring at the front of the drive, all of the required information could be obtained instantaneously in a “single shot” from a geospatially referenced scanner.

Cavity detection model from GPR images considering reinforcing bars in tunnel segment lining

Chaemin Hwang*, Seunghun Yang, Sangyeong Park, Hojong Kim & Hangseok Choi
Korea University, Seoul, Republic of Korea

ABSTRACT: Since the quality of backfilling the tail void of the segment lining cannot be visually inspected, its evaluation heavily relies on non-destructive testing techniques such as Ground Penetrating Radar (GPR). However, the presence of reinforcing bars (rebars) within the segment lining creates a strong masking effect on electromagnetic waves, making the inspection of GPR challenging. To overcome this limitation, this study considered the scattered and noisy GPR images induced by rebars in the segment lining and proposed an automatic detection model based on the YOLO algorithm. Firstly, numerical analysis using Finite-Difference Time-Domain (FDTD) simulations was conducted to generate GPR images of segment linings with and without the presence of rebars. Subsequently, the YOLOv5 object detection model, which utilizes the convolutional neural network, was trained to detect cavities (i.e., not completely backfilled) behind the segment lining. To enhance the detection accuracy of cavities, the GPR images without rebars were adopted in the training dataset. The model presented in this study successfully detected nearly all cavity signals in the GPR images, and the applicability of the detection model to the on-site GPR results, which are noisier than the numerical results, was further investigated. This advancement contributes to more reliable and efficient quality control of backfilling the tail void of the segment lining.

Keywords: Ground penetrating radar (GPR), YOLOv5, Tunnel segment lining, Object detection, Grout-filled tail void

1 INTRODUCTION

Tunnel segment linings cannot be modified or demolished owing to their size and complexity in tunnel construction. Therefore, non-destructive testing should replace visual inspection for segment maintenance to assess the segment's condition and identify various defects.

One of the defects in tunnel lining structures is cavities. These can result from tunnel deterioration, environmental effects, and improper construction and maintenance. Cavity defects, often found in the backfill grout that fills the tail void during shield TBM excavation, can lead to tunnel degradation, exposing the tunnel to hazards such as leakages and ruptures. Therefore, it is imperative to investigate the presence of cavities in the segment structure to mitigate these tunnel risks.

Ground penetrating radar (GPR) has proven effectively in detecting cavities (Qin et al. 2020). GPR is non-destructive and highly effective, requiring minimal inspection time for the entire survey. However, the propagation of electromagnetic waves is influenced by factors such as antenna characteristics, target geometry, and material properties, requiring specialized GPR measurement and interpretation techniques. Moreover, the interpretation of GPR data

can be subjective, leading to different analysis results among experts (Benedetto and Pajewski 2015). Additionally, rebars within the tunnel segment can cause clutter in the GPR image, scattering the hyperbolic signal from the target and making it challenging to distinguish the cavity signal within the backfill grout.

Recently, the prevailing approach has been the use of convolutional neural networks (CNN) to detect underground target signals in GPR inspection results. Various studies have applied automatic object detection algorithms with a CNN structure to GPR images for purposes such as crack detection in pavements (Zhang et al. 2017; Zhang et al. 2020; Liang et al. 2022). Nairit Barkataki et al. (2022) proposed a CNN model to predict the size of buried objects from GPR B-scans.

To overcome the difficulties associated with GPR measurements of tunnel linings, this study employed an object detection algorithm that adopts a CNN to detect the parabolic signals of cavities. The finite-difference time-domain (FDTD) method was used to numerically analyze GPR results with and without rebars in the segment lining. These results were then used as training data to compare and analyze CNN models for the automatic detection of cavities in the grout-filled tail void of a segment lining. The

YOLOv5 algorithm was employed to quickly detect objects in the GPR images.

2 CAVITY DETECTION MODEL DEVELOPMENT

2.1 Database

In this study, finite-difference time-domain (FDTD) numerical analysis was performed to create a GPR image database for assessing the backfill grout behind the shield tunnel segment lining. In three-dimensional FDTD, the electric and magnetic field components are spatially located in Yee cells and approximated by discretizing Maxwell's equations in time and space, as originally proposed by Yee (1966), as shown in Figure 1.

Maxwell's partial differential equations can be formulated in a three-dimensional Cartesian coordinate system,

$$\frac{\partial H_x}{\partial t} = \frac{1}{\mu} \left(\frac{\partial E_y}{\partial z} - \frac{\partial E_z}{\partial y} - \sigma^* H_x \right) \quad (1)$$

$$\frac{\partial H_y}{\partial t} = \frac{1}{\mu} \left(\frac{\partial E_z}{\partial x} - \frac{\partial E_x}{\partial z} - \sigma^* H_y \right) \quad (2)$$

$$\frac{\partial H_z}{\partial t} = \frac{1}{\mu} \left(\frac{\partial E_x}{\partial y} - \frac{\partial E_y}{\partial x} - \sigma^* H_z \right) \quad (3)$$

$$\frac{\partial E_x}{\partial t} = \frac{1}{\epsilon} \left(\frac{\partial H_z}{\partial y} - \frac{\partial H_y}{\partial z} - \partial E_x \right) \quad (4)$$

$$\frac{\partial E_y}{\partial t} = \frac{1}{\epsilon} \left(\frac{\partial H_x}{\partial z} - \frac{\partial H_z}{\partial x} - \partial E_y \right) \quad (5)$$

$$\frac{\partial E_z}{\partial t} = \frac{1}{\epsilon} \left(\frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} - \partial E_z \right) \quad (6)$$

Figure 1. Single FDTD Yee cell geometry of the electric and magnetic field in three-dimensional Cartesian coordinate system.

where E is the electric field (V/m), H is the magnetic field (A/m), ϵ and μ are the permittivity (F/m) and permeability (H/m) of a material, respectively. Moreover, σ is the electrical conductivity (S/m), and σ^* is the magnetic resistivity.

The FDTD analysis was performed to simulate cavities in the backfill grout using the gprMax program, an open-source Python-based code (Giannopoulos 2005). Material properties of concrete, backfill grout, and air were input as numerical model parameters (Cassidy 2008). Table 1 provides a comprehensive list of material properties used in the FDTD model. Rebars were modelled as a perfect electrical conductor (PEC), meaning their electrical resistance equal to zero. The analysis utilized an 800 MHz GPR transmitted signal with a Gaussian waveform.

Table 1. Electromagnetic properties of materials used in numerical models.

Material	Relative permittivity	Conductivity	Relative permeability	Magnetic loss
Concrete	7	0.005	1	0
Grout	12	0.005	1	0
Air	1.045	0	1	0

To create the dataset for the automatic detection model, the geometry was divided into segments with and without reinforcement. The simulated tunnel lining consisted of a 200 mm thick segment and a 500 mm thick grout-filled tail void, analysed in 2D cross-sections. To prevent overfitting of the detection model, variables like rebar spacing, rebar starting position, cavity position, and the number of cavities were randomized. The rebar spacing in the segment was set to 300 mm, 400 mm, or 500 mm. The number of cavities in the backfill grout varied from 0 to 3, and some cavities were also placed at the boundaries to facilitate object detection for fault waveforms that did not exhibit a complete parabolic shape. In addition, some GPR images without defects were included to reduce false positives in the detection model. The FDTD analysis was performed 100 times for each of the reinforced and unreinforced segment models. Figures 2 and 3 provide an example of the model geometry and B-scan data.

Figure 2. Example of geometry illustration of FDTD analysis model.

Figure 3. FDTD analysis B-scan result of the geometry shown in Figure 2.

2.2 Detection algorithm – YOLOv5

YOLO (You Only Look Once), a CNN-based object recognition algorithm, boasts a straightforward training pipeline that allows for rapid learning and prediction while achieving high accuracy compared to existing object recognition algorithms (Redmen et al. 2016; Bochkovskiy et al. 2017).

YOLOv5 consists of three blocks of stages (backbone, neck, and head), the same as the overall structure of YOLOv4, as depicted in Figure 4. In the first stage, it employs the cross-stage partial (CSP) connection method to enhance model learning capabilities, enabling the swift and precise extraction of features. The second stage consists of a path aggregation network (PANet) that integrates feature maps of various sizes to enhance detection performance. In the last stage, the features extracted from the neck are utilized for object detection. YOLO integrates these tasks into a single neural network to achieve rapid object detection.

Several metrics were selected to quantitatively evaluate the predictive performance of the trained model. Precision, which represents the percentage of defects correctly classified by the model as actual defects, and recall, indicating the percentage of actual defects that the model correctly identifies as defects, were employed as performance metrics (Everingham et al., 2015). Precision and recall are defined as follows:

$$\text{Precision} = \frac{TP}{TP + FP} \quad (7)$$

$$\text{Recall} = \frac{TP}{TP + FN} \quad (8)$$

where true positive (TP) and false positive (FP) are the number of targets correctly and incorrectly classified as positive samples; false negative (FN) is the number of targets that are incorrectly classified as negative samples.

In addition, mAP (mean average precision) is the mean of the average precision (AP) of each class, and AP is defined as follows:

$$AP = \int_0^1 P(r) dr \quad (9)$$

This study calculated mAP@0.5, which represents the mean AP when IoU (intersection over union) is set to 0.5, and mAP@0.5:0.95, which represents the mean mAP across different IoU thresholds (from 0.5 to 0.95 in steps of 0.05). The model was trained for 300 epochs using a batch size of 16, with an initial learning rate set at 0.01.

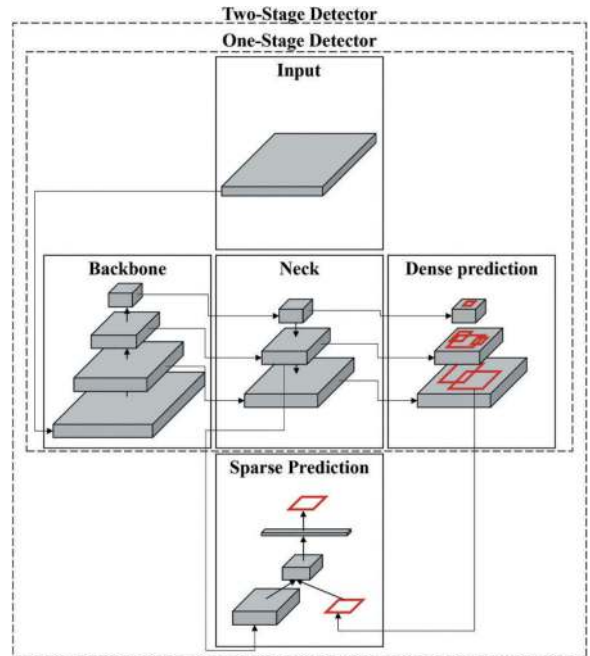

Figure 4. Object detection structure of YOLOv5 (Bochkovskiy et al. 2020).

3 DETECTION RESULTS

The YOLOv5 algorithm was utilized to detect cavities in the backfill grout behind the tunnel segment lining. In this study, three models were constructed according to the configuration of the GPR training dataset: Model A (dataset measured on unreinforced segments only), Model B (dataset measured on reinforced segments only), and Model C (composite dataset of reinforced and unreinforced segments).

Figure 5 initially shows the training and validation results for each epoch for the three models. Here, ‘box loss’ and ‘obj loss’ refer to errors in the bounding box and object class, respectively.

The validation loss for the models trained on the different databases consistently decreased as the epoch progressed in all models, indicating that no overfitting occurred. Model A, which exclusively consisted of parabolic signals from cavities without rebar signals, exhibited a low initial loss in the bounding box and object detection. In contrast,

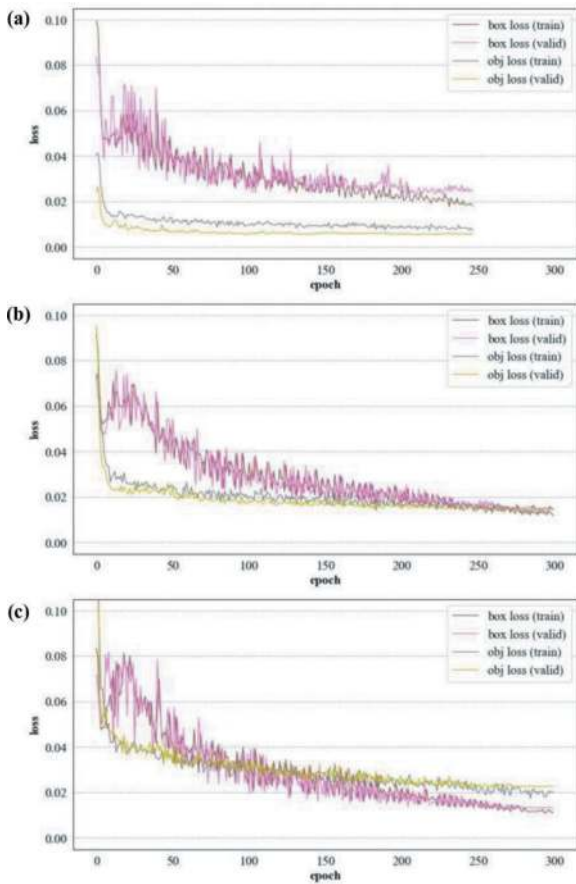

Figure 5. Box and object loss for each model's train and validation results: (a) Model A, (b) Model B and (c) Model C.

Model C, which consists of a composite dataset, suffered some classification losses for rebar and cavity detection in the early epochs but gradually improved during training. Furthermore, two models, except for Model A, completed all 300 training epochs. Model A, however, ceased training early because no improvement was observed in the last 50 epochs.

Figure 6 shows the results of each performance metric for the three models. When the IoU threshold is set to 0.5 for $mAP@0.5$, all three models exhibit high-performance scores. Nonetheless, Model A records lower scores for the $mAP@0.5:0.95$ metrics compared to the other two models. This lower performance indicates that Model A struggles to precisely match the bounding boxes of actual object positions with those predicted. This outcome can be attributed to the simplified nature of the configured database and the limitations in feature extraction.

For comparison with each training model, object detection was performed on GPR images that were not included in the training database. First, the results of cavity detection in the backfill grout were compared for unreinforced and reinforced segments. In segments without rebars, all models automatically detected parabolic cavity signals with reasonable accuracy, as shown in Figure 7. The accuracy indicated in the bounding box for the object was slightly higher for Model B and Model C than for Model A.

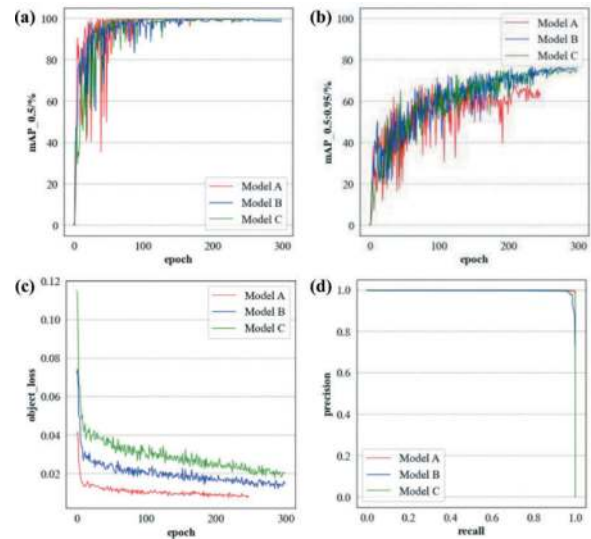

Figure 6. Detection performance results for the three YOLO models: (a) $mAP@0.5$, (b) $mAP@0.5:0.95$, (c) object loss and (d) precision-recall curve.

Figure 7. GPR cavity detection results with unreinforced segments for the YOLO model: (a) Model A, (b) Model B and (c) Model C.

Furthermore, all models successfully detected cavities on the rebar segments, as depicted in Figure 8. However, Model A could not detect the parabolic rebar signal in the GPR test image because the rebar waveform was not part of its training, and the cavity detection accuracy was lower than the other models due to the clutter generated by the rebars. Between the remaining two models, Model C, with composite data, showed a 0.0467 and 0.022 higher cavity detection accuracy than Model B.

By acquiring a database of images obtained under different conditions, it is possible to train various GPR images of cavity signals that might be obscured by clutter, resulting in high detection performance.

In this detection test, the detection accuracy was examined when cavities were clustered, and the parabolic cavity signals became noise to each other, that is indistinguishable due to their proximity. The automatic detection results of each model, when three cavities

Figure 8. GPR cavity detection results with reinforced segments for the YOLO model: (a) Model A, (b) Model B and (c) Model C.

under the rebar segments were clustered together, are shown in Figure 9. The lowest parabolic cavity signal was significantly masked by the upper rebars and the other cavity signals, resulting in a low detection accuracy.

Figure 9. Cavity detection results in GPR images when cavities were clustered: (a) Model A, (b) Model B and (c) Model C.

4 ON-SITE APPLICATION

The cavity detection model was developed using a database generated by numerical analysis. In this section, its applicability was verified by comparing with actual backfilled tail void measurement data. In real-world GPR results, there are target echoes mixed with noise, making it difficult to detect cavities compared to numerical simulation results. The usability of the detection model was evaluated using data from experiments conducted with TBM shield tunnel segments.

The GPR measurement experiment setup is illustrated in Figure 10. Starting from the top, the first layer represents the TBM segment lining without rebars. The second layer consists of soil to simulate the backfill grout, with styrofoam cubes placed at two locations to represent cavities. A MALA GX HDR GPR equipped with a 750 MHz center

frequency antenna was used in the test to obtain GPR images, as depicted in Figure 11. In the measurement result used for on-site application verification, two parabolic cavity signals were present, but they were challenging to distinguish due to noise.

Figure 10. Configuration of a cavity detection experiment for GPR data acquisition.

Figure 11. Labeled data for on-site application verification of cavity detection models.

In the analysis of the on-site data using the three detection models, both models A and B failed to detect any reflected signals. Model C, however, managed to detect one of the two cavity signals, albeit with a low detection accuracy of 0.4701, as shown in Figure 12. The reason for these poor on-site applicability results is that the reflection signal obtained by numerical analysis exhibited low noise levels, and the models trained with clean data struggled to perform well in the presence of noise in actual measurement data.

Therefore, to successfully detect cavities within the backfill grout, it is necessary to consider further training the models using realistic GPR data that includes noisy cavity signals. Alternatively, a method that can introduce noise into numerical analysis to generate echoes of reflected signals may contribute to improving the performance of the detection model.

Figure 12. Cavity bounding box and accuracy results in a real-world GPR image for detection Model C.

5 CONCLUSIONS

In a crucial study focused on developing an automatic detection model for cavity defects that occur within grout-filled tail voids behind the shield segment following GPR exploration of lining segments, this research aimed to establish a database consisting of GPR signal results obtained through FDTD numerical analysis. The training database for the CNN model was categorized into three type: measurement results for (1) unreinforced segments only, (2) reinforced segments only, and (3) a combination of unreinforced and reinforced segments. The CNN models were validated by comparing their performance in detecting cavities in test images. The training was performed using the object detection algorithm YOLOv5. The findings can be summarized as follows:

- 1) Model A performed poorly compared to the other models for $mAP@0.5:0.95$, one of the performance metrics. Since only GPR images of unreinforced segments were used, a feature map with insufficient variety and detail was extracted. Consequently, it failed to satisfy the high IoU threshold.
- 2) For validation purposes using GPR test images, Model A showed slightly lower detection accuracy than the other models. This could be attributed to the fact that the training data for Model A did not include the rebar clutter that masks the parabolic cavity signals.
- 3) The automatic detection model performed poorly under on-site conditions due to the discrepancy between the noise in GPR images and the numerical results. To improve the applicability of the model, future research can concentrate on methods for filtering out clutter in GPR images or simulating noise in the numerical analysis.

Combination of modelling and monitoring in assessing stability of a tunnel constructed in highly deformable rock and fragilized by fire

Tohid Kazerani* & Etienne Garin

Department of Transportation & Infrastructure. WSP, Lausanne, Switzerland

ABSTRACT: As one of the major trans-Alpine transport routes between France and Italy, the Fréjus road tunnel is currently the tenth longest road tunnel in the world. It has been constructed in the 1970s by drilling and blasting in a highly deformable Alpine schist which is known for its significant progressive deformation behaviour. During and since the construction, several monitoring campaigns were set to record tunnel's section convergence and stresses in the lining and the ventilation slab. In 2005, the tunnel was subjected to a fire at the Italian side. The aftermath studies suggested that the ventilation slab may have been exposed to temperatures up to 400°C. In addition, following the excavation of a parallel emergency tunnel in the 2010s, a sudden rise to rock deformation was seen where few sections started presenting very concerning section convergences and some minor failures began to appear on the lining. To assess the situation, several rounds of inspection and instrumentation were set that suggested that in some locations the slab could be loaded by the lining movements. The present paper through describing the instrumentation and inspection methodology shows how advanced numerical modelling along with on-time monitoring programme can help assess such a delicate situation. For this purpose, a slip-bond model has been developed for the slab reinforcement based on the recent literature which integrated in a FEM scheme allows to assess the current tunnel state and to predict probable developments in its future behaviour.

Keywords: Fréjus Tunnel, Convergence, Bond-slip model, Visco-elastoplastic, Damage mechanics, Monitoring

1 INTRODUCTION

The current intense circulation across the Alpine underground axes in Europe has made it very difficult to perform major repair or rehabilitation works which by nature require stopping circulation. This situation in the case of Fréjus road tunnel which is excavated in a deformable Alpine schist is much critical, as the tunnel lining has been long exposed to strains exerted by the ground creep movements. In addition, the tunnel has been twice subjected to fire in 2000 and 2005, that the latter incidence, based on the chemical studies done on concrete samples, is believed to have induced very high temperatures into the ventilation slab.

This paper, after presenting a brief history of the asset, describes the monitoring system adopted for the follow-up of the ground movements. Then two models are described: A model to examine the lining behaviour made of plain concrete using a visco-elastic damage constitutive law, and a second model to study

the fragilized slab using a bond-slip law developed for the reinforced concrete allowing to consider material properties degradation due to high temperature.

At last, the simulations' results are discussed to show how modelling combined with instrumentation can aid engineer in evaluating the asset current state, and its behaviour in the long run.

2 PROBLEM STATEMENT

2.1 *Fréjus Road Tunnel*

The Fréjus Road Tunnel runs under Col du Fréjus in the Cottian Alps between Modane in France and Bardonecchia in Italy. It is one of the major trans-Alpine transport routes between two countries being used for 80% of the commercial road traffic.

Construction of the 12.8 km long tunnel started in 1974, and it came into service on 12 July 1980, leading to the closure of the motorail shuttle service in the Fréjus rail tunnel. The construction of the tunnel

* Corresponding author: tohid.kazerani@wsp.com

Figure 1. Fréjus road tunnel (right), new second tube (left) and a bypass (SFTRF, 2020).

which is currently the tenth longest road tunnel in the world, cost 2 billion francs (equivalent to €1 billion at 2023 prices).

2.2 2005 Fire incidence

The 2005 fire breaks out in a truck carrying tires from France to Italy. The tragedy occurred in the middle of the tunnel where the flames spread rapidly, and made other vehicles be set to fire.

2.3 2010s Second tube construction

The European directive on tunnel safety issued in 2004 led to the decision of constructing the road tunnel's emergency gallery at the end of 2009. This was to bring the tunnel into conformity with the obligation for all tunnels in the trans-European network to be equipped with safety shelters no more than 500 m apart.

The main objective of this operation was to increase the number of safety shelters in the Fréjus tunnel from 11 to 34 by building bypasses to the emergency gallery every 400 m on average.

On November 17th, 2014 excavation of the tube, using a tunnel boring machine, was completed (SFTRF, 2020).

This second tube will be opened to single lane traffic (in the direction Italy-France), while the existing tunnel will also be operated for single lane traffic (in the direction France-Italy). This project costs €550 million (2014 value).

3 ROCK MASS CREEP BEHAVIOUR

The existing Fréjus tunnel has been constructed by drilling and blasting. As a result, and as it is the case in most tunnels excavated by this method, the excavation surfaces are very irregular, such that the lining, which was planned to be about 40 to 70cm thick, has been casted with even more than 1m-thick plain concrete (see Figure 7).

Due to the rock mass high creep tendency, the road tunnel was let unlined for few months after excavation to allow it to undergo as much its creep deformation as possible before casting the concrete lining. Nevertheless, in some sections, the creep was that high that required section readjustments before lining.

The tunnel section convergence was recorded during the excavation and the unlined period. Figure 2 shows the variation of these convergences

(measured after 1 month from passing the tunnel face by the measurement point) versus the overburden along the tunnel axis.

The measurements showed a significant rock mass creep behaviour particularly at very early days after excavation (the first ten days or so), where rock mass was developing a very rapid deformation toward the tunnel at a rate of around 1cm/day. Though later the creep deformation decelerated, it never stopped such that even after 3 months (when the primary measurements were removed for placing the lining) no sign of stability was seen.

Figure 2. Overburden variation versus 1-month primary convergence for the French side. i.e., the first 6400m of the tunnel.

As seen in Figure 2, the tunnel section convergence does not follow the rock overburden pressure. As a matter of fact, it is more dependent of the local rock mass foliation than its overall stress level. This foliation has a variable dip angle along the tunnel between 10° to 25°.

3.1 Impact of second tube construction

The excavation of the second tube and the subsequent change in the rock mass stress state gave rise to the rate of convergence in the existing tunnel. This behaviour was more pronounced where the bypasses were excavated from the second tube toward the tunnel. Due to this issue, new measurement devices including displacement and stress gauges were mounted in 2011 along the tunnel liners, inside the new excavations, and over the ventilation slab.

As illustrated in Figure 4, following a general jump right after the second tube excavation (2013 measurements compared to 2007 measurements of Figure 3), except for four places (whereabouts of 2000m, 5400m, 6900m and 7800m), the lining convergence seems to reach again stability. In these four critical places, tunnel behaviour required an enhanced monitoring and numerical analysis which is the subject of the presented study.

3.2 Lining and ventilation slab overstress

The lining section lacks a bottom slab (Figure 7). Therefore, against the progressive rock mass creep,

Figure 3. Convergences recorded before the second tube excavation (data for the French side).

Figure 4. Convergences recorded after second tube excavation (data for the French side. i.e., the first 6400m of the tunnel).

the lining could only resist through two mechanisms: (a) Flexural mechanism, as a result of that the arch crown is compressed at its inner fibre and tensioned at the outer fibre; (b) Ventilation slab reaction, as a result of which the slab is strained axially.

The mentioned compressions have already led to concrete punctual spalling at the arch crown inner surface. As the carried out concrete core samplings confirm a highly resistant material whose mean compressive strength is about 40 to 50 MPa, the arch at the spalling regions should be and have been under very high levels of compression.

In addition, as the tractions induced at the lining unseen outer surface (extrados) may have already exceeded the limited tensile strength of the plain concrete, the liner may have fractured very likely at that surface.

Figure 5. Spalling over in arch inner surface.

From the ventilation slab perspective, the growth of axial strains threatens its stability. Although in French side, the ventilation slab is placed separated

from its supports using 1.5cm-thick polystyrene layers, in the Italian side, it was casted in direct contact with the lining.

The in-situ observations at the French side confirm that in some sections the polystyrene layers have been completely crushed and the slab is already touched by the lining.

4 MODELLING

4.1 Lining: Viscoelastic damage mechanics modelling

The goal of the study project defined for the asset was to provide a comprehensive picture of the lining currents status, and to put forward solutions to guaranty its long-term durability. For this purpose, a large number of simulations were performed for different parts of the tunnel. This paper only summarizes the modelling fundamentals without going in much detail, and instead it aims at providing the reader with the most important outcomes.

4.1.1 Rock mass behaviour

The modelling needed to take creep effects into account due to their importance in predicting structure behaviour. For this purpose, the rock was modelled using a visco-elastoplastic (VEP) law, where rock viscous behaviour is formulated using a series of Kelvin elements as follows, where η is the material viscosity (ZSoil, 2020).

$$\eta \dot{x} + kx = f(t)$$

As a general form, the calculation code allows to define creep displacement as follows,

$$x(t) = x_{ep} + x_{cr} = x_{ep} + \sigma C(t)$$

where, X_{ep} and X_{cr} are the elastoplastic (EP), and creep components of displacement. The latter is formulated do that being dependent of the model stress field through a so-called “creep function”, $C(t)$. For this study, a logarithmic creep function is opted,

$$C(t) = A \ln(1 + Bt)$$

where A and B are the so-called “creep parameters” which need to be calibrated using the experimental data. This has been done using the convergence data recorded during excavation works. The rock mass is modelled as a homogeneous isotropic continuum with properties as listed in Table 1.

Table 1. Rock mass characteristics.

Unit weight	Elastic modulus	Poisson's ratio	Friction angle	Cohesion
27 kN/m ³	15 GPa	0.2	40°	5 MPa

4.1.2 Concrete behaviour

The lining was simulated using a visco-damage mechanics (VDM) model. The damage mechanism is the one introduced by Omidi and Lotfi (2012). The viscous part of the modelling is defined by the creep formulation proposed in the Eurocode 2 (EN1992-1-1, 2004), where both the long-term deformation and the material maturation (increase in stiffness and strength) are incorporated into the simulation using the equations provided by the Eurocode.

Figure 6. Compressive (left) and tensile (right) behaviours in concrete damage model.

4.1.3 Model geometry

In the course of the study, many models were created to examine different aspects of the tunnel. Figure 7 illustrate the geometry of one of the 2D models used in a section presenting the highest current convergence rate.

The modelling was carried out using ZSoil finite elements package (ZSoil, 2020).

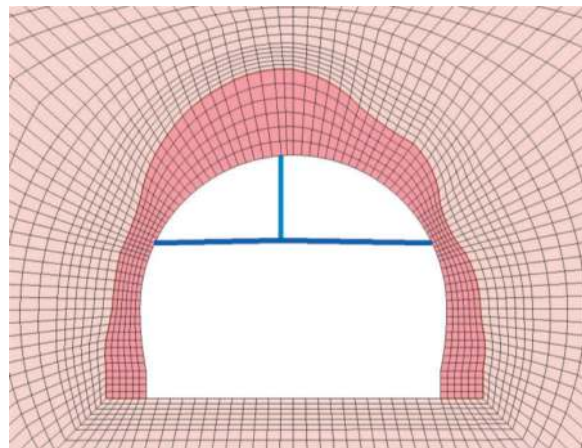

Figure 7. 2D Model geometry with lining varying thickness as a result of excavation by drilling and blasting.

4.1.4 Validation

In order to validate the model, the results of a simulation for the tunnel deformations after the construction of the second tube (2010s works) are compared to the in-situ measurements. Note that the creep parameters are calibrated using convergences recorded in the unlined tunnel during the 1970s excavation works.

Figure 8 shows that the model reproduces the tunnel deformations accurately. Note that the

Figure 8. Model comparison with secondary and tertiary convergence measurements.

modelling presents a relatively sharp displacement jump at the second tube excavation, while measurements suggest a more moderate deformation rate. This is because in reality, the confinement effect around the excavation front makes the hole converge less rapidly than the 2D model does which lacks such a confining effect. Apart from this shortcoming, the model can well reproduce the deformation rates before and after construction works.

In addition, lining stress measurements carried out in the arch crown by means of flat jacking suggest that as of 2020 concrete stress at a distance of 30 cm from the surface has been about 8.0 MPa. Figure 9 shows that the model at the same location and at the same concrete age produces the same stress.

4.1.5 Discussion on concrete creep effect

The concrete creep behaviour is normally neglected in calculations as it is generally admitted that in terms of stress, material damage behaviour is more important than its creep.

However, when rock creep enters the play, it requires the model to include a large time span of the structure lifetime or even its whole. In such a case, concrete creep becomes important.

Incidentally, the stress relaxation in concrete due to creep has a favourable effect as illustrated by following images presenting the tunnel lining stress once calculated with no creep assumption for the concrete (Figure 10) compared to Figure 9 presenting stresses in the model with concrete creep.

In both figures, the stresses are scaled between 0 and 10 MPa. As seen, while no-creep assumption leads to some unrealistically large areas of overstress (coloured in dark blue) including at the ventilation slab connection point, the model with concrete creep suggests much more reasonable stress values. Note that in the section inspections, not lining failure due to overstress has been reported at the slab support point.

In addition to modelling significance, these results put forward an important practical remedy in dealing with tunnels excavated in deformable rock, that is, the use of light-weight concrete, which is more prone to creep, instead of using normal concrete.

Light-weight concrete can be obtained by using large aggregates with little to no fine aggregates

(pervious concrete), or with a controlled use of gas producing agents in the mixture (porous concrete).

This way, the deformations imposed by ground creep can be absorbed by concrete creep gradually, thereby lining stresses are relaxed.

Figure 9. Lining horizontal stress with creep for concrete.

Figure 10. Lining horizontal stress with no creep for concrete.

4.2 Ventilation slab: Bond-slip model

This chapter presents the analysis performed to check the current and future state of the slab at location that it has been once exposed to fire in 2005.

This chapter after reviewing the adopted methodology, applies the presented method to the slab and examines its response in post-fire state to deformations imposed by the section convergence.

4.2.1 General behaviour at low temperatures

The bond between steel rebar and concrete consists of (a) chemical adhesion, (b) skin friction and (c) interlocking. Chemical adhesion has a negligible effect, which disappears as soon as the initial slip-page at rebar-concrete interface occurs. Subsequently, the frictional force generated by the mechanical interlocking of the steel ribs in concrete develops gradually and becomes the main component of rebar's bonding action.

Numerous analytical studies have been carried out to investigate the behaviour of tensioned rebars in concrete at room temperature. These analytical studies provide useful information on rebars deformation process

and failure modes. Based on experimental and analytical studies, certain calculation methods have also been established to assess the ultimate bond stress. In addition, numerous studies have attempted to propose a closed-form mathematical expression for the relationship between local bond stress and rebar slip.

The bond-slip stress model which is most widely used in the literature is certainly that specified by Model Code (2010), originally developed by Eligehausen et al (1983).

This slip model defines the local bond-slip relationship by four stress levels as follows:

$$\tau_s = \begin{cases} \tau_{max} \left(\frac{s}{s_1}\right)^m & S \leq S_1 \\ \tau_{max} & S_1 \leq S \leq S_2 \\ \tau_{max} - (\tau_{max} - \tau_f) \left(\frac{S-S_2}{S_3-S_2}\right) & S_2 \leq S \leq S_3 \\ \tau_f & S_3 < S \end{cases}$$

where τ_s and s are the bond stress and the slip between the rebar and the concrete; m is a coefficient that defines the ascending branch of the bond-slip curve, set at 0.4 according to the 2010 Model Code.

The results of these tests highlight the fact that, if rebars are sufficiently confined by cover, their failure mainly takes place by a complete pull-out of the rebar after a significant displacement of the latter in concrete, where concrete remains intact (pull-out). On the other hand, when rebars are covered by a relatively thin concrete cover, with or without transversal reinforcement, radial cracks propagating from the bar-concrete interface reach the concrete surface, and failure occurs by splitting the concrete cover (cleavage).

The parameters defining bond stress according to Model Code 2010 are summarized in Table 2 for different failure modes.

For the case of ductile failure (i.e., pull-out or cleavage in concrete reinforced by stirrups), when the slip reaches rebars ribs spacing (l_s), mechanical interlock between steel rebar and concrete becomes negligible, and residual bond stress, τ_f is mainly ensured by the action of friction.

The residual bond stress is set at $0.40\tau_{max}$ in pull-out case, and $0.20\tau_{max}$ for cleavage case. In addition, the interfacial slip corresponding to l_s (in the case of pull-out) and $0.5l_s$ (in the case of cover cleavage) is defined as s_3 .

Table 2. Model Code 2010 bond law parameters.

Parameter	Pull-out	Cleavage	
	Sufficient concrete cover	Unconfined rebar (no stirrups)	Confined rebar (with stirrups)
S_1	1.0 mm	0.6 mm	0.6 mm
S_2	s_1+1	s_1	s_1
S_3	l_s	$1.2s_1$	$0.5l_s$
τ_f	$0.40\tau_{max}$	0.00	$0.20\tau_{max}$

In the absence of confining stress around rebars, post-peak bond stress is negligible, thereby τ_f can be assumed null.

The Model Code proposes values for τ_{max} , which depend only on the compressive strength of the concrete (varying between *Lausanne* and $2.0\sqrt{f_{ck}}$ regardless of cover thickness or rebar diameter. For this reason, and given the importance of these parameters, in the present study we rely on the following analytical equation proposed by Gao et al (2019):

$$\tau_{max} = \frac{1.81cf_{ct}}{(1.05 - 3.56d \times 10^{-3})d}$$

Where f_{ct} is concrete tensile strength (MPa) and c and d are cover thickness (calculated from the reinforcement axis) and the rebar diameter, both in mm.

4.2.2 Bond degradation high temperature

Estimating the residual bond of steel bars that have been subjected to fire is more complicated than in the case of intact material. This can be explained by the fact that, due to the difference between thermal expansion coefficient of steel and concrete, thermal stresses can occur in the steel/concrete interface at high temperature. If the temperature remains relatively low, the circumferential tensile stress around the rebar will remain lower than concrete tensile strength, and concrete cover will remain intact. However, as temperature rises, tensile stress increases and may reach the material tensile strength, leading to concrete cracking. As a result, in the post-fire state, concrete exhibits partial cracking over a certain radius around reinforcement.

In the literature, several pull-out tests have been carried out to investigate the bond strength of reinforcing rebars during or after exposure to heat (Ergün et al 2016, Bingöl and Gül 2009, Hlavička 2017, Deshpande et al 2020, Yang et al 2018, Yin et al 2011, Ma 2017, Tariq and Bhargava 2020, Zhang et al 2019, and Rashid et al 2019). The results of these tests indicate that bond strength considerably decreases, particularly when concrete temperature exceeds the 400°C limit.

Analytical studies have also been carried out to propose bond-slip models at high temperature (i.e., in the heated state before cooling), like the work of Khalaf and Huang (2019), and also for the bond degradation after exposure to high temperature (i.e., residual bond after cooling), e.g., the study carried out by Wang et al. (2022)

4.2.3 Bond degradation of corroded reinforcement

Reinforced concrete structures located in humid areas and exposed to aggressive environments are subject to carbonation and chloride penetration. As corrosion progresses, circumferential tensile stresses induced by the corroded steel expansion, would they exceed the material tensile strength, can lead to concrete cracking and spalling at cover zone, resulting in a loss of bond between steel and concrete.

As tunnels, specially road tunnels, are subject to CO2 emission from cars exhaustion, concrete in these assets is highly prone to carbonisation.

4.2.4 Empirical models of bond strength degradation

Experimental study of bond stress degradation of reinforcement after exposure to elevated temperatures has been subject of several scientific investigations. For the present study, we rely on data from one of the most extensive experimental investigations in this field, carried out in 2020 by Tariq and Bhargava. The aim of that study was to investigate the extent to which the bond properties of ductile steel rebars anchored in normal-strength concrete deteriorate under the combination of corrosion and high temperature.

To this end, the bars were exposed to accelerated corrosion to achieve desired corrosion levels in terms of mass loss percentage (2%, 4%, 6%, 8%, 10%, 12%, 14%, 16% and 18%) and then to target temperatures (200°C, 400°C, 500°C, 600°C, 700°C and 800°C). The specimens were tested to failure in pull-out mode to study the sliding behaviour of rebars. The results indicate a significant reduction in bond stress due to the superposition of the two phenomena.

Tariq and Bhargava has not proposed an analytical form for adhesion loss as a function of temperature and corrosion. Based on their results, we have developed a mathematical equation for the maximum residual adhesion stress, which can be expressed as follows:

$$\tau_{max}(T, C) = \tau_{max} \times H(T) \times R(C)$$

Where τ_{max} is the maximum bond stress of an uncorroded rebar at room temperature as given described earlier, and $H(T)$ and $R(C)$ are two statistical functions representing respectively reducing effects of high temperature and steel mass loss due to corrosion:

$$H(T) = \frac{1}{2} - \frac{2.5 \times 10^{-3}(T - 500)}{\sqrt{1 + 2.5 \times 10^{-5}(T - 500)^2}}$$

$$R(C) = \begin{cases} \frac{5}{8} - \frac{25(C-0.03)}{\sqrt{1+2500(C-0.03)^2}} & 20^\circ C < T \leq 200^\circ C \\ \frac{5}{8} - \frac{30(C-0.02)}{\sqrt{1+2500(C-0.02)^2}} & 200^\circ C < T \leq 800^\circ C \end{cases}$$

4.2.5 Degradation of reinforced concrete properties

When estimating the slab residual strength, the degradation of concrete and steel mechanical properties, in particular strength and elastic modulus, must be properly assessed.

Elastic modulus degradations of steel and concrete and after fire (AF) can be defined according to the equations proposed by Liang (2008). The equations are given below, where $E_{s,TA}$ and $E_{c,TA}$ are the residual elastic moduli of reinforcement and concrete after exposure to fire. $E_{s,0}$ and $E_{c,0}$ represent the elastic moduli of steel and concrete at room temperature.

$$\frac{E_{s,TA}}{E_{s,0}} = \frac{1}{1 + 0.505 \times (T/1000)^{7.36}}$$

$$\frac{E_{c,TA}}{E_{c,0}} = \frac{1}{1 + 18.5 \times (T/1000)^{2.47}}$$

The permanent degradation in concrete tensile strength after fire is taken into account using the equation below, obtained by Qin et al. (2004) and republished by Wang et al. (2022):

$$\frac{f_{ct,TA}}{f_{ct,0}} = 1.02 - 0.00111T$$

Where $f_{ct,TA}$ and $f_{ct,0}$ are concrete tensile strengths after exposure to high temperature, T , and at room temperature, respectively.

As explained in FIB (2008), the degradations in the compressive strength of concrete during and after exposure to fire must be assumed to be identical, based on a safety approach. These degradations are taken into account by the equations proposed by Eurocode 2, part 1-2 as for siliceous and calcareous aggregates.

4.2.6 Estimation of the slab post-fire strength

This section aims at applying the formulation developed above to estimate the ventilation slab residual strength. To reach this purpose, a thermo-mechanical FEM model has been developed in which the presented formulations were applied.

In addition, the equations proposed by Eurocode 2, part 1-2 for change in material thermal properties, i.e., conductivity, heat capacity, and thermal expansion coefficient, were also incorporated into the model, enabling it to automatically simulate the structure behaviour at rising temperature. The simulation is carried out at four temperature levels: 20°C, 200°C, 400°C and 600°C. The simulation aims at examining whether the deterioration in rebar-concrete bond and the materials' strength could have led to a reduction in the structure load-bearing capacity under the transversal compression induced by the tunnel section convergence. To answer this question, buckling strength of the compressed slab under lateral bending due to its self-weight is studied.

The simulation, modelling one metre of the slab length, is carried out under the following assumptions:

- Buckling is taken into account using a second-order approach by applying tunnel convergence in 1-mm steps, where nodal coordinates are updated at each step to incorporate large deformations and geometric non-linearity into calculation.
- Concrete class is assumed C30/37. The elastic modulus and characteristic compressive strength of concrete at 20°C are taken 30 GPa and 30 MPa, respectively.

Figure 11, showing the modelling results for the slab's bending moment and deflection before and

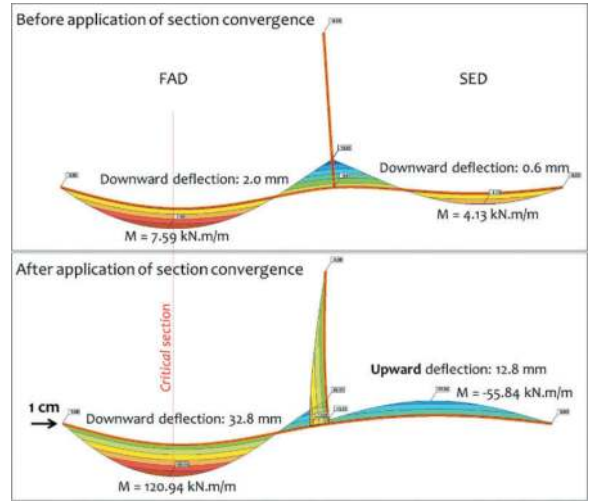

Figure 11. Slab model before and after application of the tunnel convergence FAD load.

after the application of the lateral convergence load (1.0 cm), shows that:

- Under the effect of self-weight alone, the two slab spans, separated by the vertical partition, bend downwards and the maximum bending moment occurring at the mid-span on each side is 7.59 kN.m/m (for the fresh air duct, FAD) and 4.13 kN.m/m (for the smoke extraction duct, SED).
- As the cross-section in the FAD is wider, it deflects more ($\Delta_{FAD} = 2.0$ mm), so the partition-slab connection point rotates counter-clockwise.
- The applied compression produces two second-order moments ($M = P\Delta$), the larger of which is generated in the FAD ($\Delta_{FAD} > \Delta_{SED}$). This makes the connection point rotate further in counter-clockwise direction under the resulting moment ($P\Delta_{FAD} - P\Delta_{SED}$). Under this mechanism, Δ_{FAD} increases but Δ_{SED} decreases.

The continuation of this mechanism makes the slab span in the SED be deflected upward.

Under section convergence, it is the slab span in the FAD that is subjected to the greatest stresses and is therefore considered to be the critical cross section of the structure.

In this cross section, there are two reinforcement layers: the lower layer comprises 20 mm diameter rebars spaced 20 cm apart, and the upper layer, where reinforcement is provided by two reinforcement positions: one with 10 mm diameter rebars spaced 20 cm apart, and the other with rebars of the same diameter but longer and spaced approximately 30 cm apart.

Figure 12 shows the MN interaction curves (including buckling effect) as calculated for the critical section under different temperature levels. In the same figure, the model results for the evolution of bending moment as a function of normal force exerted by the displacement imposed at the slab support (convergence load) are also presented. These results highlight that:

- As the bond and strength degrade under heat impact, the ultimate bending moment and normal force of the section decrease as a function of temperature.
- The degradation of concrete elastic modulus due to fire has made the slab less stiff at its post-fire state. Consequently, a slab fragilized by fire responds less firmly to convergence-imposed displacements than an intact slab.
- This mechanism by compensating section strength reduction increases the slab's ability to attenuate the imposed deformations and enables it to withstand higher levels of section convergence in post-pic state compared to its pre-fire state. For example, when an intact slab withstands up to 0.6 cm of axial compression, a slab that has been subjected to a temperature of 400°C can withstand displacements as high as 0.9 cm.

Figure 12. Bending moment - normal force interaction diagram of the slab including buckling (dashed lines) and the curves showing bending evolution as a function of normal force under application of convergence load (solid lines).

ACKNOWLEDGMENTS

The authors would like to thank the Fréjus tunnel French motorway company (Société Française du Tunnel Routier du Fréjus, SFTRF) for its permission to publish the study outcomes. The authors are especially grateful to Monsieur Nicolas Miché of the SFTRF for his kind support during the preparation of the paper.

ABSTRACT: A full-scale research study was conducted for the bored tunnelling undercrossed an existing building structure in the Klang Valley Mass Rapid Transit - Putrajaya Line in Kuala Lumpur, Malaysia. The research study, which aims to investigate tunnel-soil-pile interaction and pile responses at various stages of the tunnel excavation by means of full-scale field measurements and numerical analysis, contributed to a more in-depth understanding of the transient effects of shield tunnelling on existing loaded pile. A fully instrumented experimental pile was installed, pre-loaded and monitored in real-time condition throughout the tunnel construction. The in-pile instrumentation comprised of vibrating wire strain gauges, inclinometer and distributed fibre optic sensing using Brillouin Optical Time Domain Analysis (BOTDA). BOTDA is a novel technique of measuring strains in a continuous manner which has inherent advantages over the conventional point-based sensors when evaluating three-dimensional pile deformation such as bending and lateral displacement. This paper presents the setup of the experimental pile, instrumentation regime, field monitoring, interpretation of measurement results and discussion. Tunnelling-induced pile transient lateral responses are examined in detail. It allows engineers to understand the transient behaviour of a loaded pile during tunnel advance.

Keywords: Bored tunnelling, Field measurement, Lateral pile movement, Distributed fibre optic sensor, Tunnel-soil-pile interaction

1 INTRODUCTION

The Putrajaya Line, previously known as Sungai Buloh-Serdang-Putrajaya Line, is the second of three planned mass rapid transit rail lines under the Klang Valley Mass Rapid Transit (KVMRT) Project. The 57.7 km-long alignment covers a span of 13.5 km underground tunnels running through the Kuala Lumpur city centre. Given the dense urban setting, bored tunnelling was adopted for the metro tunnels. The twin 5.8 m I.D. bored tunnels were constructed using closed face tunnel boring machine (TBM) and pre-cast steel fibre reinforced concrete segments. The tunnel route passed underneath, inter alia, about 200 buildings and 30 infrastructures, and divided into 8 tunnelling sections.

A full-scale research site was identified at the Education Quarters located within the central business district of Kuala Lumpur. The tunnels traversing through the Quarters from north-west Hospital KL

Cross-over towards south-east direction before arriving at Raja Uda Station (formerly known as Kampung Bharu North Station) as shown in Figure 1.

The southbound tunnel crossed underneath a 5-storey building and faced obstruction from the existing building foundations. The affected piles had to be removed and the underpinning work was carried out in advance of the passage of TBM. The underpinning work comprised of the installation of micropiles capped under a reinforced concrete transfer structure to straddle across the tunnel. Prior arrangement had been made to install an additional 'experiment' micropile to allow for comprehensive in-pile instrumentation and real-time monitoring during tunnel construction.

The research study, which aims to investigate tunnel-soil-pile interaction and pile responses at various stages of the tunnel excavation by means of full-scale field measurements and numerical analysis contributed to a more in-depth understanding of the transient effects of shield tunnelling on existing

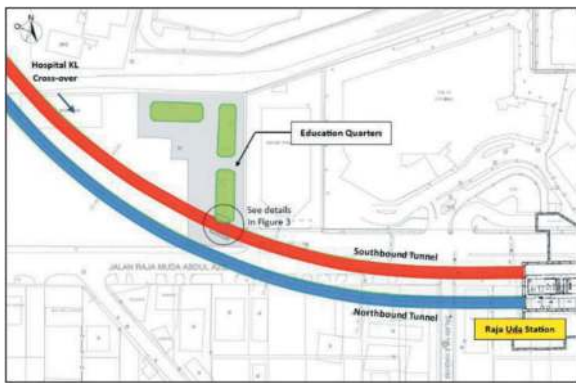

Figure 1. Location plan of the research site.

loaded pile. This paper presents the setup of the experimental pile, instrumentation regime, field monitoring during tunnel advance, interpretation of measurement results and discussion. Transient lateral responses of a loaded pile to advancing tunnel are examined in detail in this paper.

2 SITE CONDITIONS AND SET-UP

2.1 Ground and hydrogeological conditions

The site is located within Kuala Lumpur Limestone according to the geological map of Kuala Lumpur (1993 version). Generally, the terrain of the site can be described as flat ground with average level of RL34 m. The site investigation boreholes confirmed the expected regional geological setting, i.e. alluvium overlying limestone bedrock. However, the bedrock levels at the site location were predicted to be erratic and possible cavities due to the inherent karstic features of limestone formation. The alluvium typically comprises interbedded layers of loose sand and soft clay/silt with SPT (standard penetration test) value below 10. Figure 2 shows the interpreted geological profile along the southbound tunnel alignment.

Based on the groundwater monitoring records, the water tables were between 1.3 m and 5.2 m below existing ground level. The general trend observed indicates groundwater drops gradually from RL33.5 m at HKL Cross-over to RL30.5 m at Raja Uda Station. At the research site location, groundwater was found at a depth of 4 m, with typical seasonal fluctuation of ± 0.5 m.

2.2 Underpinning scheme and pile removal

The underpinning work consisted of seven 330 mm diameter micropiles capped under a 1 m thick reinforced concrete (RC) transfer structure that straddles across the tunnel. This structure was used to safely support the column loads before the removal of the affected piles. Figure 3 illustrates the plan view and cross-section of the tunnel in relation to the existing building foundation, newly installed underpinning piles and the experimental pile.

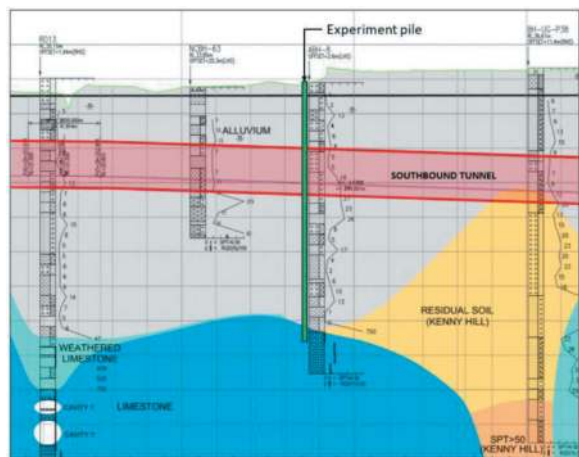

Figure 2. Interpreted geological profile along southbound tunnel.

Figure 3. Plan view and cross-section of the underpinning works.

To facilitate the excavation for construction of the transfer structure, ground treatment in the form of jet grout columns ($q_u = 600$ kPa) was deployed to act as temporary retaining structure together with 1 m thick base grout forming the soffit. Tan et al. (2019) presented the methodology to remove the existing 300 mm RC square piles identified to be clashed with the tunnel.

3 THE EXPERIMENTAL PILE AND INSTRUMENTATION

The experimental pile, having a diameter of 300 mm and located at 1.5 m away from the extrados of the southbound tunnel, is reinforced with API (American Petroleum Institute) pipe of 177.8 mm outer diameter with 10.36 mm wall thickness. The experimental pile was installed to socket 1.5 m into the limestone bedrock at 32.3m below ground level. The micropile (grade G30) design capacity is 600kN.

Figure 4. Pre-loading jack configuration.

As shown in Figure 4, a temporary steel casing was left-in until the soffit of ground treatment layer (i.e. 3 m below ground level) to protect the pile head section and to ensure that the cabling survived the construction process. It should be highlighted that the pile head was protruded above the transfer structure within a pre-installed 400 mm dia. 6 mm thick steel sleeve. The pile was preloaded to its working load and maintained throughout the tunnel advance monitoring period. Reaction anchorage method was used to apply the load to the experimental pile. The reaction frame consisted of two UC300x300x87 kg I-beam with 4 nos. of 32 mm dia. SAS (Stahlwerk Annahutte Steel) traded bars anchored into the transfer structure. The hydraulic jack which was used to load the pile to the designated working load was rested between I-beam and the top of a hollow circular end plate welded to the pile head. Load cell was used to measure the amount of load transferred to pile and Linear Voltage Displacement Transducers (LVDTs) installed on an independent reference frame were used to measure pile top settlement in addition to precise optical leveling. During the preloading stage, the jack loads were stepwise increased up to 600 kN, at 10 steps of load increment with 10 minutes withholding time each step, and the strain distribution along the pile was measured. Upon reaching the working load, the applied load was kept constant (i.e. re-jacked if necessary) throughout the monitoring period. In this study, it is assumed that the working load applied to the pile remains constant and does not change because of the tunnel excavation. This assumption may be considered acceptable if the superstructure is flexible and statically determined.

The in-pile instrumentation was essentially designed and arranged in such a manner to provide real-time data on the tunnelling-induced transient pile responses with respect to the pile head vertical displacement, pile shaft horizontal deformation and pile axial load distribution as well as pile internal forces. The instruments installed on experimental pile consisted of both the conventional vibrating wire strain gauges and inclinometer as well as the novel fibre optic distributed sensors. Figure 5 depicts the details of in-pile instrumentation and arrangement.

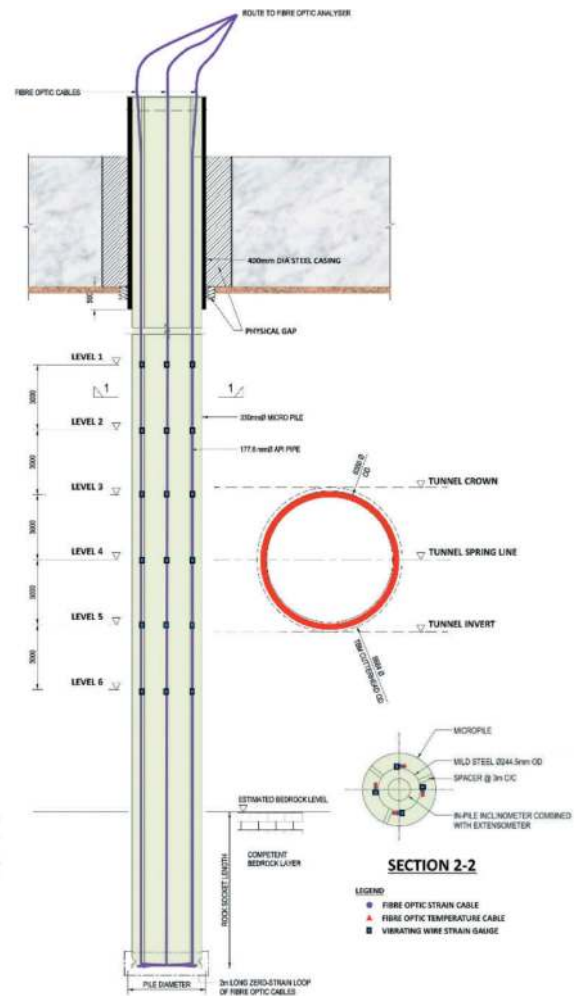

Figure 5. Arrangement of in-pile instrumentation.

Six levels of vibrating wire strain gauges (VWSG) were attached to the pile reinforcement (API pipe). VWSG were placed at every 3 m intervals starting at a depth of 4 m below ground surface in corresponding to each of the important measuring levels, i.e. Level 1 – 6 m above tunnel crown, Level 2 – 3m above tunnel crown, Level 3 – tunnel crown, Level 4 – tunnel spring line, Level 5 – tunnel invert, and Level 6 – 3 m below tunnel invert. Strain gauges were installed at 4 sides (i.e. 2 pairs per level) with each pair positioned to be parallel and perpendicular to the tunnel alignment. The strain gauges were spot

welded on 10 mm steel band before being tied up to the designated levels on API pipe. Unfortunately, not all sensors survived the installation process. Inside the API pile is an inclinometer casing that was pre-installed during the grouting process and provide redundancy for pile deflection measurements.

As one of the key instrumentations, the distributed fibre optic sensing based on stimulated Brillouin scattering (SBS), thorough the so-called Brillouin Optical Time Domain Analysis (BOTDA), is a novel technique of measuring strains in a continuous manner which has inherent advantages over the conventional point-based sensors when evaluating the interaction of the forces between the pile-tunnel structures and the soil (Soga et al., 2008). The sensors can be configured and integrated into the pile to measure three-dimensional deformation such as bending and lateral displacement. It provides more precise information about the pile response over the whole pile length. This method has been successfully employed in monitoring the performance of large civil and geotechnical structures such as piles (Ohno et al., 2002, Klar et al, 2006), test piles (Mohamad et al., 2009, Tee et al., 2016; Tee et al., 2017), retaining walls (Mohamad et al., 2011), bridges and tunnels (Mohamad et al., 2010; Mohamad et al., 2012). The measurement principle and details are described in Mohamad et al. (2009).

The fibre optic sensing cable, consists of a single core single mode optical fibre reinforced with six strands of steel wires and polyethylene cable jacket, was fixed along the two opposite sides of the API pipe with a loose or coiled section at the pile tip before it was extended along each side of the pipe as it was lowered into the borehole. In essence, there are two loops (i.e. A1-A2, B1-B2), four equally spaced at a direction perpendicularly (axis $x-x$) and parallel (axis $y-y$) with the tunnel alignment. Another pair of temperature sensing cable (T1-T2) was also installed side by side with A1-A2 cable to measure the temperature changes in order to compensate the differential temperature effect to strain reading if any.

In this field measurement, the variations and fluctuations of temperature in the pile were found to be insignificant throughout the monitoring period. Each optical sensing cable used in the field measurement have been calibrated in laboratory with the strain coefficient obtained to be $20 \mu\epsilon/\text{MHz}$. All fibre optic cables were pretensioned aiming to keep it in a straight line along the main axis $x-x$ and $y-y$ and hence the positions of sensing sections can be identified when reading from the data trace. The baseline measurement used for the interpretation was performed one month (i.e. 9 April 2019) before the TBM reached the target in order to eliminate all the strain induced by the installation process.

On top of the in-pile instrumentation, settlement markers, inclinometers and piezometers were also installed in the ground adjacent to the experimental pile. The building that the tunnel undercrossed was also closely monitored. Hence, the tunnelling-induced effects and pile-soil-structure responses can

be investigated comprehensively. Figure 6 shows the ground and structure instrumentation surrounding the experimental pile. In this paper, only relevant instrumentation data will be presented.

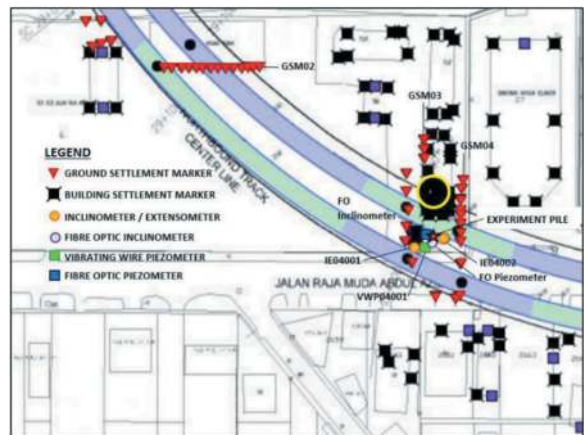

Figure 6. Ground and structure instrumentation.

4 TBM ADVANCE AND ITS DRIVING RECORDS

The installation of the instrumented experimental pile was completed in March 2018 and followed by pile removal work in advance of the passage of the TBMs. Construction activities have been coordinated such that the enabling work does not interfere with the tunnelling activities or in another word, affect the permanent tunnel lining. Consolidation due to piling and ground treatment works was presumed to have completed prior to TBM advance owing to the high permeability of the alluvium sandy soil.

Variable Density (VD) slurry shield machine was selected for excavating the tunnels from HKL Cross-over to Raja Uda Station. The VD tunnel boring machine can be operated in four different tunnelling modes and thus perfectly adapted to different geological conditions. It is a further development of the multi-mode TBM, which combines the advantages of the earth pressure balance (EPB) and slurry supported mix-shield modes. Further details can be referred to Schaub & Duhme (2014). In particular, the TBMs were driven in EPB mode at this tunnelling section.

This study focused on the TBM advance for a distance between approximately $y = -10D$ to $10D$ from the target (i.e. experimental pile) of the south-bound tunnel, where y is the distance between the tunnel face to the experimental pile and normalized by the tunnel diameter (D). Distance where the TBM passed beyond the pile is taken as positive. Figure 6 shows the time-location relation of the TBM while Table 1 listed the recorded tunnel mining and ring build dates for the respective locations. In short, this stretch of tunnel was completed from 3 May 2019 to 16 May 2019. It should be taken note that the TBM stopped for planned cutterhead intervention on

6 May 2019 and 7 May 2019, which was carried out in a grout block as indicated in Figure 7. For the purpose of this paper, the solid lines marked on the subsequent charts indicate the time when the face of the tunnel boring machine first arrived at the particular distance, e.g. solid bold line indicates the tunnel face arrived at the experimental pile location. The excavation at the cutting face, the tail void grouting, and the erection of a new lining ring during standstill are taken into account simultaneously.

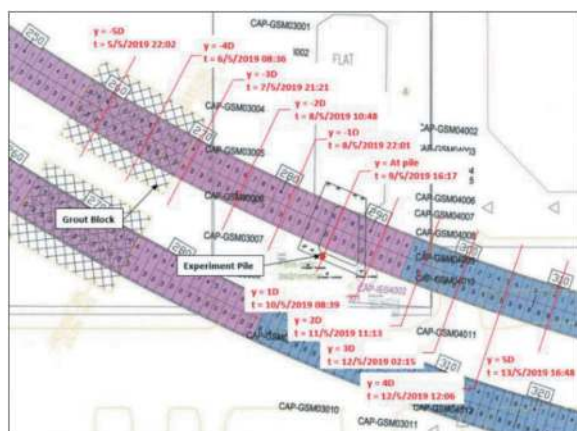

Figure 7. Time-location of the southbound TBM in relation to the experimental pile.

Table 1. Record of tunnel mining and ring build dates.

TBM Location, y	Ring No.	Mining Date	Ring Build Date
-10D	238	3 May 2019	4 May 2019
-5D	260	5 May 2019	6 May 2019
-4D	265	6 May 2019	8 May 2019
-3D	270	7 May 2019	8 May 2019
-2D	276	8 May 2019	9 May 2019
-1D	281	8 May 2019	9 May 2019
At pile	286	9 May 2019	10 May 2019
1D	291	10 May 2019	11 May 2019
2D	296	11 May 2019	12 May 2019
3D	300	12 May 2019	12 May 2019
4D	305	12 May 2019	13 May 2019
5D	310	13 May 2019	14 May 2019
9D	329	15 May 2019	16 May 2019

Generally, a range of face support pressure was provided continuously as the TBM progresses. Figure 8 shows the allocation of the six earth pressure sensors over the cutter head in excavation chamber. Whilst Figures 9(a) and 9(b) shows the recorded individual point pressures and averaged pressure respectively. It is observed that a higher face pressure was applied ahead of the experimental pile. The face pressure was gradually increased from 2 bar (at -3D distance away) to maximum 2.6 bar as the TBM cutterhead reached the experimental pile location and eventually decreased to the normal face pressure at 1D distance away.

Figure 8. Allocation of TBM face support pressure sensors.

(a) Individual point pressure

(b) Averaged pressure

Figure 9. Recorded excavation chamber pressures (a) individual point pressure (b) averaged pressure.

From the Instrumentation Data Management System, the normal range of advance speed was 20 – 50 mm/min with an average of 34.5 mm/min for this length of bored section. Advance thrust forces and advance group pressures were fluctuated between approximate 10 – 17 MN and 50 – 150 bar respectively. The grouting pressure at the grout ports remains relatively constant throughout the tunnel drive with averaged pressures around 30.5 bar. In this paper, the pile lateral response is evaluated with respect to the TBM face pressures only.

5 MEASUREMENT RESULTS AND DISCUSSION

5.1 Pile axial strains

All signal responses from the fibre optic sensors were analysed and compared with the readings obtained

from the common method of instrumentation such as VWSG and inclinometer. An overview of the measured axial strain profiles is presented in Figure 10 with reference to the nearest borehole ABH-08 which was sunk at experimental pile location. The strain profiles were processed by averaging the data from four sets of optical cables (see Figure 5) and presented in terms of the date of measurement (daily average) during the TBM advance.

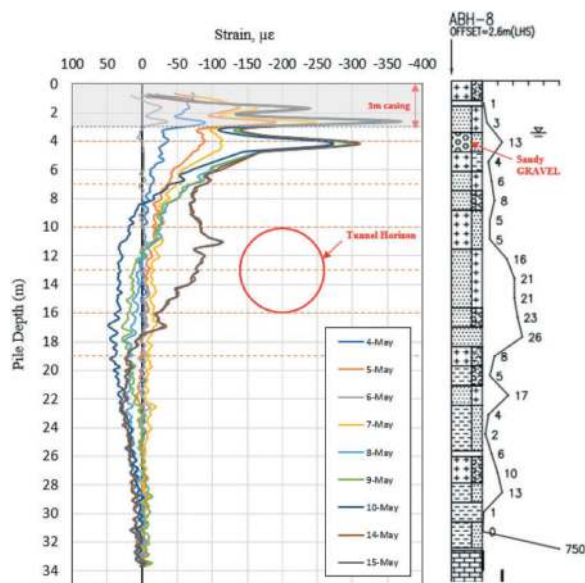

Figure 10. Axial strain profiles measured by fibre optic sensing.

As mentioned earlier, a temporary steel casing was left-in until 3 m below ground level. The cross-sectional area of the pile should be consistent within this area. However, localized strains spike can be observed, and the causes cannot be determined with certainty. It could be possibly due to the laitance that was not being able to be flushed out before the standard length of casing was cut down to 3 m. Localized higher strains have also been observed at approximately 3 m to 5 m deep from the pile top level. This is the depth just below the temporary casing where sandy gravel materials were detected in borehole ABH-08 sunk at the experimental pile location, see Figure 10. Highly possible that some of the soil from this granular layer may had collapsed into the bored hole and contaminated the grout during withdrawal process of the temporary casing. Consequently, integrity of the grout was compromised which directly lower its Young's modulus and contributed to relatively higher strain. Mohamad et al. (2016) demonstrated that typical defects of bored cast-in-situ piles can be identified from distributed strain measurement.

Figure 11 exhibits the transient behaviour of strain profiles in comparison with the VWSG data for four measurement dates which are corresponding to the critical period of TBM advance; (i) Pre-

loading stage (-3D/7 May 2019), (ii) Arrival of TBM face (At pile/9 May 2019), (iii) Passing of TBM shield (1D/10 May 2019), and (iv) TBM passed beyond the experimental pile (>5D/14 May 2019). Compressive strain is taken as negative while tensile stress as positive. Excellent agreement between the fibre optic sensors and VWSG measurements on all measurement dates.

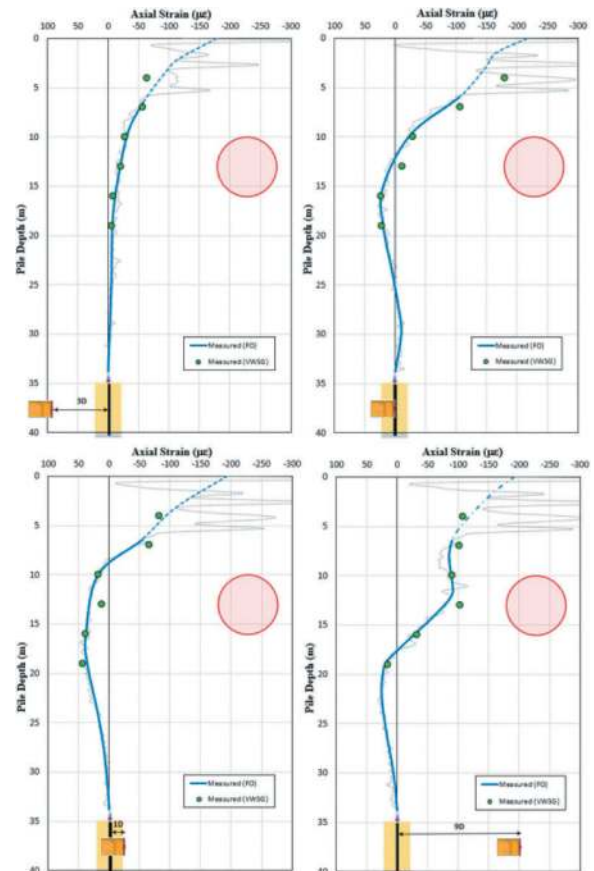

Figure 11. Transient axial strain responses of the experimental pile at different stages of tunnel advance (a) pre-loading stage, $y=-3D$; (b) arrival of TBM face, $y=at$ pile; (c) passing of TBM shield, $y=1D$; (d) TBM passed beyond the experimental pile, $y=>5D$.

It can be seen that axial strains in the experimental pile have responded as the TBM approaching. When the TBM arrived at the pile location on 9 May 2019, tensile strains were started to be detected at pile depth between 12 m and 25 m whereas the upper part of pile was in higher compressive strain. The tensile strain became more apparent and continued to rise above the tunnel axis level as TBM was passing the pile. The tensile strain profile was observed extending upward above the tunnel spring line and reached a maximum value of about 50 microstrains once the TBM (excavation face) had passed beyond the experiment pile. When the TBM shield has been driven completely passed the pile ($y > 2D$) and the tunnel linings have been erected, the tensile strains within the tunnel horizon

were reverted to compressive strains. The compressive strains increase to a maximum just above the tunnel axis level and stabilised on 14 May 2019 (TBM at $y > 5D$). The redeveloped compressive strains were higher than the values registered during the pre-loading stage is a clear evident of dowdrag (negative skin friction) occurred due to tunnelling-induced ground settlement. The measured strain reached a residual value with the lower portion of the pile, i.e. from 2 m below tunnel invert level remain in tensile state.

All in all, the distributed fibre optic data are better in describing the complete behaviour of the pile as compared to the discrete data of VWSG (Hisham et al., 2023). In this case, the experimental pile had undergone various tension and compressive loadings due to the interacting tunnelling effects.

5.2 Pile lateral deflection

The optical fibre strain data can be converted to relative displacement by looking at the curvature changes between two opposite fibres placed symmetrically with respect to the referenced axis. By integrating the curvature once, the inclination/gradient, j of the pile can be calculated; and by integrating it twice, the lateral displacement, u of the pile is obtained as per equations below.

$$j(z) = \int \kappa dz + A \quad (1)$$

$$u(z) = \int j dz + B \quad (2)$$

In specific, the lateral displacement of the pile is subjected to prescribed displacement at one end and fixed on the other end. For this rock-socketed pile, the tip is taken as reference datum with the zero horizontal and rotational movements and hence the constants A and B were set as zero. Similarly, the computation of pile displacement at any section is not affected by the uncompensated temperature.

Figure 12 shows the interpreted lateral displacement of the pile in two directions. Axis A +ve denotes away from tunnel in transverse direction while Axis B +ve denotes from tunnel face in longitudinal direction. It can be seen that the pile was generally being pushed outward both in transverse and longitudinal directions when the TBM approaching the experimental pile. Once the TBM face had passed the pile, the lateral deflection at tunnel level immediately moved back toward the tunnel as the distance increases before it was released again as shown by the measurements dated 14 May 2019 where TBM at $y > 5D$. Figure 13 provides a closer view of time-based pile movement path at the six measurement depths.

Further study was also carried out to appraise the ground lateral movements measured from inclinometer IE04002 positioned 1.5 m away from the tunnel extrados. Figure 14 illustrates the measurements

Figure 12. Interpreted pile lateral displacements at different stages of tunnel advance.

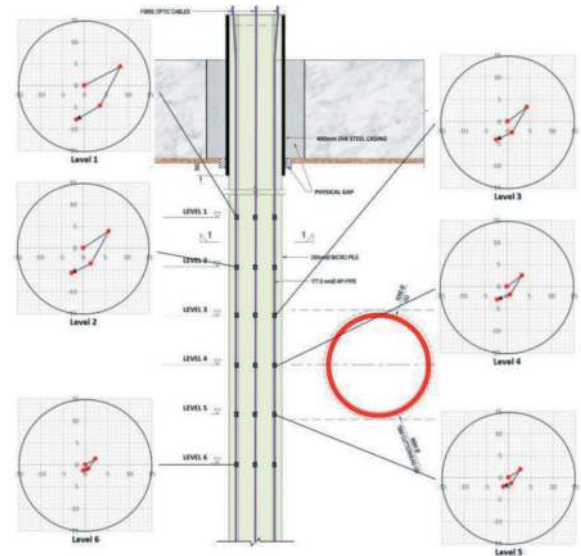

Figure 13. Time-based pile lateral displacements at different depths.

taken between 5 May 2019 and 15 May 2019 with its Axis A-A in transverse direction and Axis B-B in longitudinal direction of the tunnel alignment. Noticeably, the ground has generally moved inward both in transverse and longitudinal directions when TBM approaching the inclinometer location. In contrast, the ground movements reversed outward and being pushed away when TBM arrived at the inclinometer on 9 May 2019. Upon passing of the TBM face, the lateral deflections rebound back with a concave profile observed at the tunnel horizon. This was suspected because of the gaps between the shield and the surrounding ground, including cutter head overcut, conical or telescopic-shaped shield and the tail void. The deflection remained constant for the most part of the monitored period after TBM passed the inclinometer. The data, coupled with the in-pile instrumentation monitoring results, has demonstrated the time-dependent transient behaviour of

Figure 14. IE4002 inclinometer readings.

pile-soil lateral movements induced by the tunnelling operation.

5.3 Main findings and discussion

These emerged observations are in line with the hypothesis of pile movement paths made by Loganathan (2016) for negative face loss case. According to him, when a TBM face pressure is greater than the mobilised earth pressure at the face, the ground, and hence the pile, is pushed away from the TBM face, thereby inducing heave at the surface and sub-surface ground movement away from the TBM face. This was evidenced from the measured ground surface heaving as depicted in Figure 15. On the other hand, the measurement of building settlement, as shown in Figure 16, further verified the observations. See Figure 6 for the locations of the instrumentation.

Figure 15. Ground settlements.

When the TBM has passed, a positive shield and tail loss occurs (closing of the physical gap), meaning the ground will move toward the tunnel and followed by dissipation of pore pressure generated due to tunneling, resulting in subsequent ground settlement. It should also be noted that, in some cases, shield pressure and back grouting pressure can be as

Figure 16. Building settlements.

high as face pressure and piles may not move towards the tunnel.

6 CONCLUSIONS

This paper focuses on the transient effect of pile lateral movements due to TBM advance in a research study. It presented the setup of the experiment pile, instrumentation regime, field monitoring during tunnel advance, interpretation of measurement results and discussion.

Measurement of tunnelling-induced pile lateral movements was successfully demonstrated by using distributed fibre optic sensors via BOTDA and cross-validated with vibrating wire strain gauges and inclinometer. The strain measurements obtained from the fibre optic showed excellent agreement with that derived from VWSG. The in-pile instrumentation data, coupled with inclinometer IE04002 positioned at 1.5m away from tunnel extrados, has revealed the time-dependent transient behaviour of pile lateral movements induced by tunnelling operation.

Based on the tunnel drive and TBM operating parameters described above, the findings supported the hypothesis of pile movement path for negative face loss case as made by Loganathan (2016). It is of great interest for this research study to investigate the transient pile responses to advancing tunnel. It is believed that, if this approach of negative face loss can be adopted at the site coupled with appropriate face pressure control for a safe tunnelling operation, it will bring significance benefits to the tunnelling project by the way of realistic engineering and risk assessment.

ABSTRACT: It has been recently reported that ground heaves threatened the stability of road tunnels and the safety of road users during the maintenance stage. Constructing additional invert is effective to reinforce the tunnels, however it would require a lot of time and cost to excavate the bottom of the tunnels using a small machinery if a part of the lanes could be open to the traffic. The purpose of this research is to propose new invert structure that enable to reduce the volume of the excavation. Model experiments were conducted to compare the load-bearing performances between the standard and the 3 newly proposed inverts, for example, the shape of which was flat. As a result, the maximum loads of the proposed inverts, which could reduce the volume of the excavation 30-50%, were slightly over 50% of that of the standard one. It was also found that the failure processes of the 4 test cases were different, therefore they were evaluated in terms of not only the maximum loads but also the capabilities to restrain the ground heave and to transfer bending moment and axial force by analysing the measured deformations and strains of the tunnel models.

Keywords: Ground heave, Reinforcement, Shape

1 INTRODUCTION

Invert is considered as an important support structure to ensure the stability of a tunnel by restraining the ground deformation. Therefore, nowadays, it has been advised to construct it in the area with poor geological conditions during the construction stage in Japan. Table 1 shows the standard combination of support members for a tunnel with standard cross-sectional width, approximately 8.5-12.5m, shown in the technical standard of road tunnel and its interpretation -Part of tunnel structure- (2003). Even though rock class is categorized as CI or CII, namely hard rock, it would be advised to construct invert if rock type is mudstone from the Tertiary, tuff, serpentine and so on. Figure 1 shows an example of support pattern DI of a road tunnel chosen in the area with relatively poor geological conditions. The thickness of the invert would be between 40 and 50cm. The ratio of the

radius of the invert to that of the lining is between 2 and 3.

Recently, it has been reported that ground heave occurred in road tunnels during the maintenance stage, resulting in cracks of road pavements and so on as shown in Figure 2. It could threaten the stability of road tunnels and the safety of road users. Such ground heave was more likely to occur in the part of tunnels where invert was not constructed during the construction stage. Constructing additional invert is effective to reinforce such tunnels. On the other hand, it requires a lot of time and cost to excavate the bottom of a tunnel using a small machinery while a part of the lanes is open to the traffic. This would cause the long period of traffic control, leading the inconvenience for road users. The purpose of our research is to propose new invert in terms of its shape, used materials and so on which enable us to reduce the volume of excavation. In this paper, we report the results of 4 model experiments, where the load-bearing performances of

3 newly proposed inverts were compared with that of the standard one.

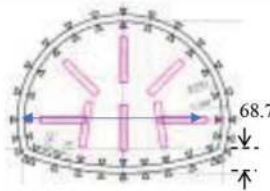

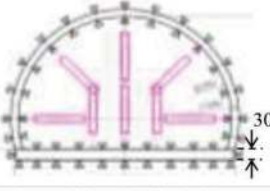

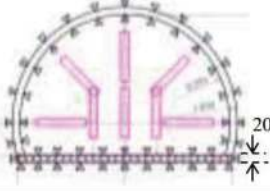

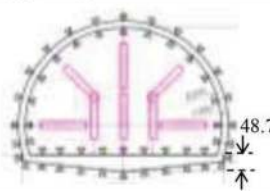

2 MODEL EXPERIMENTS AND TEST CASES

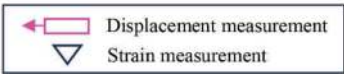

The authors have conducted model experiments where the ground was modelled by steel bars to understand the influence of the shape of invert on its load-bearing performance as reported by Nakazato et al (2022). The widths of the tunnel models in the experiments were approximately 80mm, so we analysed the deformation modes of a series of test cases, but could not analyse them in details. Therefore, in this experiment, we used two-dimensional loading apparatus owned by Public Work Research Institute to load tunnel models, the diameters of which were 600mm as shown in Figure 3. The tunnel models were made of mortar. The thicknesses of their linings were 20mm and the inner diameters R_1 were 280mm. It can be said that the sizes of the models are scale to about 1/20 of an actual road tunnel.

The descriptions of the 4 test cases are shown in Table 2. Case 1 represented the standard invert typically used to reinforce existing tunnels in Japan. Case 2-4 represented newly proposed inverts in this research. We discussed new invert structure which enable to reduce the volume of the excavation in constructing additional invert. Their features were, in short, flat & thick, flat & reinforced and pentagon in the order of Case 2-4. The ratios of excavation volume, R_{ex} were calculated by obtaining the areas below the floor lines of Case 2-4 and comparing them to that of Case 1. As a result, R_{ex} of Case 3 was only 40%. The depth of the pentagonal invert of Case 4 was determined as 48.7mm so that its R_{ex} could be smaller than 70%.

In the experiments, the tunnel model was located in the apparatus as shown in Figure 3, then the outer space of the models was filled with dry sand so that the dry density of the sand was 1.47g/cm^3 . The

Case	Name • R_{ex}	Descriptions of models and locations of measurements
1	Standard • 100%	 <p>The radius of invert is 2.7 times larger than that of arch.</p>
2	Flat & thick • 59.5%	 <p>The shape of invert is flat. It is 30mm thick and is 1.5 times thicker than the standard.</p>
3	Flat & reinforced • 39.7%	 <p>The shape of invert is flat. It is reinforced with copper pipes ($\phi 9.5$, $t 0.8$, @50mm)</p>
4	Pentagon • 68.1%	 <p>The lower shape is triangular and the upper shape is flat, considering concrete placement.</p>

Displacement measurement
 Strain measurement

bottom side of the apparatus was loaded by 3 hydraulic jacks. As the displacement increased by 1mm, the loads, displacements and strains were measured. Furthermore, deformations such as cracks on the inner side of the tunnel model were observed through a small window in the cover of the apparatus.

From the uni-axial compression tests using cylindrical specimen of mortar, it was found that the average compressive strength was 22.7N/mm^2 , the average Young's modulus was 15.62kN/mm^2 and the average Poisson's ratio was 0.195.

3 LOAD-BEARING PERFORMANCE AND FAILURE PROCESS OF STANDARD AND PROPOSED INVERTS

3.1 Relationships between load and displacement

Figure 4 shows the relationships between the sum of loads of the 3 hydraulic jacks and the average displacement of the 3 hydraulic jacks of Case 1-4. It is obvious that Case 1 showed the highest peak load among the 4 cases. In Case 2 and Case 3, the loads decreased once, as for example, the displacement of Case 2 was approximately 24mm, and then they increased again. Figure 5 shows the relationships between the upward displacements of the inner sides of the tunnel models and the average displacement of the 3 hydraulic jacks. It was clear that the trends of Case 2 and 3 were different from those of Case 1 and 4; the displacements of the inner sides of Case 2 and 3 increased rapidly, for example, after the jack displacement of Case 2 was 16mm.

It seemed that Case 1-4 showed the different deformation modes and the failure processes. Thus, the load-bearing performances of Case 1-4 were evaluated in the consideration of the deformation modes and failure processes in the following sections.

3.2 Failure process of case 1 (standard)

Based on the analysis of the transition of the displacements and strains of Case 1, its failure process

Figure 4. Relationships between load and displacement of case 1-4.

Figure 5. Relationships between displacement of inner surface of model and jack displacement of case 1-4.

Figure 6. Relationships between load and displacement of case 1.

Figure 7. Deformed tunnel model of case 1.

was divided into 3 stages. Figure 6 shows the relationship between the load and displacement, and the division of the 3 stages. Figure 7 shows the deformed tunnel model at the end of the experiment. Table 3 shows the representative distributions of the displacements and strains of the tunnel model at each stage.

Table 3. Representative distributions of displacements and strains of case 1 at stage 1-3.

Stage	1	2	3
Sum of loads (kN)	11.8	156.9	470.4
Ave. jack displacement (mm)	4.3	18.8	31.8
Displacement of model (mm)			
Strain of model (μ)			

At stage 1, the first crack was observed on the inner side at the centre of the invert (270°). At this stage, the strains of the invert were tensile inside and compressive outside, indicating that the strains of the invert were mainly caused by bending moment.

At stage 2, cracks were also observed on the inner side between the centre and the corner of the invert ($330^\circ, 220^\circ$) as well as of the roof (90°).

At stage 3, as the compressive strains increased on the outer side of the invert and inner side of the arch, the brittle destruction occurred in the end. The compressive strain at the right part of the invert (330°) was approximately 3500μ just before the destruction occurred. Therefore, it was thought that the shear destruction occurred due to the excessive axial compression.

On another note, the compressive strains at the arch of lining were approximately $2,000 \mu$ just before the destruction occurred. If a piece of lining fell from the arch, it would severely threaten the safety of road users. Thus, it can be said that the results of the measurement here indicate the importance that not only the road pavement but also the arch and the roof have to be inspected carefully in the tunnel where ground heave is observed.

3.3 Failure process of case 2 (flat and thick)

Based on the analysis of the transition of the displacements and strains of Case 2, its failure process was divided into 3 stages. Figure 8 shows the relationship between the load and displacement, and the division of the 3 stages. Figure 9 shows the deformed tunnel model at the end of the experiment. Table 4 shows the representative distributions of the displacements and strains of the tunnel model at each stage.

At stage 1, the first crack was observed on the inner surface at the centre of the invert (270°). Hereafter, the strains of both the inner and outer sides of the invert did not increase as shown in Table 4. It was thought that this meant that the invert of Case 2 became unable to transfer both the axial force and the bending moment after the first crack occurred.

At stage 2, the width of the first crack mentioned above continued to increase, and another crack was

also observed on the inner side of the roof as the ground heave increased. From Figure 5 shown in 3.1, the ground heave increased rapidly after the jack displacement was 16mm. This indicated the change of the deformation mode of Case 2, thus it was defined as stage 3 hereafter.

At stage 3, the invert bended notably at its centre. The load decreased once when the jack displacement

Table 4. Representative distributions of displacements and strains of case 2 at stage 1-3.

Stage	1	2	3	Reference
Sum of loads (kN)	11.8	82.8	156.9	157.6
Ave. jack disp. (mm)	4.3	14.7	19.9	30.2
Disp. of model (mm)				
Strain of model (μ)				

Table 5. Representative distributions of displacements and strains of case 3 at stage 1-3.

was 24mm, then it increased slowly as shown in Figure 8. It was thought that the load-bearing performance of the tunnel model reduced at this time, then the load was distributed to the ground around the tunnel model. Therefore, the load-bearing performance of Case 2 was regarded as the peak of solid line shown in Figure 8.

3.4 Failure process of case 3 (Flat and reinforced)

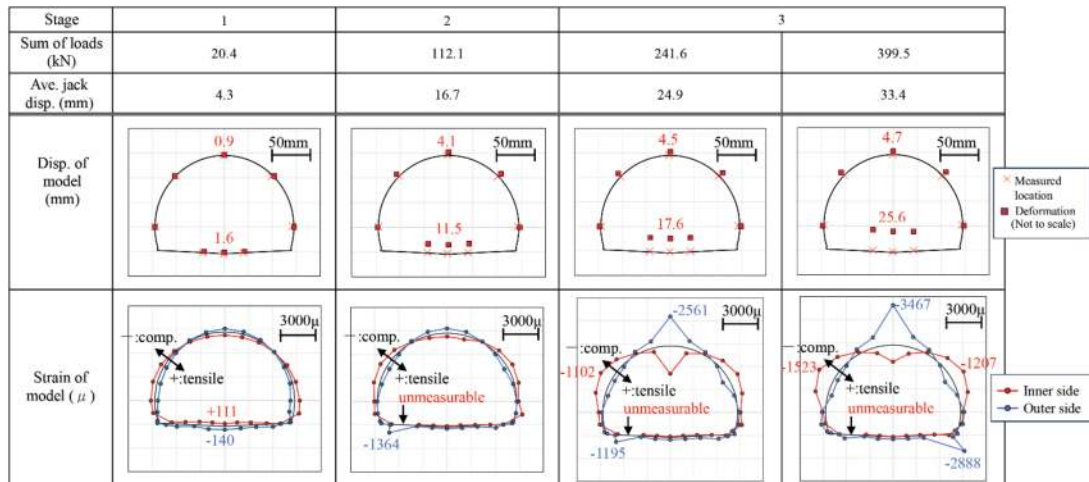

Based on the analysis of the transition of the displacements and strains of Case 3, its failure process was divided into 3 stages. Figure 10 shows the relationship between the load and displacement, and the division of the 3 stages. Figure 11 shows the deformed tunnel model at the end of the experiment. Table 5 shows the representative distributions of the

displacements and strains of the tunnel model at each stage.

At stage 1, the first crack was observed on the inner side of the left part of the invert (235°) although it was assumed that the first crack would occur at the centre of the invert. The tunnel model of Case 3 was reinforced with copper pipes, and the cover of mortar was not completely the same at every location. In this way, the first crack occurred slightly far from the centre of the invert probably because the accuracy of modelling.

At stage 2, as another crack was observed on the inner side of the roof of the model, a lot of thin cracks occurred widely at the invert. Similarly to Case 2, the ground heave of Case 3 increased rapidly after the jack displacement was 23mm, which was defined as stage 3.

Table 6. Representative distributions of displacements and strains of case 4 at stage 1-3.

At stage 3, the load increased, and then it became almost stable. It was thought that the load-bearing performance of the tunnel model reduced at this time, following the load was distributed to the ground around the tunnel model, similarly to Case 2. Therefore, the load-bearing performance of Case 3 was regarded as the peak of solid line shown in Figure 10.

The invert as well as the reinforcement pipes were bended at the end of the experiment. The failure process of Case 3 was similar to Case 2, the shape of which was also flat. On the other hand, the stage 2 of Case 3, where the ground heave was relatively restrained, lasted longer than that of Case 2. The strains of both the inner and outer sides of the invert increased at stage 2 and 3, following the model was able to transfer both the axial force and the bending moment to a certain degree. These differences were caused by the effect of the reinforcement of Case 3.

3.5 Failure process of Case 4 (Pentagon)

Based on the analysis of the transition of the displacements and strains of Case 4, its failure process was divided into 3 stages. Figure 12 shows the relationship between the load and displacement, and the division of the 3 stages. Figure 13 shows the deformed tunnel

Figure 12. Relationships between load and displacement of Case 4.

Figure 13. Deformed tunnel model of Case 4.

model at the end of the experiment. Table 6 shows the representative distributions of the displacements and strains of the tunnel model at each stage.

At stage 1, the first crack was observed on the inner side of the right part of the invert (335°).

At stage 2, another cracks were observed on the inner sides of the left part of the invert (205°) and the roof (90°).

At stage 3, as the compressive strains on the outer side of the roof and on the inner side of the arch increased, the brittle destruction occurred in the end. At this time, dry sand flowed into the model through the crack at the left part of the invert (205°), but the right part (335°) was also destroyed. As the compressive strain on the outer side at the right part of the invert was approximately 3000 μ just before the destruction occurred. Thus, it was thought that the shear destruction occurred due to the excessive axial compression, similarly to Case 1.

Unlike Case 1-3, a crack did not occur at the centre of the invert in Case 4. Cracks occurred between the centre and the corner of the invert, which resulted in the destruction in the end. This was because the centre of the invert of Case 4 was so thick that the cross-sectional bearing capacity here was large. In addition to it, as the shape of the invert was down to convex, the location of the maximum bending moment was thought to be shifted from the centre of the invert. When it came to brittle destruction, Case 4 was similar to Case 1. However, differences between Case 1 and 4 were also found, for example, strains of Case 4 were relatively small at stage 2 and 3.

3.6 Comprehensive evaluation of test cases

The failure processes as well as the deformation modes of Case 1-4 were examined in the previous sections. Figure 14 shows the maximum load of Case 1-4. As the maximum load of Case 1 was expressed as a standard (100%), that of Case 2 was only 25% and those of Case 3 and 4 were slightly over 50%. Furthermore, Table 7 shows the ratio of the maximum load, R_1 , the ratio of the volume of excavation, R_{ex} and the R_1/R_{ex} . If R_1/R_{ex} was smaller than 1, it was thought that the disadvantage of the smaller load-bearing performance would predominate the advantage of the smaller volume of the excavation, which was not effective. Among Case 2-4, only the R_1/R_{ex} of Case 3 was higher than 1, and that of Case 2 was the lowest 0.42.

In order to conclude the model experiments, each of the newly proposed invert here, Case 2-4 would be evaluated hereafter. Firstly, the maximum load and the R_1/R_{ex} of Case 2 were the lowest. Furthermore, considering that it became unable to restrain the ground heave and to transfer the bending moment and the axial force after stage 2, the proposed invert of Case 2 would be difficult to put into practice.

The R_1 of Case 3 and Case 4 were slightly over 50%. However, as they enable to reduce the volume of the excavation, it would be possibly put into practice in the situation where the potential risk of the ground heave would be relatively low, but the factor of safety against it would need to be improved. The R_1/R_{ex} of Case 3 was higher than that of Case 4. However, the reinforcement would of course

Figure 14. Maximum load of case 1-4.

Table 7. Ratio of maximum load and excavation volume of case 1-4.

Case	Max. load (kN)	Ratio of max. load, R_1 (%)	Ratio of excavation volume, R_{ex} (%)	R_1/R_{ex}
1	776.0	100.0	100	1.00
2	196.2	25.3	59.5	0.42
3	398.5	51.4	39.7	1.29
4	418.9	54.0	68.1	0.79

influence the cost and the schedule of the construction work, therefore further investigations would be needed. In addition, copper pipes were located in the centre of the cross section of the invert in this experiment, but such reinforcement structure including its shape and location would need to be considered. Uniquely in Case 4, any crack did not occur at the centre of the invert unlike the other cases, which would need to be investigated by simulating the model experiments by numerical analysis in the future study.

4 CONCLUSIONS

We are developing invert structure which enable to reduce the volume of the excavation in constructing it additionally during the maintenance stage. In this research, the 4 model experiments were conducted to compare the load-bearing performances of the newly proposed invert with that of the standard one, Case 1. Based on the analysis of the measured loads, displacements and strains, the failure process of each case was examined by dividing it into mostly 3 stages. Then the feasibilities of the proposed inverts

were examined, paying attention to the maximum load, the reduced volume of the excavation and capabilities to restrain the ground heave and to transfer the bending moment and the axial force.

Case 2 (shape: flat, thickness: 30mm): Its maximum load was only 25% of that of Case 1. Huge floor heave occurred as the invert bended at the crack at the centre of the invert caused by the bending moment.

Case 3 (shape: flat, reinforced with copper pipes): Its maximum load was approximately 51% of that of Case 1. It could reduce the volume of the excavation the most. With the effect of the reinforcement, a lot of thin cracks occurred at the invert but it restrained the ground heave without losing the capability to transfer the bending moment and the axial force in the meanwhile. It must be noted that the floor heave occurred before the invert was destroyed.

Case 4 (shape: pentagon): Its maximum load was approximately 54% of that of Case 1. A crack did not occur at the centre of the invert unlike the other cases. The brittle destruction occurred between the centre and the corner of the invert.

In conclusion, it was found that the maximum loads of the newly proposed inverts were lower than that of the standard one. However, it was advantageous that they enable to reduce the volume of the excavation. Furthermore, the newly proposed inverts could be applied to the area with relatively poor geological conditions where invert would be possibly needed in the construction stage. As the cost of constructing newly proposed inverts would be lower than that of standard one, road administrator could reasonably use them from the viewpoint of preventative maintenance.

We continue to research on the reasonable invert structure and the situations where they could be put into practice. In addition to it, the correspondence between the load in the model experiment shown in this paper and the actual ground heave would need to be further analysed to design invert properly.

A noncontact mobil system using camera module for tunnel inspection

Chulhee Lee*, Donggyou Kim & Dongku Kim

Department of Geotechnical Engineering Research, Korea Institute of Civil Engineering and Building Technology (KICT), Gyeonggi-Do, Republic of Korea

ABSTRACT: In the field of tunnel maintenance, computer vision-based noncontact mobile tunnel inspection systems are being developed and used to replace the traditional manpower-based inspections. However, there are existing technical issues regarding its effectiveness mainly due to traffic control caused by the slow inspection speed and motion blur within inconsistent image quality during the high-speed shooting in dark conditions. To efficiently shoot cracks and leaks in tunnel lining walls, it is necessary to optimize the components and requirements for the camera module, which is the core device of the computer vision-based tunnel inspection system. In this study, therefore, the issues and the relevant improvements are defined through indoor shooting tests obtained with area image sensor and light source according to shooting speed. This study developed a high-speed translational rotating panel device capable of simulating driving speeds up to 70 km/h. The device was equipped with a test chart to evaluate image quality. IMATEST® software, one of the reduced reference image quality assessment (RR-IQA) methods, was used to estimate quantitative values for motion blur. The relationship between the exposure speed of the camera and the lighting illuminance was analyzed, and correlations were analyzed to evaluate the optimal image quality. With a higher the camera shutter speed, the darker the image; to compensate for this point, there is a method of increasing the international organization for standardization (ISO) sensitivity of the camera or the lighting illuminance. The results indicate a relationship in which faster exposures darken the image but increase sharpness. In this study, at a shutter speed of 100 us (microsecond), the illuminance of 40,000lux, ISO of 1600, and the F value of 2.8, approximately 120% of motion blur occurred at 70 km/h than at the pause status, and it was difficult to obtain high-quality images through the exposure performance of the camera. Therefore, future studies need to focus on reducing the percentage of motion blur to less than 50% by using fast shutter speed and high luminance lighting.

Keywords: Mobile tunnel inspection, Area image sensor, Light source, Motion blur, MTF (modulation transfer function)

1 INTRODUCTION

Civil engineering structures are designed to be durable for their designated lifetime; however, most tunnels require regular inspections and maintenance to extend their service life. Visual inspection of tunnels has been conducted by human inspectors, and it is generally carried out at night along with high safety risk conditions (Panella et al., 2020). Proposals such as lowering risks to which inspectors are exposed in tunnels, reducing the site inspection time for collecting data, lowering repetitive and labor-intensive work costs, and reducing the time required for simple work by highly skilled inspectors have been increasingly put forward (Attard et al., 2018). In response, there has been continuous research on the development of

computer vision-based noncontact mobile systems for more efficient inspection and subsequent maintenance. Especially, computer-vision technologies continuously developed over the last few years have been used to detect damage such as cracks and leaks in tunnels from video images (Huang et al., 2021).

In Korea, three area scan camera-based tunnel scanning systems (KMTL, MTEC, and Deep inspection) have been developed through national R&D to inspect tunnels. They can capture images at a maximum driving speed of 50 km/h, and have software for detecting cracks and damage via deep learning (Lee and Kim, 2023). Camera-based tunnel scanning systems in Japan have been continuously developed since approximately 20 years ago. In 1996, Ukai et al. (1996) first developed a railway

*Corresponding author: lch@kict.re.kr

tunnel scanning system using a line scan camera. Currently, six systems have been registered and used in the New Technology Information System (NETIS) of Japan. The systems that use line scan cameras are MIMM-R, Tunnel tracer, and GT-8K; and the systems that use area scan cameras are MMSD II, TC-3, and eQ Doctor T (NETIS, 2023). The Japanese tunnel scanning system is equipped with cameras and LiDAR to analyze the shape and displacement of the tunnel lining through point clouds. In China, there are tunnel fast detection system (TFS) developed by Wuhan ZOYON company using an area scan camera (Gong et al., 2019), and TDV-H2000 developed by Shanghai TJGEO technology company (Ynag et al., 2018). In addition, Zhejiang Scientific Research Institute of Transport developed the Tunnel Image Fast Acquisition System, which detects cracks of width 0.2 mm from captured images. However, approximately 10% of the errors occur when the crack width is less than 0.3 mm owing to the influences from image processing and pixels, requiring improvements to curb these errors (Wang et al., 2022).

Motion blur is likely to occur in images captured under high speed. It is common in images taken using mobile devices and is caused by camera and subject movements, or a combination of these motions (Abdullah-Al-Mamun et al., 2021). Motion blur is contrasted with sharpness as an important factor to evaluate the quality of images. However, image quality defects such as motion blur have not been considered in previously developed tunnel scanning systems. Image quality is assessed only by subjective (qualitative) evaluation in the human cognitive realm from the video image of the crack width. Quality images are a requirement for high-accuracy damage detection of tunnel lining through deep-learning based on video images; studies on this approach are ongoing. Deep-learning performance depends on the quality of images; it is more important to develop data-quality oriented AI models rather than the AI model development specialized in deep-learning algorithms to meet the high accuracy and precision required for maintenance.

Digital images in image processing systems, such as camera-based tunnel scanning systems, can be degraded at any stage of their life cycles such as image creation, compression, storage, and transmission, resulting in the loss of visual information (Choi et al., 2021). As a result, reliable quality assessment indicators for digital images are required to select high-quality images. Although human subjective image evaluation is reliable, it requires a great amount of time and effort to apply (Dey et al., 2022). Consequently, an objective image quality assessment (IQA) is necessary as it sophisticatedly reflects the image quality perception feature of the human visual system (HSV) (Bae and Kim, 2015). IQA helps objective image quality evaluation by scoring the quality of images. In general, the IQA method can be divided into full reference IQA (FR-IQA), reduced reference IQA (RR-IQA), and No Reference IQA (NR-IQA), depending on the dependence on

reference images for quality evaluation (Wang et al., 2004). FR-IQA is a method of measuring image quality by using original images without damage and images with damage. RR-IQA evaluates quality using information that is combined from the damaged images and other damaged images from additional pathways. NR-IQA is a method for assigning a quality score to an image based on only the damaged images without information from reference images (Moorthy and Bovik, 2011).

The required performance of a camera-based tunnel scanning device depends on the driving speed limit per road; the maximum speed of freight vehicles on Korean highways is 80 km/h. Furthermore, a high image resolution of 0.3 mm/pixel or less is required to detect cracks with a width of 0.3mm or less in terms of maintenance. According to such demands, this study aims to develop a tunnel scanning system that can obtain video images of 0.3 mm/pixel at a maximum driving speed of 80 km/h. The recently developed camera-based tunnel scanning systems are used to capture images in tunnels at a completed or prototype stage, and their performance is analyzed. The crucial device in the tunnel scanning system is the camera and lighting, and huge costs are required to re-design and re-develop a device once selected. Consequently, if the performance of cameras and indoor lighting using a device that can simulate driving speeds is tested, it would be possible to reduce trials and errors in the development process.

This study developed a high-speed translational rotating panel device capable of simulating driving speeds up to 80 km/h. The device was equipped with a test chart to evaluate image quality. IMATEST® software, one of the RR-IQA methods, was used to estimate quantitative values for motion blur. The relationship between the exposure speed of the camera and the lighting illuminance was analyzed, and correlations were analyzed to evaluate the optimal image quality.

2 SETUP

2.1 Proposed approach

The quality of video images can be generally evaluated by pixel-based metrics such as root mean square error, peak signal-to-noise ratio, or structural similarity index (SSIM). However, these metrics have the disadvantages of first requiring original video images and being poorly correlated with the motion blur level. As for camera systems, modulation transfer function (MTF) is a well-established measure of sharpness (Dinh et al., 2023). Sharpness can be measured by the rise distance of the edges within images. With this technique, sharpness can be determined by the distance of a pixel level between 10% to 90% of its final value. Rise distance is measured in the frequency area, where the frequency is measured in cycles or line pairs per distance

(millimeters, inches, pixels, image height, or sometimes angle [degrees or milliradians]). The relative contrast at a given spatial frequency (output vs. input) is called MTF, which is used interchangeably as spatial frequency response in IMATEST® software. The most common method is to derive MTF from the tilted edge of a standardized test chart. Figure 1 shows the rise distance, and the sharpness of the edge for deriving MTF when motion blur occurs by using IMATEST® (IMATEST, 2023).

2.2 Experimental setup

A high-speed translational rotating panel device was designed, as shown in Figure 2, to analyze the performance of cameras and lighting devices through motion blur, which is the image quality, by simulating high driving speed. The maximum rotation speed is 100 km/h, and the speed is adjustable in units of 10 km/h. An

eSFR ISO test chart of IMATEST® was attached to the panel to measure MTF. A daylight-colored light-emitting diode floodlighting with a color temperature of 5600 K was placed at a 45° angle in front of the test chart. The used machine vision area scan camera was CMOS image sensor with a resolution of 4096 x 2304. The minimum exposure was 5 μs, and a global shutter was used. The shooting distance was 2 m, and the image resolution was set to 0.2 mm/Pixel.

3 EXPERIMENTAL RESULTS

3.1 Test condition

In a conventional single-exposure photograph, moving objects or moving cameras cause motion blur. The exposure time defines a temporal box filter that smears the moving object across the image by convolution

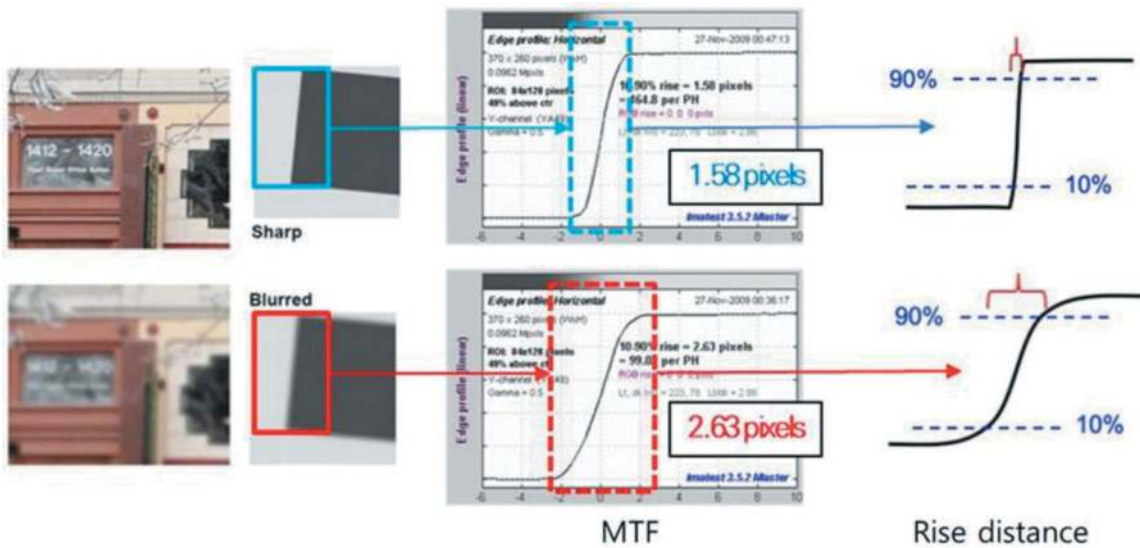

Figure 1. MTF and rise distance graph between sharpness and motion blur (IMATEST, 2023).

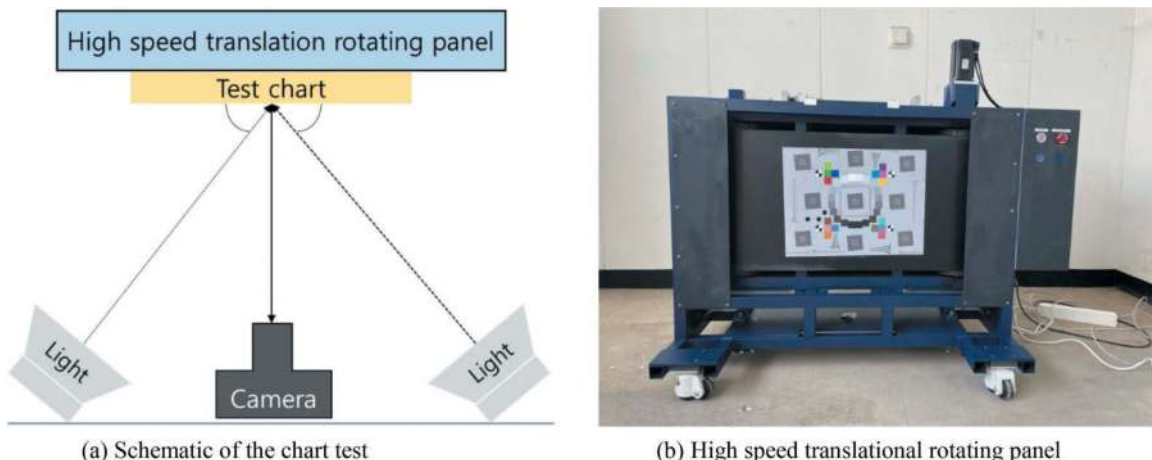

Figure 2. Motion blur capturing on high-speed translational rotating panel in the laboratory.

Table 1. Test condition for capturing motion blur using rotating panel and area scan camera.

Panel speed	Shutter speed	ISO sensitivity	FPS	F-number	Illuminance
0 km/h	250 us	1,250			
10 km/h					
30 km/h	100 us	1,600	100	2.8	15,000 lux
50 km/h					40,000 lux
70 km/h					

(Raskar et al., 2006). To shoot motion blur, it is important to assume motion and find the fastest exposure time that can make a moving object appear to be motionless. In this study, the lens aperture value F was fixed at 2.8, the shutter speed was set to 250 and 100 us, and ISO was changed to 1250 and 1500, while shooting at a speed of 70km/h. The illuminance of the chart surface was measured with an illuminometer, which was 15,000 and 40,000 lux. By analyzing the MTF of the captured images, this study attempted to identify correlations between the optimal combination of the camera and lighting device. The test conditions are presented in Table 1. The speed of the high-speed translational rotating panel was shifted to 10, 30, 50, and 70 km/h while shooting.

3.2 Analysis of experimental results

To analyze the image quality according to the rotating-panel speed variation and the exposure speed of the camera through the quantitative value of motion blur, the shooting took place under the test conditions shown in Table 1 (and Figure 3). The faster the shutter speed, the darker the image; this can be compensated by increasing the ISO of the camera or the lighting illuminance. The results indicate a relationship in which faster exposures darken the image but increase sharpness. In the case of

Figure 3. Relationship between shutter speed and ISO.

Figure 4. Calculating MTF graph (rise distance) by IMATEST®.

increasing the illuminance from 15,000 and 40,000 lux, the sharpness was improved due to the higher brightness in the image with shutter speed of 100 us. To confirm this, IMATEST® software was used, and motion blur was analyzed in the width (in pixels) at 10 – 90% of the rise distance measured at the center of the eSFR ISO test chart (Figure 4). Figure 5 shows the difference in shutter speed at an illuminance of 15,000 lux. When coming to a halt at a shutter speed of 250 us, the rise distance of MTF was 3.99 pixels, and 19.43 pixels at 70 km/h, indicating that motion blur increased by approximately 388% (Figure 5(a)). At a shutter speed of 100 us, it was 3.81 pixels and increased to 8.46 pixels at 70km/hm, indicating an increase of approximately 122%; it can be observed that the sharpness was improved (Figure 5(b)). When the shutter speed was increased to 100 us, the motion blur was approximately 50% less than that at 250 us.

Figure 6. presents a comparison of the MTF rise distance according to the difference in lighting illuminance between 15,000 lux and 40,000 lux. Figure 6(a) shows the difference in motion blur at a shutter speed of 250 us, and ISO of 1250, and Figure 6(b) present the comparison at a shutter speed of 100 us and ISO of 1600. When the shutter speed is 250 us, the difference in rise distance due to illuminance difference tends to increase as the rotation speed increases. On the other hand, at 100 us, the difference in rise distance due to illuminance difference tends to remain constant. Figure 7 shows the difference ratio in MTF due to illuminance and shutter speed. At 100 us, the MTF difference ratio is relatively constant at 4 ~ 6%, whereas at 250 us, the result of the illuminance difference gradually increases to approximately 11.5% at a speed of 70 km/h.

3.3 Discussion

The performance of the core devices (camera and lighting) was analyzed through indoor experiments to develop a camera-based noncontact mobile tunnel inspection system.

Quantitative values of motion blur against sharpness, which is an important factor in IQA, were derived by a high-speed translational

(a) Results of MTF graph (rise distance): shutter speed 250 us, ISO 1250, 15,000 lux

(b) Results of MTF graph (rise distance): shutter speed 100 us, ISO 1250, 15,000 lux

Figure 5. Results of MTF graph (rise distance) on the 15,000 lux.

rotating panel device. The rotation speed and the exposure performance of the camera were compared and analyzed via MTF graphs. The exposure of the camera is determined by the shutter speed, ISO, and the aperture F value of the lens. In this study, the analysis was conducted after setting the following conditions: the aperture F value was fixed at 2.8, the shutter speed was divided into 250 and 100 us to respond to the rotation speed, and the illuminance was divided into 15,000 and 40,000 lux. The results suggest that it is necessary to secure fast exposure performance that can respond to rotation or movement speed to capture clear and high-quality images. In this study, a shutter speed of 100 us was used, and approximately 120% of motion blur occurred at 70 km/h than at the status of pause. Further studies are needed to reduce the rate of motion blur to less than 50% when shooting at high speeds. Furthermore, considering that there are diverse image quality factors besides motion blur such as noise, color accuracy, and distortion, it is necessary to select cameras and lighting devices that consider the image quality in future studies.

4 CONCLUSIONS

This study conducted indoor performance experiments on cameras and lighting devices to develop a camera-based noncontact mobile inspection system capable of obtaining images of 0.3 mm/pixel at driving speeds of more than 80 km/h in a tunnel. A high-speed translational rotating panel device, which can simulate driving speeds of up to 100 km/h, was developed, and the motion blur of the images was measured for comparative analysis using the MTF value after attaching the eSFR ISO test chart. The conclusions drawn from the results of the indoor shooting test are as follows.

1. The higher the camera shutter speed, the darker the image; to compensate for this point, there is a method of increasing the ISO of the camera or the lighting illuminance. The results indicate a relationship in which faster exposures darken the image but increase sharpness.
2. As for a shutter speed of 250 us at an illuminance of 15,000 lux, the rise distance of MTF was 3.99 pixels at a pause status, and it became 19.43 pixels at 70 km/h, leading to approximately

(a) MTF rise distance: shutter speed 250 us between 15,000 lux and 40,000 lux

(b) MTF rise distance: shutter speed 100 us between 15,000 lux and 40,000 lux

Figure 6. Comparison MTF graph (rise distance) for shutter speed between 15,000 lux and 40,000 lux.

Figure 7. Difference ratio in MTF due to illuminance and shutter speed differences.

388% of motion blur. On the other hand, at a shutter speed of 100 us, it increased from 3.81 pixels to 8.46 pixels at 70 km/h, increasing approximately 122%. It can be considered that the sharpness was improved. Therefore, when the shutter speed increased to 100 us, the motion blur decreased by approximately 50% compared to the status at 250 us.

- As a result of comparing MTF rise distance due to the difference in lighting illuminance of 15,000 and 40,000 lux, the difference ratio in MTF at 100us was relatively constant (4 ~ 6%), whereas, at 250 us, the result of illuminance difference gradually increased to approximately 11.5% at the speed of 70 km/h.
- In this study, at a shutter speed of 100 us, the illuminance of 40,000lux, ISO of 1600, and the F value of 2.8, approximately 120% of motion blur occurred at 70 km/h than at the pause status, and it was difficult to obtain high-quality images through the exposure performance of the camera. Therefore, future studies need to focus on reducing the percentage of motion blur to less than 50% by using fast shutter speed and high luminance lighting.

Tunnel indirect monitoring and damage identification method based on SET-Swin Transformer*

Qi Li, Xiongyao Xie & Kun Zeng

Department of Geotechnical Engineering, School of Civil Engineering, Tongji University, Shanghai, China
Key Laboratory of Geotechnical and Underground Engineering of Ministry of Education, School of Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: Addressing the limitations of current tunnel indirect monitoring and damage identification methods, which struggle with high noise and extensive data, this paper proposes a tunnel indirect monitoring and damage identification method based on SET-Swin Transformer. Initially, an exposition of the principles and procedures of this method is provided. The measured vertical dynamic response slices of the train are simultaneously passed through the corresponding trained classifier to determine the location, type and degree of tunnel damage in one step. Subsequently, the feasibility of this method is validated through model test. Lastly, an efficiency comparison is drawn between this method, employing short-time Fourier transform time-frequency diagrams as algorithm inputs, and the conventional training of convolutional neural networks. The outcomes demonstrate that the proposed method enables a one-step identification of tunnel damage while reducing the composition of the training set and the input data length, with a relatively faster algorithm convergence rate.

1 INTRODUCTION

As an important part of urban rail transit, subway plays a vital role in alleviating the traffic pressure in large cities. With the increase of service time, diseases such as uneven settlement, segment deformation, segment peeling, and cavity back of tunnel appear in subway tunnels under the combined action of environmental erosion, material aging, and train cyclic load, which make the maintenance cost of tunnels in operation period increasingly high.

Once the tunnel and its attached structure are damaged, it will seriously affect the travel of residents. If the subway tunnel in operation period cannot be monitored and maintained in time, serious subway accidents are likely to occur. At present, the monitoring of subway tunnels can be divided into manual monitoring and automatic monitoring, among which manual monitoring is time-consuming and laborious (He, 2018). The sensor monitoring system with fixed position can generally only be monitored in some key areas of the tunnel (Yang et al., 2012), and the mobile detection vehicle integrating 3D laser scanner, digital photography and ground penetrating radar technology can only work in the early morning (Yang and Fang, 2017), which is difficult to achieve full-time and full-area monitoring. Therefore, it is of great significance for subway operation safety to find an efficient,

economical and full coverage subway tunnel state perception method to detect tunnel damage in time.

In view of the limitations of existing subway tunnel monitoring technologies, Li et al. (2021) proposed an indirect tunnel monitoring method that uses the dynamic response of the service train to identify tunnel anomalies or damage. The proposed scheme is to install the acceleration sensor on the bogie of the service train, collect the vertical dynamic response of the train when the train is running, and determine the tunnel damage by comparing the characteristic quantity of the vehicle body response before and after the tunnel damage.

Li et al. (2021) verified the proposed damage index through theoretical derivation, simplified numerical model and model test. On this basis, Zhang et al. (2022a, b) proposed a damage identification method based on deep learning, and verified the algorithm by obtaining data from the laboratory model. However, Li's method is prone to interference caused by noise and inconsistency of data. Although Zhang uses deep learning to reduce the interference to a certain extent, the proposed VMD-CNN-LSTM method needs to go through multiple classifiers continuously to identify damage location and type step by step. The training set of each classifier contains a lot of cases and the data length of each case is large, which is difficult to adapt to the train test in real scenes.

This paper proposes a tunnel indirect monitoring and damage identification method based on SET-Swin Transformer. Initially, the vertical acceleration response of trains undergoes SET to obtain time-frequency diagrams, which serve as input to train slice classifiers within the Swin Transformer. The new measurement data are input into each slice classifier at the same time after passing through the same slice. According to the results of the classifiers, the damage location, type and degree can be determined in one step. Subsequently, a model test is conducted to validate the feasibility of this identification method. Finally, the recognition efficiency of the proposed method is compared with that of the short-time Fourier transform time-frequency diagram as the input of the algorithm and the common convolutional neural network for training.

2 METHODOLOGY

2.1 SET principle

Synchroextracting transform (SET) belongs to the post-processing process of short-time Fourier transform (STFT). This algorithm only preserves the time-frequency coefficient of the short-time Fourier transform results on the mid-frequency ridge, thereby removing most of the divergent energy to obtain the time-frequency distribution with higher resolution (Yu et al., 2017). Taking harmonic signal $x(t) = A \cdot e^{i\omega_0 t}$ as an example, synchroextracting transform is mainly divided into three steps:

- (1) Perform the short-time Fourier transform on time-domain signal to obtain time-frequency spectrum $G_e(t, \omega)$:

$$\begin{aligned} G_e(t, \omega) &= \int_{-\infty}^{+\infty} x(u) \cdot g(u-t) \cdot e^{-i\omega(u-t)} du \\ &= \frac{1}{2\pi} \int_{-\infty}^{+\infty} \hat{x}(\xi) \cdot \hat{g}(\omega - \xi) \cdot e^{i\xi t} d\xi \end{aligned} \quad (1)$$

Where $\hat{g}(\omega - \xi)$ is the Fourier transform result of the window function $g(u-t)$, $\hat{x}(\xi)$ is the Fourier transform result of the signal $x(t)$:

$$\hat{x}(\xi) = 2\pi A \cdot \delta(\xi - \omega_0) \quad (2)$$

Substituting (2) into (1) can obtain the short-time Fourier transform result of the signal $x(t)$:

$$G_e(t, \omega) = A \cdot \hat{g}(\omega - \omega_0) \cdot e^{i\omega_0 t} \quad (3)$$

The result of formula (3) shows that the time-frequency energy of the signal is mainly concentrated near the frequency $\omega = \omega_0$, and the maximum amplitude $A \cdot \hat{g}(0)$ is found in the region near this frequency.

- (2) Obtain instantaneous frequency estimation $\omega_0(t, \omega)$ based on the phase information of the time-frequency spectrum:

Calculate the partial derivative of the short-time Fourier transform result:

$$\partial_t G_e(t, \omega) = G_e(t, \omega) \cdot i \cdot \omega_0 \quad (4)$$

Further obtain instantaneous frequency estimation:

$$\omega_0(t, \omega) = -i \cdot \frac{\partial_t G_e(t, \omega)}{G_e(t, \omega)} \quad (5)$$

- (3) Remove the divergent energy near the instantaneous frequency to obtain a new time-frequency spectrum $T_e(t, \omega)$:

Set extraction operator $\delta(\omega - \omega_0(t, \omega))$:

$$\delta(\omega - \omega_0(t, \omega)) = \begin{cases} 1, & \omega = \omega_0 \\ 0, & \omega \neq \omega_0 \end{cases} \quad (6)$$

Remove the divergent energy near the instantaneous frequency of the signal in the original time-frequency spectrum to obtain the time-frequency spectrum after synchroextracting transform:

$$T_e(t, \omega) = G_e(t, \omega) \cdot \delta(\omega - \omega_0(t, \omega)) \quad (7)$$

2.2 Swin Transformer architecture

Swin Transformer is a network model proposed by Microsoft Research Asia for image classification, object detection and semantic segmentation, which is dedicated to simultaneously solving computer vision tasks and natural language processing tasks (Liu et al., 2021). The model adopts hierarchical design, and the attention calculation is limited to one window by shifted window. On the one hand, the locality of CNN convolution operation is introduced, and on the other hand, the calculation amount is saved.

The architecture of Swin Transformer is shown as Figure 1. The core of the algorithm is to extract image deep features through multiple Block and multiple Patch Merging operations. In each Block, image features are extracted by self-attention mechanism, followed by Patch Merging downsampling to reduce the resolution of feature maps and increase the number of channels.

The specific structure of the Block is shown as Figure 2, which consists of four key modules: Layer Normalization (LN), Windowed Multi-head Self-Attention (W-MSA), Shifted Window Multi-head Self-Attention (SW-MSA) and Multi-Layer Perceptron (MLP). The W-MSA module is used for multi-head self-attention calculation in the window, while the SW-MSA module shifts the window, recombines and integrates features in a local area, and retains the relative position relationship between the windows while obtaining a larger range of information.

2.3 Damage identification method

This paper proposes a tunnel indirect monitoring and damage identification method based on SET-Swin Transformer as shown in Figure 3.

Initially, the acquired train dynamic response is filtered based on the results of fast Fourier transform, and the high energy frequency band is retained while

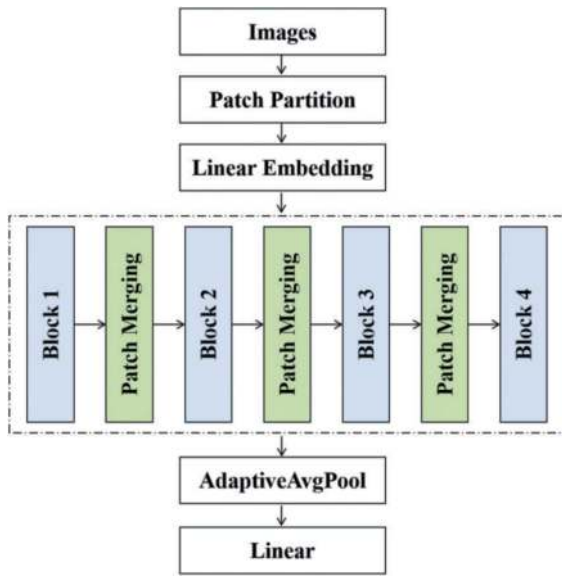

Figure 1. Swin Transformer architecture.

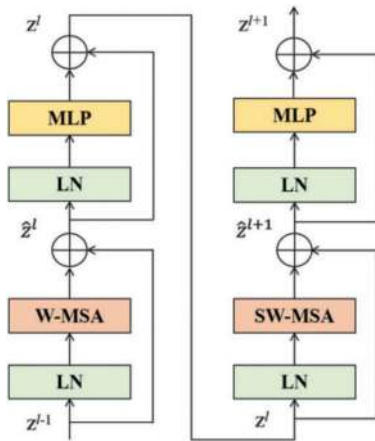

Figure 2. Block structure.

the noise is removed. Then, the denoised signal is sliced according to the actual situation (the real running train can be divided according to the station). When damage occurs in the corresponding tunnel section of a slice, it mainly affects the dynamic response of the train in the slice, but has little impact on the dynamic response of the other slices. Subsequently, SET is carried out on the slicing signals and time-frequency diagram is drawn. The time-frequency diagram is trained as the input of Swin Transformer. A classifier is constructed for each slice, in which the input of each slice classifier is the slice data under the condition of the whole healthy section and the data of different damages in the corresponding tunnel section of the slice.

For the newly acquired train dynamic response, after the same filtering and slicing operation, the time-frequency diagram of each slice data after SET is input into the corresponding trained slice classifier. The results of the slices corresponding to the tunnel section without damage will be output health after

the classifier. The type and degree of damage will be output from the slices corresponding to the tunnel section where the damage is located through the classifier, thus realizing the indirect identification of tunnel damage.

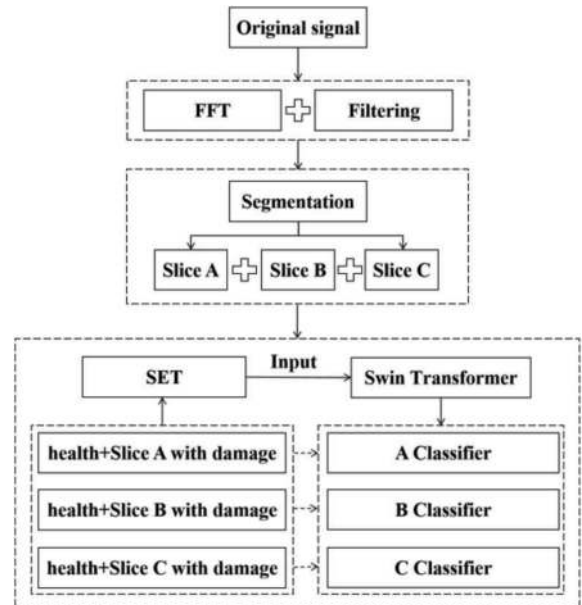

Figure 3. Method flow chart.

3 MODEL TEST AND METHOD VALIDATION

3.1 Model test

In order to verify the feasibility of the proposed method, this paper adopted the test system as shown in Figure 4 to carry out the model test. The test system includes sand box, tunnel model, train model, train traction control system and data acquisition system. The tunnel model includes the tunnel structure, track plate and steel track made by 3D printing. The automatic traction and control system includes

Table 1. Test cases.

Case	Damage degree	Damage location
0	—	—
1	1	A
2	2	A
3	3	A
4	4	A
5	1	B

11	3	C
12	4	C

track, motor and chassis, which jointly control the train in the tunnel to do a cycle of uniform speed.

As shown in Figure 4, the wireless acceleration sensor was glued to the train model with AB adhesive in this test, and the sampling frequency was set at 100Hz to continuously collect the triaxial acceleration response of the train. 3D printed resin was placed under the side of the tunnel to simulate the cavity damage. Four resins of different sizes were set in the test to simulate the damage of different degrees (as shown in Figure 5), and the resin was placed on the left, middle and right sides of the tunnel respectively (as shown in Figure 5), in a total of 13 cases as shown in Table 1. The train ran for 15 minutes in each case.

Figure 4. Test system and sensor installation.

Figure 5. Degree and location of damage.

3.2 Model test data preprocessing

In this paper, the vertical acceleration response of the train is selected for analysis. Figure 6 shows the first 200s data in case 12, including C→A and A→C directions. Bandpass filtering is carried out according to the fast Fourier transform spectrum diagram of the signal (as shown in Figure 7), and the signal with relatively concentrated energy of 10-20Hz is retained. Further, the original data is segmented according to the acceleration response of the train running direction. Figure 8 shows the acceleration response of the C→A direction after filtering and segmentation. According to the method mentioned in 2.3, the acceleration response in the C→A direction is divided into three slices: 0~2.5s, 2.5~5s, and 5~7.5s, which correspond to the three damage locations respectively, as shown in Figure 9.

Figure 6. Original signal.

Figure 7. FFT spectrum diagram.

Figure 8. Signal in the C→A direction.

3.3 Algorithm training and testing

Figure 10 shows the results of the STFT and the SET, which produces a more energy-focused time-frequency representation. With the time-frequency diagram of SET as input, a Swin Transformer classifier is constructed for each slice. The cases of the training set of each classifier are shown in Table 2. Only the healthy case and the two cases with damage in the tunnel section corresponding to the slice are used for training, and the ratio of training set and validation set is 4:1. In this paper, a pre-trained Swin Transformer network is used to speed up the training, which has been pre-trained on a larger dataset. Figures 11, 12 show the training results of the B classifier, including training loss, training and validation accuracy.

Figure 9. Three slices of signal in the C→A direction.

Figure 10. Time-frequency diagram of STFT and SET.

Table 2. Composition of classifier (C→A direction).

Classifier	Time period	Training set cases composition
C classifier	0~2.5s	0, 10, 12
B classifier	2.5~5s	0, 6, 8
A classifier	5~7.5s	0, 2, 4

Three case 4 data that did not participate in the training are tested through the trained classifier, and the test results are shown in Table 3. The data are segmented into three slices and then passed through the corresponding classifier. The results of the C and B classifiers are case 0 (health), while the results of

Figure 11. Training loss of the B classifier.

Figure 12. Training and validation accuracy of the B classifier.

the A classifiers are case 4. The damage location and damage degree identification are realized, which is consistent with the expected results of the method proposed in 2.3, proving the feasibility of the method.

Table 3. Test results of new Case 4 data (probability/%).

Classifier	Case	Test result	Test result	Test result
		1	2	3
C classifier(0~2.5s)	0	99.9980	99.9921	99.9991
	10	0.0017	0.0070	0.0005
	12	0.0003	0.0009	0.0005
B classifier(2.5~5s)	0	80.7251	99.9677	99.0626
	6	0.0087	0.0002	0.0009
	8	19.2662	0.0321	0.9366
A classifier(5~7.5s)	0	0.0069	0.0113	0.0027
	2	8.4056	25.7911	0.0550
	4	91.5875	74.1976	99.9423

4 DISCUSSION

As shown in Figure 13, the training loss of the B classifier with the short-time Fourier transform time-frequency diagram as the input of Swin Transformer tends to be stable after 32 epochs, while the training loss of the SET time-frequency diagram as the input of the algorithm (Figure 11) tends to be stable after 24 epochs, which is converging faster.

Figure 13. Training loss of the B classifier (STFT-Swin Transformer).

Figure 14 shows the training loss of the B classifier using the commonly used ResNet18 network. Compared with the result of Swin Transformer (Figure 11), the convergence of ResNet18 requires more epochs, and the training loss after 50 epochs is 0.058, which is higher than 0.001 of Swin Transformer.

Figure 14. Training loss of the B classifier (SET-ResNet18).

5 CONCLUSIONS

This paper proposes a tunnel indirect monitoring and damage identification method based on SET-Swin

Transformer and the feasibility of the method is validated through a model test. The primary conclusions are as follows:

- 1) Model test results demonstrate that the tunnel indirect damage identification method based on SET-Swin Transformer can achieve one-step identification of tunnel damage location and degree utilizing multiple slice classifiers.
- 2) In comparison with the previously tunnel indirect monitoring method based on VMD-CNN-LSTM, the classifiers constructed in this paper show reductions in training set composition and data length, allowing adaptability to diverse testing scenarios.
- 3) Compared with using the STFT time-frequency diagram as the algorithm input and using the commonly used ResNet18 network for training, the proposed method in this paper exhibits faster training convergence and lower loss.

Future work aims to accumulate more data by setting different types and degrees of tunnel damage through model tests to further train the proposed method, and subsequently deploy the algorithm into field applications.

ABSTRACT: The characterization of rock fracture is essential for revealing and understanding the fracture mechanism. In this research, the fracture of sandstone is characterized from the perspective of the 3D morphology of fracture surface. The 3D morphology is quantified by two fractal dimension (D) calculation methods: cubic covering method (CCM) and surface area method (SAM). The applicability of both methods is verified by two special cases of which one is a 2D plane and another one is a novel surface model with a dimension of 3. However, in actual application, one shortcoming of the CCM rooted in the algorithm is exposed, which introduces a distorted D for the surface with a small degree of undulation. On the contrary, relying on a new algorithm proposed to calculate the fracture surface area, the SAM can completely avoid the distortion problem. Based on the SAM, the 3D morphologies of a series of fracture surfaces of sandstone in the conventional triaxial test are quantified. It is observed that D has a strong correlation with the fracture mechanism. With the transition of failure mechanism from tension fracture to shear fracture, D presents a decreasing trend. The reason underlying this correlation is analyzed. In Discussion, several improved CCMs are introduced, and whether the improvements have solved the distortion problem is verified. The accuracy of the SAM is also evaluated using the Takagi fractal surfaces.

1 INTRODUCTION

Rock fracture is one of the key issues in the field of rock mechanics. A better understanding of the rock

fracture mechanism is essential to the design and safety of the underground construction. The 3D morphology of the fracture surface is the direct record of the fracture process, and contains amounts of

*Corresponding author: xieagle@sdu.edu.cn

information about the fracture characteristics. Effectively characterizing the 3D morphology of the fracture surface is of great significance to understand and reveal the fracture mechanism.

To date, scholars have done a lot of work on the characterization of the roughness of the surface profile. ISRM recommended that the roughness could be described by the inherent unevenness and waviness of the joint surface relative to its mean plane.(1978; Brady and Brown 2006; Li et al. 2016; Li et al. 2020; Patton 1966; Yang et al. 2001) To quantitatively characterize the roughness, Barton proposed the joint roughness coefficient (JRC) and defined 10 typical joint roughness profiles.(Barton 1973; Barton and Choubey 1977) However, it is highly subjective to quantify joint roughness by visual comparison.(Hsiung et al. 1993; Kulatilake et al. 1995; Maerz et al. 1990) In addition, some scholars proposed statistical parameters to quantify rough surfaces or profiles, which can be categorized broadly into amplitude parameters (Myers 1962; Tse and Cruden 1979), spacing parameters(Sayles and Thomas 1977; Tikou et al. 2000; Wu and Ali 1978; Yu and Vayssade 1991) and hybrid parameters(Chen et al. 2016; El-Soudani 1978; Ge et al. 2014; Tatone and Grasselli 2013; Xue et al. 2020). It should be noticed that the statistical characteristics of the aforementioned parameters are highly dependent on the sampling interval,(Miller et al. 1990) and comparisons between different parameters cannot be performed. Therefore, it is necessary to find an integrated parameter with scale invariance to characterize the morphology of fracture surface. Coincidentally, fractal theory based on the self-similarity of geometry object perfectly meets these requirements.

Since Mandelbrot proposed fractal theory in 1983,(Mandelbrot 1967; Mandelbrot 1977) it has been widely used in the related research of rock mechanics, such as crack propagation pattern(Nara et al. 2006; Yang et al. 2021; Yu et al. 2021; Zhang et al. 2018), rockburst mechanism and prediction(Feng et al. 2016; Feng et al. 2012; Liu et al. 2013; Xie and Pariseau 1993), and pore structure characterization(Ju et al. 2014; Schlueter et al. 1997a; Schlueter et al. 1997b), et al. Numerous studies have shown that the rock fracture surface can be described as a self-affine fractal, and its morphology can be quantitatively characterized by fractal dimension.(Babanouri et al. 2013; Ding et al. 2021; Ehlen 2000; Jafari and Babadagli 2013; Jiang et al. 2006; Raimbay et al. 2017; Xie and Wang 1999b; Xu et al. 2018) However, due to the lack of equipment to obtain the 3D morphology data of fracture surface, the fractal dimension was indirectly determined based on 2D profiles in early studies.(Berry and Lewis 1980; Kulatilake et al. 2006; Liebovitch and Toth 1989; Malinverno 1990; Matsushita and Ouchi 1989; Orey 1970) Considering the anisotropy and heterogeneity of fracture surface, these indirect determination methods are incomplete or even biased. (Archambault et al. 1997; Belem et al. 1997)

With the development of non-contact measurement technologies, the 3D fracture surface reconstruction can be realized. Methods directly determining the fractal dimension were proposed. (Chen et al. 2020; Clarke 1986; Kwaśny 2009; Xie et al. 1998; Zheng et al. 2021; Zhou et al. 2013) Zhou and Xie proposed the cubic covering method (CCM), and successfully employed it to calculate the fractal dimension of a 3D fracture surface.(Zhou and Xie 2003) Zhang et al. pointed out that the complexity and authenticity of fracture surface cannot be well characterized by the CCM and proposed an improved cubic covering method (ICCM), which calculated the number of cubes from a unified reference plane. (Zhang et al. 2005) T. Ai et al. suggested that the CCM and ICCM did not take heights of the intermediate points in the cubes into account, resulting in the fracture surface not being completely covered. Therefore, the differential cubic covering method (DCCM) and relative differential cubic covering method (RDCCM) were proposed.(Ai et al. 2014)

Inspired by the simple “walking divider” method (Goodchild 1982) for quantifying a line, Clark introduced the surface area method (SAM) to determine the fractal dimension of topographic surface.(Clarke 1986) The surface area was calculated by the triangular prism surface area method in which the four nodes and the center point of each grid formed four triangles and the sum of triangle areas on the surface was the surface area. To simplify the calculation of surface area, Xie et al. proposed a projective covering method, in which the grid area surrounded by four nodes was approximately computed by two triangles.(Xie and Wang 1999a)

Theoretically, the fracture surface roughness of self-emulation fractal is only correlated in a limited range(Smith 2014), and different scale ranges may produce different fractal dimension values. Xie pointed out that the fractal dimension estimated in the linear part of the log-log plot of the measurement vs the measured step can represent the roughness of the fracture surface.(Xie et al. 1997) Most previous studies have focused on the calculation of fractal dimension of fracture surfaces and the establishment and correction of calculation methods. The most important aspect in rock engineering practice, however, is that the fractal characterization could be applied to reveal rock fracture mechanism. The applicability of established fractal dimension calculation methods for characterizing rock fracture surfaces has not been discussed, and more importantly, the relationship between fractal dimension and fracture mechanisms has rarely been investigated.

In this study, the CCM are reviewed first. However, when CCM is applied to characterize the rock fracture surface, the distortion problem is exposed. By analyzing the algorithm of the CCM, the cause of the distortion problem is revealed. Then, the SAM is adopted to determine the D instead, in which a new method for calculating the fracture surface area is proposed. Compared to the CCM, the SAM can accurately

identify the small undulation on the fracture surface and avoid the distortion problem. By applying the SAM to a series of fracture surfaces of sandstone in the conventional triaxial test, a negative correlation between the fractal dimension and the confining pressure is observed. This negative correlation results from the transition of fracture mechanism with the variation of confining pressure, and the underlying mechanism for how the fracture mechanism alter the 3D morphology of fracture surface is analyzed. In the Discussion, whether the improved CCMs still suffer from the distortion problems is checked, and the accuracy of the SAM is evaluated using the Takagi fractal surface.

2 CUBIC COVERING METHOD

2.1 Algorithm of CCM

The CCM is evolved from the box-counting method (Russell et al. 1980), and their algorithms are similar. Dividing a fracture surface into $n \times n$ grids by a scale of δ , taking the ij -th grid as an example, the elevations of the four nodes are $z_{i,j}$, $z_{i+1,j}$, $z_{i,j+1}$, and $z_{i+1,j+1}$. The elevation difference of the grid is denoted as Δz . Covering this grid by cubes with a size of δ , the number of cubes $N_{i,j}$ can be expressed as:

$$\Delta z = \max[z_{i,j}, z_{i+1,j}, z_{i,j+1}, z_{i+1,j+1}] - \min[z_{i,j}, z_{i+1,j}, z_{i,j+1}, z_{i+1,j+1}] \quad (1)$$

$$N_{i,j} = F\left(\frac{\Delta z}{\delta}\right) + 1 \quad (2)$$

Where $F(a)$ is the floor function whose value is the maximum integer not greater than a . According to equation (2), the number of cubes $N(\delta)$ required to cover the entire surface can be calculated as:

$$N(\delta) = \sum_{i=1}^n \sum_{j=1}^n N_{i,j} \quad (3)$$

According to the fractal geometry theory, $N(\delta)$ and δ have the following relationship:

$$N(\delta) \sim \delta^{-D} \quad (4)$$

Taking the logarithm of both sides of equation (4) gives:

$$\lg N(\delta) \sim -D \cdot \lg \delta \quad (5)$$

According to equation (5), under the bi-logarithmic coordinate system, $N(\delta)$ has a linear

relationship with δ . The absolute value of the slope is the fractal dimension D .

D calculated by the CCM can be related to the dimensions of the 2D plane and 3D solid in the Euclidean geometric space. Firstly, considering a special case in which a 2D horizontal plane A, whose size is $l \times l$, is divided by a scale of δ , the number of grids N_g can be expressed as:

$$N_g = \left(\frac{l}{\delta}\right)^2 \quad (6)$$

Since the Δz of all grids are 0, and each grid only needs one cube to be covered, $N(\delta)$ is equal to N_g . Bring the equation (6) into the equation (5) to get:

$$\lg\left(\frac{l}{\delta}\right)^2 \sim -D \cdot \lg \delta \quad (7)$$

As δ changes from δ_1 to δ_2 , according to equation (7), D can be calculated as:

$$D = -\frac{\lg\left(\frac{l}{\delta_1}\right)^2 - \lg\left(\frac{l}{\delta_2}\right)^2}{\lg \delta_1 - \lg \delta_2} = 2 \quad (8)$$

Therefore, the dimensions of the 2D horizontal plane in Euclidean space and fractal geometric space are the same, both of which are equal to 2.

Considering another special case, a horizontal plane B possesses a size of $l \times l$ and an elevation of 0, as shown in Figure 1 (a). In the first iteration, B is equally divided into four grids, and the elevation of the centre node (the red point in Figure 1 (b)) is modified to l . At this time, B is converted to a spatial curved surface with a bulge in the centre, as shown in Figure 1 (b-1). Then, performing the second iteration, the four grids in Figure 1 (b) are further divided into 4 equal parts, and the elevation of the centre node of each grid (the four magenta points in Figure 1 (c)) is modified to l . After performing the third and fourth iterations, the nodes whose elevations are modified to l are marked as orange and yellow points in Figure 1 (d) and (e), and the corresponding spatial curved surfaces are shown in Figure 1 (d-1) and (e-1). Repeating the above process, the spatial curved surface gradually evolves into a cubic solid with a side length of l when the number of iterations n approaches infinity.

In this iterative process, only two types of grids are generated. The first type consists of one node with an elevation of l and three nodes with an elevation of 0 (Figure 1 (f)). While the second type contains two nodes with an elevation of l and two other nodes with an elevation of 0, and the two nodes with

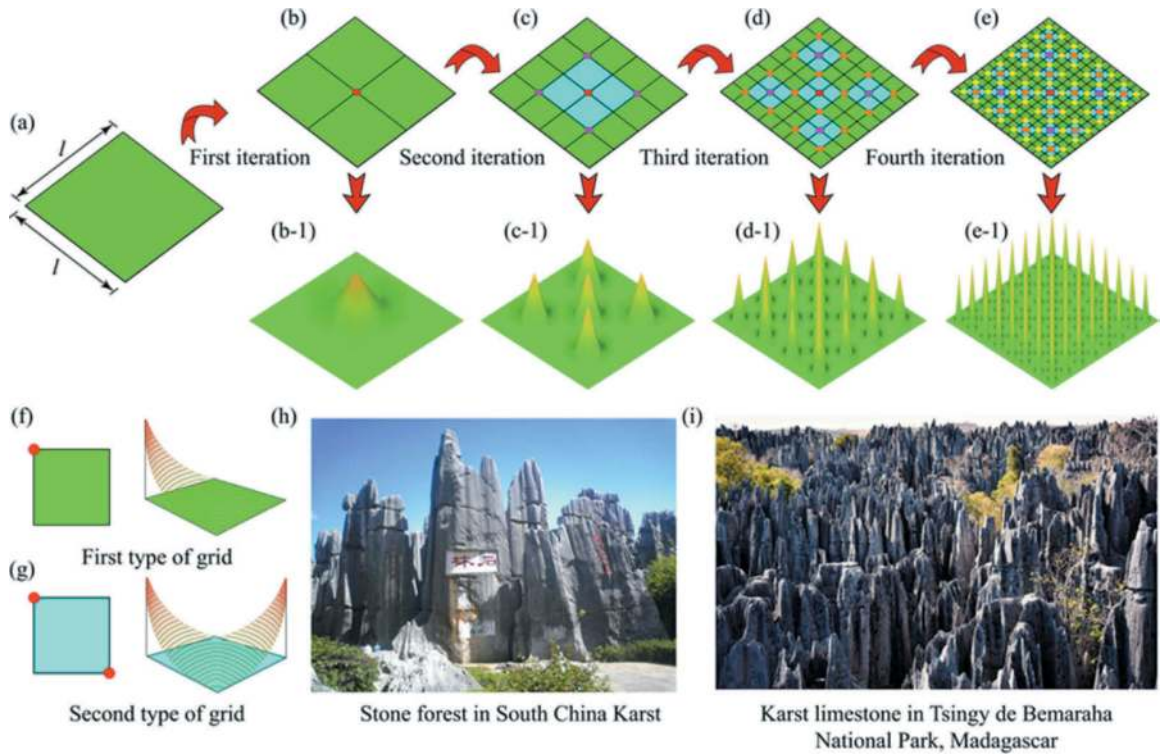

Figure 1. Another special case: (a~e) and (a-1~e-1) evolution of a 2D plane into a 3D solid cube, (f~g) two types of grids in evolution, and (h~i) geological morphologies in nature similar to evolution ^[Website 1 and 2].

the same elevation are distributed diagonally (Figure 1 (g)). The spatial curved surface after n iterations ($n \rightarrow +\infty$) is divided into grids by a scale of δ (Note: δ meets the following condition: $\delta = l/2^m$, $m \leq n$, $m, n \in \mathbb{Z}^+$, so do δ_1 and δ_2 in the text below). The numbers of the first type of grids N_1 and the second type of grids N_2 can be expressed as:

$$N_1 = \frac{2}{3} \cdot 4^m + \frac{4}{3} \quad (9)$$

$$N_2 = \frac{1}{3} \cdot 4^m - \frac{4}{3} \quad (10)$$

The Δz of the two types of grids are both l , and the number of cubes N_c required to cover a grid is:

$$N_c = \frac{l}{\delta} \quad (11)$$

The number of cubes $N(\delta)$ required to cover the entire fracture surface is:

$$N(\delta) = \frac{l}{\delta} \times \left(\frac{l}{\delta}\right)^2 = \left(\frac{l}{\delta}\right)^3 \quad (12)$$

Bring the equation (12) into the equation (5) to get:

$$\lg \left[\left(\frac{l}{\delta}\right)^3 \right] \sim -D \cdot \lg \delta \quad (13)$$

As δ changes from δ_1 to δ_2 , D can be calculated as:

$$D = - \frac{\lg \left[\left(\frac{l}{\delta_1}\right)^3 \right] - \lg \left[\left(\frac{l}{\delta_2}\right)^3 \right]}{\lg \delta_1 - \lg \delta_2} \quad (14)$$

Therefore, the dimensions of a cubic solid in Euclidean space and fractal geometric space are also consistent and equal to 3.

The morphologies in Figure 1 (b-1) ~ (e-1) are similar to stone forests in Karst Landforms, as shown in Figure 1 (h) and (i). It indicates that the evolution of the spatial curved surface in Figure 1 is not only a hypothetical geometrical model, but supported by some geological morphologies in nature. In addition, any newly proposed method for determining the D of a spatial curved surface should be verified by the above two special cases, and the calculated D s should be same as the dimensions of 2D plane and 3D solid in Euclidean space.

2.2 Distortion problem of CCM

The above proofs show that the CCM have an ability to determine the fractal dimension of any spatial

curved surface whose morphology varies from a 2D plane to a 3D solid. However, when characterizing the 3D morphology of a surface with a small degree of undulation, the CCM suffers from a distortion problem. Taking a fracture surface of sandstone obtained from the true triaxial fracture test ($\sigma_2=120.3\text{MPa}$, $\sigma_3=40\text{MPa}$) as an example, the cause of the distortion problem is analyzed.

The 3D morphology of the fracture surface is shown in Figure 2 (a). It can be observed that there are obvious unevenness and waviness on the surface, and the morphology is quite different from a 2D plane. However, the D calculated by the CCM is 2 (Figure 2 (b)). In other words, the CCM fails to detect the waviness and unevenness and incorrectly identifies the fracture surface as a 2D plane. This distortion problem is related to the algorithm of the CCM.

Figure 2 (c) is the algorithm of the CCM. The number of cubes required to cover a grid depends on $\Delta z/\delta$ (the ratio of the elevation difference to the cube side length). If $\Delta z/\delta$ is less than 1, no matter whether the ratio is 0.01 or 0.99, only one cube is required to cover this grid. It is equivalent to the condition of covering a horizontal grid ($\Delta z/\delta=0$). For a fracture surface with a small degree of undulation, if $\Delta z/\delta$ of all the grids are less than 1 under different scales of

δ , the number of cubes required to cover the entire fracture surface is equal to that to cover a 2D plane. Therefore, D is equal to 2. Only when $\Delta z/\delta$ is greater than 1, and two cubes at least are required to cover the grid, will the CCM successfully detect the unevenness and roughness on the fracture surface.

To verify this inference, meshing the fracture surface with different grid numbers, which are 20×20 , 50×50 , 100×100 , 200×200 , 500×500 , and 1000×1000 . The $\Delta z/\delta$ of all the grids are calculated. Based on the value of $\Delta z/\delta$, different colors are assigned to grids, and the color maps of the $\Delta z/\delta$ are generated, as shown in Figure 2 (d).

In general, the maps mainly appear blue and cyan, indicating that in most grids, $\Delta z/\delta$ are not greater than 0.5. When the grid number rises to 200×200 , the colors of several grids in the lower left corner approach red. As the number of grids further increases, the color map is basically unchanged.

To better visualize the distribution characteristic of $\Delta z/\delta$, the interval of $\Delta z/\delta\in[0,1]$ is equally divided into 10 sections. The number of grids contained in each section is counted, and its percentage P against the total number of grids is calculated, as shown in the Figure 2 (e).

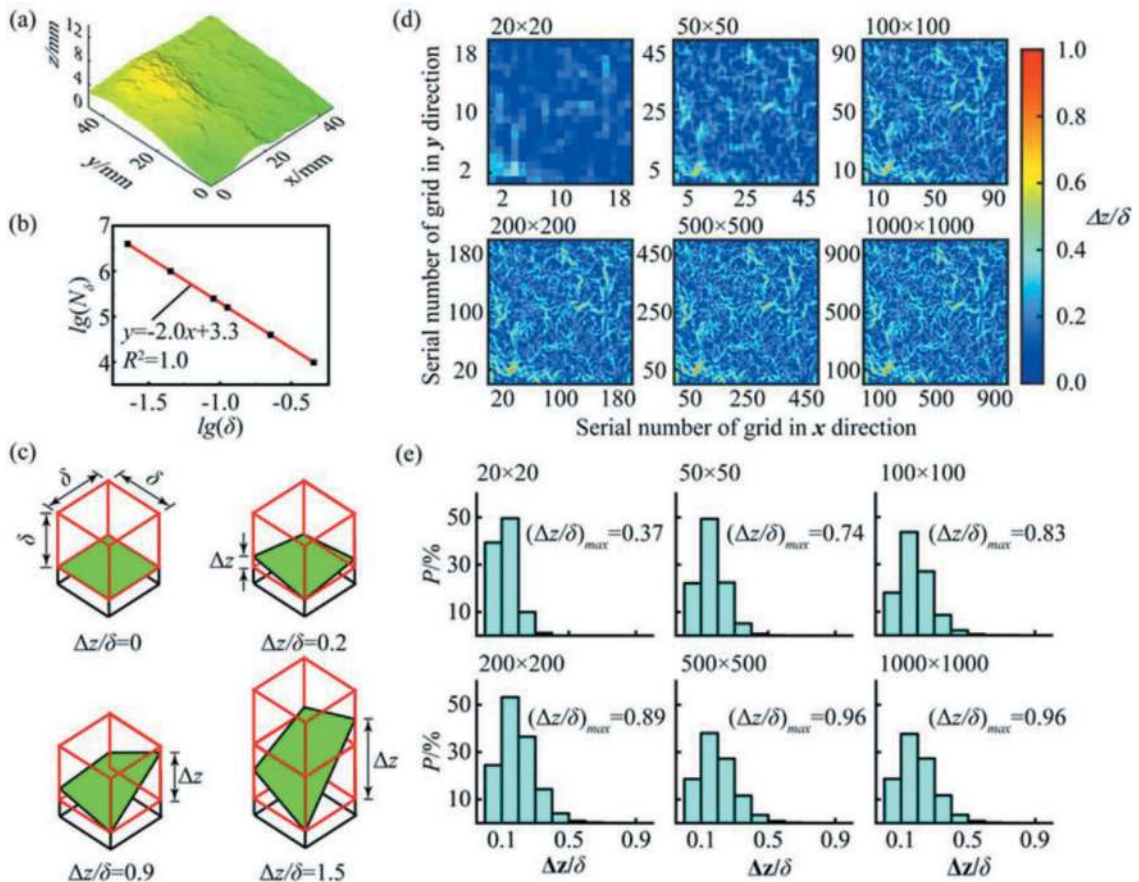

Figure 2. Distortion problem resulting from algorithm of CCM: (a) fracture surface morphology of sandstone, (b) fractal dimension determined by CCM, (c) algorithm of CCM, (d) color maps of $\Delta z/\delta$, and (e) distribution characteristic of $\Delta z/\delta$.

When the grid number is 20×20, all grids are distributed in the interval [0,0.4], and the maximum value of $\Delta z/\delta$ is 0.37. As the number of grids rises to 100×100, the distribution expands to [0,0.9], and the maximum $\Delta z/\delta$ is 0.83. When the number of grids continuously rises to 500×500, the grids are distributed in all intervals, and the maximum value reaches 0.96. With the further increase of the grid number, the distribution interval and the maximum $\Delta z/\delta$ remain unchanged.

The color maps and the distribution characteristics of $\Delta z/\delta$ verify the inference about the distortion problem. As a result, the D calculated by the CCM is equal to that of 2D plane. Therefore, it is inappropriate to characterize the 3D morphology of the fracture surface with a small degree of undulation by the CCM.

3 SURFACE AREA METHOD

To effectively characterize the 3D morphology of the fracture surface with a small degree of undulation, the SAM is adopted instead to determine the D . For the rock fracture surface, the surface area A_s and the grid scale δ have the following relationship (Clarke 1986):

$$A_s \sim \delta^{2-D} \quad (15)$$

Therefore, D can be determined by simply calculating the surface area A_s under different δ .

It is well known that the actual surface area of a fracture surface is almost impossible to be exactly calculated only by the node coordinates. However, when recognizing that meshing is actually a process of differentiating the fracture surface, A_s can be calculated approximatively by the method of surface integral.

Assuming that the fracture surface is continuum and derivable, the elevation z can be regarded as a continuous function $z(x, y)$. According to the surface integral, A_s can be expressed as:

$$A_s = \iint \sqrt{1 + \left(\frac{\partial z(x, y)}{\partial y}\right)^2 + \left(\frac{\partial z(x, y)}{\partial x}\right)^2} dx dy \quad (16)$$

The partial derivatives of $z(x, y)$ to x and y and the differential elements dx and dy are calculated in the unit of a grid. For the ij -th grid, supposing the coordinates of the four nodes are (x_i, y_i, z_i) , $(x_{i+1}, y_{i+1}, z_{i+1})$, $(x_i, y_{i+1}, z_{i, i+1})$ and $(x_{i+1}, y_{i+1}, z_{i+1, i+1})$, the dx and dy can be expressed as:

$$dx = \Delta x = x_{i+1, j} - x_{i, j} = x_{i+1, j+1} - x_{i, j+1} \quad (17)$$

$$dy = \Delta y = y_{i, j+1} - y_{i, j} = y_{i+1, j+1} - y_{i+1, j} \quad (18)$$

While, the partial derivatives of $z(x, y)$ to x and y can be expressed as:

$$\frac{\partial z(x, y)}{\partial x} = \frac{(z_{i+1, j} + z_{i+1, j+1})/2 - (z_{i, j} + z_{i, j+1})/2}{x_{i+1, j} - x_{i, j}} \quad (19)$$

$$\frac{\partial z(x, y)}{\partial y} = \frac{(z_{i, j+1} + z_{i+1, j+1})/2 - (z_{i, j} + z_{i+1, j})/2}{y_{i, j+1} - y_{i, j}} \quad (20)$$

Then, the grid area $A_{i, j}$ can be expressed as:

$$A_{i, j} = \sqrt{1 + \left(\frac{\partial z(x, y)}{\partial y}\right)^2 + \left(\frac{\partial z(x, y)}{\partial x}\right)^2} \times (x_{i+1, j} - x_{i, j}) \times (y_{i, j+1} - y_{i, j}) \quad (21)$$

Accumulating the area of all grids gives the entire fracture surface area A_s :

$$A_s = \sum_{i=1}^n \sum_{j=1}^n A_{i, j} \quad (22)$$

Similarly, the surface area method is verified by the two special cases in section 2.1. For the 2D plane, according to the equation (19) and (20), the partial derivatives of a grid can be expressed as:

$$\frac{\partial z(x, y)}{\partial x} = 0 \quad (23)$$

$$\frac{\partial z(x, y)}{\partial y} = 0 \quad (24)$$

And the grid surface area $A_{i, j}$ is:

$$A_{i, j} = \delta^2 \quad (25)$$

Accumulating the areas of all grids gives the entire fracture surface area A_s :

$$A_s = \sum_{i=1}^n \sum_{j=1}^n A_{i, j} = \left(\frac{l}{\delta}\right)^2 \times \delta^2 = l^2 \quad (26)$$

At this time, A_s is irrelevant to δ . Bringing A_s into the equation (15) and taking the logarithm on both sides to calculate D :

$$D = 2 - \frac{\log(l^2) - \log(l^2)}{\log(\delta_1) - \log(\delta_2)} = 2 \quad (27)$$

It is obvious that the D of the 2D plane calculated by the SAM is consistent with the dimension in the Euclidean space.

For the second special case, in the first type of grid, the partial derivatives are:

$$\left| \frac{\partial z(x, y)}{\partial x} \right| = \frac{l}{2\delta} \quad (28)$$

$$\left| \frac{\partial z(x, y)}{\partial y} \right| = \frac{l}{2\delta} \quad (29)$$

The grid surface area $A_{i,j}$ is:

$$A_{i,j} = \sqrt{\frac{4\delta^2 + l^2 + l^2}{4\delta^2}} \delta^2 \quad (30)$$

When δ approaches 0, δ^2 is infinitesimal compared to l^2 and can be ignored. Therefore, the equation (30) is simplified to:

$$A_{i,j} \approx \sqrt{\frac{l^2 + l^2}{4\delta^2}} \delta^2 = \frac{l \cdot \delta}{\sqrt{2}} \quad (31)$$

For the second type of grid, the partial derivatives are:

$$\left| \frac{\partial z(x, y)}{\partial x} \right| = 0 \quad (32)$$

$$\left| \frac{\partial z(x, y)}{\partial y} \right| = 0 \quad (33)$$

The grid surface area $A_{i,j}$ is:

$$A_{i,j} = \delta^2 \quad (34)$$

According to the numbers of the two types of grids N_1, N_2 in the equation (9) and (10), the entire fracture surface area A_s :

$$A_s = \sum_{i=1}^n \sum_{j=1}^n A_{i,j} = \frac{l \cdot \delta}{\sqrt{2}} \times \left(\frac{2 \times 4^m}{3} + \frac{4}{3} \right) + \delta^2 \times \frac{4^m - 4}{3} \quad (35)$$

Substituting $\delta = l/2^m$ into equation (35):

$$A_s = \frac{4l^2}{3\sqrt{2} \cdot 2^m} + \frac{\sqrt{2}l^2 \cdot 2^m}{3} - \frac{4l^2}{3 \cdot 4^m} + \frac{l^2}{3} \quad (36)$$

When m approaches infinity, comparing to the second term, the first, third, and last terms in equation (36) can be ignored. Equation (36) is simplified to:

$$A_s \approx \frac{\sqrt{2}l^2 \cdot 2^m}{3} \quad (37)$$

Bringing equation (37) into equation (15) and taking the logarithm on both sides to calculate D :

$$D = 2 - \frac{\log\left(\frac{\sqrt{2}l^2}{3} \cdot 2^{m_1}\right) - \log\left(\frac{\sqrt{2}l^2}{3} \cdot 2^{m_2}\right)}{\log \frac{1}{2^{m_1}} - \log \frac{1}{2^{m_2}}} \quad (38)$$

The dimension calculated by the SAM is the same as that in the Euclidean space. It can be observed that the SAM also have an ability to determine the D of any spatial curved surface whose morphology varies from a 2D plane to a 3D solid.

Then, the SAM is used to determine the D of the fracture surface in Figure 2 (a). The A_s corresponding to different δ are shown in Table 1, and their linear relationship in the bi-logarithmic coordinate system is shown in Figure 3. The D calculated by the SAM is 2.00397, which is significantly higher than that by the CCM. It is proved that the SAM is more effective in characterizing the 3D morphology of the fracture surface with a small degree of undulation.

The reason why the SAM can avoid the distortion problem is its ability to capture the differences in the undulation of fracture surface. Any subtle increase or decrease in the elevations of nodes will be reflected in the A_s , and then alters the linear relationship between δ and A_s , introducing the variation of D .

4 APPLICATION EXAMPLE

4.1 Effectiveness of SAM

To further verify the effectiveness of the SAM, the fracture surfaces of sandstone in a series of conventional triaxial tests are selected to analyze, as shown in Figure 4. The D s of the fracture surfaces are calculated by the CCM and the SAM, as shown in Table 2 and 3. The variation trends of D with the confining pressure σ_c are shown in Figure 5.

With the increase of σ_c , the D s calculated by the two methods show a decreasing trend. However, the

Table 1. Fracture surface areas corresponding to different grid scales under $\sigma_2=120.3\text{MPa}$, $\sigma_3=40\text{MPa}$ condition.

Figure 3. Linear relationship between A_s and δ in bi-logarithmic coordinate system.

D_s obtained by the SAM are reasonable than those of the CCM.

For the CCM, the variation of D presents a step-wise decreasing trend. The distortion problem is reflected not only by the D_s under $\sigma_c = 40\text{MPa}$ and 50MPa conditions, but also by those under $\sigma_c = 10\text{MPa}$ and 20MPa conditions. Both of the D_s under

$\sigma_c = 40\text{MPa}$ and 50MPa conditions are equal to 2, and the CCM fails to detect the undulations of these two fracture surfaces. While, the D_s under $\sigma_c = 10\text{MPa}$ and 20MPa conditions are basically equal, which indicates the CCM is unable to identify the undulation difference between these two fracture surfaces.

For the SAM, the undulation difference between the fracture surfaces under $\sigma_c = 10\text{MPa}$ and 20MPa conditions is properly identified. Although the D_s under $\sigma_c = 40\text{MPa}$ and 50MPa are close, the values are greater than 2, which indicates the undulation is effectively detected.

4.2 Correlation between fractal dimension and fracture mechanism

The calculation results obtained by the SAM show that there is a negative correlation between D and σ_c , which implies that the increase of σ_c flattens the fracture surface. In order to clarify the mechanism underlying this negative correlation, the fracture surfaces under $\sigma_c = 2\text{MPa}$ and 50MPa conditions are selected to identify the microscopic fracture characteristics.

Figure 6 is the SEM micrographs of the fracture surface under $\sigma_c = 2\text{MPa}$ condition. It is observed that the fracture surface is rough and presents a strong sense of graininess with obvious pits

Figure 5. Variation trends of fractal dimension determined by CCM and SAM with increase of σ_c .

(Figure 6 (a)). At the crystal-size scale, the crystalline mineral grains remain intact and present typical intergranular fracture (Figure 6 (b)).

Figure 7 shows the casting thin section micrographs of the fracturing path under $\sigma_c = 2\text{MPa}$ condition. The blue areas are fracture and voids, and the yellow areas are the mineral particles composing sandstone. Most of the particles on both side of the fracture remain intact. For a few scattered broken grains, a preferred orientation is observed in microcracks that aligned parallel to the direction of the fracture (Figure 7 (b)).

According to the microscopic fracture characteristics in Figure 6 and 7, the fracture mechanism under $\sigma_c = 2\text{MPa}$ condition is tensile fracture. The fracture propagates along particle interfaces with a weak cementing strength. Due to the spatial randomness and heterogeneity of the cementing strength, the fracture path is tortuous and obvious pits and uplift areas are formed, inducing an increase in the undulation degree of the fracture surface. Consequently, the fracture surface resulting from the tensile fracture possesses a higher D .

Figure 8 is the SEM micrographs of the fracture surface under $\sigma_c = 50\text{MPa}$ condition. The fracture surface is flat with a large amount of rock powder and debris adhering (Figure 8 (a)). At the crystal scale, the crystalline grains present trans-granular fracture. The sizes and shapes of the broken crystalline grain are irregular (Figure 8 (b)).

Figure 9 shows the casting thin section micrographs of the fracturing path under $\sigma_c = 50\text{MPa}$ condition. Most of the particles near the fracture surfaces are damaged. Microcracks cross the particles with no preferred orientation (Figure 9 (a)). Meanwhile, the developments of microcracks cross each other and form a diamond cross structure, resulting in the mineral particles being crushed (Figure 9 (b)).

All of the above fracture characteristics showed in Figure 8 and 9 indicate that the mechanism of the rock under $\sigma_c = 50\text{MPa}$ condition is shear fracture. When

Figure 6. Micrographs of the fracture surface of failed sandstone under $\sigma_c = 2\text{MPa}$ condition.

Figure 7. Micrographs of the casting thin section of failed sandstone under $\sigma_c = 2\text{MPa}$ condition.

Figure 8. Micrographs of the fracture surface zone of failed sandstone under $\sigma_c = 50\text{MPa}$ condition.

subjected to a strong shearing effect, the fracture propagates along the direction of maximum shear stress, and the large particles on the cracking path are sheared off or crushed. Additionally, the relative slippage and friction abrade away the surface waviness, flattening the fracture surface. Therefore, shear fracture will result in a lower D .

Based on the above analysis, it is clear that the reason underlying the negative correlation between D and σ_c is the transition of the fracture mechanism. With the increase of σ_c , the fracture mechanism gradually transforms from tensile fracture to shear fracture. (Gao et al. 2019; Yang et al. 2012) The enhancement of shear effect flattens the fracture surface and

Figure 9. Micrographs of the casting thin section of failed sandstone under $\sigma_c = 50\text{MPa}$ condition.

introduces the decrease of the surface undulation, leading to a lower D .

Inspired by this correlation, D as an index for characterizing the 3D morphology of the fracture surface can be a supplementary means to determine the fracture mechanism. The fracture surface with a larger D is subjected to a stronger effect of tension fracture. Fracture surfaces with approximate D s share a similar fracture mechanism.

5 DISCUSSION

5.1 Applicability of the improved CCM

Several improved CCMs have been mentioned in the Introduction. The purposes of the improvements are to improve the calculation accuracy and stability of CCM. To check whether these improvements help to solve the distortion problems, three improved CCMs which are ICCM, DCCM and RDCCM are chosen to determine the D s of the fracture surfaces in Figure 5, the calculation results are shown in Figure 10.

For the ICCM and DCCM, with the increase of σ_c , D s present a rising trend which is obviously not consistent with the undulation characteristics in Figure 5. This is attributed to the fact that these two methods compute the number of cubes covering the fracture surface from a unified reference plane, which brings an overcompensation effect on the cube number. The overcompensation effect becomes stronger with the decrease of the undulation degree, and results in a rising trend of D s. It is ridiculous that the improvements made by the ICCM and DCCM aggravate the distortion problem rather than solve it.

For the RDCCM, the calculated fractal dimensions are identical to those of the CCM, which implies the improvement made by the RDCCM has no contribution to solving the distortion problem.

Although the above improved CCMs have corrected some shortcomings of CCM on the issues they target, the results show that the improved CCMs are still not suitable for characterizing the 3D

morphology of the fracture surface with a small degree of undulation.

5.2 Calculation accuracy of SAM

It has been proven that the SAM is an effective fractal dimension calculation method. To evaluate the accuracy of the SAM, the Takagi fractal surface is introduced as the calculation reference.

A Takagi surface is an extension to 2D of the Takagi curve, and can be seen as a superposition of pyramids of various frequencies attenuated by a scaling factor:

$$f(x,y) = \sum_{n=1}^{\infty} b^n \psi(2^{n-1}x, 2^{n-1}y) \quad (39)$$

Where $1/2 < b < 1$ and $x, y \in R^+ = [0,1]$. The function ψ , called the generating kernel, is a separable function that consists of the product of two sawtooth function:

$$\psi(x,y) = 2 \cdot D(x,Z) \cdot 2 \cdot D(y,Z) \quad (40)$$

Where $D(x,Z)$ is the distance to the nearest integer of x .

The fractal dimension of the Takagi surface is a known value D_T related to b and given by the following formula:

$$D_T = \frac{\log(8b)}{\log(2)} \quad (41)$$

By assigning a series of values to b , Takagi surfaces with different fractal dimensions are generated, as shown in Figure 11. Then, the SAM is applied to Takagi surface to determine the fractal dimension, which is denoted as D_S . The difference between D_T

Figure 10. Variation trends of fractal dimension determined by three improved CCMs with increase of σ_c .

and D_S is defined as the error E . The calculation accuracy ε of the SAM is evaluated by the following equation:

$$E = D_T - D_S \quad (42)$$

$$\varepsilon = \left(1 - \frac{|E|}{D_T - 2}\right) \times 100\% \quad (43)$$

The physical meaning of equation (42) is the accuracy of SAM for quantifying the degree to which the morphology of the Takagi surface deviates from that of the 2D plane.

Table 4 is the fractal dimensions of Takagi surfaces calculated by the SAM and corresponding accuracies, and Figure 12 is the comparisons between D_T and D_S . When D_T s are not greater than 2.40, the values of E are relatively small, and ε s are not less than 90%. Once D_T exceeds 2.40, E begins to increase, and ε gradually decreases. Especially, for the Takagi surface with D_T equaling 2.9, ε decreases to 73.33%.

Figure 12. Comparisons between D_T and D_S , and accuracy of SAM.

The results in Table 4 and Figure 12 indicate that the SAM is not a high-accuracy method for determining D of the fracture surface. Nonetheless, considering the D s of the surfaces encountered in rock

Figure 11. Takagi surfaces with different fractal dimensions.

Table 4. Fractal dimensions of Takagi surfaces and calculated results, errors, and accuracies of SAM.

D_T	2.10	2.20	2.30	2.40	2.50	2.60	2.70	2.80	2.90
D_S	2.11	2.19	2.27	2.36	2.43	2.53	2.60	2.65	2.66
E	-0.01	0.01	0.03	0.04	0.07	0.07	0.10	0.15	0.24
ε	90.00%	95.00%	90.00%	90.00%	86.00%	88.33%	85.71%	81.25%	73.33%

mechanics and engineering are seldom greater than 2.2, the accuracy of the SAM is well enough to characterize the morphology. In addition, the reason for adopting the SAM in this research lies not in its calculation accuracy, but in its ability to effectively identify and reflect the variation trend of the undulation degree of the fracture surface.

6 CONCLUSION

In this study, to seek an effective means to characterize the fracture of rock, the CCM and the SAM are compared by determining the fractal dimension of rock fracture surface. The correlation between the fractal dimension and fracture mechanism is established. The main conclusions can be drawn as follows:

- (1) Using the CCM to quantify the 3D morphology of rock fracture surface with a small degree of undulation will result in a distorted D . This distortion problem comes from the algorithm of the CCM, in which the method for determining the number of cubes covering the surface is unable to capture the variation of surface undulation within a size equal to the height of the cube.
- (2) Based on a new algorithm for calculating the fracture surface area A_s , the SAM completely avoids the distortion problem. The reason is that any subtle variation in the undulation of the fracture surface will be reflected in the A_s and alter the linear relationship between δ and A_s , which introduces the increase or decrease of D .
- (3) There is a negative correlation between the fractal dimension and the confining pressure σ_c which results from the transition of the fracture mechanism with the variation of confining pressure. With the increase of the σ_c , the fracture mechanism gradually transforms from tensile fracture to shear fracture. The enhancement of shear effect induces the undulation degradation of the fracture surface, leading to a lower D .
- (4) Fractal dimension can be a supplementary means to determine the fracture mechanism. The fracture surface with a larger D is subjected to a stronger effect of tension fracture. Fracture surfaces with approximate D s share a similar fracture mechanism.

ABSTRACT: Most of the immersed tunnels constructed are reinforced concrete structures in China and overseas, few of which adopt transverse prestressing. Since the 1990s, composite steel-concrete structures have been widely used in Japan. In order to solve the problems of concrete pouring quality and waterproof performance caused by complex force and reinforced concrete joint, composite steel-concrete is used in Shenzhen-Zhongshan Bridge immersed tunnel. The force of composite steel-concrete element is complicated, the inner and outer plates are the main bending members, and the transverse and mediastinal plates are the main shearing members. There is a certain deviation between the theoretical and actual value of foundation settlement. The uneven settlement and local mis movement between different element during the operation period have hidden dangers to the structure safety. In this paper, an integrated monitoring system is established during construction and operation of immersed tunnel, aiming at the problems of large size, complex construction and safe operation of composite steel-concrete element in Shenzhen-Zhongshan Bridge immersed tunnel. This system can realize the continuous and long-term monitoring of key components, and build the digital life cycle of the immersed tunnel. Through the real-time perception of the stress and deformation state of the main structure, the on-line structural safety assessment is realized. Coordinate and optimize construction monitoring and operation monitoring sensor equipment to reduce tunnel monitoring costs and improve monitoring efficiency. The system has been successfully applied in Shenzhen-Zhongshan Bridge immersed tunnel.

Keywords: Composite steel-concrete, Long-term monitoring, Safety assessment

1 INTRODUCTION

In the past 10 years, driven by Chinese government policy such as the Guangdong-Hong Kong-Macao Greater Bay Area, the Planning of the Changjiang River Crossing Channel, and the development of urban construction, China has completed a large number of major and leading highway tunnel projects, such as the Hong Kong-Zhuhai-Macao Bridge (2018), Qingdao Jiaozhou Bay Submarine Tunnel (2011), Shenzhen-Zhongshan Bridge (under construction) and other large-scale tunnel projects. China's tunnel construction has made great innovations and breakthroughs in design concept, construction method, equipment technology and other aspects. At the same time, as an important infrastructure to improve the efficiency of road transportation and road service level, tunnel has been paid much more attention. Compared with other construction methods,

immersed tube tunnel has lower requirements on the foundation, and is especially suitable for engineering sites with soft foundation, river bed or seabed which are shallow and easy to excavate the foundation trough by water-based dredging facilities.

In 1910, Detroit built the first immersed tube tunnel for underwater transportation. With the development of reinforced concrete technology, the first reinforced concrete rectangular immersed tube tunnel was built in the Netherlands in 1942. Since then, reinforced concrete rectangular section has gradually become the main section form of immersed tube tunnel. At the end of the 20th century, Japan first adopted steel shell concrete composite structure type immersed tube tunnel. And two immersed tube tunnels of steel-shell concrete composite structure have been built successively. In China, the design and construction of immersed tube tunnel started relatively late. Between 1969 and 1997, five immersed tube tunnels were built in Hong Kong. In

*Corresponding author: neuzzh@126.com

1988, the construction of Ningbo Yongjiang Tunnel and Guangzhou Pearl River Tunnel led to the great development of immersed tube tunnel in China. As of 2022, the number of submerged tube tunnels has been built in China is twenty, the number of submerged tube tunnels under construction is ten, and the number of proposed submerged tube tunnels is six. With the development of China's infrastructure construction and the maturity of immersed tube tunnel design, construction and maintenance technology, China's immersed tube tunnel technology has been in the world's leading level.

In order to solve the problems of concrete pouring quality and waterproofing performance caused by complex force and many reinforced concrete elements, steel shell concrete elements are applied to immersed pipe tunnels in deep and middle passages. Steel shell concrete composite structure is a type of composite structure in which steel shell and concrete work together after filling self-compacting concrete between double steel plates. However, the force of steel shell element is complicated, the inner and outer panels are the main bending members, and the transverse and mediastinal plates are the main shear members. The foundation structure of the whole line is complex and diverse, and there is a certain deviation between the theoretical value and the actual value of the foundation settlement. Uneven settlement and local dislocation between different element during operation pose hidden dangers to structural safety. The above hidden dangers may lead to great changes in the cross section and structural form of immersed tube tunnel, from the early circular cross section gradually developed to octagonal, square, rectangular and polygon cross section forms. Gradually developed from steel shell structure to steel shell and reinforced concrete composite structure, double steel shell/steel structure sandwich composite structure, reinforced concrete structure, prestressed reinforced concrete structure forms.

The construction process of immersed tube tunnel is often complicated. In order to ensure the construction safety, provide the change information of immersed tube timely and accurately, and provide the basis for the determination of construction parameters, the construction monitoring system is very necessary. Li Harting et al. introduced the establishment and operation of the immersed tube tunnel construction monitoring system of the Hong Kong-Zhuhai-Macao Bridge from the aspects of tunnel settlement, joint differential deformation, segment tension and environmental temperature monitoring, etc., and analysed the monitoring data of differential deformation and settlement to verify the reliability of the monitoring system. Similarly, the structural monitoring system during tunnel operation can grasp the structural condition in the use stage in time, providing data support for scientific evaluation and ensuring safety and durability. Li Weiping et al. tested Ningbo Yongjiang immersed tube tunnel during its operation period and evaluated GINA water stop belt. Liu Zhenggen et al. established a real-time health

monitoring system of immersed tube tunnel composed of multiple sensors based on the background of Ningbo Yongjiang immersed tube tunnel.

Reinforced concrete structure is used as the main structure in domestic immersed tube tunnel, accounting for 89%. However, the number of immersed tube tunnels with steel shell concrete composite structure is increasing gradually. In view of the problems of large size, complex construction and safe operation of concrete composite structure, the integrated monitoring system of immersed tube tunnel structure during construction and operation is constructed in combination with the actual project of immersed tube tunnel in Shenzhen-Zhongshan Bridge. The continuous and long-term monitoring of key components is realized, and the digital life cycle of immersed tube structure is constructed. Through the real-time perception of the stress and deformation state of the main structure of the tunnel, the on-line structural safety assessment is realized. Coordinate and optimize construction monitoring and operation monitoring sensor equipment to reduce tunnel monitoring costs and improve monitoring efficiency.

2 BASIC OVERVIEW OF IMMERSSED TUBE TUNNEL

2.1 Basic overview

On the east of the Shenzhen-Zhongshan Bridge is the Hezhou Interchange in Bao'an District of Shenzhen and on the west is the Hengmen Junction in Zhongshan. It is 24 km long, including 6.8 km long immersed tube tunnel, is the world's first two-way eight-lane underwater immersed tube tunnel. The immersed pipe tunnel is composed of 32 element with a total length of 5035m, the standard pipe section length of 165m and the curve width pipe section length of 123.8m. The final connector is set between E23/E24, and the pipe section is divided into $123.8 (E1) + 22 \times 165m (E2 \sim E23) + 2.2m (final\ connector) + 4 \times 165m (E24 \sim E27) + 5 \times 123.8m (E28 \sim E32)$.

The immersed tube tunnel adopts two traffic passageways and one integrated pipe gallery structure. On the left and right side of the main traffic road, the middle pipe corridor from top to bottom are exhaust flue, safety passage and cable passage respectively. The overall external profile size of the pipe section is 46~55.46 m (width) \times 10.6m (high). The immersed tube tunnel adopts steel shell concrete composite structure, which is mainly composed of internal and external panels, transverse mediastinum plates, transverse and longitudinal stiffening ribs and welding nails.

2.2 Characteristics of steel shell immersed tube tunnel

There are five difficulties in the Shenzhen-Zhongshan Bridge: ultra-wide, changing section width, deep burial, large amount of siltation and poor formation

Figure 1. The design profile of immersed-tube tunnel.

stability in the sand pit area. By now, it is one of the most technically difficult projects in the world. The standard section length of the immersed tube is 165 meters, and the displacement is about 80,000 tons. Each of the 32 element uses an average of about 10,000 tons of steel. A single pipe section is composed of more than 2500 independent compartments, which is large in quantity, large in specifications, difficult in process parameter control and construction organization.

Ultra-wide refers to the first in the world that the immersed tube tunnel adopts the two-way eight-lane standard. It's section width reaches 46 meters. Therefore, the design and construction are difficult. Changing section width refers to the tunnel in order to meet the needs of traffic function, set 615 meters of widening section. In order to achieve the goal of multiple submerging in the tunnel, the section of the pipe section is widened from eight lanes in both directions to twelve lanes in both directions. The section width of the pipe section has been widened from 46 meters to about 70 meters. However, according to the current lack of domestic standards, such a large-scale immersed element will bring safety problems.

Deep buried means that the submerged tube tunnel is buried deep. The deepest position of the submerged tube bottom elevation is close to 40 meters from the water surface. Large amount of siltation means that the average rate of siltation in flood season is close to 2 cm per day, and the maximum rate of siltation typhoon period is more than 5 cm per day. Poor formation stability in the sand pit area means that the western island slope section is located in the super-large sand pit. And the regional formation disturbance is serious. The stability is very poor, which causes great difficulties in the excavation of the foundation groove and foundation treatment.

Figure 2. Tunnel cross-section.

3 INTEGRATED MONITORING PLATFORM DESIGN

3.1 Monitoring content

The engineering conditions of the tunnel section of Shenzhen-Zhongshan Bridge are very complicated and the environment is relatively bad. The immersed tube tunnel section is located on the weak foundation of the seabed, which is mainly composed of sea sand and sea silt. With the increase of service life, the immersed tube tunnel built in the soft soil layer may cause uneven settlement and local dislocation damage between different elements of the tunnel due to the repeated action of external variable loads such as traffic flow, tide and siltation depth, which brings great hidden dangers to the structural safety of immersed tube tunnel.

Figure 3. Tunnel attitude monitoring.

A little less, will cause a major accident, and then seriously affect the safety of the tunnel. In order to ensure the safety of tunnel engineering and forecast danger in time, it is very important to monitor and evaluate the safety and stability of tunnel engineering. Through modern detection technology, the establishment of a monitoring system to accurately understand the tunnel conditions, to achieve comprehensive monitoring of the steel shell structure and immersed tube tunnel environment during the construction and operation period, master the stress and deformation of the steel shell structure, and ensure the safety of the structure. Timely detect and forecast the occurrence of dangerous situations, and take engineering emergency measures when necessary.

Figure 4. Monitor content and location.

The main monitoring contents of the Shenzhen-Zhongshan Bridge include: element settlement, deformation, steel shell structure stress, element relative displacement and corresponding environmental temperature. The settlement and deformation of element is an important sign reflecting the stability of sunk pipe structure and surrounding strata. By monitoring the settlement of sunk element, the variation trend of element settlement and deformation can be predicted, and the basis for the precise positioning of new element can be provided. As the main carrier, the horizontal stress, non-uniform settlement and non-uniform force of steel shell element will cause the local stress concentration of steel shell, which will affect the composite system of steel shell concrete and seriously affect the structure. The relative displacement of element is an important index for the detection of uneven settlement and leakage of element in immersed pipe tunnel, which is related to the service effect of the tunnel water stop belt.

3.2 Integrated monitoring system

The traditional tunnel monitoring is divided into construction period and operation period. However, due to the problems of inconsistent monitoring subject units and incompatible monitoring equipment, tunnel

monitoring has many shortcomings such as data discontinuity, single monitoring system function, data redundancy and inaccurate monitoring results, which can no longer meet the needs of modern large-scale tunnel monitoring automation and intelligence. The immersed tube tunnel in deep and middle channel has some problems such as super width, widening, deep burial and large silt return. Based on this, the overall design idea and system architecture of the integrated monitoring system for tunnel construction operation are studied. According to the special geological and sea navigation conditions of different elements of immersed tube tunnel, a set of construction and operation monitoring system suitable for steel shell concrete composite structure is designed. In the whole life cycle of the tunnel, the functions of the construction and operation stages are different, but interrelated. In this way, the unsafe factors during construction period and operation period are captured, and the state of immersed tube tunnel structure is monitored and evaluated. When there are abnormal changes in the tunnel structure, early warning is carried out to provide data support for the whole life cycle of the tunnel construction, maintenance and management.

In order to meet the requirements of system integration, intelligence and data sharing, the system adopts distributed system architecture to collect the bridge detection data, and transmits the data through the network. The collected bridge health data information is uniformly stored in the data management centre of the system using the database, and provides data support for the tunnel health status assessment. On this basis, real-time monitoring of tunnel health status, emergency information release and early warning are realized. Improve the intelligence of tunnel

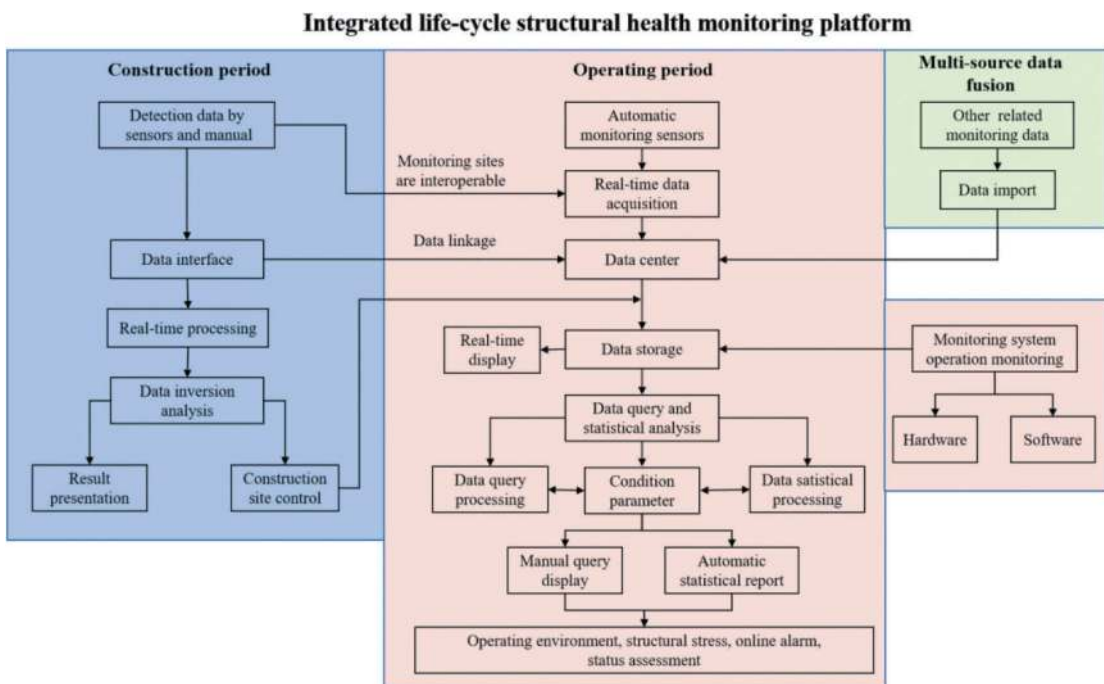

Figure 5. Integrated monitoring platform.

monitoring to ensure the safety and smooth traffic of the Shenzhen-Middle passage. Starting from the time dimension, the system is based on multi-source data fusion, mainly including construction stage monitoring module and operation stage monitoring module.

The main goal of the module in the construction stage is to invert the structure according to the actual construction data and ensure the safety of each pipe section. The main content has the following three aspects. First, the monitoring system database contains design data and sensor layout scheme information, providing basic data support for construction process simulation and construction process control. Second, during the construction phase, all sensors should be arranged according to the designed sensor layout scheme, so as to reduce the disturbance caused by the sensors after completion to the bridge structure and ensure the durability of the sensors. Third, according to the structural characteristics of the steel shell immersed tube tunnel, the focus is on the whole process monitoring of vertical displacement, vertical dislocation, water level displacement, horizontal dislocation, joint relative displacement and corresponding temperature and humidity, structural load and structural internal force to ensure the structural safety during construction. Finally, at the same time, the system saves the construction data as the basic data of the operation stage.

The operation phase module mainly conducts long-term stable health monitoring in four aspects: long-term operating environment, structural state, traffic state and structural disease. The main contents include the following three aspects. First, Automatic monitoring of structural and system damage accumulation and resistance attenuation of immersed tube tunnels in use. Second, assess the safety of the tunnel, provide intelligent early warning of possible damage conditions and even provide repair plans, control the damage, and ensure the safety, integrity, applicability and durability of the structure. Third, develop new conservation management methods, monitoring technologies and corresponding evaluation theories and methods according to their own practices during the use of the system.

4 MONITORING DATA ANALYSIS

On June 11, 2023, the final joint of the world's longest and widest steel-shell concrete immersed tube tunnel, the Shenzhen-Zhongshan Bridge submarine tunnel, was successfully launched, and the penetration measurement results showed that accurate docking with the east section (E24) was achieved. Since the start of the steel shell test section of the submarine tunnel in April 2018, a full five years later, the submarine great wall has finally closed, and the two cities of Shenzhen and Zhongshan have achieved Hand in Hand at the bottom of the Lingdingyang Sea, taking an important step for the opening of the Shenzhen-Zhongshan Bridge. A large amount of measured data has been accumulated during the construction period, and some monitoring data are mainly analyzed now. The

monitoring data include the element settlement data (E1-E23), the steel shell stress data (E1, E5, E9, E13, E18, E23, E24, E26, E29, E32), and the element relative displacement data (E1-E11).

4.1 Element settlement monitoring

Each pipe section has three settlement monitoring points, which are middle side, Shenzhen side and Zhongshan side. As shown in Figure 6, the settlement of the middle side of E1 pipe section is significantly greater than that of Shenzhen side and Zhongshan side. The vertical displacement of E1 pipe section is less affected during the locking backfill. However, the vertical displacement of element is greatly affected during the covering backfilling period. During concrete placement, the vertical displacement of element is less affected. After covering and backfilling is completed, the maximum settlement occurs in the middle end of the pipe section. Compared with the current maximum cumulative settlement of 51.88mm and the warning value of 56mm, we get that the settlement of E1 element is in a safe state.

Figure 6. The time history curve of E1 element settlement.

The final joint is located between E23 and E24, so the settlement data of the E23 element needs to be analyzed. The maximum cumulative settlement in the E23 element is -20.06 mm, which is located at the bottom of the pipe gallery in the E23 element. Compared with the warning value (56 mm), the E23 element is in a safe state.

Figure 7. The time history curve of E23 element settlement.

We have successfully monitored the absolute settlement data of all elements during construction. As shown in Figure 8, through data analysis, we get the settlement displacement cloud image of the immersed tube tunnel.

Figure 8. The cloud image of all elements settlement.

It can be seen from the figure that the maximum settlement displacement occurred in the E31 element, and the maximum value was 60 mm. The data show that E31 has a large settlement displacement after settling down. In the subsequent process, the displacement did not change much. The element with large settlement displacement are E1, E3, E6, E10, E16, E20, E26 and E31. So, in the operation monitoring, we should pay more attention to the change of settlement displacement of these immersed tube joints.

4.2 Steel shell stress

A total of 10 stress measuring points are arranged for each monitoring section. And each carriageway hole is arranged symmetrically.

As shown in Figure 9, after the sinking of the element, the steel shell in the top plate of the element shows tension, and the steel shell in the side wall on both sides of the element shows pressure. In the process of element backfilling construction, the structural stress increased steadily, no sudden increase was found, and the values of each monitoring point were less than the warning value of 224 MPa, so the element structure was in a safe state. With the completion of tunnel construction, the stress changes were small and the data were normal. The results show that the stress of each steel shell section is symmetrical and the structure does not have significant differential settlement.

4.3 Element relative displacement

The relative displacement of element is mainly used as an important index to evaluate the service effect of water stop belt. As shown in Figure 10, the displacement of E1-E2, E2-E3, and E5-E6 is positive, which can be judged as the element is open. And

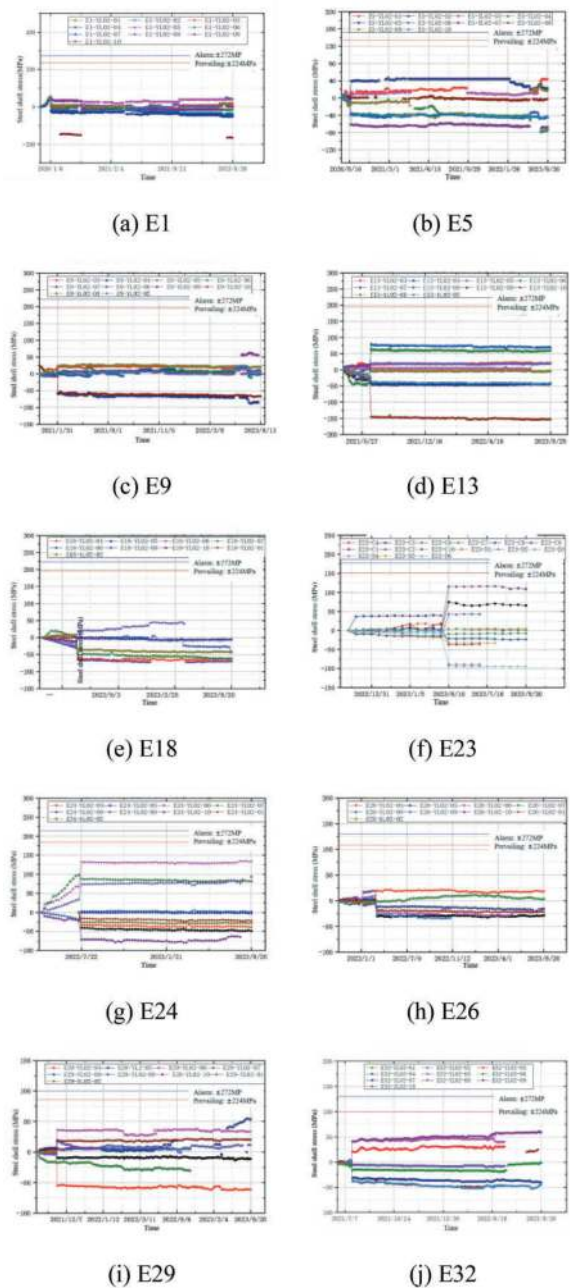

Figure 9. The time history curve of steel shell stress.

affected by the temperature, the immersed element is generally opened in the summer when the temperature is high. The displacement of the E3-E4, E4-E5 is negative, and it can be judged that the element is in a tightened posture. The reason may be affected by the uneven settlement of elements. In the initial stage, the displacement of elements changes greatly, and the maximum value is 25 mm, which occurs at the E1-E2 elements. The change of data in the later period is gradual.

During the construction process, we monitored the relative displacement values of E1~E19 elements. The relative displacement cloud image is obtained by analyzing the data of different element, as shown in Figure 11.

Figure 10. The displacement of E1~E6.

Figure 11. The displacement cloud image of E1~E19.

The tube section with larger opening size are E1-E2, E2-E3, E6-E7, E10-E11. We should pay more attention during tunnel operation. The maximum opening is 25 mm, which does not exceed the displacement limit. The position of the smallest relative displacement occurs at E13-14. The minimum value is -9 mm. The relative displacement of other elements changes little. It can be seen from the data that during the tunnel construction, the relative displacement changes little, and the service effect of the water stop belt is good.

5 CONCLUSIONS

In this paper, an integrated monitoring system was established during construction of immersed tunnel. This system can realize the continuous and long-term monitoring of key components, and build the digital life cycle of the immersed tunnel.

For the settlement displacement, the value in the middle of the element is greater than that at both ends. And the maximum occurred in the E31, and the value was 60 mm. For the steel shell stress, each steel shell section was symmetrical and the stress did not exceed the warning value. For the relative displacement, the maximum value is 25 mm, which

occurs at the E1-E2. The smallest relative displacement occurs at E13-14 and the value is -9 mm. The relative displacement changes little, and the service effect of the water stop belt is well.

Through the analysis of element settlement data, stress data and relative displacement data, it can be found that there is no large settlement deformation during the entire construction period of the tunnel. Tunnel joint attitude is maintained well. Stress concentration events did not occur. At the same time, the integrated monitoring platform can integrate multi-source data types well. Through the actual monitoring data, the system has been successfully applied in Shenzhen-Zhongshan Bridge immersed tunnel.

ABSTRACT: In mountain tunnels after construction, structural deformation often occurs due to external forces from the ground. The authors focused on distributed fiber optic sensing (DFOS), which can provide stable and high-density measurement data over a long period of time. DFOS enables quantitative structural health monitoring from construction to operation processes. This contributes rational maintenance management based on the actual condition of the structure. In this study, the installation method, measurement accuracy, and effectiveness of DFOS were considered through tests on laboratory and actual tunnel.

Keywords: Mountain tunnel, Structural health monitoring, Distributed fiber optic sensing, Laboratory test, Field installation

1 INTRODUCTION

1.1 DFOS for tunnel health monitoring

In mountain tunnels after construction, structural deformation often occurs due to external forces from the ground. For safe usage of tunnel, structural health monitoring of tunnel is important. Although tunnel deformation is usually monitored using electrical sensors such as strain gauge, the reliability of

the measurement data is lost due to reduction of insulation resistance after a few years, which limits the usage in maintenance and management where long-term operation is required.

The authors focused on distributed fiber optic sensing (DFOS) technology, which can provide stable and high-density measurement data over a long period of time along the optical fiber. DFOS enables quantitative structural health monitoring of tunnel from construction to operation. This

*Corresponding author: nonakaha@kajima.com

contributes to the rationality of maintenance and management based on the actual condition of the structure.

In this study, the installation method, measurement accuracy, and effectiveness of DFOS were explored through laboratory tests and application on an actual tunnel.

1.2 Description of DFOS technology

DFOS is based on light scattering effects and is divided into three main types; Raman scattering based distributed sensors, Brillouin scattering based distributed sensors, and Rayleigh scattering based distributed sensors. Raman systems are sensitive to only temperature, whereas Rayleigh and Brillouin systems are sensitive to both strain and temperature changes. Table 1 shows general capabilities regarding distance range, spatial resolution and repeatability of popular sensing techniques based on Brillouin and Rayleigh scattering.

Brillouin scattering based DFOS is one of the most popular fully distributed sensing technologies and is mainly divided into Brillouin Optical Time Domain Reflectometry (BOTDR) and Brillouin Optical Time Domain Analysis (BOTDA). Brillouin systems are capable of measuring long distances, which are familiar with monitoring large scale civil infrastructures. However, this sensing technology typically has limited spatial resolution and measurement accuracy.

Recently, Rayleigh scattering based DFOS is receiving increased attention as a monitoring tool for civil structures. The Optical Frequency Domain Reflectometry (OFDR) technique enables high spatial resolution and accuracy measurement, but these measurements are limited in the range of sensing distance. This system is useful in monitoring detailed behavior of structure in the small scale. The Tunable Wavelength Coherent Optical Time Domain Reflectometry (TW-COTDR) technique provides relatively high resolution and accuracy measurement over long distance. The selection of the appropriate DFOS technology must be adjusted depending on the requirements of the actual infrastructure. In this study, TW-COTDR technique is selected for tunnel monitoring which often requires high resolution and long-distance measurement. In the TW-COTDR system, the Rayleigh scattering traces which show random signature obtained at each measurement are compared with the reference state by cross-correlation. The system supplies the Rayleigh frequency shift $\Delta\nu_R$ related to changes of the fiber temperature ΔT or/and strain $\Delta\varepsilon$.

$$\Delta\nu_R = C_{\varepsilon R}\Delta\varepsilon + C_{TR}\Delta T \quad (1)$$

Where, $C_{\varepsilon R}$ is the strain coefficient, and C_{TR} is the temperature coefficient of the optical fiber sensor.

Table 1. Features of different DFOS systems (modified from Monsberger and Lienhart, 2021 and Kishida et al, 2022).

Scattering	Brillouin		Rayleigh	
	BOTDA	BOTDR	OFDR	TW-COTDR
Technique	BOTDA	BOTDR	OFDR	TW-COTDR
Distance range	≤80km	≤100km	≤0.1km	≤25km
Spatial resolution	≥20cm	≥100cm	≤1cm	≥2cm
Strain repeatability	±2με	±20με	±1με	±0.1με

2 LABORATORY TESTING FOR ACCURACY VERIFICATION

A bending test using beam specimens was conducted to verify the measurement accuracy of strain using DFOS in lining and invert.

2.1 Test descriptions

The experiment conducted is a symmetrical four-point bending test. Figure 1 illustrates the structure of the test specimen, a prestressed concrete (PC) beam of cross section 450×360mm and length 4,600mm. Three PC steel wires were arranged linearly 120mm below the beam, and prestress was introduced using the post-tension method to apply stress of 6.0N/mm² in the compressive side of the concrete. During the experiment, compressive strength was 49.7N/mm², and Young's modulus was 31.5kN/mm² for concrete; yield strength was 396N/mm², and Young's modulus was 194kN/mm² for steel.

To better comprehend the bending behavior, DFOS were installed on the upper and lower sides of the specimen. The sensors were intermittently fixed along the steel with cable ties as seen in Figure 1. In addition, to obtain control data for comparison with DFOS, strain gauges were placed in five locations on the steel, while Linear Variable Differential Transducers (LVDTs) were placed at seven locations on the lower side of the specimen. The load gradually increased, and the sensors took measurements at each loading stage.

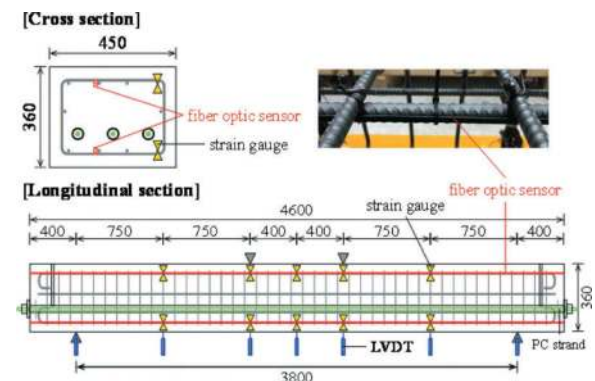

Figure 1. Schematic representation of beam structure and installed sensors (based on Taira et al, 2022).

2.2 Test results

Measurements by the DFOS were taken using the Neubrescope NBX-7030, manufactured by Neubrex, using the TW-COTDR method. The measurement interval was set at 5cm, and spatial resolution was 10cm. Figure 2 shows the strains measured by DFOS and the strain gauges (SGs) when load was at 10kN, 70kN, 90kN, prior to fracture. It is observed that compressive and tensile behaviors in response to distribution of bending moment are captured throughout the entire axis, and these measurements confirm that strain increases with load increase. In addition, strain measured through DFOS align with the results obtained from SGs. On the other hand, when load is at 90kN, a difference of approximately $30\mu\epsilon$ occurred on the tensile side. This is presumed to be due to the influence of unobservable cracks. DFOS identify localized strain in several locations. These locations are thought to capture the localized stress concentration prior to formation of cracks, as they match with positions where cracks visibly formed upon further load increment. On the other hand, it is hypothesized that measurements from SGs indicate smaller strain due to stress relief as they do not correspond to crack positions.

Figure 2. Strain profile along PC concrete beam.

Figure 3 shows displacement distribution calculated from the strain distribution obtained from DFOS. Displacement was determined by calculating the curvature from the strain measured by DFOS on both sides and integrating it twice in the span direction. The displacement based on DFOS conforms with the measurement values shown in the displacement meters, confirming that DFOS can accurately assess deformation caused by bending.

3 TUNNEL MONITORING UNDER OPERATION

To understand the existing condition of the tunnel during maintenance, strain is measured by electrical sensors installed at various points along the concrete lining. Whereas DFOS are installed along the circumferential direction of the tunnel surface, allowing for a more comprehensive understanding of the structure's

Figure 3. Displacement curves calculated from DFOS strains, measured by LVDT.

behavior. Here, installation of DFOS is assessed in a large-scale simulated road tunnel, and measurement accuracy is verified through a loading test from the tunnel crown.

3.1 Sensor installation

Figure 4 shows the three types of fiber optic sensors installed within the simulated tunnel measuring 7.1m in height and 11.2m in width. Two different shapes of sensors are installed using adhesives. The other one variant is tape which reacts to applied primer, with DFOS embedded on the tape enabling immediate attachment to the tunnel wall. The DFOS are placed on top of a fixture positioned across the longitudinal crack that were observed near the crest. It takes 2.5 ~ 3.0 hours to install DFOS along the circumferential direction of the tunnel wall (span of 20m).

Additionally, strain gauges were installed at the crest, the left and right shoulders and at two locations at SL height to verify accuracy. Pi-shape displacement transducers (crack gauges) were placed at the location of the cracks to measure the extent of the crack opening.

Figure 4. Simulated road tunnel: (a) sensors layout. (b) Fiber optic sensors. (c) fixture across crack.

3.2 Loading tests

Figure 5 shows the condition of the load test. A maximum of 47 bags of 1t soil are loaded on top of the tunnel, around the cross-section of the installed DFOS. Measurements were conducted during the loading process, which is divided into 7 loads; and the unloading process, which is divided into 6 loads. The loading step is as shown in Figure 6.

Figure 5. Loading test with bulk container.

Figure 7 shows measurement results from the DFOS and strain gauges when load is at maximum of 47t. The horizontal axis represents circumference length of the tunnel wall, where starting point 0m refers to the south tunnel base, extending along the circumferential direction to the crown at 10m, and ends at the north tunnel base at 20m. Results shows that compressive strain is seen throughout the length of DFOS, except for areas where cracks are observed at the crest, with maximum compressive strain showing at the tunnel shoulders. This is consistent with the general trend of strain with load from the top of tunnel. Furthermore, the strain gauges show similar results with DFOS where maximum compressive strain is measured at the shoulders.

Figure 6. Step of loading test.

Figure 8 shows strain measurement results during the loading and unloading processes at the right tunnel shoulder, which shows maximum strain.

Figure 7. Strain distribution of arch surface in 47t loading.

Compressive strain at both DFOS and strain gauges gradually increased as the loading progressed and showed gradual decrease during the unloading process. However, hysteresis behavior was observed during both loading and unloading processes and a residual strain of about $5\mu\epsilon$ was observed after complete unloading. This is because the tunnel structure was not in complete elastic condition due to crack near the crest. Both the DFOS and strain gauges exhibit a maximum error of $7\mu\epsilon$. This cause in discrepancy is potentially attributed to the installation environment of the sensors, such as the inhomogeneous nature of the tunnel surface. However, this error is negligible during evaluation of actual tunnel.

Figure 8. Comparison between DFOS and strain gauge measured at right tunnel shoulder.

Figure 9 illustrates strain distribution around the position of cracks at the crest during the loading process as measured by DFOS. Tensile strain was observed at crack position, gradually intensifying as loading progressed, accompanied by crack propagation. Figure 10 compares the results of crack aperture size calculated from data obtained by DFOS and those measured by the crack gauge. Aperture size obtained from DFOS measurements were calculated by summing the values within the range representing integral of strain that also exhibited tensile behavior. The same trend can be seen in both loading and unloading processes, verifying that DFOS can measure aperture size with the same accuracy as a crack gauge.

Figure 9. Strain distribution of around crack position.

Figure 10. Comparison between DFOS and crack gauge displacement.

4 TUNNEL MONITORING UNDER CONSTRUCTION

The installation of DFOS along the concrete lining of the tunnel wall and invert during the construction phase allow for timely measurement of stress patterns immediately after completion of initial construction. Consequently, it is feasible to manage structural integrity as residual strength. In this section, testing of DFOS installation along the internal concrete lining of the tunnel wall and invert were conducted.

4.1 Sensor installation

Complications when installing DFOS directly inside concrete includes bending and tensing of the cable, as well as the possibility of misplacement due to extrusion during concrete casting. As a countermeasure, the DFOS were aligned along the reinforce steel to act as a guide for accurate placement. Figure 11 depicts how DFOS were installed at the invert and at the arch lining. One span of DFOS require approximately 2~3 hours to install at the invert, and 5~6 hours for the lining. The impact of DFOS installation to the construction process is minimal.

Figure 11. Sensor installation: (a) Invert. (b) Arch lining.

To ensure proper extraction of DFOS, prior planning is necessary as the tunnel wall becomes completely enclosed after concrete was casted at the arch. To avoid disruption to the construction process and operation of the facility, a strategically placed block out box was installed at the invert shoulder. This enables extraction of the sensors from the internal wall at any desired location.

After construction of a tunnel, it is customary practice to install porous ceramic duct within the inspection corridor to facilitate the routing of electrical and communication wires. This allows for the integration of DFOS without the need for installation at the surface. By connecting the extracted DFOS for measurement purpose from the block out box to the communication optic fiber cables within the ceramic pipes, DFOS can be extended all the way to the entrances of the tunnel. Figure 12 provides a visual representation of the DFOS layout during the maintenance phase. Moreover, when measurements from multiple sections of the tunnel are required, a comprehensive observation system can be achieved by connecting these sections to a single measuring device. By combining the installation methods evaluated in this study, utilizing DFOS throughout the lifecycle of the tunnel from construction to operation is possible.

Figure 12. Conceptual diagram of DFOS layout during tunnel maintenance.

4.2 Monitoring concrete curing process

Temperature and strain measured during curing of concrete were investigated using DFOS installed at the invert. Figure 13 shows the measurement results taken at the center of the invert for the left lane of the road tunnel. It is observed that temperature rapidly increased by approximately 18°C within two days after placing. Additionally, compressive strain of approximately 50µε due to thermal expansion is

observed at the concrete. After hitting the peak, temperature gradually decreased, causing tensile strain due to compression. This confirms that DFOS were able to effectively measure the expansion and compression behaviors after concrete were placed. Similar results were observed in the sensors installed at the arch lining of the tunnel.

Figure 13. DFOS measurement results. (Curing process at invert concrete).

5 STUDY ON EFFICIENT DESIGN OF COUNTERMEASURES FOR TUNNEL DEFORMATION

An example of remedial construction to countermeasure deformation of concrete lining and invert in road tunnel was examined to evaluate the effectiveness of implementing DFOS in rationalizing remedial construction designs.

5.1 Description of target deformed tunnel

The object of this study is a road tunnel constructed using NATM. The specified segment was lined with high-strength steel fiber-reinforced concrete. During construction, a segment of the tunnel that was observed to be layers of weak clay, displayed a maximum displacement of nearly 250mm. The deformation was discovered 20 years after the tunnel was put into service. The extensive fractures were observed along the right concrete arch lining and invert of the tunnel. Although, geological surveys, boring tests and various measurements were conducted, the details of stresses and condition of external forces were not detected. Figure 14 shows the assumed geological condition based on the surveys conducted. Table 2 presents the applied physical properties of the weak ground layers and bedrock grade CII.

As the original case, a 2D skeletal structure analysis was conducted on the deformed segment of the tunnel

as shown in the model in Figure 15. The design for reinforcement measures assumed that the same load which caused failure of wall lining and invert would act on the tunnel walls in the future. This yielded the M-N resistance curve shown in Figure 16. A load of 650kN/m² was acting on the upper circumference of the tunnel and this was adopted as the design load of the structure. As a result, reinforcement chosen to reinforce the inner section of the wall lining were embedded frames (of thickness 100mm), and internal reinforcement of thickness 250mm for the invert.

Figure 14. Assumed geological condition.

Table 2. Physical properties.

Rock mass classification	Young's modulus E_0 [N/mm ²]	Coefficient of subgrade reaction K_n [N/cm ³]
CII layer	10,000	197.8
Weak layer	2,300	45.5

Figure 15. Analysis model (original case).

Figure 16. M-N resistance curve (original case).

5.2 DFOS data for efficient design

In this section, the remedial construction were designed based on the assumption that stress can be assessed using DFOS embedded in the concrete lining and invert during the construction phase. A 2D skeletal structure analysis was conducted using a tunnel analysis model, when the load is acting on the right side of the weak layer distribution as shown in Figure 17. The remedial construction selected were the same as the actual reinforcement structure; the arch lining section was internally reinforced with embedded frames and internal reinforcement for the invert.

This yielded in the M-N resistance curve shown in Figure 18. As a result, the design load is 500kN/m^2 . Reinforcement selected based on this result are the same as in the previous section for the wall lining; internal reinforcement by embedded frames (of thickness 100mm), while internal reinforcement for invert changed from thickness of 250mm to 150mm.

Thus, by continuously monitoring the stress condition of the structure with DFOS, designing appropriate remedial construction is possible.

Figure 17. Analysis model (DFOS application assumed case).

Figure 18. M-N resistance curve (DFOS application assumed case).

6 CONCLUSIONS

This study aims to evaluate the applicability of DFOS in monitoring the structural integrity of tunnels during the maintenance stage. This evaluation was conducted through lab tests, experiments at an actual tunnel, and numerical analysis. Findings from this study are summarized as below.

- Bending tests of beam specimens where prestress was applied shows that DFOS can measure compressive and tensile strains with similar accuracy as strain gauges and is effective in detecting localized strain changes before cracking becomes apparent. Moreover, deflection of the specimens derived from DFOS measurements are equivalent to those obtained from LVDT measurements.
- Load test was conducted on a simulated tunnel where DFOS were installed on the lining surface. The result from this test confirms that DFOS can measure strain with similar accuracy as conventional sensors. Furthermore, it was observed that displacement of cracks calculated from DFOS measurements is consistent with those obtained from crack gauges.
- Implementing DFOS in tunnels have minimal impact on the construction process. In consideration of conducting measurements during the maintenance phase, a wiring method was demonstrated, enabling the installation of DFOS during construction and its retention until after the completion of the tunnel.
- The effectiveness of implementing DFOS was investigated using a case study where a tunnel underwent countermeasure designs against deformation. By assuming that DFOS is capable of depicting stress distribution within the structure, sectional force was investigated. The results revealed that there is potential to implement a more rational and optimized design.

These results indicate that by implementing a long-term stable measurement method such as DFOS, it is possible to accurately measure both local and general behaviors of the tunnel structure. Furthermore, by incorporating DFOS to monitor tunnels, optimized maintenance can be achieved based on the actual conditions of the construction site.

Development of wear detection device using dye

Yoshie Omae*, Yosuke Imaoka, Hiroshi Ueda & Atsushi Nakamoto

Rui Fukui
The University of Tokyo

ABSTRACT: A wear detection device using dye has been developed. The dye is installed on the device and is linked with the bit to monitor the depth (amount of wear), and as soon as the predetermined wear amount is reached, the dye is released to the cutting face. The released dye to the cutting face is discharged together with the excavated soil, and the wear amount can be known by checking the coloration of the excavated soil.

In the development of this wear detection device, a preliminary experiment has been conducted to determine the possibility of identifying the colors with mixed soil, and it was found that identification by visual observation and image analysis is possible. Also, the appropriateness of the identifiable amount of used dye and the mechanism of dye releasing to the cutting face under the cutting face pressure was confirmed. To do this, actual site experiments at the two sites with the small and medium-diameter shields were conducted. As a result, it was confirmed that the developed wear detection device using dye can be applied to the actual shield construction sites.

Keywords: Shield, Cutter bit, Wear detection, Dye, Ultraviolet light

1 INTRODUCTION

In shield construction, continuous excavation using the cutter bit which exceeds the allowable wear amount causes troubles such as cutter damage. For this reason, it is important to monitor the wear condition of the cutter bit and manage the excavation. As conventional devices for detecting the amount of cutter bit wear, there are conduction-type wear detection device that detects the amount of wear through electric conduction, and hydraulic wear detection device that detects wear by monitoring the decrease in the hydraulic pressure. These wear detection devices need cables and piping to transmit the wear amount from the cutter face to the inner side of the shield machine. Due to the limited installation space, it is currently difficult to install these detection devices in small-diameter shield machines. Therefore, a wear detection device using dye or odor was developed that does not require cables or pipes. In this paper, an overview of the wear detection device using dye is described. Also, the results of preliminary experiments and site experiments to confirm the applicability of dye, and demonstration experiments using an actual machine are reported.

2 OVERVIEW OF A WEAR DETECTION DEVICE USING DYE

In this wear detection device, the preinstalled dye is released from the cutter bit when the predetermined amount of wear is reached. Since the released dye is discharged together with the excavated soil, the amount of wear can be monitored by checking the coloration of the excavated soil.

2.1 Dye selections

After the dye is released, it is removed and collected with the excavated soil. The physical properties of the dye must be naturally harmless taking into consideration the possibility of leakage into the ground or after treatment of the residual soil. Considering the environmental impact, fluorescent tracer dyes, which are used in groundwater flow surveys, were selected as a dye in the wear detection device. The colors are yellow-green (main component: uranine) and red (main component: rhodamine WT), the coloring property is very strong in the water, and visual observation is easy without special equipment. Furthermore, even if the dye diffuses and reaches a low

*Corresponding author: omae.yoshie@obayashi.co.jp

concentration that cannot be confirmed visually, the presence or absence of the dye can be distinguished as it emits light when exposed to ultraviolet (UV) light (Photo 1). These fluorescent tracer dyes have a low impact on the environment and are biodegradable. In addition, water quality analyses have been conducted to confirm that the system meets the drainage and soil environmental standards before application of it in the field.

Photo 1. Fluorescent tracer dye (added to water).

2.2 Dye installation methods

The dye loading part is inserted at the wear depth that is desired to be monitored (amount of wear), and then the dye is installed. Since it is necessary to release the dye against the cutting face pressure during excavation, the dye is installed under pressure. The dye installation part and the pressurizing part are installed according to the shield diameter and soil quality. For small amounts, they are installed inside the bit, and in the case of large amounts, they are installed in the spoke (Figure 1 and Figure 2). Regardless of whether it is installed inside the bit or the spoke, the dye loading and the pressurizing parts can be installed together near the bit. In this case, as cables and pipes are not required, more wear detectors can be installed than conventional wear detectors.

2.3 Detection methods

The dye released by the wear of the bit is discharged into the shield opening together with the excavated soil. Generally, the discharge of dye is detected by visual observation of staff and workers at the belt conveyor, muck car, soil pit, and so on. It can also be detected automatically by image analysis of the excavated soil. A UV light and a remote camera are installed in the location where the brightness of the environment is constant on the excavated soil transportation route inside of the shield tunnel. The excavated soil exposed to a UV light is photographed and the images are analysed using RGB values. The light emitted by ultraviolet light is stronger when the surroundings are dark, and analysis using RGB values cannot be performed correctly if the background color changes. Therefore, the detection equipment is installed in a dark place or dark room where its brightness is constant.

Figure 1. Example of installation inside of bit.

Figure 2. Example of installation in the spoke.

3 PRELIMINARY EXPERIMENTS (CONFIRMATION OF APPLICABILITY OF THE DYE TO THE SOIL)

3.1 Purpose

The selected fluorescent tracer dye is a dye used in water flow surveys, and it is known that it is easy to be detected when it is mixed with water. However, it is necessary to verify whether it can be detected even if it is mixed with the excavated soil in the shield.

3.2 Overview of experiment

First, a foamed soil (capacity: 5 L) was prepared by the addition of a foaming agent (OL-10) at a concentration of 1.0%, a foaming ratio of 10 times, and an addition rate of 20% to soil having a water content percentage of 12%. Next, red and yellow-green fluorescent tracer dyes (powder) were added to the

Photo 2. Fluorescent tracer dye (added to water).

foamed soil, and the mixture was stirred and confirmed visually and with a UV light. The foamed soil exposed to a UV light before adding the dye is shown in Photo-2. When it was exposed to a UV light, the color of the blue-purple light appeared to be reflected as it was.

3.3 Results

It is known that approximately 10 mg of red and approximately 5 mg of yellow-green is sufficiently visible in case of dissolving a fluorescent tracer dye (powder) in 5 L of water. In this experiment, the status in which 10 mg of each color of dye (powder) was added and stirred was investigated. By comparing the sample with the case before adding the dye, both red and yellow-green were colored, and it was found that the presence of the dye could be detected visually (Table 1). In addition, the coloration did not seem to be the soil itself, but also the foam material and the water such as pore water. When it was exposed to a UV light, the red dye reacted to fluorescent pink and the yellow-green dye reacted to fluorescent yellow-green, compared to the blue-purple color before the dye was added (Table 1). Next, the results of photographing and exposing the dye-containing soil to a UV light in a darkroom are shown in Photo 3. While the soil and the background appeared black, the fluorescent tracer dye emitted red and yellow-green light. From these results, it was found that visual observation can be achieved regardless of the brightness or darkness of the testing location. In the image analysis, it was shown that the presence or absence of the dye can be detected more reliably by exposure to UV light in a dark place.

These preliminary experimental results show that the fluorescent tracer dye is effective as the dye for use in a color-based wear detection device.

4 DYE DETECTION SITE EXPERIMENTS (CONFIRMATION OF APPLICABILITY OF THE DYE TO THE SITE)

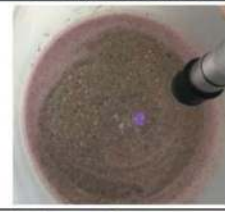

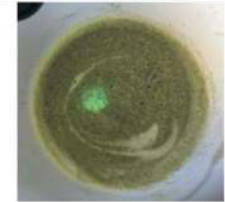

4.1 Purpose

At the medium and small-diameter shield sites, this experiment verifies whether the dye injected into the cutting face can be detected visually and by image analysis. Also, the required amount of the dye to be used should be determined by the injected amount at that time.

4.2 Experimental methods

The dye was injected directly into the cutting face, and the color of the soil discharged into the belt conveyor, muck car, and soil pit was confirmed visually and by image analysis. Two fluorescent tracer dyes (liquid), red and yellow-green, were injected into the existing mud additive line by connecting to a manual pump. Injection was performed during segment assembly when

Table 1. Status of dye mixed into foamed soil.

excavation was stopped. Since it was difficult to estimate how much the dye would be stirred and dispersed in the chamber, the subsequent injection

Method of mucking	Belt conveyer +muck car	Pressure hose +muck car

amount was increased or decreased depending on whether detection was possible or not. Table 2 shows an outline of the two sites where the site experiments were performed.

4.3 How to confirm the dye

For visual observation, a muck car at a launch shaft was confirmed visually. For automatic detection, because of different soil removal methods at the two sites, at site 1, a darkroom was set up above the belt conveyor between the screw conveyor and the muck car, and a UV light and a remote camera were installed inside the dark room. The video was taken during the belt conveyor operation and was saved at every second as a stationary image (Figure 3 and Photo 4). At site 2, a UV light and a remote camera were set up 100 m away from the tunnel entrance (Figure 3 and Photo 5). During the passing of a muck car, the system automatically turns off the tunnel lights, takes a video and saves stationary images every second. For image analysis, the taken images were decomposed into RGB, then green and red were binarized, and after that the average brightness value of the binarized image (ratio of white pixels to the total number of pixels after the binarization process) was taken. Therefore, it was possible to emphasize and capture even the slightest part of the green or red colors. For binarization, the middle 127 of the 255 brightness levels of RGB values was set as the threshold. When observing a large variation in the average brightness value, it was determined that there was a possibility of dye discharging. Humans judged visually whether the image contained dye.

Also, at site 1, the soil passes at high speed on a belt conveyor (approximately 1.6 m/s). To investigate the effect of different camera shutter speeds on visual observation by humans and by image analysis, two cameras were installed and they took pictures at two different shutter speeds (1/30 s and 1/100 s).

Photo 4. Status of equipment set up at site1.

【Segment top】

Photo 5. Status of equipment set up at site2.

4.4 Experimental results

4.4.1 Site 1

Visual observation of the soil with a muck car was sufficiently confirmed with 20 cc red and 40 cc yellow-green (Picture 6). Because of the large amount of sand and gravel, the dye floated to the surface together with the pore water due to vibrations during the transportation of a muck car. Therefore, it was thought that the dye is visible even in small quantities. Also, on the camera's video monitor, instantaneous visual confirmation was possible at 20 cc red and 40 cc yellow-green. The amount of dye injected that could be reliably identified by visual observation of the soil on the muck car, visual observation on a camera's video monitor, and image analysis of stationary images was 200 cc for both red and yellow-green (Figure 4 and Figure 5).

Table 3 shows the differences in images depending on the shutter speed. A faster shutter speed produced clearer images, but the overall image was darker because of the reduced amount of light, and in particular, it was difficult to visually confirm the red color. In the image analysis, it is generally easier to binarize and detect dye mixing when the difference in RGB values is larger and the range of brightness is wider than when the image is clear. Therefore, it was found that a somewhat slower shutter speed is better for both visual observations of stationary images and image analysis, regardless of the soil discharge rate.

4.4.2 Site 2

The visual observation of the soil on a muck car showed that it could be slightly confirmed by careful

visual observation with 100 cc red, but because of the clayey soil, the dye was encapsulated in the clay and did not separate and float to the surface, making visual observation more difficult than at site 1. In the case of the 300 cc yellow-green, the visual observation of the soil on a muck car, visual observation on the camera's video monitor, and image analysis of the still images all reliably identified the dye (Figure 6). Because of the small diameter of site 2, it was assumed that a smaller amount of dye could be used to determine that in site 1, but it was found that a larger amount of dye was needed for soil types such as the clayey soil where pore water is difficult to separate in this case.

Photo 6. Visual observation of the soil.

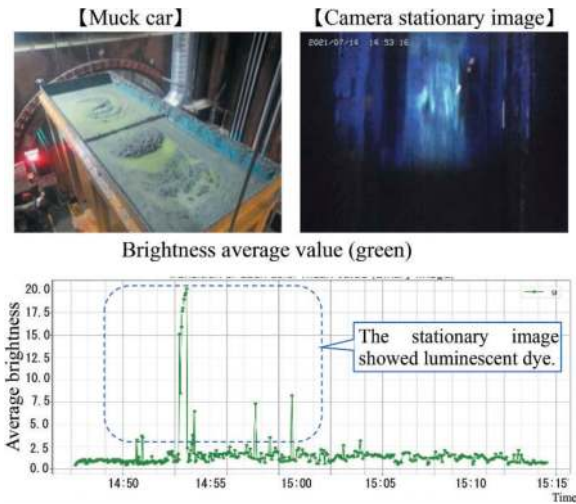

Figure 4. Result of injection of 200 cc yellow-green at site 1

5 DEMONSTRATION EXPERIMENTS

5.1 Purpose

This experiment confirms that the dye can be released into the cutting face under the cutting face pressure using the structure of the dye installing and pressurizing parts of the proposed device (spoke-installation type).

5.2 Experimental methods and results

When the shield machine was manufactured at site 2, a wear detection device was installed in the spoke

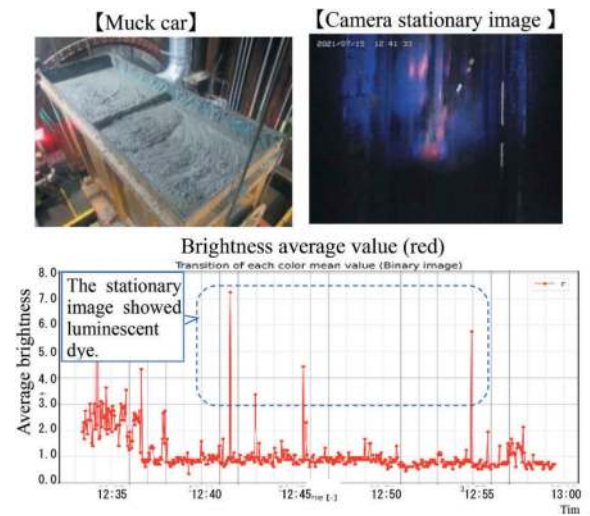

Figure 5. Result of injection of 200 cc red at site 1

(installed capacity: 300 cc) with a yellow-green dye of 10 mm wear and a red dye of 35 mm wear. The intended excavation length is approximately 3.8 km (2.5 km + 1.3 km), and the plan is to discharge the

Photo 7. Dye discharging status from the wear detection device installed in the actual machine.

yellow-green dye when excavating approximately 0.9 km and to discharge the red dye when excavating approximately 3.0 km. Currently, 2.5 km has been excavated and the first destination shaft has been reached, and the staff was able to visually detect the discharge of yellow-green-colored soil from a muck car and at the soil pit when it was excavated 1.02 km (Photo 7). After the machine's arrival, a hole in the

bit that connects the bit and the dye installation part was also confirmed. As a result, even under the cutting face pressure, the dye is reliably released when the predetermined amount of wear is reached, and it can be easily confirmed from the discharged soil visually. Additionally, it was demonstrated that the system applies to actual constructions.

6 CONCLUSION AND DISCUSSION

It was found that the wear detection device using the fluorescent tracer dye could be visually confirmed, so anyone could distinguish them, and it was also possible to understand the wear by the image analysis. At the medium- and small-diameter shield sites, the sufficiency of the amount installed dye in the spokes, and the applicability to the actual construction were confirmed. However, since the ease of detection varies depending on the soil type, it is necessary to plan the amount of dye installed by considering the soil conditions. Meanwhile, data on the relationship between soil conditions and the required installation amount is planned to be accumulated.

In the case of application to a large-diameter shield, the volume of soil in the chamber is large and the dye may be more diffused. Thus, we will perform experiments to confirm the required installation capacity of dye for large-diameter shields in the future.

In the future, we hope to increase our knowledge by applying this system in the actual construction sites, utilize this device widely and contribute to the prevention of excavation troubles caused by bit wear.

Structure health sensing network layout and monitoring based on wireless sensor network in undersea tunnel

ABSTRACT: With the rapid urbanization and the expanding use of subterranean spaces, tunnel structures have gained increasing significance in urban transportation. Given tunnels' permanence once built, assessing their structural health is vital throughout their lifecycle. Wireless Sensor Networks (WSNs) offer self-organization, high data acquisition frequency, low power consumption, and scalability. WSNs, applied in structural health monitoring, autonomously collect and transmit data using routing algorithms over their lifespan. The study focuses on undersea tunnels, known for their long distance, complex cross-sections, and high water-pressure. Taking wireless signal path loss characteristics and structure features into account, a layout for a structural health monitoring network along the tunnel axis was designed. It aims to ensure data acquisition in typical scenarios and maintain system robustness in unfavourable conditions through field experiment. The horizontal convergence of monitored tunnel sections as indicator is analysed detailedly with different geological environment and construction method. Field experiment demonstrates that the choice of signal frequency band is important in WSN system deployment and margin of signal strength will be helpful under unfavourable circumstance in maintain the system robust. In cross-sea tunnel, undersea part is more sensitive to disturbance than land part and mining part is more stable than the shield part. Daily fluctuation of the tunnel horizontal convergence has little relationship with the daily change of temperature.

Keywords: Undersea tunnel, Wireless sensor networks (WSN), Path loss, Horizontal convergence, Temperature

1 INTRODUCTION

In recent years, rapid economic development and urbanization in China have led to a significant increase in the scale of tunnel construction and the number of existing tunnels. Tunnel construction and the maintenance of existing tunnels have garnered significant attention due to their wide applicability under complex geological conditions. The widespread use of tunnels provides a convenient means to traverse water, mountains, and other challenging terrain, connecting various parts of cities and significantly reducing transportation time. However, some tunnels

under construction and in operation face considerable construction challenges and complex external environments. Complex geological conditions such as high ground stress, water, and weak interlayers are among the external environmental challenges that tunnel construction and operation currently need to overcome. These conditions also introduce certain safety risks during the tunnel construction process and subsequent maintenance and operation.

Monitoring and measurement are fundamental concepts in modern tunnel construction and serve as crucial means to ensure the safety of tunnels during both construction and operation phases (Qian, 2012). With

*Corresponding author: 09zhang@tongji.edu.cn

the development of computer science and communication engineering technologies, tunnel monitoring has gradually shifted from traditional manual monitoring towards automation. Wireless Sensor Networks (WSN) have emerged as a widely recognized monitoring method. WSN were initially applied to the short-term health monitoring of bridge structures (Lynch,2006) and to tunnels latter (Bennet,2010). WSN systems deploy tunnel safety state-aware sensor nodes like inclination nodes and settle-down node inside tunnels to continuously monitor the tunnel's condition and environment in real-time (Huang,2013; Yin and Huang,2015). These sensor nodes transmit monitoring data to gateway and cloud through wireless signals, ensuring that personnel receive timely information regarding structural health parameters. By data analysis, potential safety hazards can be promptly identified, enhancing overall tunnel safety.

Path loss and RSSI (Received Signal Strength Indication) are widely used in evaluation of wireless communication quality (Kalyankar,2020). Taking into account the long-distance structural characteristics of underwater tunnels, wireless transmission frequency bands and the maximum distance between nodes for structural health monitoring network deployment were instructed through field experiments in an effort to optimize the network layout.

2 UNDERSEA TUNNEL HEALTH SENSING NETWORK LAYOUT

2.1 Project profile

The Metro Line 8 in Qingdao City, Shandong Province, connects Qingdao North Station and Qingdao Jiaodong International Airport (TAO). The section between Dayang Station and Qingdao North Station is 7.9 kilometres long and the undersea section has a total length of 5.4 kilometres, with the maximum burial depth reaching 56 meters below the sea surface, making it the longest underwater subway tunnel in China at the time. In all the undersea part, the eastern of 2.9 kilometres was constructed using the slurry shield tunnelling method, while the western of 2.5 kilometres was constructed using mining and dual-mode TBM (Tunnel Boring Machine) methods. The different construction methods employed resulted in distinct cross-sectional forms on the eastern and western sides.

This section, as a representative underwater tunnel, underwent field testing of the wireless communication system for the structural health monitoring and the actual deployment of the relevant monitoring systems as described in this article.

2.2 Wireless signal transmission field experiment

2.2.1 Experiment introduction

The deployment of wireless sensor networks is not only influenced by the monitoring object's location and energy consumption but also by the quality of wireless

signal communication. Excessive single-hop communication distances can result in poor signal quality and increased energy consumption. According to relevant regulations from the Ministry of Industry and Information Technology in mainland China, three recommended ISM (Industrial, Scientific, and Medical) wireless signal frequency bands tested in this article for structural health monitoring are 433MHz, 868MHz, and 2.4GHz.

During field experiment, the same part of the tunnel was tested in these three different frequency bands. The receiving end remained stationary while the transmitting end moved away from the receiving end and maintained a signal transmission frequency of 1Hz to simulate real-world structural health monitoring scenarios. The purpose is to determine the maximum transmission distance by observing how path loss changes with distance in different frequency bands within the tunnel environment. When the receiving end is unable to receive signals from the transmitting end, and the transmitting end remains stationary for 30 seconds without reconnection, the distance is considered to be the maximum single-hop transmission distance for that frequency band.

2.2.2 Experiment analysis

The experiment was carried out in a 1400-meters-long straight undersea part of Qingdao Metro Line 8 and tests for 443MHz and 868MHz were repeated immediately to confirm the communication ability. It should be noticed that due to regulation, the transmitting power of 2.4GHz is 3 dBm and in comparison, that of other 2 frequency band is 20 dBm. The maximum single-hop transmission distance is shown in Table 1.

Table 1. The maximum single-hop transmission distance.

Test number	Frequency band	Maximum distance(m)
1	443MHz	428
2	443MHz	495
3	868MHz	1286
4	868MHz	1060
5	2.4GHz	207

Signal in high frequency band will perform better in straight transmission. The signal of 868MHz frequency band can reach more than one kilometre in single hop, which is more than twice that in the 433MHz band, suited better to address the transmission requirements in the context of unidimensional long-distance scenarios, such as underwater tunnel deployments.

For the 868MHz frequency band, further field experiment was conducted. Four characteristic positions were selected within the single-hop transmission range, specifically at 500m, 700m, 900m, and 1100m. At each of these positions, the transmitting end remained stationary for 5 minutes (transmitting 300 data packets) to simulate real-world data transmission quality in order to ensure the proper functioning of the

monitoring system after deployment. The path loss of these characteristic positions is shown in Figure 1.

Figure 1. Path loss in 868MHz in field experiment.

According to the Friss formula, which describes signal attenuation in free space, the increase of path loss or the attenuation of signal strength (dBm) is log-dependent with distance.

$$PL = -27.56 + 20\log_{10}(d) + 20\log_{10}(f) \quad (1)$$

Where, PL is path loss (dBm); d is distance(m); f is frequency of signal (MHz).

The trend is also illustrated in test with a fast decline in near region and a slower decline in far region. Considering the shadow, multi-path effect and obstacle, the curve describing relationship of path loss and distance is not smooth but fluctuates a lot and even in the same position the path loss also alters with time. The median of all the data collected in characteristic position test decline with the increase of distance. However, there is no significant correlation between the fluctuation amplitude and distance of path loss. In other word, it is possible that a node in a much near position malfunction with a node with larger distance functioning well due to the fluctuation. The statistical analysis of characteristic position test is shown in Table 2.

Within the 868MHz frequency band test system, a reception threshold of -112dBm has been configured and this setting ignores signals weaker than this threshold, resulting in packet loss. Based on the 300 data packets, signal at 500 meters is badly influenced by the obstacle and fading, results in strength ranging from -84dBm to -112dBm, namely a nearly 1000-fold difference in milliwatts for transmission power. This observation aligns with rapid and substantial fluctuations in path loss-distance characteristic curve in Figure 1. This variation in signal strength highlights the importance of margin to ensure reliable data transmission in such conditions.

Small signal strength and large variance can detrimentally impact communication quality, notably by increasing the packet loss rate. This conclusion is

Table 2. The statistical analysis of characteristic position test.

Distance(m)	Packet Loss Rate(%)	Signal strength(dBm)		
		Range	Average	Variance
500	1%	[-84, -112]	-92.65	20.2
700	0.66%	[-91, -99]	-94.63	2.867
900	10.7%	[-93, -106]	-99.09	8.217
1100	1%	[-99, -109]	-103.73	2.753

supported by the comparative analysis of data collected at distances of 500m, 900m, and 1100m. The data from 500m, characterized by the highest variance yet relatively high average signal strength, and the data from 1100m, characterized by the lowest average signal strength but small variance, both show favourable packet loss rates due to the low probability of signal strength falling below the threshold. On the contrary, the data from 900m, featuring second lowest average signal strength and second largest variance, reveals a significant deterioration in communication quality, with a packet loss rate exceeding 10%. This adversely impacts the efficiency of the monitoring process.

In this project, despite the potential for single-hop transmission to cover distances exceeding 1200 meters, it is advisable, for the sake of leaving some margin and ensuring monitoring quality, to maintain a separation distance of less than 700 meters between the two nearest nodes.

2.3 Layout for the monitoring system

Wireless sensor network for infrastructure health monitoring is a multi-hop ad-hoc network. Consequently, the selection of node locations assumes importance, as these placements are intricately linked to energy consumption, communication proficiency, and the specific attributes of the monitored infrastructure. The undersea tunnel is a typical unidimensional linear structure with long distance and few entrance. The layout aims to build a robust monitoring system with least manned maintenance and monitoring valuable structural health attributes under the limitation of communication ability.

Undersea tunnel of Qingdao Metro Line 8 has some feature like dual construction methods, large depth, long distance and complex geology. Seven monitoring sections are chosen to focus on the influence of longitudinal grade, connected aisle, construction methods and geology which are shown in Figure 2. All the seven sections are divided into two groups according to distance and each group is assigned a gateway to convey and transmit monitoring data into cloud. The gateways are installed between section No.2 and No.3 and near section No.6.

The deformation of tunnel structures is a crucial indicator of safety performance during the operation

Figure 2. Longitudinal layout for monitoring system.

of tunnel structures. Some safety indicators for tunnels, such as bolt stress, joint separation, and concrete stress, are challenging to obtain. In contrast, changes in tunnel diameter are relatively easy to measure and can be used as a reference for calculating the critical state of other safety indicators through numerical methods (Wang, 2015). Therefore, changes in tunnel diameter are commonly utilized as a key indicator of tunnel cross-sectional safety performance.

Considering that the Qingdao Metro Line 8 undersea part utilizes both shield tunnelling and mining methods for construction, there are significant differences between the cross section of these two construction methods. Tunnels built by shield tunnelling method are typically constructed by immediately connecting and assembling multiple prefabricated segments using bolts after the tunnel boring machine excavation and tunnels built by mining method are initially supported after blasting out the debris and then undergo a secondary lining with shotcrete.

Because of the interaction between initial support and secondary lining, monitoring data can only partially indicate the actual deformation of tunnel structures under external loads. Therefore, two omnidirectional inclinometer sensor nodes with laser ranging function are installed in the shield method sections (No. 5, 6 and 7) to monitor horizontal diameter changes and settlement at the top of tunnels. In the mining method sections (No. 1, 2, 3 and 4), only one omnidirectional inclinometer sensor node with laser ranging function is installed to monitor horizontal diameter changes. The detail of sensor nodes layout in cross section is shown in Figure 3 and the parameters of omnidirectional inclinometer sensor node are in Table 3.

3 MONITORING DATA ANALYSIS

Given that the target tunnel is in a state of stable operation and its maintenance is less convenient compared to conventional tunnels, the monitoring frequency has

Figure 3. Sensor nodes layout in cross section.

Table 3. The parameters of sensor node.

Node	WISEMESHNET@6F07

initially been established at an interval of once per hour. Notably, the monitoring frequency will be adjusted to once every five minutes during the period from April 10th to May 1st in order to acquire detailed information regarding structural deformation.

3.1 System reliability and robustness

Radio connectivity stands as the paramount focal point concerning the reliability and robustness of WSN systems. Despite the WSN monitoring system's configuration as a multi-hop ad-hoc network, all nodes are strategically deployed within 600m. The multi-hop transmission capability functions as a protective buffer, reinforcing the system's robustness against unfavourable conditions.

The data of mesh network demonstrates good results about the radio connectivity. All nodes deployed connect to gateway directly in normal operation and multi-hop transmission capability functions well when the subway trains pass with the electromagnetic environment deterioration. With the distance increasing, the train-influenced signal strength of direct connection is more likely to go down under the threshold and trigger the multi-hop transmission mechanism. To show how reliable and robust the system is, the packet loss rate and direct connection rate is defined as follow:

$$\text{Packet Loss Rate} = 1 - (n_r/n_s) \quad (2)$$

$$\text{Direct Connection Rate} = n_1/(n_1 + n_2) \quad (3)$$

Where, n_r is number of data packet from the node which cloud received; n_s is ideal number of data packet send by the node; n_1 is number of data packet come from direct connection between nodes and gateway; n_2 is number of data packet send by multi-hop transmission.

The approximate 14000 packet of monitoring data from April 4th to September 13th is analysed about the connectivity. The radio connectivity of each node is shown in Table 4.

Owing to the data packet retention and subsequent retransmission feature integrated into the system's configuration, the packet loss rate will be strictly controlled and be 0 in this system. The node deployment strategy adheres to recommended guidelines, with nodes positioned at a distance less than 700 meters from gateway.

Table 4. The radio connectivity of each node.

Group	Node number	Distance from gateway	Packet loss rate	Direct loss rate
1	1	520m	0	0.08%
	2	519m	0	0.44%
	Gateway 1			
	3	114m	0	0.11%
	4	495m	0	0.18%
2	5-1	520m	0	0.81%
	5-2	520m	0	1.09%
	Gateway 2			
	6-1	Less than 20m	0	0.30%
	6-2	Less than 20m	0	0.50%
	7-1	Less than 20m	0	0.21%
	7-2	Less than 20m	0	0.46%

In most scenarios, monitoring data is routed directly to the gateway, with a diversion to another nodes for transmission assistance occurring only when there is a disruption in the link. The direct loss rate serves as an indicator, quantifying the proportion of data packets transmitted through intermediary nodes rather than being routed directly to the gateway. High direct loss rate means the connectivity margin caused by the multi-hop transmission mechanism functions greatly and the location of this node is not good when considering about the link to gateway.

3.2 Preliminary monitoring results

The convergence is a vital indicator of shield tunnel health and excessive horizontal convergence will lead to unfavourable stress condition, shrinking space inside and tunnel disease influencing the safety status and the usage function simultaneously. The sensor nodes in system could provide an unmanned method to monitor the horizontal convergence with high frequency (1 time per hour). For different type tunnels, the threshold of convergence during operations stage varies. With reference to design description and the relevant specifications for shield tunnels, the limit of horizontal convergence in this tunnel is set at 10mm in mining method part and 2‰ outer diameter (13.4mm) in shield method part.

3.2.1 Undersea section and land section

The sensor nodes 6-1 and 7-1 are installed to monitor the convergence. There is the air shaft No. 2 between the two cross-sections, with section No. 6 and No. 7 situated at a spatial separation of approximately 25 meters. Notably, section No. 6 lays in the undersea part, while section No. 7 lays in the land part. Except the outer environment, two sections are in similar condition, being good monitoring object for the influence caused by sea. The monitoring data is shown in Figure 4 and the descriptive statistics of monitoring data is in Table 5.

The system error caused by instrument accuracy is inevitably introduced in the monitoring, making the

Figure 4. Raw monitoring data of section no.6 and 7.

Table 5. The descriptive statistics of monitoring data of section no.6 and 7.

Monitoring Section	Horizontal convergence (mm)	
	average	variance
No.6 (undersea)	0.700	0.092
No.7 (land)	0.304	0.032

data less creditable. To reduce the impact of instrument error, the Kalman filter algorithm which can real-time denoise data without variation of data size (Kalman, 1960) is introduced in data processing. Kalman filter algorithm predict the state with both physical estimation and measurement and then update the parameter for next prediction, obtaining a more creditable data. The processed monitoring data is shown in Figure 5.

Figure 5. Filtered monitoring data of section no.6 and 7.

The horizontal convergence of section increases about 0.5mm in the past 5 months in both monitored sections. However, there are obvious differences in the trend of change with fast increase and then decrease in undersea section No.6 and slow increase in land section

No.7. Hence, in descriptive statistics, the average horizontal convergence delta of section No.6 is more than 2 times of that of section No.7. It can also be found that both sections respond similarly to disturbance but with different amplitude. It is also understandable that undersea section No.6 are more sensitive than the land section No.7 to the influence of semi-day tide of Jiaozhou Bay causing the difference of amplitude. Another potential factor is that the land section is subject to more vertical pressure from upper soil layer which make it less sensitive to the disturbance. The possibility of a periodic trend in the horizontal convergence of the tunnel cannot be ruled out. Therefore, the large peak value of the undersea part (more than 1mm) observed in the monitoring data should be paid attention to in future monitoring.

Before the WSN system installation, the total station-based monitoring is main method to monitor the tunnel deformation. However, due to the extreme length of cross-sea tunnel, manual measurements will take several days. Hence, the manual deformation monitoring will be carried out once a year. The tunnel was put into use in December 2020, so the first monitoring was carried out in January 2021 and latest recorded monitoring was in March 2023. The horizontal convergence of Section No.6 and No.7 increased 0.5mm from February 2022 to March 2023, which showed the same magnitude and trend as deformation monitored by WSN (0.700 for No.6 and 0.304 for No.7 from April 2023 to September 2023). Noticeably, comparing with the designed horizontal convergence, horizontal convergence of Section No.6 and 7 decreases by 2.08 and 2.72, respectively. This can be interpreted to mean that the section reaches a new equilibrium due to the deformation caused earth pressure after the completion of the shield construction and in the long run, the vertical earth pressure is the main load of the section, so the horizontal convergence increases slowly on the basis of the existing equilibrium state. The current deformation level is still far below the deformation threshold, so it can be considered that the tunnel is in a good safety state.

3.2.2 Shield tunnelling section and mining section

The sensor nodes 4 and 5-1 are installed to monitor the convergence of different type of section forms due to construction method. At the intersection of the shield and mine construction areas, the section was specially designed and reinforced and no embedded troughs are designed for device installation. Section No.4 and Section No.5 are the first section with the embedded troughs in mining method part and shield tunnelling part respectively with a distance of 25 meters. In the shield section, the internal deformation is directly related to the external load because there are no additional structural layers, however, in the mining section, external load causes the inner deformation through the deformation of first lining and subsequent shotcrete layer which make the monitoring data can not indicate the health condition so effectively. The monitoring data and filtered monitoring data are shown in Figure 6 and

the descriptive statistics of raw monitoring data is in Table 6. Based on current deformation, it can be considered that the section where the construction method is changed is in a good safety state.

(a)

(b)

Figure 6. (a) raw and (b) filtered monitoring data of section No.4 and 5.

Table 6. The descriptive statistics of monitoring data of section no.4 and 5.

Monitoring Section	Horizontal convergence (mm)	
	average	variance
No.4 (shield)	-0.138	0.068
No.5 (mining)	-0.302	0.044

The filtered monitoring data of section No.4 and 5 change in a same trend but with different amplitude. The horizontal convergence decreases slightly with about 0.1mm/month. The special structural design and strata reinforcement make the section subject to greater horizontal resistance than the general sections with an unusual decrease in horizontal convergence. The mining section with less variance is in line with

the knowledge that structure form make it less sensitive to the outside disturbance and tent to be stable.

3.2.3 Monitoring data and temperature

All the monitoring data shows a daily fluctuation and daily temperature change is a potential factor that result in the phenomenon. The installed sensor nodes have extra function of temperature measurement and every data packet has its own temperature data which could be used to analyse the relationship. The R^2 was used as an evaluation index of correlation and data from the nodes mentioned in 3.2.1 and 3.2.2 are visualized to show the relationship in Figure 7. The R^2 of monitoring data is shown in Table 7.

The correlation index is too small to take the relationship between monitoring convergence and temperature into consideration and the point in graph also do not show the significant mathematic relationship between convergence and temperature. The laser ranging sensor is not sensitive to temperature changes in the operating temperature range. The daily fluctuation of monitoring data may come from the influence of Jiaozhou Bay semi-diurnal tide and the relationship need further research and analyse.

Table 7. The correlation of monitored convergence and temperature.

Monitoring Section	correlation index R^2
No.4 (shield)	0.09
No.5 (mining)	0.30
No.6 (undersea)	0.03
No.7 (land)	0.08

4 CONCLUSIONS

This paper evaluates the ISM band signal transmission path loss characteristic in undersea tunnel field experiment and characteristic position test was carried out for the recommended wireless signal of 868MHz band in order to introduce the influence of shadow fading and obstacles into consideration of the wireless channel quality. Based on the existing configuration of wireless sensor network structural health monitoring system, the recommended maximum single-hop layout distance in undersea tunnel is proposed, and the recommended distance and the undersea tunnel structure character instruct the layout of monitoring system. The approximately six-month monitoring data from system is analyse to study about the structure deformation in different environments. The main conclusions are shown as follows:

1. Limited by the codes and technical configuration, the 868MHz frequency band performs best in the path loss characteristics of the undersea tunnel, the maximum single-hop transmission distance reaching 1200m.
2. Fading and obstacle have negative impact on the wireless channel causing high variance of signal strength and the multipath effect also degrades the communication quality in some areas. To make sure the reliability and robustness of system, a 10dBm margin of signal strength should be considered to remain for potentially unfavourable condition.
3. As an important indicator of tunnel health condition, the convergence of tunnel grow at a speed of 0.1mm/month at the both side of junction of undersea part and land part, but with larger fluctuation in undersea part. Due to the special structural design and strata reinforcement, the convergence at the junction of construction methods decreases slightly.

4. The monitoring data shows significant daily fluctuation and the temperature monitored is verified that no close relationship between convergence and temperature.

It should be noted that the filed experiments only support the conclusion limitedly. Curves and section forms of tunnel will influence the channel in some extent and the pass loss characteristic should take these factors into consideration. Convergence monitoring only last about 6 months and have the possibility missing the annual trend of tunnel which is found in other monitoring project. More data covering longer period is needed to analyse precisely.

Innovative shaft inspection system for the Gotthard Base Tunnel

Martina Puglia, Peter Spohn & Klaus Wachter*
Amberg Infra 7D, Regensdorf, Switzerland

Leandro Chelini & Shuan Xiao
Amberg Technologies AG, Regensdorf, Switzerland

ABSTRACT: Amberg was commissioned by the Swiss Federal Railways SBB to develop a measurement system and execute an inspection of the 800 m deep Sedrun shaft B at the Gotthard Base Tunnel. A special shaft module equipped with multiple sensors was built to acquire a reliable data base. The inspection and condition assessment were performed based on this data using an in-house inspection and data management platform. This paper presents the innovative measurement system developed and highlights the challenges encountered during this project.

Keywords: Shaft, Measurement, Inspection, Maintenance, Structural Health Monitoring

1 INTRODUCTION

Mobility is a cornerstone of our modern society. It enables us to travel, exchange goods and get in touch with each other. However, the structural infrastructure used for this purpose is subject to a natural ageing process. To assure a long service lifetime and the necessary integrity of such facilities, regular inspections, maintenance and renovation measures must be carried out, all of which involve costs. To make the best use of available financial resources and to ensure the longevity of these important facilities, it is crucial to develop effective maintenance strategies and to create a reliable data basis.

Inspection data provides information about the condition, performance, and potential problem areas of the infrastructure. They thus form the basis for strategic planning of measures and investments. However, depending on the structure and prevailing conditions, the collection of reliable data is not possible with standard tools and calls for new and innovative approaches.

This paper presents the specially developed measurement system developed for the inspection of the Sedrun shaft B at the Gotthard Base Tunnel and highlights the challenges encountered during this project. In the meantime, this system has also been used for the shaft inspection of other tunnel systems in Switzerland.

2 GOTTHARD BASE TUNNEL

The Gotthard Base Tunnel is a symbol of Swiss precision and innovative inspiration, 57 km long at the heart of the Swiss Alps connecting people through the generations to come. It is composed of an intrinsic complex system of tunnels, numerous crossovers, and access tunnels, as well as shafts.

The tunnel is subdivided into the five sections Erstfeld, Amsteg, Sedrun, Faido, and Bodio (north to south). The following Figure 1 shows a schematic overview of the tunnel system.

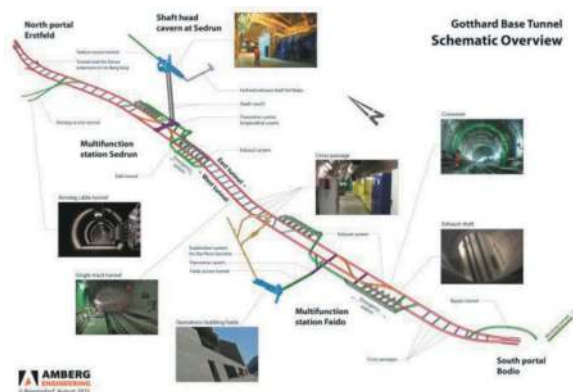

Figure 1. Schematic overview Gotthard Base Tunnel (*Source: Tunnelling the Gotthard, STS Tunnelling Society, 2016*).

*Corresponding author: kwachter@amberg.ch

In the Sedrun section, an intermediate access is provided by a nearly one-kilometer-long access tunnel and two about 800 m deep vertical shafts leading down to the railway tunnel level. In the following, the focus will be led on shaft B in Sedrun (former known as shaft II).

Shaft B is located about 40 m from shaft A in a side niche. The shaft was constructed by raise-boring in the first stage and enlarged to a final excavation diameter of 7.0 m with a shaft boring machine in the second stage. Rock support was composed of wire mesh, rock bolts and shotcrete with steel fibre reinforcement and a layer thickness of 22 cm. The shotcrete serves as both rock support and permanent lining. In order to be able to fulfil its function as an exhaust ventilation shaft even in case of a fire, the shaft was additionally lined with an 8 cm thick shotcrete layer composing polypropylene fibres to ensure fire protection. In case of a fire, the smoke rising through the shaft is directed through an additional inclined tunnel out of the mountain, bypassing the cavern.

In the original concept of Sedrun section, shaft B was not included. The decision for building a second shaft was taken at a later project stage for reasons of construction operations, ventilation, and safety. During the ongoing railway operating phase, shaft B serves as an exhaust air shaft for ventilation in normal operation and in case of an incident. Since this function is crucial for operational safety, the structure must be included in the inspection and maintenance planning for the Gotthard Base Tunnel.

Figure 2. Geological profile of the Gotthard Base Tunnel, with localisation of the Sedrun Shaft (Source: *Tunnelling the Gotthard*, STS Tunnelling Society, 2016).

Built in 1998, shaft B was already operational for almost 18 years when the commercial operation of the Gotthard Basis Tunnel started in December 2016. With its almost 800 m depth, carrying out inspection services is a real challenge in terms of accessibility and health and safety.

During the construction time of the tunnels a heavy-duty hoist and an emergency hoist were installed in the shaft. After completion however, all equipment was deinstalled. As a result, carrying out inspection services in a shaft of this length becomes a real challenge.

In 2019, a pre-inspection of shaft B in Sedrun was performed to conduct several data acquisition tests

and gain experience about the shaft environment. It was carried out by staff from Amberg and SBB, who were lowered into the shaft B using the emergency equipment for shaft A.

Due to safety concerns in case of technical malfunctions, further inspections involving personnel in the shaft were forbidden. To overcome this, Amberg was asked by the Swiss Federal Railways SBB to develop an innovative solution for the inspection of Sedrun shaft B.

3 MULTI-CAMERA INSPECTION SYSTEM (MCIS)

To address the challenge given, the first step was to develop an automatic measuring system capable of gathering all the necessary data for an office inspection. To ensure a reliable data set it was defined that the measuring system needed to capture both photos and scan data and provide them with a precise vertical position - a second significant challenge. The third challenge arose from the requirement that the measuring system had to be attached to the crane using only a single rope, making it vulnerable to rotations. To answer these three challenges, the Amberg Multi-Camera Inspection System (MCIS) was developed.

In the following subchapters, the technical solutions for the three challenges highlighted above will be outlined in more detail.

3.1 Inspection sensors

Traditionally, Amberg uses laser scanners for inspection data. Hence, the high-performance laser scanner *Amberg Profiler 6012* was the best sensor for integration into the MCIS. This approach had several advantages, including independence from a light source and the elimination of focusing issues to measure the relative diameter of the shaft.

As an additional source of information, six standard single-lens reflex cameras were included in the MCIS to provide high resolution and coloured images of the shaft surface. Given that the radius of shaft B did not change significantly, fixed camera focus was possible. Moreover, six 24 MP full-frame cameras captured significantly more data than a single laser scanner. However, the usage of cameras also necessitated the attachment of a light source to the MCIS. This presented a challenge, not only in illuminating the 6.4 m diameter shaft but also in positioning the light sources carefully to create consistent illumination throughout the shaft surface. Otherwise, over- and underexposed photos would reduce the general data quality in the deep, dark shaft. In the end, 24 LED lights were attached to the system, 12 above and 12 below the cameras, to provide the more than enough illumination.

To power the MCIS, detailed considerations of the necessary electrical power for the 5 V, 24 V and 220 V devices had to be made. Especially the 24 LED lights consume the biggest amount of electrical power. At the current state, multiple battery packages enable the MCIS to acquire data for about 30-40 minutes, which was more than enough time to measure shaft B for two times.

3.2 Positioning

It was soon evident that the entire system needed to be time-triggered. The alternative of establishing a data link through cable or radio over the ca. 800 m deep shaft B in Sedrun proved almost impossible. Consequently, all MCIS subsystems had to be controlled by a single computer to generate relatively precise timestamps.

The solution to the second challenge was to measure the relative height of the MCIS by measuring the used length of the steel rope of the crane to lower the MCIS into the shaft. Here an exception to the “one computer controls all devices” concept had to be made since other direct methods were unreliable. The most effective solution involved attaching an optical odometer to the diverter pulley of the crane which could be controlled and observed by a second computer. The odometer logged the revolutions together with an absolute timestamp directly to an internal memory.

3.3 Rotations

To counter any rotations caused by the single rope hanging, a highly precise inertial measurement unit (IMU) was required. The *Amberg Measurement Unit 1030* (AMU1030) is designed specifically for measuring rotations and was therefore the ideal solution to master this challenge. This choice was also advantageous as the AMU1030 was already integrated into the *Amberg IMS5000* system, a trolley system used to scan railroad tracks, which also included the high-performance laser scanner *Amberg Profiler 6012*. This ensured the compatibility of the systems used.

4 SHAFT MEASUREMENT AT THE GOTTHARD BASE TUNNEL

4.1 Data acquisition at shaft B

The data acquisition for inspecting the shaft B occurred on the 11th and 12th of July 2021, around midnight when a free slot in the train traffic schedule was available. In coordination with Amberg, the SBB provided a special crane with over 800 m of rope and a case for the MCIS installation. Before the measurement, everything was installed and tested on-site. Just before entering the shaft from its top, the MCIS with all its subsystems was initiated, and autonomous data recording commenced.

Figure 3. MCIS before entering the shaft B.

The *Amberg Profiler 6012* scanner rotated at 100 revolutions per second, capturing 10,000 points per rotation, resulting in a data acquisition rate of 1 million points per second. Simultaneously, the AMU1030 recorded the MCIS rotation for post-processing correction.

Using the odometer, it was possible to measure not only the depth but also the travel speed, which aimed to maintain a target speed of 0.5 m per second with an accuracy of ± 0.05 m/sec throughout the entire shaft depth. The speed value was transmitted directly to the crane operator to adjust the speed if necessary.

The camera system was controlled by the measuring computer via a trigger box, capturing simultaneous images from all six cameras at 3-second intervals. Consequently, a series of pictures was taken every 1.5 m, providing a 360° imaging of the shaft. The lenses were manually focused, and each had a focal length of 15 mm, ensuring sufficient overlap for later panoramic image creation.

Within less than an hour, the entire shaft was measured twice, creating over 150 GB of data. The data was stored on a hard drive on site.

4.2 Data post processing

After data collection, the first step in post-processing was synchronizing all the timestamps from each different sensor. Since most sensors were controlled by the MCIS computer, only the separate odometer data required synchronization with the MCIS timeline. Scan data and camera data were generally post-processed independently.

Figure 4 below shows the data processing workflow.

Figure 4. Data processing flow chart.

The odometer data was applied to the scan data to render a tube out of the measured thousands of scan lines during the data acquisition. Subsequently, IMU data was applied to the scan data to correct for rotation movements during data collection. This resulted in a point cloud representing the shaft's geometry accurately from a relative perspective, enabling the extraction of profiles and other data for inspection and other purposes.

The camera data was also post-processed in a similar manner to the scan data. Photo corrections, such as exposure, vignetting, and white balance adjustments, were applied to achieve homogeneous pictures of the shaft surface. Since all photos were taken simultaneously from each camera in sets of six, 360° panoramic images were created using photo-stitching techniques. The final step involved vertically sorting and cropping each panorama picture to generate a complete picture of the vertical shaft surface. Figure 5 below shows the 360° panoramic image at the shaft head: The blue objects are the safety barrier which were installed around the open shaft. Right below the red shaft cover is visible. Under the shaft cover a chamber is visible on the right-hand side. This is the “exhaust” that leads the air to the turbines. The lower part of the images shows the shaft surface with marked defects in blue and red.

Figure 5. 360° panoramic image of the shaft surface.

Based on the referenced point cloud, horizontal profiles of the vertical shaft were created in the software *Amberg Tunnel*. These profiles were centred to the least-square centre point of the measured profile points to best fit the theoretical circle-shaped reference profile for deformation analyses.

5 SHAFT INSPECTION

5.1 Scope of an inspection

According to the Swiss standard SIA 469 (1997), an inspection is defined as the determination of the condition of a structure by targeted (usually visual), simple examinations with evaluation of the same.

As a standard procedure, this determination is achieved by a manual inspection of the structure with the aid of adapted access platforms, including simple on-site surveys as crack width measurement and the search for hollow sounding areas with a hammer. All the information collected on site is then displayed in a structural defects map.

In case of an office inspection as performed for shaft B in Sedrun, the quality of the data acquisition is essential for a visual identification of any structural defects. This is assured by using different types of sensors on the MCIS for the acquisition of complementary information for a better inspection and assessment of the structure.

5.2 Amberg inspection cloud

For conducting condition assessments, a special inspection and data management software was developed in house – the *Amberg Inspection Cloud* (AIC). This online platform is a comprehensive image-based inspection platform for planning, managing, capturing, and reporting on visual surface conditions. It is designed to act as a single source of information for inspection data allowing for easy visualisation of defects and statistical analysis for every defect category. When uploading inspection data from different points in time, the software allows for a direct defect comparison and thus identification of any development of a defect over time.

More than an inspection tool, the AIC is a conservation management tool as it complements existent data bases of the owners with detailed information about the condition of the structure, showing potential areas of concern. As the data of the inspections over time is centralized and built up on a reliable basis, it becomes possible to predict future needs more accurately.

5.3 Defect mapping

Before starting the inspection and defect mapping, the project had to be set up in the AIC. This not only includes the upload of the images but also the definition of the defect catalogue in accordance with the client's standard. For the detailed assessment the shaft was divided in different zones of about 10 m length each.

According to the plans, the shaft was built with a different diameter on the approx. last 9 m at its top at the connection to the shaft cavern, but no dimensions were given. This change of the diameter could be clearly seen and measured from the point cloud data,

allowing for an update of the technical data of the structure.

The mapping of defects in the AIC is performed by an experienced inspector based on a visual inspection of the acquired images. Due to the high-resolution and quality of the data generated by the MCIS, structural defects such as sub-millimetre cracks can be detected. Most importantly, structural defects can be distinguished from any aesthetic or construction caused phenomena.

Figure 6. Detail of the background image generated by the MCIS.

The structural defect map was delivered to the client digitally in the AIC with no further treatment of the data such as CAD drawings being necessary.

5.4 Condition assessment

According to the Swiss standard SIA 469, art. 3.22, 3.23 and 3.24., the condition assessment must include an evaluation of the condition of the structure and the determination of any measures to ensure the required safety (structural safety, serviceability, and operational safety). In addition, a forecast of the development of the condition is required.

The defect mapping introduced above is one essential information for the condition assessment. Nevertheless, the data acquired by the MCIS allows for additional analysis.

Based on the georeferenced point cloud, a deformation analysis can be performed. Compared to the perfect circular nominal profile, the measured profile is influenced by slightly changing shotcrete thickness and the roughness of its surface, as much as by the geology that was traversed. The comparison

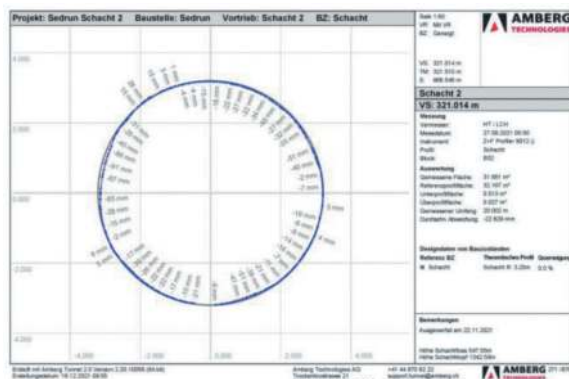

Figure 7. Results of the deformation analysis.

between the circular nominal profile in the calculated centre and the measured profile at shaft B shows profile differences along the shaft. Figure 7 below shows the result of the deformation analysis at position 321.014 m measured from the bottom. The blue dotted line represents the point cloud, the grey circle represents the nominal shaft profile.

In fact, deformations are not only assessed based on the profiles from the deformation measurements. Deformations due to force redistribution in the rock mass or due to water ingress cause certain damage patterns in the lining, which can be detected by mapping the damages on the images that were taken during the data acquisition. The inspection based on the panoramic images is therefore also decisive for the assessment of the deformations.

The differences between the designed circular profile and the measured one along the shaft were locally up to 100 mm. This would indicate significant deformations. In fact, such deformations would cause cracks in the shotcrete lining. Since no such cracks were found during the defect mapping, it can be concluded that the profile differences are not caused by local deformations but are either due to the construction or any material changes (e.g., calcite concretions).

As a result of the inspection, no severe damages were identified and therefore no structural measures are required. For further inspection it is recommended to collect complementary information about the shaft to refine the condition forecast. This might include a water analysis and some core drilling to obtain further information on the condition of the concrete. All this information will be also useful for planning structural measures in the future.

6 CONCLUSIONS

In this paper an innovative measurement system developed for the inspection of the Sedrun shaft B at the Gotthard Base Tunnel is presented.

The Multi-Camera Inspection System (MCIS) is a data acquisition module equipped with multiple sensors that can be used to collect reliable and high-quality data for inspection purposes.

For the Sedrun shaft B, the digital workflow based on panoramic images and point clouds enabled maximum condition information with minimum risk to people and impact on tunnel operations.

Since its first mission was successfully carried out at the shaft B in Sedrun, the MCIS system has also been used for the shaft inspection of several other tunnel systems in Switzerland.

ACKNOWLEDGMENTS

The authors would like to thank the Swiss Federal Railways SBB for the openness to innovative solutions and the good collaboration in this project.

Finally, the Amberg team thanks Mr Thomas Heiniger for being the mastermind and driving force behind the development of the MCIS.

Fault diagnosis system for tunnel boring machines based on electrical energy monitoring

Yuan Qin*, Chengjie Zhang, Sheng Huang, Zhaoyu Wu, Hui Shen & Jun Sun
Shanghai Urban Construction Tunnel Equipment Co., Ltd., Shanghai, China

ABSTRACT: The purpose of this study was to improve the continuity, economic viability, and stability of tunnel boring machines (TBMs) during construction. A comprehensive technical system for electrical energy monitoring, state analysis, and intelligent fault warning was established for the core power components of TBMs, in addition to the development of corresponding software and hardware systems. Based on the electrical energy transmission path of the core power components of the TBM, an effective and reasonable sensing device was installed to collect the data of various electrical, energy consumption, and key physical characteristic parameters. Accordingly, a basic model of the electrical energy consumption and quality of the core power components was proposed. During the operation of the TBM in the construction process, a data chain was established with the tunnel construction parameters, and an algorithm for evaluating the standard energy consumption during the tunnel construction process was established according to the construction conditions. Abnormal states of the core power components were detected, and a comparison analysis was performed between real-time energy consumption, standard healthy state energy consumption, and external state characteristics to determine an intelligent fault identification and warning model for the core power components.

Keywords: Electrical Energy Monitoring, Intelligent Data Collection, Fault Diagnosis System

1 BACKGROUND AND TECHNICAL STATUS

A serial relationship exists between the operation of various systems and equipment of a tunnel boring machine (TBM), and often, a malfunction of one system or device can cause the entire TBM to stop working. Reducing the failure rate of TBMs and pre-diagnosing and pre-eliminating failures are important aspects of maintaining the high efficiency of TBM construction.

Electricity, as a standard way of energy transfer, powers all mechanical equipment on TBMs. By monitoring the electrical energy data, the health state of a TBM can be perceived. Considering the research and development of electrical energy monitoring systems for large equipment, studies have been conducted to identify anomalies from real-time data based on the characteristic energy consumption data and classify them into distorted and non-distorted data. Qualitative and quantitative analyses are then performed to process the data using data mining methods, such as rule-based judgments, cluster analysis, and outlier analysis, to make decisions on issuing alarms upon detecting abnormal data.

However, studies based on TBM electrical energy monitoring are limited. Nevertheless, several theoretical analyses and data simulation explorations have been conducted. For example, researchers have proposed an energy-based analysis method for TBM fault diagnosis for non-catastrophic faults in three fault units: cutterhead, propulsion, and screw machine^[1]. Currently, most of the relevant analyses based on tunnel machinery energy consumption monitoring are focused on the energy consumption analysis of individual sub-devices, and research remains at the theoretical and experimental stage, without any precedent studies for comprehensive tunnel applications of TBMs. Therefore, a complete fault diagnosis and online prediction system is required to improve the continuity, economic viability, and stability of TBM construction.

2 RESEARCH ON ELECTRICAL ENERGY HEALTH ASSESSMENT SYSTEM

For intelligent TBMs, information data are defined into four main levels. First level constitutes a comprehensive perception level, wherein sensing technology is utilized to comprehensively perceive

*Corresponding author: qinyuan@stecmc.com

various states of the TBM to ensure data completeness. The second level is the data collection level, wherein preliminary processing is performed on collected data and backups are stored to ensure data integrity. The third level comprises the data sharing level, wherein data is exchanged between various systems to ensure data link reliability. The final level constitutes data mining, wherein various types of artificial intelligence modules are employed to mine and condense various types of data to ensure data usability.

2.1 Comprehensive sensing of electrical energy data

Comprehensive sensing of electrical energy data is divided into three parts. The first part is the comprehensive sensing of electrical equipment. This is achieved by integrating various sensing devices to the core electrical equipment of the main operating components of the TBM, such as the high-power motor and its starting circuit that provides power to the hydraulic system. The second part constitutes the comprehensive sensing of electrical energy indicators. To analyze the electrical energy indicators in addition to the conventional current and voltage, it is necessary to collect electrical energy indicators, such as phase angles, high-order harmonics, active and reactive power, and power factor. The third part is the comprehensive sensing of the physical state of electrical equipment, including environmental temperature and data such as motor vibration.

By optimizing sensor selection, improving the range, accuracy, and response speed of the sensing system, and redesigning the sensing system for energy consumption monitoring, core power, and vulnerable components of the TBM, the comprehensive sensing of electrical energy data can be achieved, thereby solidifying the foundation for data analysis and improving the efficiency and accuracy of data analysis.

2.2 Collection and storage of electrical energy data

For engineering equipment, such as TBMs, conventional data acquisition systems are developed with the construction object as the main focus, often overlooking the collection of operational state data for mechanical equipment. Therefore, a data acquisition system for equipment needs to be developed.

Generally, the data acquisition system used for construction has an interval of more than 1 s. The data obtained at such a frequency cannot indicate characteristic changes when analyzing equipment failures. Considering the refresh rate of a programmable logic controller (PLC) and the time cycle for communication between the upper computer and the PLC, the data acquisition frequency is differentiated and configured for different targets. The collection interval for routine equipment data is

not less than 1 s, whereas the collection interval for captured characteristic fault data of the core system is not less than 0.2 s. At the same time, the time length for capturing characteristic fault data of the core system is not less than 10 s before and after the occurrence of fault. This approach can facilitate the capture of characteristic states and avoid the overloading of the system due to the requirement to record large sets of data.

2.3 Standard health model and diagnosis

At the data mining layer, combined with actual construction conditions, big data analysis and machine learning methods are employed to extract feature data closely related to the health state of the TBM. These data are analyzed and refined to extract steady-state and dynamic characteristics of TBM health at different construction states, based on which a standard model for the electrical and mechanical health of the TBM is established. Based on this standard health model, a real-time system is developed to evaluate the health of the TBM and diagnose faults, design a safety architecture for the various systems of the TBM^[2], and develop reasonable and effective redundancy schemes and measures to rapidly diagnose and accurately locate faults, improve maintenance efficiency, and reduce equipment failure downtime. By integrating intelligent sensing devices and comparing equipment operating characteristic curves, the relationship and matching of key system and component operating parameters, construction parameters, and environmental parameters of the TBM are further studied. Mechanism models, knowledge engineering, and data-driven methods are adopted to construct fault characteristic parameter judgment models, thereby realizing the fault pre-diagnosis for the key system and components of the TBM^[3].

2.4 Visualization platform based on digital twin technology

In addition to the standard model, real-time health state data of the TBM, fault diagnosis information, and online prediction results are integrated into a digital platform for visualization. The digital twin model of the TBM is then built using light weighting and model transformation technologies to navigate fault points and guide maintenance.

Figure 1. Health assessment interface.

Figure 1 depicts the energy monitoring module. Considering the real-time and historical analyses of electrical parameters together with the construction conditions, a data chain is established between the energy consumption of key dynamic components and TBM construction parameters to obtain the characteristics of energy consumption changes. A standard construction energy consumption model and dynamic component health assessment model are established, displayed, and analyzed on the platform^[4].

3 ENGINEERING PRACTICE

The project relies on the Shanghai-Nantong Railway Cross-River Tunnel Project, which has a total length of 6770 m and uses an 11 m-diameter slurry-balanced TBM designed and constructed by Shanghai Tunnel Engineering Co. The TBM used in this project integrates a health intelligent assessment system and is designed specifically to collect electrical energy data and vibration information of the motor.

3.1 Sensing system

The TBM is powered by power transformers with the following parameters: four oil-immersed power transformers with rated capacities of 2500, 1600, 1600, and 1000 kVA and a low-voltage distribution system. Communication modules are present in the power cabinet. The entire TBM electrical energy system can be monitored through the perception system, as shown in Figure 2.

Figure 2. Configuration of the perception system.

The corresponding power supply systems are also tested to determine different specifications for collecting electrical energy data, which are classified and collected.

To obtain the motor vibration and temperature, a vibration sensor with the magnetic suction mounting mode is selected for this design. The sensor has a magnetic base that can be directly attached to the motor. The sensor measures the data via wired Modbus RS485 communication transmission and can collect the vibration data in the horizontal and vertical directions of the equipment as well as temperature^[6].

3.2 Acquisition system

In this project, a dedicated data collection system is configured for the targeted development of TBM electric power monitoring. The system monitors high- and low-frequency electrical energy data to obtain the data ignored by the conventional TBM data collection system, such as operating data of the electrical energy system, dynamic startup data of the motor, and physical operating state of the motor. These ignored data are essential for diagnosing the faults in the electrical energy system. The data are collected into the on-site database through the data bus and mirrored backup to the cloud to improve the overall system redundancy. Such targeted development renders the data transmitted to the data platform more comprehensive, reliable, and accurate, as shown in Figure 3.

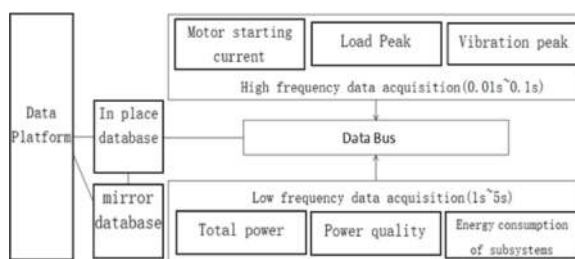

Figure 3. Configuration of the data acquisition system.

3.3 Data mining module

Thousands of sensing devices installed in each system of the TBM are responsible for recording real-time data of each device. The transmission and storage of sensor data provide rich data support for the data mining of TBM construction. These real-time construction data of equipment can reflect the faults of the devices themselves and to certain extent reflect the corresponding real-time parameters and even the overall operating state of the TBM. Therefore, using machine learning and deep learning algorithms to fully mine and analyze the shield collection data and visualizing the analysis results, an effective reference can be provided for TBM construction. An abnormal detection model based on deep learning is constructed to monitor the important electrical energy parameters during TBM excavation, learn the behavior and distribution characteristics of electrical energy parameters under normal conditions, and output the corresponding abnormal information of electrical energy parameters when abnormal behaviors different from normal data are detected, providing references for on-site construction personnel to make correct decisions. Additionally, a performance evaluation index and prediction model of shield machine attitude control based on machine learning are constructed to analyze the influence of key parameters on the attitude control performance and assist on-site construction personnel in rapidly identifying the factors that cause abnormalities in TBM control when such abnormalities occur, thereby guiding the advancement of the TBM^[7].

Figure 4. Model for detecting abnormal energy consumption parameters and grading energy consumption level.

In this project, Autoencoder (AE) was used for data mining, which is an artificial neural network that can be used for unsupervised learning. The purpose of autoencoder is to reconstruct the input vector $\hat{X} = (\hat{x}_1, \hat{x}_2, \dots, \hat{x}_n)$ into an output vector $X = (x_1, x_2, \dots, x_n)$ with the same dimension. This model typically consists of two main parts, namely an encoder used to map the input vector X to an m -dimensional intermediate vector F and a decoder used to map the intermediate vector F to an output vector. Vector X and vector \hat{X} have the same dimension, that is, n dimension. Here $n \neq m$, and $n > m$.

$$\phi : \mathbb{R}^n \rightarrow \mathbb{R}^m$$

Encoders and decoders can be defined as functions and, $\psi : \mathbb{R}^m \rightarrow \mathbb{R}^n$ and the purpose of autoencoders is to fit an identity function:

$$\arg \min_{\phi, \psi} \|X - \psi(\phi(X))\|^2$$

This definition implies the need for appropriate functions ϕ and Ψ to make the input vector X and the reconstructed output vector \hat{X} as close as possible.

$$F = \sigma(WX + b)$$

In the encoding stage, the autoencoder maps the input vector $X \in \mathbb{R}^n$ to the intermediate vector $F \in \mathbb{R}^m$ using the following function. Here $W \in \mathbb{R}^{m \times n}$ is the weight matrix, $b \in \mathbb{R}^m$ is the bias vector, and σ is the encoding layer activation function.

$$\hat{X} = \hat{\sigma}(\hat{W}F + \hat{b})$$

Finally, calculate the reconstruction error between the reconstructed vector \hat{X} and the original input vector X

$$E(X, \hat{X}) = \sum_{i=1}^m \|\hat{\sigma}(\hat{W}\sigma(Wx_i + b) + \hat{b}) - x_i\|^2$$

On this basis, the goal of the autoencoder is to minimize reconstruction errors. This is equivalent to learning appropriate weight matrices W and \hat{W} , as well as bias vectors b and \hat{W} , through gradient descent and backpropagation, to minimize^[8].

3.4 Visualization platform based on digital twin technology

The data collected and analyzed are loaded onto a visualization platform based on digital twin technology. These data are distinguished based on their real-time nature, with the first part being the current state of the TBM, which provides information regarding the machine health and fault points to the on-site personnel. The other part is the historical data record, which can serve as a sample for the self-learning of the intelligent system.

Figure 5. Fault navigation module.

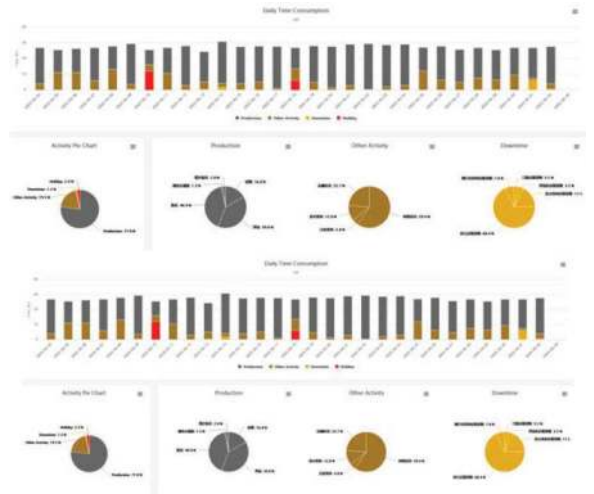

Figure 6. Construction record module.

Figure 5 shows the fault node navigation module in the TBM fault diagnosis platform. Using digital panoramic technology, the entire model and system of the TBM are mapped onto the platform, and the location of the fault points is navigated within the model to help rapidly troubleshoot faults. By studying the energy consumption in different construction states through the platform, parameter optimization strategies are provided to meet economic objectives during the construction process^[9].

Figure 6 is the construction record module of the TBM fault diagnosis platform, where the data from the data collection system are linked to the on-site maintenance platform. The intact rate is quantified as the ratio between the time when the equipment is completely normal during construction and the total construction time. This quantitative value is used to

evaluate the design and maintenance effect of the equipment, forming the entire closed loop of fault warning, fault diagnosis, fault maintenance, and feedback during the maintenance and repair process. It provides detailed data support for the full lifecycle management of the TBM^[10].

4 EXAMPLE OF FAULT WARNING AND OVERALL EFFECT OF APPLICATION

In the case of the slurry mixing system, the mixing motor stirs the cement slurry to prevent it from solidifying through the reducer. A rubber seal between the reducer and the cement slurry prevents cement slurry from entering the reducer and causing equipment damage. In previous system failures, equipment maintenance was often due to damage to the sealing system, which allowed cement slurry to infiltrate the reducer and cause irreversible damage. As this system operates continuously, such equipment failures directly lead to downtime.

Figure 7. Current of the stirring motor.

After collecting and analyzing the load data of the motor, the average load of the motor is found to slowly increase, as shown in the Figure 7.

At 300 cycles, the health system alerted that the load torque of the motor exceeded the set working threshold. During the shutdown maintenance phase, maintenance personnel performed a targeted comprehensive inspection of the system and found that the parts in contact with the seal and cement slurry had bonded together, and certain parts were damaged. Additionally, the cement slurry tended to enter the reducer. Maintenance personnel immediately replaced the seal, and the system working load was returned within the normal working threshold.

Similarly, in the case of a cutterhead system, the health system found that the fluctuation amplitude of the current of the No. 1 cutterhead motor was larger than that of the other cutterhead motors, which was extremely abnormal. When

this characteristic waveform is ignored, a small fault can easily turn into an irreversible major fault, such as damage to the large bearing. With the guidance of the health system, maintenance personnel discovered that the load balance setting of the No. 1 cutterhead motor was not enabled through an inspection of the parameters of the frequency converter. This caused the over-hard mechanical characteristics of the motor, rendering the rotating frequency of the No. 1 cutterhead

Figure 8. Current of the cutterhead frequency converter.

motor unresponsive to load changes, in contrast to the case of other cutterhead motors. After enabling the load balance function, the system returned to normal.

The stable operation of equipment is a key factor for construction safety. Mechanized equipment, particularly substantially large engineering machinery, such as TBMs, inevitably requires maintenance during construction. The two aforementioned characteristics regarding the fault warning of the system can enable the advance planning and conduction of the maintenance without affecting construction, thereby avoiding sudden interruptions caused by equipment failure. Figure 9 shows statistics on the failure rate of TBMs for three construction projects. In this comparison, the failure rate for TBMs is defined as the ratio of the downtime caused by faults

Figure 9. Comparison of project failure rates.

during construction to the actual construction time. The failure rate of the TBM equipped with the intelligent health system is significantly lower than that of other TBMs of the same diameter.

5 CONCLUSIONS

The proposed system for the health assessment of TBMs is formulated through the integration of multiple disciplines, including artificial intelligence, mechanical engineering, information engineering, and electrical engineering, in the field of underground engineering. It breaks through the framework of conventional passive maintenance of equipment and represents a new generation of active, precise, and real-time health assessment and fault warning system for intelligent equipment. It can be implemented on large equipment, such as TBMs, wherein multiple industrial disciplines, such as civil engineering, mechanical engineering, electrical engineering, information technology, and optics, are involved. The system can effectively integrate multiple disciplines and complex artificial intelligence technologies as well as facilitate the development of intelligent platforms^[11].

The fault warning and health assessment of equipment help to enhance the equipment integrity, reduce the downtime caused by equipment failure, improve construction safety, and increase the construction efficiency. These factors can in turn shorten the construction period and minimize the impact on the surrounding environment owing to the specific nature of underground engineering. By improving the construction efficiency, resource utilization can be effectively achieved; construction resource costs can be reduced; and energy conservation and emissions reduction goals can be achieved.

Pivotal role of instrumentation & monitoring in construction of Mumbai Metro Line 3 in an urban setting

Ashish Rawat*

Hindustan Construction Company Limited, Mumbai, India

Ravi Ranjan Kumar & Subodh K. Gupta

Mumbai Metro Rail Corporation Limited, Mumbai, India

ABSTRACT: Instrumentation and Monitoring has played a major role in urban tunnelling and safeguarded the structural stability of the structures in the Zone of Influence of excavations. A thorough monitoring reduces potential risks and enables timely interventions in order that precautionary measures are undertaken prior to any exigencies. Successful completion of a Project without any adversities depends on the veracity of Instrumentation and Monitoring. UGC02 Package of the Mumbai Metro Line 3 comprises of twin-bored tunnels and four stations by cut & cover and conventional drill and blast methods. This stretch is one of the oldest and the most densely populated areas of Mumbai, with heritage structures, some approximately 160 years old and others with an average age of 70 to 75 years adorn the area. Complexities arose during the course of excavations in the form of settlement of structures, apprehensions of depletion of water levels within the premises of Heritage structures, blast induced vibrations during excavation, frivolous claims for damage to property and a number of litigations in courts. An exhaustive Instrumentation and Monitoring regime along the stretch commenced prior to the start of the Metro construction works, which helped in overcoming all complications. The Paper establishes the relationship between the TBM boring operations and a). Tunnel induced settlements, b). Excavation induced vibrations and c). Water level depletion. Effects of settlements in surrounding structures during construction along with corrective and remedial measures are deliberated. Seepage control measures are also discussed. Blasting efficiency and vibration control measures in adjacent structures also find a mention.

Basis the extensive instrumentation including Real-Time monitoring, a successful and timely completion of the Project was achieved despite it being one of the most complex packages in the entire Mumbai Metro Line 3. All litigations won and the local populace convinced through the far-reaching Instrumentation Reports generated.

Keywords: Instrumentation, Real-Time Monitoring, Settlements, Vibration, Water Level Depletion

1 INTRODUCTION

Mumbai Metro Line 3 (MML3) is a 33.5km long underground corridor extending from Colaba to SEEPZ consisting of twin tunnels and 27 integrated stations. MML3 aims at providing a Mass Rapid Transit System that would supplement the existing suburban railway system of Mumbai. UGC02 package with its extent of circa 8km twin tunnels from the Chatrapati Shivaji Terminus (CST) to Mumbai Central Station. UGC02 is the most complex packages in MML3 with 1004 structures in the Zone of Influence, majority of them being in a dilapidated state.

Instrumentation and Monitoring in an urban infrastructure project is of prime importance as it helps to mitigate great risks to life and property. Instruments provide early warning through real time monitoring for any excessive ground settlements affecting the

adjoining structures. An important aspect of a thorough Instrumentation regime is that it is a safeguard and provides legal protection against claims by the owners/residents persisting for damages inflicted to their property during metro construction works.

2 PREPAREDNESS

Series of public hearings were conducted to ward off the resistance from some of the residents and to create a conducive environment for the works to start. Prior to the start of the construction works, an extensive Pre-Construction Building Condition Survey (PCBCS) was conducted as per the Building Damage Classification (Burland 1977). Around 120 structures could not be surveyed due to permissions not being granted by the Owners/Residents and were hence served

*Corresponding author: aashumml3@gmail.com

Table 1. Details of structures in UGC02.

Total Structures	PCBCS completed	Very Severe	Severe	Moderate	Slight	Very Slight	Negligible
1004	884	28	238	417	176	12	13
Heritage Structures: 51/884							
Supported/Repaired Structures prior to Metro Works: 100/884							
Instrumented and Monitored Structures: Approx. 950/1004							
Structurally Audited Structures: 150/884							

notices for granting permissions or owning responsibilities for any damages whatsoever to the structures. Details of the structures and their Classification is provided in Table 1.

Average age of the above structures is 70 to 75 years. Some Heritage structures, which are also places of worship, are nearly 160 years old.

Based on the PCBCS classification of structures, structural auditing of approximately 150 dilapidated structures was completed and the reports shared with concerned authorities. Upon submissions of structural audit reports, structures, which were beyond repairs, were taken up for demolition and the rest were taken up for structural repairs and temporary supports as well.

A comprehensive Instrumentation and Monitoring regime was followed keeping in view the complexity and the close proximity of structures to the excavations. Monitoring of structures along the tunnel alignment and in close vicinity of cut and cover excavations for settlements, cracks, tilt and vibrations was taken up diligently. In addition, ground water level in existing wells and installed Piezometers was monitored during the course of TBM boring and station excavations.

3 COMPLEXITIES DURING THE COURSE OF CONSTRUCTION

TBM mining for the Down Line (Vaitarna-1) started on 6th December 2017 with the breakthrough on 13th August 2019 and the Up Line (Vaitarna-2) started on 24th February 2018 with the breakthrough on 30th April 2020. Few thought-provoking aspects emerged during the course of TBM drive as well as cut & cover construction of station boxes from CST to Mumbai Central.

3.1 *Reported construction induced settlement and consequent damage to surrounding structures*

Several claims on damage to structures cropped up during the course of the construction in UGC02. The claimed damages in forms of cracks and spalling of concrete in most of the structures were refuted with the help of previously prepared PCBCS Reports, which already had these anomalies documented. Litigations in courts of justice were annulled, basis the PCBCS, relevant structural audit and Instrumentation Reports. TBM boring induced settlements

recorded along the alignment were bare minimal to a tune of only a few millimetres which were non-significant.

However, specific reference is made to settlement and cracks in a dilapidated structure in close proximity to the Girgaon station for which a litigation was filed associating the damage to metro construction works. The Building Condition Survey conducted a couple of years earlier along with the structural audit and assessment reports proved useful in establishing that the structure was dilapidated prior to the start of the construction works. The Primary reason for the recorded settlement and development of new cracks was therefore in contrary to the claims.

3.2 *Depletion of water levels*

Apprehensions of water level depletion were raised by managing authorities of two 160-year-old Heritage structures, which were important places of worship. Both the structures have four water wells in their premises and the water is considered as 'holy water'. Concerns regarding seepage into the TBM tunnel while boring beneath the structures would deplete or even drain the water out from the 'sacred wells' were raised off and on during the course of tunnelling. Extensive daily monitoring of all the eight wells and standpipes was in place during and after the TBM mining. As a precautionary measure, several recharge wells were constructed in close proximity to the structures to cater to the depletion of water in case the need arose. A relation between the TBM progress in this specific reach and the water level readings was established which is discussed in detail later in this paper.

3.3 *Vibrations during TBM mining*

Geotechnical investigations had established that the proposed Kalbadevi station box consisting of two shafts would encounter hard and compact fresh Basalt rock. Ambiguous claims by the residents of vibrations due to mining in hard compact basalt were negated by vibration monitoring reports carried out in the structures above.

Due to the absence of no-disturbance zones on structures for monitoring of vibrations, several abrupt peaks were observed due to local disturbances, which were inexplicable. Since there were no noise correction options available in the monitors installed, the prerogative was to establish the vibration levels at ground during TBM boring.

A sub-way near the Metro Cinema under which the TBM was to pass through hard compact basalt of Rock Class I to Class II was selected as a disturbance free monitoring zone during the night as the sub-way is non-operational for the public between 2100 hours and 700 hours. Correlation between the Face activity at the TBM and the vibration recorded during the night shift validated the actual vibrations imparted to the surface during mining in hard compact strata. Results of TBM mining induced vibrations are discussed later.

4 INSTRUMENTATION & MONITORING-DATA ANALYSIS

Instrumentation and Monitoring scheme for the UGC02 package was extensive considering the complexity of the alignment, which traversed through dilapidated structures and varied geological formations and a significantly high ground water table.

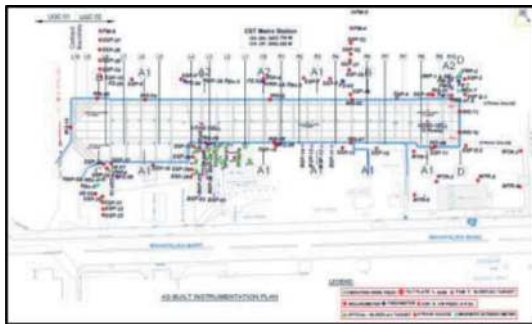

Figure 1. Typical instrumentation - station box.

Figure 2. Typical instrumentation - tunnel section.

All structures within the Zone of Influence (ZOI), which was demarcated as 50m from the centreline of each tunnel and 35m from the station box excavation were included in the monitoring scheme. These structures were monitored for settlement, tilt, vibration and cracks besides Real-Time monitoring. Roads and pipelines were monitored for settlements. Groundwater level monitoring was taken up in installed Piezometers and existing water wells in the ZOI. Some instances with remarkable outcomes are stipulated as below:

4.1 Settlement graphs

Settlement issues by residents during TBM mining

Ground settlement due to TBM mining was recorded and were within the design limits in some rare instances. The limited settlements were due to the hard and compact strata encountered during the course of tunnelling. A classic case of settlement not related to TBM mining is discussed below which highlights the remedial measures adopted for settlements and the importance of Instrumentation and monitoring. Several unethical claims by residents were proved frivolous based on the PCBCS Reports compiled some three to four years earlier. Claims of settlements and cracks due to TBM boring were raised on a number of occasions by the residents. On detailed inspection, claims for the newly developed cracks were found to be irrelevant and thus rejected based on the PCBCS Reports and structural audit reports.

4.2 Ekta society settlement

A dilapidated structure stood in close proximity to the excavated walls of Girgaon station box. Extensive monitoring of the structure was in place, which started even prior to the start of the construction works. On October 8, 2020, a sharp and sudden drop in settlement was recorded to the tune of (-) 10mm in the installed optical targets and several cracks were observed in the structure. Settlement was also observed on the road adjacent to the structure and despite the fact, that the settlement was not related to the Metro construction works, immediate remedial measures were taken up to minimize the settlement.

Picture 1. Location of ekta society vis-à-vis girgaon station.

Due to minor seepage on the walls of the excavation, cement grouting was initiated at the first instance and was undertaken with refusal pressures of 2 to 3 bars from within the excavation. The structure, because of these grouting measures was uplifted to a certain extent and width of nearly all major cracks was reduced. Optical targets installed in the structure reflect the settlement and uplift depicting the efficacy of the grout. Following pictures depict the condition of cracks immediately upon settlement of the structure and after the uplift and the crack width reduction

Picture 2a & 2b. Crack-1 prior to and after grouting measures.

Picture 3a & 3b. Crack-2 prior to and after grouting measures.

The graph representing the settlement and heave of the structure is as shown below. A heave of 13mm from the original position of the specific corner of the structure was observed.

Figure 3. Settlement graph – ekta society.

Thorough scrutiny, to establish the actual cause of the settlement revealed that a leakage in a sewer and subsequent leakage in a nearby water pipe-line was the sole cause of the settlement. Due to the water seepage, ground settlement occurred and thereafter settlement and crack development in the structure. Residents of the building filed a litigation in the court of law claiming that the damage was due to Metro construction. The court of law annulled the appeal

basis the dilapidated condition of the structure recorded in the PCBCS reports prior to the start of Metro works. However, crack repairs and strengthening of the structure were undertaken as a mark of social responsibility, which is being adhered to diligently ever since the start of the project.

4.3 Construction induced ground water depletion

Behaviour of the ground water table during TBM mining operations can be best exemplified by their manifestations in soft Breccia and hard compact basalt. A major drop in the water table to the tune of 7 to 9m was apparent in soft breccia within a Zone of Influence of 45 to 50m, mined in a span of 7 days.

Figure 4. Location of PZ-18 vis-a-vis TBM rings.

Data from this standpipe for the Down Line, the centre line of which is 24m away and corresponds to Rig No. 856 in the Down Line, recorded a drop from the mining of Ring number 834 and return to original levels after mining of ring number 866 which corresponds to a ZOI of 32 rings or a length of 45m.

Figure 5. Drawdown in PZ-18 V/S down line TBM progress.

The water level in the standpipe, located at a distance of 12m from the Up Line near ring number 855, started dropping as the TBM started the mining of ring number 823 on February 11, 2019 and continued to drop until the mining of ring number 858. Completing of ring 858 initiated the rise in water level thus demarcating the zone of influence as 35 rings equivalent to roughly 49m in the Up Line TBM.

Figure 6. Drawdown in PZ-18 V/S up line TBM progress.

Increase in water level recorded during the course of tunnelling is attributed to the ground recharge by rainwater. Variation in ground water levels during the rainy season and dry spell is to the tune of 3 to 4m.

On the other hand, ground water table was monitored in open wells inside the premises of two heritage structures of prime importance. In contrast to the apprehensions raised by the authorities of the Atash Behram, no water depletion was recorded in any of the eight numbers of ‘sacred’ wells.

Figure 7. Drawdown in well no. 1 V/S up line TBM progress.

4.4 Vibrations during TBM boring

Various claims and counter-claims were raised during TBM mining from CST to Mumbai Central. Vibration monitoring was carried out in structures above the TBM with Instantel vibration monitors. Local disturbances due to their placement in structures were abundant and were reflected in the reports as peaks. Explanations for these abrupt peaks related to local disturbances were not understood by the residents. Subsequently, a disturbance free zone for vibration monitoring was delineated in a nearby subway (Figure 8) and monitoring, during mining under it, was initiated during the night when the subway is closed for public. Face activity of the TBM Mining for Ring number 207 in hard rock, during the shift perfectly correlated with the vibration data recorded during this period. This was further established with the mining of rings

208 & 209. Actual range of vibrations (Peak Particle Velocity) during mining by TBM in hard

Figure 8. Location of sub-way vis-à-vis up line and down line.

and compact basalt can therefore be estimated between 0.182 mm/sec to 0.291 mm/sec.

Vibration monitoring graphs for TBM mining displayed below have demonstrated the accuracy of the data collected in the disturbance free zone with a total disappearance of abnormal peaks in the recorded data. Vibration monitors were placed in the sub-way during the mining of ring numbers 207 and 208 and data from three different units for the mining of ring 207 at the same time is similar and most importantly without any abruptly recorded peaks. The data collected was then corroborated with the daily activity reports of the tunnel face. A perfect relation between TBM boring and elevated peaks of vibration and ring building activity reflected as insignificant vibration levels. Three separate Instantel units with Identification Numbers 11694, 11695 and 11207 were installed during the night shift during TBM mining in the subway. Overburden at this particular location was 15m and the subway at a depth of 5m. Thus, the effective depth of vibration measurement was approximately 10m above the tunnel. The correlation of TBM mining and vibrations imparted on Ground are as shown below:

MINING FOR RING NO. 208 (SUBWAY)

5 CONCLUSIONS

This paper deals with three distinctive aspects of the importance of Instrumentation and Monitoring (I&M) during the construction phase of a complex Metro Project. The I&M data is of prime importance

Figure 12. Vibration graph – ring no. 208.

in refuting the frivolous claims by the residents. The three aspects are:

1. Refuting claims for construction induced settlements using Pre-Construction Building Survey reports and reversal of settlements through grouting techniques.
2. Effect of Tunnelling on Ground Water Table and demarcation of a Zone of Influence of approximately 50m in Breccia and
3. Actual vibrations imparted on ground during the course of TBM boring in hard compact basalt in the range of 0.182 to 0.291 mm/sec.

Geotechnical instrumentation for road tunnels: Success cases in Colombia

Víctor Restrepo*, Héctor Salazar & Jean Piedrahita
Grupo Geoandina, Bogotá D.C., Colombia

ABSTRACT: In this article, the implementation of geotechnical instrumentation systems using Multipoint Borehole Extensometers (MPBX), pressure cells, and strain gauges in two (2) significant road tunnels in Colombia is presented. For one of these tunnels, the records and results obtained during the stabilization of a critical area during construction and recently in its operational phase will be presented. On the other hand, the geotechnical monitoring records of a road tunnel affected by the influence of a landslide are presented. The first case involves a tunnel with a length of 3.50 km, which traverses an active regional geological fault along its alignment. For monitoring purposes, an instrumentation system consisting of six (6) MPBX extensometers, eight (8) NATM-type pressure cells, and eight (8) strain gauges distributed in two (2) critical sections of the tunnel was implemented. This system allowed for recording the deformation behavior of the cross-section, demonstrating the effect of construction phases along its length and its final stabilization, comparing the actual maximum values with those initially estimated using numerical models.

The second tunnel, approximately 700 m in length, is in a fluvio-glacial deposit that has experienced mass movement processes since 2019, affecting the last 200 m of the tunnel. Therefore, an instrumentation system consisting of fifteen (15) MPBX extensometers distributed in three (3) sections of the tunnel was implemented, allowing for a direct correlation between surface rainfall regimes and the surface and subsurface displacement velocity over time. Additionally, an analysis of the current results is included in the context of the expected behavior of the tunnel, particularly after a seismic event occurred near the study area.

1 INTRODUCTION

During the construction of the Tesalia Tunnel, which is nearly 3.50 km long, in the Department of Caldas, Colombia, one of the most critical engineering challenges was to traverse the Patía geological fault. The excavation had to be carried out with great rigor, at a slower advancement rate, and in a stepwise manner to control potential displacements and convergences that could pose an imminent collapse risk. For this project, two (2) instrumented sections were defined, each equipped with three (3) multipoint extensometers, four (4) NATM-type pressure cells, and four (4) strain gauges. The purpose was to continuously monitor displacement, pressure, and deformation during the excavation process and subsequent tunnel operation.

In the case of a tunnel affected by the landmass degradation process in one of Colombia's most important road arteries, it was necessary to monitor the progress of displacement through three (3) analysis sections, each equipped with five (5) multipoint extensometers. These results were correlated with

external observations obtained from Ground-Based Interferometric Synthetic Aperture Radar (GBInSAR) and precipitation monitoring in the area.

This article describes the general aspects of the two mentioned projects, the instrumentation equipment used, its location within each tunnel, and the results recorded during the project phases. It highlights the benefits of precisely monitoring displacement, pressure, and deformation to verify geotechnical behavior and compare it with design premises or other related parameters.

2 SUCCESS CASES OF GEOTECHNICAL INSTRUMENTATION SYSTEMS IN ROAD TUNNELS

2.1 *Overview of the Tesalia Tunnel and the Patía geological fault*

The underground structure is currently in its operational phase and is in an intermediate zone of the

Western Cordillera, forming part of the Pacific Connection Highway 3 project in the Department of Caldas, Colombia. It consists of the main tunnel and an emergency gallery tunnel parallel to the main one. These tunnels are approximately 3.50 km long and provide a connection between the rural area of El Cairo (entrance portal) and La Libertad (exit portal). Due to its length, it currently stands as the longest tunnel in the Coffee Region of Colombia.

For its construction, the conventional drilling and blasting method was primarily used. However, in areas where geological faults were encountered, mechanical excavations were employed. In the design and planning phase of the underground project, it was projected to cross four (4) geological faults, with the largest and most critical being the Patía geological fault.

The challenge of crossing this latter fault through mechanical excavations necessitated monitoring the subsurface behavior using specialized instruments based on MPBX extensometers, NATM pressure cells, and strain gauges.

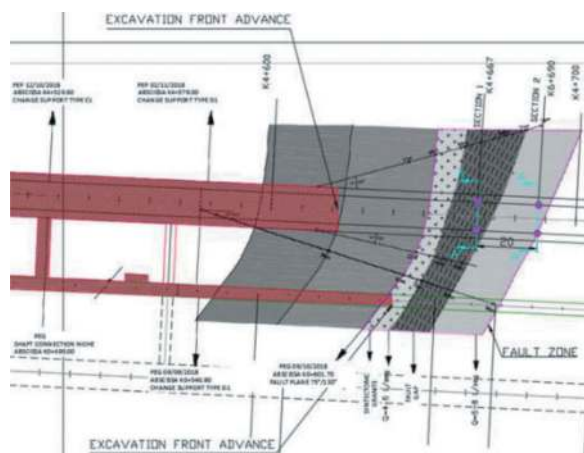

Figure 1. Location of instrumentation stations in the main tunnel.

These instruments allowed for the evaluation of convergence and a possible increase in stresses in 2 sections near the Patía fault, which could indicate zones of rock mass plasticization. Displacement and stress graphs over time were created from the measurements, aiding in understanding and validating stress trends in these sections.

2.1.1 Installation process of geotechnical instrumentation in Patía fault sections

Based on the geological-geotechnical models, 2 monitoring stations were defined at abscissas K4+667.30 and K4+686.70, approximately 20 meters apart, for analysis. For each of these monitoring stations, 3 multipoint MPBX extensometers with vibrating wire technology were installed.

In the extensometer borehole, 3 depths of analysis were defined at 6 meters, 9 meters, and 12 meters.

These depths were used to rigorously monitor the main contacts of the Patía fault zone during both the construction and subsequent operational phases.

To construct the borehole or hole for instrument installation, a jumbo-type machinery with a drilling capacity of 12 meters was required.

Figure 2. Drilling process for MPBX extensometers.

The installation of the extensometers was carried out according to the specified lengths, and to eliminate friction between these instruments and the injection mortar, PVC pipes were assembled around the metal anchor bars.

Once the drilling was completed, bars with anchors at the analysis depths were inserted into the holes, and the extensometer head with a vibrating wire extensometric sensor with a range of 100 mm for each anchor bar was installed.

After installing the sensors in the head and securing the head to the ground, grouting was injected through the instrument's tubes.

In consideration of the hydrogeological conditions in the installation area, a waterproofing additive was implemented, allowing the grouting material to set in the presence of water.

This procedure was replicated for each monitoring location in the tunnel's cross-section, which were positioned at the top (keystone), on the left and right sides.

With the injected and set grouting, final adjustments were made to the head, and the initial reading was recorded for each sensor to establish the baseline or reference.

On the other hand, for NATM-type pressure cells with vibrating wire technology, a small excavation was made on the sides of the sections to allow the insertion of 2 of these instruments, oriented radially and tangentially to the tunnel section's geometry.

These pressure cells were anchored to the ground with bolts, and to create a uniform surface between the rock mass and the instrument, waterproof grouting was applied around the cells, followed by sealing the excavation with the same cementitious material, ensuring consistent confinement of the instruments.

Once the grouting had set, the NATM-type pressure cells were pressurized to eliminate any void spaces that could lead to erroneous readings, and initial readings were recorded for monitoring baseline.

Figure 3. Installation of NATM pressure cells.

For monitoring deformations in the sections, 2 strain gauges with vibrating wire technology were installed on each side (left and right) of the section, anchored with bolts in the ground.

Like the NATM-type pressure cells, the instrument was covered with waterproof grouting to create a uniform surface between the rock mass and the sensor.

Figure 4. Installation of strain gauges.

After the instruments were installed, each of these geotechnical monitoring points was centralized using protective pipes and 4-core wiring, allowing the information from the instruments installed per section to be transmitted to recording equipment at strategic locations, facilitating periodic readings without major complications.

These locations were defined on both sides of the tunnel section, centralizing 2 extensometers on the right side and 1 on the left side.

Regarding the tunnel excavation process, initially the stages of execution of the geometry in the upper zone of the tunnel were initially outlined to generate a stabilized surface with which mechanical excavation work could be done.

The excavations of the tunnel front were done using a “mushroom” shape; that is, the upper area of the tunnel section and the central sector of the section was excavated for access to the excavation machine.

The edges were left unexcavated to provide the tunnel section with the necessary stability to facilitate the tunnel excavation and stabilization.

Figure 5. Locations for instruments in sections of the Tesalia tunnel.

After making a tunnel construction advance of approximately 30 m or at the moment when, technically, the stability of the tunnel section was assured, the shoulders were excavated.

Figure 6. Tunnel excavation section in Patía geological fault - Tesalia tunnel.

2.1.2 Behavior during the construction and operation progress of the tunnel

Based on the results obtained from extensometers in different sections of the tunnel, the relative displacements of the rock mass at various depths were accurately evaluated.

The graphs below represent the displacements recorded by extensometers installed in both sections of the tunnel. In the first section (K4+667.30), after 06/10/2019, a change in trend is recorded.

This behavior is primarily seen in the instrument installed at the top of the tunnel section. The event is consistent with the start date of excavation at the work face, during which displacements of approximately 1 mm were observed. Variations in displacements can also be seen starting from 10/30/2019, coinciding with the excavation of the shoulders in the tunnel section.

Figure 7. Monitoring results for relative displacements - section K4+667.30.

Figure 8. Monitoring results for relative displacements - section K4+686.70.

Similar behavior is recorded in pressure cells (pressure values up to 1.3 MPa) and strain gauges (recordings up to $-1650\mu\epsilon$).

For the second section (K4+686.70), changes in recorded displacements occur starting from 11/17/2019 due to progress in excavation work, with values up to -0.5 mm. Additionally, significant variations in the behavior of extensometers installed on the sides of the tunnel cross-section are recorded between 25 and 26 November 2019, with recordings of up to -2.7 mm.

This coincides with the excavation of the shoulders in the tunnel section, and similar behavior is observed in pressure cells (pressure values up to 0.1 MPa) and strain gauges (recordings up to $-2100\mu\epsilon$).

instruments towards the center of the tunnel, causing the extensometers to displace positively relative to the initial position.

For NATM-type pressure cells, positive values were defined as pressure forces on the instrument, and negative readings as depressurization conditions. For strain gauges, positive values in the readings would indicate tensile stresses, and negative values would indicate compressive stresses.

In addition to the previously mentioned relative displacement analyses, unit deformations were validated for each anchor.

These deformations were obtained from the difference between the displacements recorded in one reading and the reading of the same instrument for the immediately preceding record. For the anchor at a depth of 3 m, deformations with respect to themselves were also considered.

Figure 9. Monitoring results for relative pressures - section K4+667.30 and K4+686.70.

Figure 10. Strains readings to extensometer- section K4+667.30.

Regarding the conventions used for displacement analysis, positive values represent tensile rock behavior, while negative values represent compressive forces. The rock mass mostly moves the

During the monitoring of the tunnel in its construction phase, unit deformations of up to -0.4 mm/m were recorded for anchors at 6 m and 9 m depth. In contrast, for the anchor at a depth of 12 m on the left shoulder,

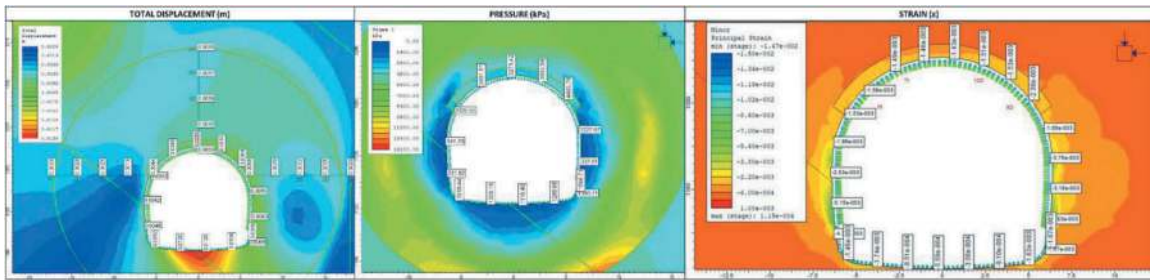

Figure 11. Maximum stress values obtained from numerical modelling.

a unit deformation of approximately -0.18 mm/m was recorded. For the anchors at 12 m from the top of the tunnel section and the right shoulder, positive unit deformations of 0.81 mm/m and 0.20 mm/m were recorded, respectively.

The information obtained through the monitoring of MPBX extensometers in the Tesalia tunnel provided first-hand data to better inform the technical area about the progress processes and other design issues during the excavation and construction phase.

2.1.3 Comparative evaluation of maximum values

Based on the numerical models created during the tunnel design stage, it can be observed that the historical records of displacements, pressure, and deformation show stable behavior for both sections, with slight increases in thresholds that do not pose a risk to the stability of the roadway tunnel.

It is also evident that the maximum values recorded are isolated data points without continuity; therefore, they are considered as anomalies or instrumental noise. Hence, the structures built for the Tesalia main tunnel are operating under the initially proposed conditions.

Regarding the lining, based on the simulations, an average maximum displacement of 0.005 m was obtained for the keystone, 0.005 m for the sidewalls, and 0.009 m for the base plate.

Figure 12. Comparative analysis of thresholds – displacement.

Based on the simulations, estimative calculations were used to determine the stresses to which the primary support would be subjected. These stresses,

under static conditions, were recorded on average as 3.70 MPa for the keystone, 0.85 MPa on the side-walls, and 1.40 MPa on the base plate.

Figure 13. Comparative analysis of thresholds – pressure.

Regarding the presented models, estimative calculations were performed for the unit strains in the tunnel section. These unit strains averaged between $-1400 \mu\epsilon$ (microstrains) and $-2400 \mu\epsilon$ (microstrains).

Figure 14. Comparative analysis of thresholds – strain.

2.2 Overview of Tunnel 13 – Mesa Grande Zone and K58 landslide (Guayabeta)

In 2013, excavation was carried out using mechanical equipment, without blasting, and in dry conditions for two consecutive roadway tunnels (Tunnel 13 and Tunnel 14), passing through fluvio-glacial terrace material.

Since 2018, significant cracks were identified on the terrace slope, and within Tunnel 13, after 2019, displacement events affecting the normal operation of the K58+000 road section of Vía Al Llano and the planned tunnels were recorded. Due to these landslides, the last nearly 200 m of Tunnel 13 were affected, showing considerable signs of displacement and cracking.

In order to understand the displacement trends and the overall behavior of the underground structure, a geotechnical monitoring system based on MPBX extensometers was installed for three tunnel sections (K57+228, K57+270, and K57+335). From the records obtained through these instruments, the relative displacement between two measurement points for each sensor was estimated.

2.2.1 Installation process of MPBX extensometers in Tunnel 13

For each monitoring extensometer well, three analysis depths were defined: 3 m, 6 m, and 9 m, respectively.

Similarly, to the case of the Tesalia tunnel, once the locations of the monitoring points were redefined in the field using a specialized jumbo machine, the respective drillings were carried out to the maximum anchoring depth of 9 m.

Figure 15. Installation process for MPBX extensometers in tunnels.

Following this, a similar installation process was conducted for each of the extensometers. In coordination with the client, the monitoring zones were defined.

Figure 16. General location of the instruments in the cross section of the tunnels.

Once the installation process of the MPBX extensometer head was completed, the cables and pipes were centralized to carry out readings from the sides of the tunnel using manual switchbox reading equipment.

With the three tunnel sections instrumented, an assessment of the tunnel's behavior was conducted. The instruments installed for this project have a measurement range of 150 mm.

2.2.2 Results of displacement changes and correlation with rainfall in the area

Based on the results of the implemented instrumentation system, the behavior of the area where Tunnel 13 was excavated, and which was affected by the earth slide process that occurred on the slope of Mesa Grande, Guayabetal, Colombia, was validated.

Figure 17. Monitoring results for relative displacements - section K57+228.

The extensometers mainly recorded tensile displacements (negative values), with values of up to -22.63 mm. Generally, maximum displacements were recorded in the sections of the extensometers installed on the left side of the tunnel cross-section.

Sections K57+228 and K57+270 of Tunnel 13 showed occasional compression displacement trends recorded in the left shoulder areas, with displacements of up to 8.20 mm.

Based on climate records (precipitation monitoring) in the Mesa Grande area, a correlation can be observed between increased precipitation and the displacements recorded by the tunnel instrumentation.

According to precipitation data, more than 500 mm of monthly rainfall was recorded in August 2021. During this period, the instruments reported significant variations in ground displacement.

Figure 18. Strains readings - section K57+228.

With the objective of monitoring the surface behavior of the K58 Mesa Grande slope, the installation of a robotic SSR429SAR-X radar station with LiSa technology was carried out.

With the previous monitoring technology, it was determined that, due to the precipitation events that occurred between April and October 2021, a change in trend was evident in the displacements of the material present on the slope.

Therefore, it is possible to conclude scenarios of synchronous behavior between the measurements inside the tunnel and the monitoring of surface displacements using SAR-X terrestrial radar technology (Figure 20).

On August 17, 2023, a seismic event with a moment magnitude of M6.1 was recorded near the municipality of Guayabetal.

Readings were taken from the instrumentation installed in Tunnel 13, and the results of these recordings showed significant variations in displacement

trends for each of the tunnel section instruments in the hasty areas.

3 CONCLUSIONS

The implementation of geotechnical instrumentation during the construction and operation of the described tunnels has been essential to obtain on-site data on engineering parameters such as unit strain (strain gages), relative displacements (extensometers) and pressure (NATM cells).

In the case of the Tesalia Tunnel, the instrumentation reading with the advance of the excavation front allowed the dimensioning of the orders of magnitude of deformations and stresses crossing an active geological fault. The changes in stress states were evident during the tunnel excavation of the cross section in different stages and subsequently its stabilization over time to relatively stable final values in expected magnitudes according to the tunnel design numerical models.

Regarding Tunnel 13, affected by the influence of a landslide, a direct correlation was observed between precipitation events in the Mesa Grande area and displacement records inside the tunnel. It was observed that during increased precipitation, the displacement trend is linear and progressive.

After lighter rains, the trend changes from linear to regressive. Additionally, it was noted that after the seismic event with a magnitude of M6.1 near the municipality of Guayabetal, variations in displacement results were recorded for each of the sections of Tunnel 13.

ACKNOWLEDGMENTS

In reference to this article, we wish to express our gratitude to the field and office technical team whose hard work and commitment were paramount to the successful implementation of the monitoring technologies. Their unwavering dedication under often challenging conditions has been an invaluable asset to previous projects and countless other work settings.

Figure 19. Correlation between the behavior of the tunnel and rainfall in the area.

ABSTRACT: Clogging is one of the main problems encountered in mechanized tunnelling with EPB-TBM in fine-grained soils. This issue is usually addressed by soil conditioning, i.e. the addition of water, foam and other chemical agents during the excavation phase. Over the last two decades, encouraged by the exponential increase of tunnels excavated with EPB-TBMs, many research studies have been carried out, leading to the development of several laboratory tests and classification systems to assess the risk of clogging in fine-grained soils and the effect of conditioning. Nonetheless, due to the complexity of the phenomenon, a number of limitations remain in defining and predicting potential clogging. This also emphasizes the lack of appropriate and widely accepted test standards and the inconsistencies of the classification systems. This paper is part of a larger experimental study on clogging carried out over the last 4 years on more than 20 natural fine-grained soils sampled from real EPB-TBM tunnel projects and subjected to a series of tests aimed at determining the clogging potential. The results of the laboratory tests were systematically compared, highlighting the advantages and limitations of each test and exploring the correlations between them. The results of this investigation, also in light of the great number of tests performed on a wide range of natural soils, can be of assistance in making informed use of the existing laboratory tests and clogging risk classification systems.

Keywords: Clogging, Laboratory testing, Fine-grained soil, Conditioning, Classification

1 INTRODUCTION

Clogging is one of the most critical issues in the excavation of tunnels with Tunnel Boring Machines (TBMs) in fine-grained soils. The phenomenon of clogging is essentially due to the so-called adhering and cohering; the former refers to the forces exchanged between soil particles and metal components of the TBM cutterhead, the latter to the forces exchanged between soil particles (Thewes and Burger, 2005). The occurrence of clogging leads to the increase in torque and consumption and, in extreme cases, to the blockage of the cutterhead.

When excavating with TBMs equipped with Earth Pressure Balance technology, it should also be considered that it is necessary to modify the characteristics of the excavated soil in order to make it suitable

for transmitting a stabilization pressure to the excavation face.

This is done by conditioning the soil, that is the addition of water, foam and possibly other additives such as polymers or others. Conditioning, from physical, chemical and mechanical points of view has a number of effects on the excavated soil, mainly summarized as: (1) change in water content and consequently in consistency index; (2) change in the degree of saturation by injection of foam composed mainly of air; (3) chemical modification of the soil with more or less noticeable and lasting effects depending on the chemical composition and dosage of the conditioning agents injected.

For the purposes of this publication, it is important to consider that the conditioning process, in addition to chemically modifying the soil, changes its water

*Corresponding author: diego.sebastiani@geeg.it

content and, consequently, its consistency in a range which is generally considered between the 0.4 and 0.6 (Feinendegen et al, 2010; Hollmann and Thewes, 2013). From this point of view, therefore, it is of particular interest to know the evolution of the clogging phenomenon as the consistency index changes.

The study of clogging should start from the analysis of the characteristics of the soil to be excavated, as the correlation of this phenomenon with certain characteristics, such as the percentage of clay and the plasticity of the soil, is rather well known. Indeed, there are different abacuses and classification schemes in the literature (Thewes and Burger, 2004; Hollmann and Thewes, 2013; Fang et al., 2023) that are quite useful in understanding the “potential clogging” of certain formations based on the analysis of their grain size distribution and Atterberg limits.

To investigate the phenomenon, several tests have been proposed over time, starting with the Hobart mixing test, in the original and later integrated and modified versions (Zumsteg and Puzrin, 2012; de Oliveira et al., 2019), and the pull-out test in flat, conical, and convex versions to assess the clogging potential (Feinendegen et al, 2010; Di Giulio et al., 2018; Spagnoli et al., 2019; Khabbazi et al., 2019). The study of clogging is constantly evolving and new tests and models are proposed annually in an attempt to refine the predictive capabilities of this phenomenon (Chen et al., 2022; Fang et al., 2023).

Each of these tests and models, however, has its advantages and limitations and it is only able to provide a partial view of the problem; therefore, conducting multiple tests and evaluations in parallel can be an effective methodology in order to achieve the broadest and most complete picture possible. Nonetheless, universally accepted procedures for the evaluation of a soil’s clogging potential are still lacking.

To fill this gap, an experimental research project has been underway for several years, systematically testing a large number of natural fine-grained soils. The first results of this research project were initially published in Sebastiani et al. (2024), where the results of mixing and pull-out tests were compared, highlighting strengths and weaknesses, and also finding useful correlations between the results of the two tests and between the test results and the clay fraction.

This paper builds on the initial findings by extending the investigation to soils with higher clay content and higher plasticity. The results presented herein also allow to further test the validity of the previous findings against a larger data set.

Testing is currently continuing on an even larger scale and on a wider range of natural soils. Several conditioning agents are also being tested.

2 MATERIALS AND METHODS

As mentioned above, this study builds on the findings reported by Sebastiani et al. (2024) by extending the experimental research to soils with higher clay

content and higher plasticity. Samples S9, S10 and S11 were carefully collected at the tunnel excavation depth at three different jobsites and characterized to determine their intrinsic properties.

2.1 Soil samples

Table 1 and Table 2 list the grain size distributions and the Atterberg limits of the soil samples determined according to ASTM D6913, ASTM D4318 and AGI Recommendations. *LL* and *PL* represent respectively the liquid and the plastic limit, *PI* the plasticity index and *A* the activity of the clay.

Along with the samples used in this study, the properties of the samples used by Sebastiani et al. (2024), samples S1 to S8, are reported for convenience.

2.2 Laboratory tests

The samples were tested to measure their clogging potential (Hobart mixing test and pull-out test). Prior to laboratory testing, the samples were completely dried, quartered and then brought to the desired water content. The tests methods are briefly described below.

2.2.1 Hobart mixing test

The Hobart mortar mixer (Figure 1) for soil conditioning testing, described by Zumsteg and Puzrin (2012), is often used to produce a homogeneous clay-chemical paste.

To quantify the clogging potential of soft clayey mixtures, the weight of soil sticking to the mixing tool after mixture preparation can be weighted; the clogging potential increases as this weight increases.

The stickiness ratio λ , which quantifies the tendency of the soil paste to remain stuck on a mixing tool, is defined as:

$$\lambda = G_{MT}/G_{TOT} \quad (1)$$

where G_{MT} is the weight of soil sticking to the mixing tool and G_{TOT} is the total weight of soil involved in the mixing process.

Table 1. Grain size distribution of the soil samples.

Sample	Clay %	Silt %	Sand %
S9	45	42	13
S10	50	38	12
S11	47	51	2
S1	40	60	0
S2	37	43	20
S3	50	42	8
S4	28	52	20

S6	46	22	24	0.69
S7	35	20	15	0.63
S8	48	19	29	0.97

Figure 1. Hobart mixing test equipment.

2.2.2 Pull-out test

The pull-out test, in its many variations, is a widely used system for indirectly assessing the clogging potential by measuring the pull-out force registered by a tool first placed in contact with the sample. Different authors, following different approaches, have used this test to measure both the clogging tendency of a soil and the beneficial effects of soil conditioning (Feinendegen et al, 2010; Di Giulio et al., 2018; Khabbazi et al., 2019).

The most common versions of the test are those proposed by Feinendegen et al. (2010), using a conical tool, and by Thewes and Burger (2005), using a flat plate. In this study, the modified version described in Sebastiani et al. (2024) was adopted, essentially applying the same test methods but with a slightly convex plate (Figure 2).

3 RESULTS

In this section, the results of the laboratory tests will be presented and discussed; particular focus will be placed on correlating the results obtained with the water content and I_C value of the soil samples tested.

The following Figures 3, 4 and 5 show the results of the Hobart mixing tests performed on soil samples S9, S10 and S11 at different water contents w (and hence consistency index I_C). The results are interpolated by a Gaussian curve as a function of I_C . The results are well fitted by Gaussian curves for all

Figure 2. Detail of the pull-out test plate.

Figure 3. Hobart mixing test results for soil S9.

Figure 4. Hobart mixing test results for soil S10.

Figure 5. Hobart mixing test results for soil S11.

three soils studied. It should be noted that at high values of I_c there are some difficulties in performing the mixing test, which lead to consider the branch of the curve associated with lower values of I_c more reliable (de Oliveira et al. 2019).

Figures 6, 7 and 8 show the results of the pull-out tests carried out on soil samples S9, S10 and S11 at different water contents. Again, the results are well interpolated with a Gaussian curve. It can be noted that these results are substantially in agreement with those of the mixing test in terms of consistency index, with the peak values slightly shifted towards higher values of I_c .

Finally, Figures 9 and 10 compare the results of this study with those obtained by Sebastiani et al (2024) in terms of mixing tests and pull-out test results respectively.

Figure 6. Pull-out test results for soil S9.

Figure 7. Pull-out test results for soil S10.

Figure 8. Pull-out test results for soil S11.

Figure 9. Comparison of the mixing tests results.

Figure 10. Comparison of the pull-out tests results.

By comparing the results obtained through the mixing tests performed on all the investigated clays, it can be noted that, although the more clayey and plastic soils (i.e. higher CF and PI) have a slightly shifted peak toward higher consistency indices, there are no remarkable differences in terms of maximum stickiness ratio. Instead, the Gaussian curves obtained through the pull-out tests highlight that as the clay fraction and plasticity increase, the peaks of the curves increase and are slightly shifted toward higher I_c values (lower water content). This results further confirm the effectiveness of the pull-out test in measuring the clogging potential, as it is well known that the clogging risk increases with the clay fraction and the soil plasticity.

4 CORRELATIONS WITH CLAY FRACTION AND BETWEEN TESTS

As said, this study aims to extend the results reported by Sebastiani et al. (2024) to soils with higher clay fraction and plasticity, and also to test the validity of the correlations found in the above study by adding new results to the data set.

The following Figures 11, 12 and 13 show the correlation between the values of peak adherence λ_{pk} and pull-out force F_{pk} estimated through the Gaussian parameters and clay fraction CF , overlaid on the interpolation proposed by Sebastiani et al. (2024).

The results show that the correlations remain valid also in light of the new data, accounting for some dispersion of the experimental data. The behaviour shown by the new soils strengthens the experimental bases on which the correlations are based and extend it to fields (i.e. $F_{pk} > 200$ N) that previously could not be reached.

The new pull-out results are in better agreement with the correlations than the mixing tests ones. Pending further investigation, this suggests that the pull-out test is more versatile and more effective in providing a measure of the clogging potential of soils with higher clay content and higher plasticity index.

5 CONCLUSIONS AND FUTURE DEVELOPMENTS

This paper is part of a larger study focused on the determination of the clogging potential of natural soils through laboratory tests. The research activity carried out, now for several years, has been based on a few basic fundamentals: 1) performing laboratory tests on natural soils from real tunnels and underground works projects; 2) correlating the results of laboratory tests performed to measure the clogging risk to a strong and comprehensive geotechnical characterization and 3) developing laboratory tests in parallel to investigate their limitations and reliability, to compare results and provide useful correlations.

Figure 13. Correlation between estimated mixing and pull-out peak values.

The experimental activity described in this paper aimed to extend the findings of Sebastiani et al. (2024) to soils with higher clay content and plasticity and to test the validity of the proposed correlations in light of the new data.

The new data confirm that:

- gaussian curves well describe the mixing and pull-out results with respect to water content and consistency index;
- the peak of the gaussian curves resulting from the pull-out tests is slightly shifted towards higher values of consistency index than that provided by the mixing tests;
- the pull-out tests shows a greater sensitivity in measuring the clogging potential as its results amplify the differences between various soils.

The results also allowed to:

- the correlation between mixing test results and clay fraction seems to be weaker than that with the pull-out test results;
- extend the validity range of these correlations for F_{pk} values above 200 N;
- find that as the clay fraction of the soil and plasticity increase, the peaks of the curves increase and are slightly shifted toward higher values of consistency index (lower water content)
- observe that the pull-out test is more effective in detecting the increase in clogging potential associated with higher clay content and plasticity index.

ABSTRACT: Structural health monitoring is crucial for ensuring tunnel safety during construction and operational stage. Wireless sensor network (WSN) based monitoring has the advantages of real time and high frequency in data collecting, wireless transferring of data and ease of installation. In real practice, the placement of wireless sensors is needed to be optimized due to the limitation of monitoring cost. Furthermore, shield tunnel linings are subjected to random external loads in operational stage. A robust sensor placement (RSP) scheme should be able to capture the variation of random loads and place the sensors at structural sensitive locations. In order to design a robust sensor placement scheme, this paper proposes an information entropy based optimization method considering the randomness of external loads acting on tunnel linings. The proposed method mainly contains four parts: mechanical model construction, load uncertainty modelling, information entropy calculation and optimization of sensor placement scheme. A case study of Mawan cross-sea passage tunnel is conducted to show the effectiveness of the proposed method. For the large diameter shield tunnel with ten segments, the most sensitive location to external random loads is founded to be 138° (segment B2).

Keywords: Wireless sensing, optimal sensor placement, information entropy; shield tunnel, random analysis

1 INTRODUCTION

Tunnel cross-section deformation is a key factor for evaluating tunnel structural performance (Loganathan and Poulos, 1998; Mair, 2008; Pinto and Whittle, 2014). Therefore, it is crucial to monitor the tunnel cross-section deformation during the construction and operation stages. For shield tunnels assembling with precast segments, the inclination deformation of each segment makes a great influence to tunnel horizontal convergence and joint opening (Wang et al., 2020a). Traditional tunnel structural health monitoring focused on the horizontal convergence and often neglected the segment inclination. Tunnel convergence is an overall indicator and cannot reflect the unsymmetric deformation of lining (Wei et al., 2023).

Wireless sensor network (WSN), having the advantages of easy deployment, reliability, flexibility, real time monitoring, is increasingly used in structural health monitoring (SHM) (Lynch, 2007; Abdulkarem

et al., 2020). However, due to the limited cost, wireless sensors are unfeasible to densely deploy in a large scale of infrastructure. Thus, the optimization of sensor deployment scheme is essential to well capture the structural performance during operational stage (Yi et al., 2011). As seen from Figure 1, the operational shield tunnel lining was subjected to adjacent pit excavation (Huang et al., 2019). Wireless tilt sensors were installed at different segments, giving completely disparate monitoring data. The sensors on the right side monitored the segment deformation variation caused by the pit excavation, while the sensor on the bottom-left side could not capture such variation. In this case, the sensor performances were largely dependent on the location they placed. In reality, the pit excavation could not be anticipated before the sensor placement. To systematically evaluate a sensor placement scheme, the uncertain external loads should be carefully modelled. Additionally, there is a need for quantitative standard for assessing sensor performance.

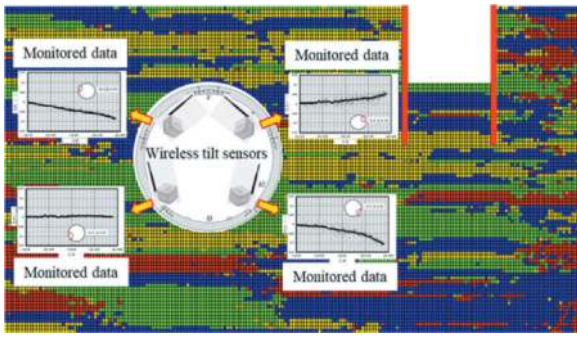

Figure 1. The necessity of RSP for wireless sensing.

In this study, the authors proposed the concept of robust sensor placement scheme (RSPS) and the framework of obtaining RSPS. The RSPS of wireless tilt sensor deployed on shield tunnel lining was taken as an example to apply the proposed framework. Information entropy was adopted to evaluate the performance of each sensor placement scheme.

2 THE CONCEPT AND FRAMEWORK OF RSPS

2.1 The concept of RSPS

The concept of RSPS was originated from the uncertainty of structural performance which was caused by the uncertainty of external loads. As illustrated in Figure 2, the indeterministic external loads acted on engineering structures in spatial-temporal domain. Thus, the structural responses presented with uncertainty and could be modelled using probability distributions. For point directly measured sensing technique, sensors could only monitor the structural response where they were placed. The sensor measurements varied due to the different placement location. Given the same external loads, the sensor measurements at “Location 1” varied less than the sensor measurements at “Location 2”. In other words, the sensor measurements at “Location 2” were more sensitive to the variation of external loads. “Location 2” gave more information about the change of external loads according to information theory.

Figure 2. The comparison between different sensor deployment schemes.

More information was expected to be obtained by the installed sensor. The RSPS was the placement scheme which maximized the obtained information confronted with load uncertainty. “Robust” here meant the sensor placement scheme could well capture the variation of external loads. By adopting RSPS, the overall uncertainty of structural performance was minimized given the limited number of deployed sensors.

2.2 The framework of obtaining RSPS

Based on the concept of RSPS, the framework of obtaining the RSPS could be designed. The whole framework consisted of five steps as shown in Figure 3.

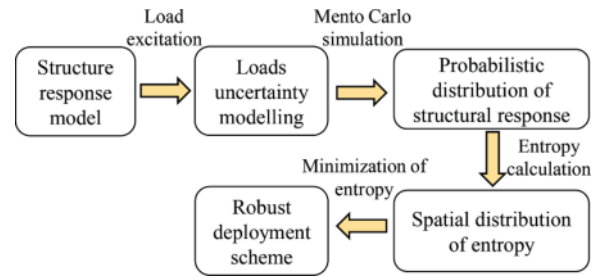

Figure 3. Framework for the determination of RSPS.

Step 1: Established the mechanical model of the structure being monitored. The model must be able to capture the main mechanical properties of the structure and predict the desired structural response. The mechanical model was often an analytical formula or a finite element, finite difference numerical model. The structure itself, together with the different kinds and distributions of loads acting on it, were all included in the mechanical model. To optimize sensor placement scheme, a plausible mechanical model must be established.

Step 2: Modelled the uncertainty of external loads acting on the structure. The load types were usually prescribed. The load level was commonly modelled using one-dimensional or multi-dimensional probabilistic distributions. Random field theory was adopted if spatial variety of load was considered.

Step 3: Using external loads and mechanical models, predicted the desired structural performance indicators, such as internal force and deformation. It was important to sample numerous times for the specified external load distribution in order to acquire the probability distribution of structural response, and then to run a Monte Carlo simulation to do so.

Step 4: Determined the spatial distribution of information entropy by computing the information entropy at various sensor installation places based on the probability distribution of structural response.

Step 5: Placed the monitoring sensors at the location where the structural information entropy was largest so that the structure’s overall information entropy dropped most quickly.

3 RSPS OF LARGE DIAMETER SHIELD TUNNELS

3.1 Mechanical model of large shield tunnels

This section takes the lining structure of Mawan cross sea passage tunnel as an example to show the effectiveness of the proposed framework. Figure 4 shows the lining structure for Mawan cross sea passage. This shield tunnel has an outer diameter of 15m. Each ring is composed of 10 segments which has a thickness of 0.65m and a ring width of 2m. Among the 10 segments, there are 1 wedge-shaped block with an angle of 12.857° , 2 adjacent blocks with an angle of 38.571° , and 7 standard blocks with an angle of 38.571° . The longitudinal joint is connected using one diagonal bolt. In the longitudinal direction, staggered joint assembly is used to improve the overall stiffness, and 28 longitudinal diagonal bolts are connected between adjacent rings.

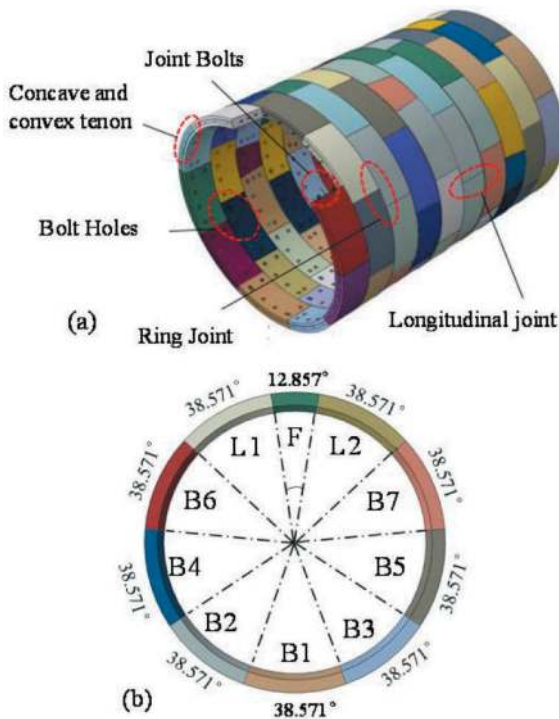

Figure 4. Lining geometry of large diameter shield tunnel.

For the above large-diameter shield tunnel lining structure, previous research has proposed many mechanical models, such as analytical solutions of uniform continuous ring, jointed continuous ring, beam spring model, and shell spring model, as well as refined three-dimensional finite element model. Among the numerous mechanical models of shield tunneling, the jointed continuous ring model proposed by Lee and Ge (2001) is widely used, as shown in Figure 5.

This model simplified the longitudinal joint as an elastic hinge with bending stiffness, and the entire ring structure was equivalent as a continuous jointed ring. Lee and Ge (2001) proposed the load

Figure 5. Structural model and loads pattern of the shield tunnel lining.

distribution on shallow shield tunnels during operation based on on-site measured data, as shown in Figure 5. Among them, p_1 is the vertical earth pressure at the arch top, p_2 is the reaction force at the arch bottom, p_3 is the lateral earth pressure at the arch top, p_4 is the difference between the lateral earth pressure at the arch bottom and arch top, p_5 is the self weight of the tunnel lining, and p_6 is the ground resistance. In such a load distribution situation, Lee et al. (2001) used the force method to solve the analytical formula for the internal force and deformation of shield tunnels. Nevertheless, this analytical solution faces difficulties in determining the bending stiffness of joints. In fact, the bending stiffness of a joint varies with the level of internal forces.

To get over the mentioned issue, this paper used the modified analytical solution suggested by Wang et al. (2020b). This modified solution included an analytical model for the joint bending stiffness that created a function of joint stiffness based on the joint's geometrical dimensions, the material properties of the concrete and bolts, the axial force, and the joint's bending moment. The modified solution automatically solved the stiffness at each joint position through iteration, requiring no prior input of joint stiffness.

3.2 Load uncertainty modelling

Regarding the mechanical model of large-diameter shield tunnels discussed earlier, only the lateral pressure coefficient K_0 and the ground resistance coefficient K_s required to be taken into account because the burial depth H was typically a constant over the cross-section. For the sake of simplicity, this study made the assumption that the soil in the cross-section was homogeneous and that the uncertainty of K_0 and K_s could be approximated using random variables.

K_0 and K_s were assumed to be two-dimensional normal distributions. The mean and covariance matrix totally described the joint probability distribution of K_0 and K_s . The mean and coefficient of variation (CoV) of the marginal distribution of K_0 is

μ_{K_0} and cov_{K_0} , respectively. The mean and CoV of marginal distribution of K_s is μ_{K_s} and cov_{K_s} , respectively. The correlation coefficient between the two random variables is ρ . So the mean vector of the joint probability distribution of K_0 and K_s is $\mu=(\mu_{K_0}, \mu_{K_s})$, and covariance matrix Σ is shown in Equation. (1) as follows,

$$\Sigma = \begin{pmatrix} (\mu_{K_0} \times cov_{K_0})^2 & \rho \times \mu_{K_0} \times \mu_{K_s} \times cov_{K_0} \times cov_{K_s} \\ \rho \times \mu_{K_0} \times \mu_{K_s} \times cov_{K_0} \times cov_{K_s} & (\mu_{K_s} \times cov_{K_s})^2 \end{pmatrix} \quad (1)$$

Set $\rho=0.5$, $\mu_{K_0}=0.5$, $cov_{K_0}=0.2$, $\mu_{K_s}=0.5 \times 10^4 \text{kN/m}^3$, the joint probability distributions were shown in Figure 6 considering three levels of $cov_{K_s}=0.5, 0.3$ and 0.1 . The joint probability density of K_0 and K_s tended to be concentrated with the decrease of cov_{K_s} . 500 sets of K_0 and K_s values were acquired by sampling from each joint distribution.

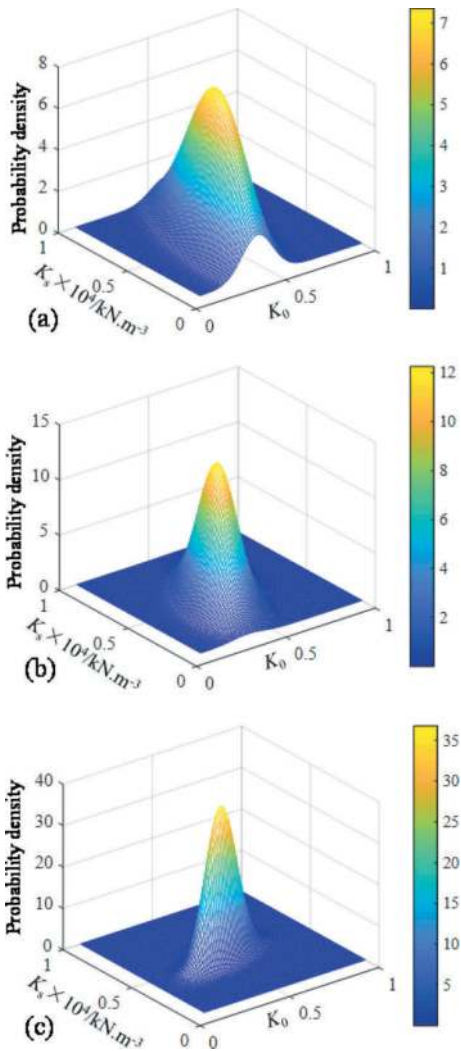

Figure 6. Loads uncertainty modelling using two-dimensional Gaussian distribution: (a) $cov_{K_s}=0.5$; (b) $cov_{K_s}=0.3$; (c) $cov_{K_s}=0.1$.

3.3 Probability distribution of tunnel deformation

After obtaining 500 samples of input parameters, Monte Carlo simulation was conducted to acquire the probability distribution of inclination deformation. Took the input parameters $H=20\text{m}$, $K_s=5000\text{kN/m}^3$, $\mu_{K_0}=0.6$ and $cov_{K_0}=0.3$ as an example. The angular coordinates φ characterized the position along the tunnel ring. Tunnel crown tunnel was set as 0° and tunnel invert was set as 180° . The results of six typical positions, namely, $\varphi=10^\circ, 40^\circ, 70^\circ, 100^\circ, 140^\circ, 170^\circ$ were selected and shown in Figure 7. The probability distribution of inclination deformation at each position could be well fitted with a normal distribution.

Figure 7. Probability distribution of inclination deformation at different locations along tunnel springline: (a) $\varphi=10^\circ$; (b) $\varphi=40^\circ$; (c) $\varphi=70^\circ$; (d) $\varphi=100^\circ$; (e) $\varphi=140^\circ$; (f) $\varphi=170^\circ$.

As can be seen from the probability distribution in Figure 7, the probability distribution of inclination deformation at $\varphi=10^\circ, 40^\circ$, and 70° was identical, and the probability distribution of inclination deformation at $\varphi=100^\circ, 140^\circ$ and 170° was identical as well. This kind of similarity for probability distribution was caused by the deformation mode of large-diameter shield tunnels. Shield tunnel cross-section deformation was predominated by segment rotation, which resulting in a “lying duck egg” or “standing duck egg” deformation mode. The deformation probability distribution was identical if the evaluated points were located at the same segment.

3.4 Determination of RSPS using information entropy

Based on the deformation probability distribution, it is possible to determine the information entropy at different locations along the lining. Deformation uncertainty is measured by information entropy. The

information entropy of the certain point's inclination deformation increases with the increasing of uncertainty. Deploying monitoring sensors is therefore more essential in order to eliminate uncertainty. The information entropy En can be calculated using the following formulas for a particular probability distribution (Shannon, 1948).

$$En(X) = - \sum_{i=1}^n p(x_i) \log p(x_i) \quad (2)$$

Where, En is the information entropy; $p(x_i)$ is the probability of deformation range $[x_i - \Delta x/2, x_i + \Delta x/2]$; n is the number of discrete x_i .

In fact, inclination deformation x_i is a continuous random variable. Integration is needed to accurately calculate the information entropy. This study replaced the accumulation of probability density in a small range $[x_i - \Delta x/2, x_i + \Delta x/2]$ by the probability $p(x_i)$ of equivalent discrete variable $[x_i - \Delta x/2, x_i + \Delta x/2]$. Δx is the very small division of deformation range acquired from Monte-Carlo simulation. The information entropy for inclination deformation along tunnel springline was obtained and shown in Figure 8.

Figure 8. Inclination entropy distributed along the tunnel springline.

As illustrated in Figure 8, block B2 is where the information entropy of the inclination deformation is highest, followed by block L1 and block B6. These three segments have relatively high information entropies, and variance within the same segment is generally modest. Segment B1 and B4 have various information entropies inside the same segment. Therefore, in the case of limited monitoring expenses, priority should be given to installing tilt sensors on segment B2, following with the order of priority being B2, L1, B6, B4, B1, and F blocks. More specifically, the highest entropy within the block B2 was $\varphi=138^\circ$.

3.5 Influence of load uncertainty modelling

The influence of external load uncertainty modelling on information entropy and RSPS was discussed in this section. As two-dimensional normal distribution was used to model the main uncertainty source K_0 and K_s , the influence of CoV and ρ were investigated. The influence of K_s 's CoV was evaluated in Figure 9.

Figure 9. Influence of K_s 's CoV on information entropy.

With the increase of K_s 's CoV, the information entropy of each point increased, but the overall distribution pattern remained unchanged. The order of information entropy between the blocks was still B2, L1, B6, B4, B1 and F. Similarly, the effect of correlation coefficient ρ between K_0 and K_s on information entropy was investigated in Figure 10.

Figure 10. Influence of correlation coefficient ρ on information entropy.

When the correlation coefficient ρ increasing from 0.1 to 0.5, the information entropy change was not significant, but when ρ increasing from 0.5 to 0.9, the information entropy of each point significantly increases. This indicated that reasonable modeling of external loads had a significant impact on the uncertainty analysis of segment inclination deformation. If there were multiple external loads, the correlation of various loads must be reasonably considered. The above analysis indicated that the stronger the correlation between different loads were, the greater the uncertainty of deformation would be. However, the variation of ρ still had no impact on the distribution pattern of information entropy along the tunnel springline.

4 CONCLUSIONS

In real SHM practice, the placement of wireless sensors is needed to be optimized due to the limitation of monitoring cost. The concept of robust sensor placement scheme (RSPS) was proposed in this paper to capture the variation of random loads and place the sensors at structural sensitive locations. In

order to design a RSPS, this study proposed a practical framework. The proposed framework included three steps: the first step was constructing appropriate mechanical models of shield tunnels; the second step was random modelling of external loads acting on shield tunnel lining; the third step was calculating the information entropy based on probabilistic distribution of tunnel deformation. The whole study was concluded as follows.

- (1) For the large diameter shield tunnel with ten segments, the most sensitive location to external random loads was founded to be 138° (segment B2). The sensor placement priority was decided according to the information entropy ranking among different segments.
- (2) Load uncertainty modelling including the CoV and correlation coefficient ρ had a significant influence on information entropy, however, they had no distinct effect on the information entropy ranking among segments.

ABSTRACT: Shaft and Tunnel Excavation Monitoring System (STEMS) developed on MissionOS[®] is being implemented in Singapore's Deep Tunnel Sewerage System Phase 2 (DTSS2) project to support the construction of 50 km of bored tunnel sewer, another 50 km of link sewer pipe laying, and associated deep shafts, manholes, hydraulic structures, etc. The STEMS is designed to provide centralised data management and integration of various construction and tunnelling data across the project to ensure the adequate level of geotechnical control is achieved on various construction activities. The system is capable of linking up with multiple data sources and devised to deliver quality engineering data with common analytics and reporting capability for risk identification and to assist in decision-making process. Engineering geological data, geotechnical instrumentation data, excavation data, Tunnel Boring Machines (TBM) operation and pipe jacking machine data, construction progress, design information and other relevant data across the projects are taken into the system for processing and integrated into various user definable formats to facilitate quick review, combined analysis and interpretation. The web-based and integrated nature of this centralised processed data management system also has real-time TBM monitoring capability and automatic SMS alerting features. This paper describes the STEMS and highlights the technical capabilities of the system with emphasis on geotechnical control for deep excavation and TBM works.

Keywords: DTSS2, STEMS, Data Management System, TBM, risk identification

1 INTRODUCTION

Since Tunnel Boring Machines (TBM) are more and more used to construct tunnels in challenging environments, such as built-up areas, the predictive risk analysis becomes ever more important (Festa et al. 2012). Recognising the advent of cloud-computing power and applicability of data management systems in predictive risk analysis, Singapore's National Water Agency, PUB implements Shaft and Tunnel Excavation Monitoring System (STEMS) in Deep Tunnel Sewerage System Phase 2 (DTSS2) Project as a centralised integrated data management system for processing, integration and delivery of a large volume of diverse construction and engineering data. The DTSS2 conveyance system has 100 km of deep tunnels and link sewers, of which 50 km is

constructed by 19 TBMs via 5 Design & Build contracts. Another 50 km of link sewer pipe laying work being executed by micro TBM and pipe jacking methods will be delivered by 12 Build-Only contracts (Figure 1). Several deep shafts and manhole excavations are also required for construction of hydraulic structures and to launch and receive TBMs.

The DTSS2 tunnel alignments run largely under major expressway corridors at a depth between 35 to 55 m. They are bounded by transportation infrastructures, various buildings, underground structures, and subterranean services. It is known that excavation and tunnelling processes inevitably cause disturbance to surrounding ground and further lead to ground settlement and can even induce severe hazards to structures and services (Yin et al. 2017, Wang et al. 2019, Yin et al. 2020, Zhang et al.

*Corresponding author: aung_ko_ko_soe@pub.gov.sg

Figure 1. DTSS Phase 2 Project Layout.

2021). Therefore, a comprehensive and robust monitoring regime is vital to identify and control the potential risks to ensure the performance and integrity of structures and services in excavation/tunnelling influence zone are not affected.

The TBMs used in the DTSS2 project are heavily instrumented for efficient operation and better control to minimise the risk of over-excavation. Likewise, extensive arrays and several clusters of geotechnical instruments are installed along the tunnelling and pipe jacking corridors for monitoring. As the data acquisition and monitoring are a time-based continuous process, a robust data management system is required for processing and integration of a large volume of captured data, and timely delivery to end-users with appropriate analysis tools for interpretation and to assist in risk identification and decision-making process. All relevant data such as geological data, instrumentation monitoring data, TBM data, construction and excavation data are taken into STEMS's centralised data environment. Therefore, more thorough and comprehensive analysis can be carried out with all vital construction information including those which would not be readily available in conventional systems or hidden in the diverse field data.

2 BACKGROUND

STEMS is developed as a web-based integrated data management system on MissionOS[®] platform which is designed to work with diverse engineering and construction data. This system is neither a desktop application nor a ready-made software. It is, in fact, a bespoke software and configured based on DTSS2 contract specifications and requirements. This system runs on back-end server and can be assessed by using any popular web browser through internet. STEMS is different from conventional instrumentation monitoring systems or TBM monitoring systems as it also functions as a coordinated and integrated data management platform which bring together various construction data and transform them into useful engineering information. It captures various data directly from their respective sources and process them in a way that everything can be combined and viewed

over common parameters such as time series, changes, etc., in a single common platform (Figure 2).

Nowadays, the availability of megabit-speed internet protocol on large excavation and tunnelling projects in urban environment allows STEMS to interface seamlessly with various data sources. Real-time automatic data are processed and published in real time and notification/alert messages are triggered automatically when pre-set values are breached. STEMS is equipped with tools and functions that are needed for efficient monitoring and analysis. It has various modules covering the key aspects of geotechnical building works such as instrumentation monitoring & data analysis, construction progress monitoring, data visualisation, reporting, TBM monitoring, pipe jacking machine monitoring and quality control plus documentation. Various reports in pre-designed format can also be prepared and generated with readily available information in the system. Other relevant information or documents can also be uploaded and archived systematically for instant access.

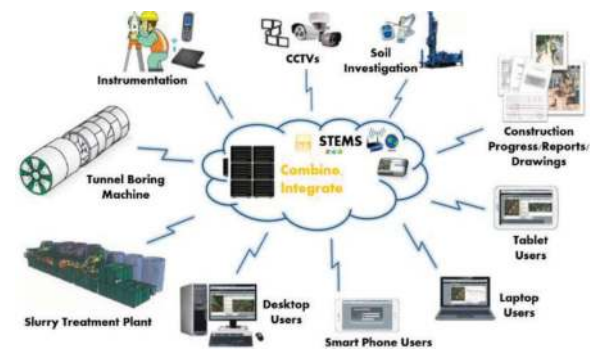

Figure 2. Schematic of STEMS configuration.

3 NETWORK STRUCTURE

STEMS is built using standard web scripting languages on a LAMP (Linux, Apache, MySQL, PHP) architecture for server and client-side processing. The architecture is designed as a component-based scalable system allowing a high degree of expandability with flexibility for rapid development without the need for hard coding. It utilises the Amazon Web Service (AWS) server to provide scalable architecture to manage increasing data volume and processing requirements without interruption. For security, data is archived using rolling daily, weekly, and monthly snapshots and can be restored in less than 2 hours. Moreover, a separate local server is installed, and data is mirrored daily.

As shown in Figure 3, STEMS's structure has three layers – underground layer, site layer and web layer. The underground layer constitutes the data from shaft excavations and TBMs. The site layer represents the instrumentation data, drawings, reports, records, and other construction data. The

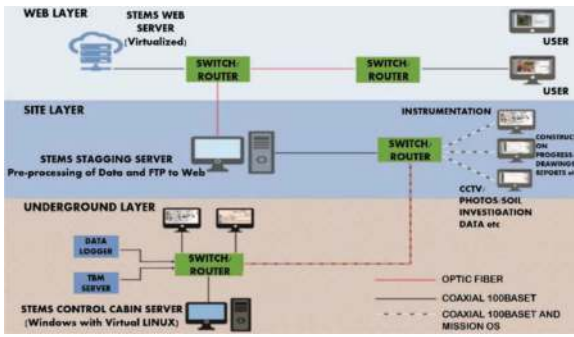

Figure 3. STEMS network structure.

web layer only has STEMS server or cloud server. In that web layer, all data from underground and site layers are processed, stored, and retrieved upon request. Therefore, the web layer is the key component in the structure and subject to strict exploitation, quality control and operational performance.

4 KEY FEATURES

4.1 Portal

The main interface in STEMS is the map/drawing window where different types of georeferenced maps/drawings can be configured to display as a background in it. Aerial images, geological maps, street maps, site plans, combined services plans, instrumentation plans, soil profiles, cross sections, TBM drawings, etc., can be called to display in the map window (Figure 4 & 5). The portal is furnished with basic tools such as zoom controls, digitizer and distance measurement tools, map selection tabs, legend control, drop-pin button and element selection menu.

Figure 4. Main portal with different background maps.

All elements displayed in the map window are interactive. Therefore, key information will be outlined in the information pane and can be further explored when an element is selected. For instance, easting/northing/ground level, installation depth, review level, calibration certificate (if applicable), installation records and

photo attachments will be displayed when an instrument is selected either in the map window or in the data window. Similarly, a complete bore log will be displayed in PDF format and AGS chart when a borehole point or an ID is selected.

Moreover, pins are also available to mark specific locations on the map window interactively. Different pin shapes are available and can be used to indicate shafts, manholes and TBM cutter head intervention locations. The colour of the pin can be changed to indicate the construction status such as active, non-active and temporary. In addition, pins also provide a place to park the documents pertaining to that site and can also publish the time-based information such as daily activity, photographs, records, name and contacts of engineer-in-charge and emergency rescue teams etc. Furthermore, a digitizing tool is also available to draw new elements to identify existing or custom structures to include in 2D sections and 3D models.

Figure 5. Soil profile and TBM drawings shown in map window.

4.2 Project dashboard

The project dashboard is a one-stop location which outlines the comprehensive overview of the project. It is designed to provide up-to-date information on construction/tunnelling progress, and the instruments which have recorded substantial readings in past few days. The dashboard tabulates the progress for every shaft/manhole excavation, TBM and pipe jacking drives. The statistics outlined for shaft excavation progress include current excavation level, target excavation level and percentage of excavation completed. For TBM drives, statistics shown in the dashboard are current drive status, ring-built number, head chainage, completed distance, percentage of completion, progress bar and production summary (Figure 6).

TBM daily production chart can also be obtained for any time period. Links are also provided to display TBM locations, soil profile and real-time display of TBM parameters. The TBM progress updates are real time, and each individual progress is automatically consolidated to derive the project wide progress as shown in Figure 7. The total tunnelling and pipe jack distances completed, numbers of shafts/manholes being excavated and completed are tabulated and indicated on the map as shown in the figure below. But this option is only available to authorised users.

Figure 6. Dashboard showing tunnelling progress in a contract.

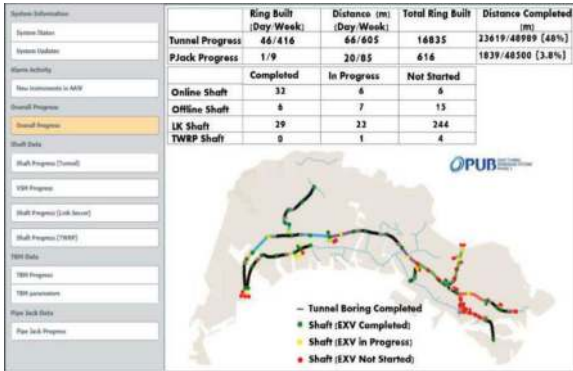

Figure 7. Dashboard showing project-wide construction progress.

4.3 Instrumentation monitoring data

Basically, STEMS takes only raw readings from both real-time and non-real-time instruments. Real-time monitoring data are automatically pushed forward to STEMS by respective web servers. Other than manual uploading, non-real-time data can also be transferred electronically through web interface or by emailing to a dedicated email server using a provided template file. Incoming raw data are instantly processed according to respective data models configured in the system. Data models are in fact the calculation templates and each type of instrument have their own data model.

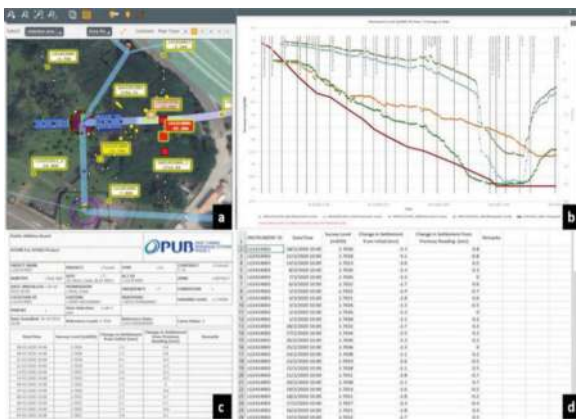

Figure 8. Instrumentation readings formats; (a) highlights and labelling in map window, (b) chart view with construction activity timeline, (c) table format, (d) text format.

They are also used to translate the output results into various units and formats between the graphing engine and the database. Therefore, graphs can be plotted in various engineering units and allow for integration with other instrument readings or excavation depth (Figure 8b). Other than chart format, readings can also be presented in table and text format (Figures 8c and 8d). During the processing, rate of change is also computed to detect spikes and notify the originator for confirmation to avoid erroneous readings. The same algorithm is used to predict when the readings will reach preset threshold values and caption in the chart.

Instruments in array or cluster can also be grouped and enabled to produce section plots to depict the ground movement in relation to excavation progress. Furthermore, it also enables to produce user-defined cross-section in which every object within a user defined distance from a cutting line will be plotted. An option is also available for the section to overlay on the soil profile as shown in Figure 9. So that ground movement/water drawn down can be visualised more clearly and allows the users to observe the risk or identify the area of concern more easily.

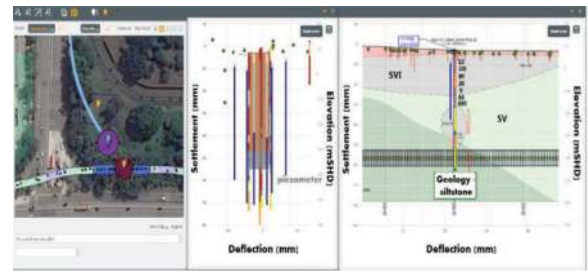

Figure 9. Indication of instrumentation readings in cross-section.

4.4 Automatic alerts

When an instrument reading reaches or breaches pre-set threshold limits, SMS and email messages will be triggered automatically to a dedicated group of users. Meanwhile, it will highlight the breached instruments in distinct colour for easy identification in the map window – yellow for alert level (AL), pink for predetermined level (PDL), and red for work suspension level (WSL) (Figure 10). In addition, all breached events are registered in the system and event blogs are created to start interim communication to share views, opinions and justification.

The event blogs are structured to take inputs on description, site activity/observation, other instrument readings in the vicinity, actions taken, recommendation and remarks. Every single input given in the blog is logged and forwarded to all designated emails. This draws an attention from key personnels and helps everyone aware of the development. Then the close out report can be generated and archived in the database. This process is system guided and automated. But no authority is given to end-users to edit

Figure 10. (a) Highlight of breached instruments, (b) breached report.

or delete it. The report format was designed after discussion with all relevant parties across the project.

4.5 Data visualisation

There are a few built-in algorithms to analyse the instrumentation readings and borehole data with different abstraction in STEMS. Interpolation is one of the available features and it uses the Inverse Distance Weighted (IDW) method to draw contours of instrument readings except for inclinometers. In addition, rockhead contour or depth to specific soil layers can also be drawn (Figure 11). The contours are solid filled but they can be overlaid on different backgrounds.

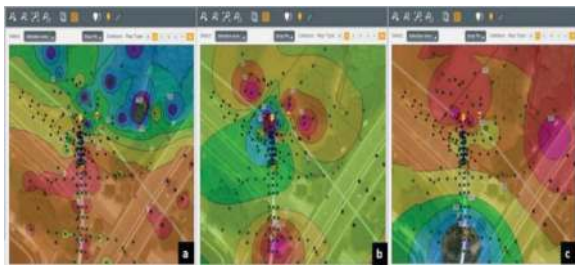

Figure 11. Instrument reading contours, (a) ground settlement, (b) piezometric level, (c) rockhead level.

Similarly, instrumentation arrays or clusters for bored tunnel monitoring can be grouped and pre-configured to compute volume loss using settlement readings (Figure 12a). The calculation methods and applied models used in the system were checked and verified by all project parties during the development stage. On the other hand, the system is also able to identify TBM locations on the soil profile with respect to ring number and chainage (Figure 12b). Therefore, detailed geotechnical condition of current mining stretch can easily be found out.

4.6 TBM data

The DTSS2 project deploys 19 TBMs, of which 18 are Slurry Pressure Balance Machines (SPBM) and only 1 is the Earth Pressure Balance (EPB) machine. There are fibre internet connections available to all TBMs. Therefore, STEMS can connect to TBM data

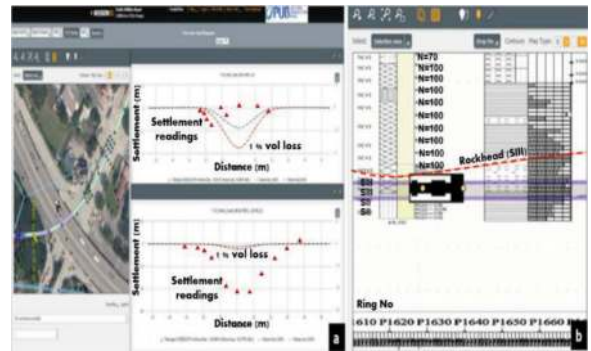

Figure 12. (a) Volume loss (Gaussian curve), (b) automatic display of soil profile at active tunnelling stretch.

servers from all active TBMs through provided IP addresses, usernames and passwords, and streamline the data in real time.

The TBM data are continuous and transmitted with 5 to 7 sec intervals. They are processed and stored in a ring file (last erected ring no is assigned) in the database. A ring file contains clock-synchronised machine data from various sensors on the TBM. These data are designed to display in the main and secondary TBM monitoring tabs (Figure 13 & 14) in real time for TBM operation monitoring.

Figure 13. Real-time TBM monitoring dashboard tabs; (a) key operation parameters, (b) AEM data.

Like other TBM monitoring systems, records of parameters can also be plotted against time, chainage, net stroke or ring number. These parameters are not limited to view within the TBM module itself. They can also be combined with instrumentation data or other information in a single graph over time series axis. Therefore, the effect or the influence of TBM operation parameters on ground movement or their correlation can be studied and identified. Moreover, ring footprints displayed in the map window can be colour coded based on the average value of any operation parameter. As mentioned above, cutter head intervention locations can also be indicated by designated shape of pins (CHI pin). Therefore, all relevant information and documents can be described and attached to CHI pins. Cutter head intervention permits, compressed air dive records, face logs, photographs and cutter head intervention reports etc., are

attached to CHI pins for easy reference. This TBM module greatly assists the tunneling and supervision teams by provision of an efficient real-time monitoring platform.

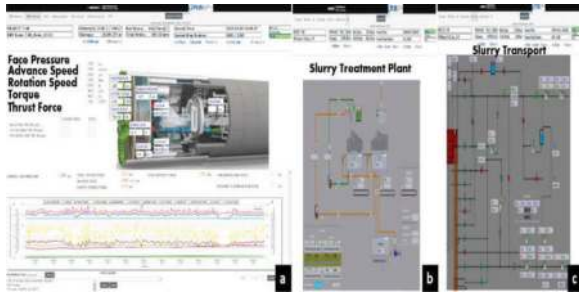

Figure 14. (a) Operation parameter trend plots, (b) STP data dashboard, (c) STS data dashboard.

4.7 Pipe jacking machine monitoring

There are several pipe jacking drives being carried out for the DTSS2 link sewer construction. The machines with a diameter of 2 m and above have onboard data loggers and are connected to STEMS for real-time monitoring (Figure 15). As the number of sensors and instruments on pipe jack machines are much lesser than on TBMs, the parameters streamlined to STEMS are not extensive. Typically, data from the pipe jacking machines come in at 5 seconds interval and key parameters are displayed in the composite dashboard tabs show below. All incoming data are stored in the database and can be presented in chart format or retrieved in text format as and when needed.

Figure 15. Pipe jacking monitoring dashboard.

4.8 Reporting

A Shift reporting tool is also available in the system in order to standardise the reporting format among tunnelling contracts in the whole of DTSS2 project. By using this built-in tool, engineers can prepare a daily or shift report at the end of the day or shift by simply selecting the relevant activities from the list and indicate the timing. For TBM shift reporting, shoving, stoppage and ring building timings will be automatically populated because they are extractable from incoming signals from TBMs. Therefore, it is

more accurate than the manual way of doing it in spread sheet or word processing software. Review and approval process is fully online and can be routed automatically to dedicated managers for review and approval. Upon completion, PDF version will be generated and parked in the designated folder with name being given automatically. Another benefit is that it can produce downtime and production statistics from the captured activities and timing. Therefore, end-users can obtain the overview of the production/downtime and be able to develop maintenance strategies to minimise the downtime or improve the production. Figure 16 shows the shift reports generated from the system.

Figure 16. A TBM shift report and downtime data.

4.9 Others

STEMS also has direct connections with CCTVs installed at various locations including at TBMs. The links are established by API interface and the footages are stored for 48 hours. Therefore, construction sites and key locations can be monitored in real time without a need to switch over to another platform or input another username or password. Moreover, STEMS is also connected to biometric systems from all 5 tunnel contracts. Thus, manpower on site can also be checked and monitored in real time. In addition, various other metadata such as drawings, photos, soil investigation reports, pre-construction survey reports, CHI reports, weekly interpretative reports, monthly instrumentation reports, weekly meeting minutes, excavation permits, GIBR and TBM protocols reports, etc., are hierarchically saved in the form of a tree menu and can be accessed instantly. This modular menu structure allows systematic documentation and easier to find as needed.

5 DISCUSSIONS

STEMS shows a high versatility in data collection and transparency in processing. The collection and collation of data from different sources and creating a common data environment allow engineers to focus solely on analysis and interpretation rather than processing of data. Real-time access to TBM operation parameters allows managers to monitor

tunnelling operation from anywhere and be able to make prompt and correct instruction. The system is capable of opening and running all real-time TBM monitoring dashboard tabs at any one time without affecting the speed and performance. Table 1 provides the summary of the type and number of real-time connections established in STEMS during the peak period when the system had most number of real time connections. Total data size in STEMS to date is about 6 Terabytes and projected to reach about 8 Terabytes by end of the project.

Table 1. Real-time connections in STEMS.

Real-Time Connection	Total Number	Remark
TBM & STP	17	2 more drives are yet to start
Pipe Jack Machine	15	57 more connections to make
Vertical Shaft Sinking Machine (VSM)	1	Repeated use for 5 shafts
CCTV Camera	213	~50 more to setup
ATMS	12	with 960 prisms altogether
Real-Time Vibration Meter	41	-
Automatic Expressway Monitoring System	9	with 900 reflector-less points
Biometric System	5	-

STEMS users are of different levels: engineers, supervisors, managers, project officers, directors, consultants, and it is therefore designed to support various job roles across the project. Project managers and construction managers can obtain accurate and up-to-date construction progress and be able to visualise it in graphical plots, 2D sections and 3D models. Detailed construction activities, status of TBM drives/pipe jacking drives, their daily/weekly and monthly production can be tracked instantly. CCTV streams and biometric connections are very useful especially for the safety team to remotely monitor high risk operations and identify unsafe behaviours and carry out check/audits on manpower. The system also helps instrumentation teams and design teams by automation and saving of man-hours on processing, reporting and data presentation. Canvas reporting is one of the automations which enables the generation of weekly/monthly factual instrumentation reports, and daily and ring reports. Moreover, various interactive analysis tools are also available and able to generate various integrated cross sections/combined graphs for interpretation and reporting. Likewise, the consolidated TBM monitoring dashboard is found to be very useful as it allows key parameters to be visualised in real time in user-friendly formats. Similarly, report preparation and sign-off procedures are machine driven and thus a need for paper reports is eliminated.

Various reports, drawings, records, permits, photographs etc., are sorted systematically and orderly in respective archive folders for documentation purposes. Therefore, every relevant job role can take part in quality control and document auditing. The instant access to these documents is very helpful for meetings and discussion. Not much time is needed for preparation before meetings because all relevant documents can be opened and presented with a few mouse clicks during the meetings. Latest instrumentation readings, real-time TBM parameters, and volume loss which are key components and subjects of discussion in daily meetings can also be displayed instantly. The induced settlement and TBM operation parameters can be correlated and presented straight away. Furthermore, for instant presentation, interactive canvas tool allows the creation of a content-rich summary report with charts and figures which would be updated automatically with latest readings when reproduced at any later stage. This tool provides significant time savings as well as eliminates a need to export and exchange data. In general, the system interface is user-friendly and even a user who is not familiar with the system can operate it.

The PUB DTSS2 department and its consultant team strictly administers the security and ensure the confidentiality of the data. Performance tests and penetration tests are carried out regularly to check the functionalities and system security. Most importantly, users are only allowed to see their part of the project and some part of the adjacent contracts in interface areas. The project-wide cross contract access is only given to the project directorate office and project management team.

Throughout the project, STEMS plays a crucial role in geotechnical control over various excavation and tunnelling works, and in risk identification process. The summary of its applicability can be summarised as follows.

1. **Data Integration** – The system consolidates data from various sources such as TBM sensors and equipment, geotechnical instruments, geological survey, geotechnical investigation works, excavation and construction activities. It ensures that all relevant engineering data are in one place and can correlate for combined analysis and interpretation.
2. **Data Analysis** – Data analysis, data visualisation, statistical prediction, and trends comparison with all vital information allow to identify potential areas of concern and construction impact to surrounding areas.
3. **Real-Time Monitoring** - Real-time monitoring of tunnelling and construction activities and geotechnical data allows managers, engineers and consultants to get instant updates on how the machines are being operated, and what is happening on sites and underground. Instant access to see operation parameters in real-time provide additional layers of supervision and risk control.

4. **Centralised Data Access** - Stakeholders from different locations can access the data through a web interface. This facilitate collaboration among project teams, even if they are geographically dispersed.
5. **Alerts and Notifications** – These systems can issue alerts notifications via email and SMS when predefined thresholds or conditions are reached or breached. It makes every key personnel be aware of the issue and help to ensure that prompt actions are taken to control the issue within tolerable limits.
6. **Reporting** – System-guided and automated reporting feature make the process simple and easier. It provides accurate updates and summary of project progress, activities, potential issues together with downtime and production statistics in standard and well-structured format. Down-time and production statistics stamped in the report highlight the areas or activities that require improvement such as more maintenance or supervision etc.
7. **Customisation** – Users can customise the system to monitor specific parameters or aspects of the project for automation in the process that are critical to their needs.
8. **Scalability** – The system can scalable to accommodate increasing amounts of data as the project progresses.
9. **Historical data** – The system can archive historical data, which is valuable for post-project analysis, arbitration, and future planning.
10. **Compliance and Documentation** – This assists in maintaining records and documentation required for regulatory compliance, audits and legal purposes as a part of project quality plan.
11. **Cost Saving** – By automation and providing instant access and better visibility into project progress and potential problems the system can help to prevent costly delays and construction mistakes. It is obvious that operator intensiveness is greatly reduced, and significant manpower saving is achieved.
12. **Security** – Robust security features are essential to protect sensitive project data from unauthorized access and cyber threats.

6 CONCLUSIONS

The volume of data and information in underground infrastructure projects is huge and how they are managed and utilised is crucial to identify risks and formulate solutions for mitigation. The biggest source of

risk or challenge within major excavation and tunneling works has often been the ground-related factors and reaching of 65% contribution to overall challenges (Clayton, 2001). Fortunately, digital tools are more and more advanced, and the industry is moving forward. And the way the digital tools is used in underground infrastructure projects is the way to help solving these potential issues and challenges.

In the DTSS2 Project, STEMS has proven its effectiveness not only in managing and delivering substantial quantities of monitoring and construction data from different sources but also in identification and prediction of potential geotechnical risks during excavation and tunnelling works. Data transparency and visualisation are very much improved with more reliable accuracy and loss of information is avoided or minimized. It provides one source of truth which is important for arbitrations and dispute management in the future. STEMS has turned out to be more than an instrumentation monitoring system or TBM monitoring system as it provides optimization and integration potentials with all vital engineering data and information. Workload reduces and time efficiency improves as most part of the process is system guided or automated. Moreover, digitalisation of construction data with centralised storage offers instant access which enables construction managers to make fast and correct decisions and thus positively impact the construction efficiencies.

Research on concrete strength detection method based on digital drilling and machine learning

Rong Wu*

China Railway Construction Heavy Industry Corporation Limited, Changsha, China

ABSTRACT: A concrete strength testing method based on digital drilling and machine learning is put forward in the paper in regards of the problems such as large error, long cycle and high cost existing in the established tunnel concrete strength testing methods. Relying on the energy conservation law and Mohr-Coulomb strength criterion as the theoretical basis, this paper obtains drilling parameters by building an experimental rig to drill concrete blocks for testing. The drilling parameters further function to predict the concrete structural strength through combining theoretical formula and machine learning. As revealed by the study, a big error exists between the calculation results of DP-UCS theoretical model and those of the actual compressive strength. The model is further trained by diverse machine learning methods and tested for validation. According to the results, three machine learning training models are superior to those of DP-UCS theoretical model, indicating that digital drilling test technology can effectively predict concrete strength. Besides, the prediction result of SVM nonlinear regression-based training model differs little from the actual compressive strength of concrete, with an error rate less than 10%, indicating that the model has high accuracy and can serve as a prediction model for the subsequent integrated program of concrete strength digital drilling product detection system.

Keywords: Concrete, Uniaxial Compressive Strength, Digital Drilling, Drilling Parameters and Machine Learning

1 INTRODUCTION

Concrete strength serves as an important index to measure construction quality and ensure construction safety in bridge and tunnel construction. As the main support means of tunnel construction, shotcrete strength test has a significant impact on the stability and deformation control of the tunnel surrounding rock and growth characteristics of surrounding rock pressure. There are numerous concrete strength test methods, including rebound method, penetration method, core drilling method, pull-out method, maturity method and piezoelectric sensor detection method. The rebound method can only measure the strength of concrete surface layer but cannot characterize the internal strength by measuring the rebound value to infer the compressive strength of concrete. The penetration method is easily influenced by the concrete surface condition and the type of concrete aggregate, with errors aroused from such. The core drilling method requires on-site sampling and transportation to the laboratory for uniaxial compressive test analysis, which is cumbersome in operation, long in cycle and

high in cost, affecting the integrity of the testing surface and not portable on site. The maturity method and piezoelectric sensor detection method require embedded sensors, which are complex to operate and narrow in scope of application. Moreover, impedance analyzers and other equipment are expensive and bulky, not conducive to field operation. Therefore, it is necessary to develop a convenient, fast and accurate test method suiting concrete strength in tunnels.

Digital drilling test technology^[1,2] is a technology to monitor and quantitatively control some parameters while drilling such as penetration rate, rotation speed, torque and propulsion force during drilling. In the current stage, it is mainly used in the realm of rock mechanics and also suitable for concrete strength testing after curing. Sufficient studies have shown that a strong correlation exists between drilling parameters and mechanical parameters such as uniaxial compressive strength. Cohesion, internal friction angle and uniaxial compressive strength (UCS) constitute the basic mechanical parameters of concrete and rock. According to the energy conservation law and Mohr-Coulomb strength criterion, the digital drilling method based on drilling parameters can test the rotating speed, torque,

*Corresponding author: 1239283439@qq.com

propulsion force and other drilling parameters during the drilling process of the drill bit, no matter in the field or laboratory. The test makes the DP-UCS model available to realize effective and convenient testing of concrete strength. According to the research findings of Song Ling et al. [3], the drilling parameters are correlated with uniaxial compressive strength. Sajjad Kalantarib [4] of Isfahan University of Technology in Iran estimated the rock strength parameters using borehole data by carrying out multiple borehole tests as well as calculation and analysis of data, so as to obtain the calculation models between uniaxial compressive strength and cohesion, bit angle (15°), friction angle (contact friction angle) between bit cutting surface and compression fracture zone, friction angle between compression fracture zone and intact rock, and internal friction angle. YASAR et al. [5] put forward empirical formulas for drilling parameters and uniaxial compressive strength through experiments. Wang Qi et al. [6] found that the conventional mathematical model and empirical formula cannot bring about the ideal results esp. when the rock mass quality is poor. Hence, the method of machine learning to obtain more accurate uniaxial compressive strength is a hot research topic for scholars.

This paper establishes a concrete strength prediction model through diverse machine learning and regression analysis methods on the basis of drilling parameters. Compared with the conventional DP-UCS theoretical calculation model, the training model based on SVM nonlinear regression has better accuracy, which is similar to the actual situation of samples, producing high engineering application value.

2 PRINCIPLE ON STRENGTH TESTING OF DRILLING PARAMETERS

The cohesion c and internal friction angle φ of rock and concrete are the most basic parameters characterizing strength properties (referred to as parameters c - φ for short). As revealed by the laboratory tests and numerical simulations, the c - φ parameters of rock is capable of controlling the cutting failure process. Therefore, establishing DP- $c\varphi$ relationship has the desired feasibility by considering the mechanical analysis of rock cutting failure process.

Traditional indoor tests (uniaxial and triaxial tests) have complicated test steps, long cycle and high cost, and field measurement is infeasible in this case. According to the energy conservation law of cutting and drilling:

Total drilling and rock breaking work $W =$ torque work $W_M +$ pressure work W_F

The energy consumed in the drilling process $W =$ energy in rock cutting and breaking $E_C +$ friction consumption between drill bit and hole bottom E_F , so:

$$W_M + W_F = E_C + E_F \quad (1)$$

Therefore, the quantitative relationship between cohesion c and internal friction angle φ and drilling

parameters (DP) such as penetration rate, rotation speed, torque and thrust during drilling is established.

According to the Mohr-Coulomb strength criterion of rock and concrete:

The relationship between uniaxial compressive strength R_c and cohesion C , internal friction angle φ is as follows [7]:

$$R_c = \frac{2C \cos \varphi}{1 - \sin \varphi} \quad (2)$$

Then, a quantitative relationship model (DP-UCS model) between drilling parameters and uniaxial compressive strength is established to serve as the basis for strength testing. Scholars at home and abroad have validated through multiple experimental tests.

2.1 Drilling test scheme

As shown in Figure 1-3, the test equipment is built with a hydraulic motor drill scheme, including an aluminum profile experimental frame, an optical axis support seat, a hydraulic motor drill and a data monitoring and acquisition system. C10-C60 standard test blocks are used for the test, with the dimension of concrete sample of 150mm*150mm*150mm, as shown in Figure 4. An alloy diamond coring bit with a diameter of 10mm is used. In the test, a single variable is controlled, and a flow valve is used to control the hydraulic motor flow rate to maintain 20L/min. The thrust force is changed by changing the gravity borne by the object. Drilling inspection tests are carried out under different downward pressures, and

Number of cutting edges (2)	k

multiple groups of repeated tests are carried out for each downward pressure.

The data that can be directly monitored in the test are listed in Table 1 below. Laser displacement sensor is used to measure the rotary cutting speed of drill bit. Torque and rotation speed are calculated from the monitoring data of hydraulic motor (inlet and outlet oil pressure and flow value of hydraulic motor, as well as drilling speed of drill bit, etc.). Combined with the mathematical models of drilling parameters and concrete strength in references [4] and [8], the strength of concrete test blocks is calculated accordingly.

2.2 Test results

Some experimental test data are shown in Table 2. The monitoring curves of displacement, flow rate

and pressure parameters that are monitored during the experiment are listed in Figure 5.

The test results are calculated using the drilling measurement models recommended in References [4] and [8], and further compared with concrete uniaxial compressive strength measured by a press. It is found that the error is relatively large and some results have magnitude differences, which impair the reliability of the results. Refer to Table 3 for details.

3 MACHINE LEARNING AND REGRESSION PREDICTION

Due to the inaccurate prediction results of conventional mathematical models and empirical formulas in concrete strength drilling measurement, this paper establishes a concrete strength prediction model through diverse machine learning and regression analysis depending on the original model established with drilling parameters, so as to obtain higher goodness-of-fit.

Machine learning training prediction methods mainly include BP neural network nonlinear regression prediction, SVM nonlinear regression prediction and RBF neural network nonlinear regression prediction. SVM can theoretically approximate any nonlinear function in a global sense, which improves the

generalization ability of the model by following the principle of structural risk minimization and can obtain better statistical laws even when there are few statistical samples.

To improve the effectiveness of machine learning model training, the experimental equipment shown in Figure 1 is used to increase the data size of borehole test samples for parameter detection while drilling to 119 groups (including 112 groups of training samples and 7 groups of test samples, as shown in Table 4 and Table 5, respectively). Besides, three types of non-linear regression prediction are adopted to establish a training model.

3.1 Establishment of BP neural network model

Artificial neural network is an algorithm simulating the physical structure of human neural network

system to enable the neural network system to have partial intelligence of human brain through high-speed simulation calculation of computer. The neural network simulates the uncertain thinking mode of human brain through the process of learning and acquiring knowledge from external environment and using the connection strength of internal neurons to store the acquired knowledge.

The BP neural network in MATLAB 2014a is adopted, with its nonlinear training prediction logic diagram shown in Figure 6.

Figure 8. Prediction results of BP neural network nonlinear training model test samples.

Considering the unique characteristics between uniaxial compressive strength of concrete and drilling parameters in experimental boreholes, a BP neural network model for predicting uniaxial compressive strength parameters of concrete is established, which is referred to as RMP-BP model, as shown in Figure 7 for details.

The prediction results of BP neural network nonlinear training model test samples are shown in Table 6 and Figure 8.

As shown by Figure 7, the similarity of the established BP neural network nonlinear regression training prediction model is 90.96%. According to the prediction results of the test samples of the BP neural network nonlinear prediction model for predicting concrete uniaxial compressive strength parameters in Table 6 and Figure 8, the test results

however are not ideal due to the great difference between the prediction results and the actual strength value, indicating that the prediction error is large.

3.2 SVM-based nonlinear regression training prediction

Support Vector Machine (SVM) can be used for pattern classification and nonlinear regression, mainly aiming to establish a classification hyperplane as a decision surface, so as to maximize the isolation edge between positive and negative examples. The concept of inner product kernel between “support vector” $x(i)$ and input space extracted vector x is the key to construct support vector machine learning algorithm. The support vector machine is composed of a small subset extracted from the training data by an algorithm, with its structural model shown in Figure 9.

Theoretically, SVM can approximate any nonlinear function in a global sense by improving the generalization capacity of the model by following the principle of structural risk minimization so as to obtain good statistical laws even when there are few statistical samples. The non-linear regression training model of SVM based on the training sample data listed in Table 4 is shown in Figure 10.

The prediction results of SVM non-linear regression training model test samples are shown in Table 7 and Figure 11.

As shown by Figure 10, the established SVM nonlinear regression training model has a similarity of 99.6%, with an equivalent error of ± 0.06 and a high degree of fit. According to the prediction results of test samples of the SVM nonlinear regression training model for predicting concrete uniaxial compressive strength parameters in Table 7 and Figure 11, there is little difference between the prediction result and the actual strength, with an error rate less than 10%, indicating a higher model accuracy.

3.3 RBF neural network nonlinear regression prediction training model.

RBF neural network is the type of feedforward neural network, having the structure resembling that of multi-layer feedforward network, which is a three-layer feedforward network. Basic Rules: RBF functions as the “basis” of hidden elements to

Figure 13. Prediction results of RBF neural network training model test samples.

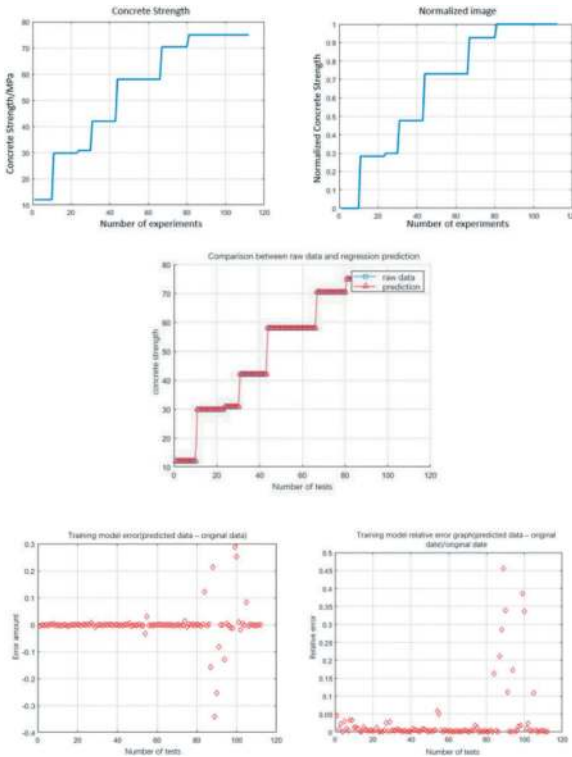

Figure 12. RBF neural network training model.

form a hidden space, and the hidden layer transforms the input vectors and low-dimensional pattern input data into high-dimensional space, so that linear

inseparability in low-dimensional space are linearly separable in high-dimensional space. The RBF neural network is characterized by simple structure, concise training and fast learning convergence speed, which can approximate arbitrary nonlinear functions.

SVM nonlinear regression training model based on the training sample data listed in Table 4 is shown in Figure 12.

The prediction results of RBF neural network training model test samples are shown in Table 8 and Figure 13.

According to Figure 12, the RBF neural network nonlinear regression prediction training model that is established has a high degree of fit, with a similarity of 99.91%. However, as shown in Table 7 and Figure 13, the prediction results of the sample with a drilling pressure of 255N are too different from the concrete strength, and there are some errors in the prediction results.

4 CONCLUSION

- (1) The conventional DP-UCS model has great errors as the intensity detection basis. Reasonable selection of machine learning methods and establishment of nonlinear regression models are conducive to improving the accuracy of prediction models;
- (2) For BP neural network prediction and RBF network regression, the established model has the

Table 8. Comparison of test sample data and RBF training model prediction.

1	20.4515	1.5812	0.7	181	29.8	29.7996
2	19.5811	1.5016	1.6	259	29.8	29.7958
3	19.9492	1.6829	1.7	348	29.8	29.7989
4	19.7461	1.6651	2.1	460	29.8	29.7988
5	19.4221	1.8773	2.6	550	29.8	29.7964
6	20.1088	1.9052	0.8	255	30.8	0.4883
7	20.0503	1.858	0.8	255	30.8	658.8614

degree of fitness more than 90%, but the difference rate of test sample prediction results is high;

- (3) According to the prediction results of three machine learning training models, SVM has more accurate prediction results since SVM is a general machine learning method developed on the basis of statistical learning VC dimension theory and structural risk minimization principle, which is mainly used for pattern recognition, classification and regression. It shows multiple unique advantages in solving problems such as small sample, nonlinear, high dimension and local min. value. Consistent with the small number of our data samples, SVM can serve as a predictive model for subsequent product inspection system integration procedures.

ABSTRACT: To study the response characteristics of seepage and stress fields induced by underwater shield tunnelling in cobble stratum, similar materials applicable to model tests were developed from the perspective of solid-fluid coupling similarity theory. Twenty-five test schemes were designed for mix proportions to prepare similar materials using orthogonal test. Therein, 6~8 mesh, 10~20 mesh and 70~140 mesh quartz sand, barite powder and gypsum were used as raw materials, and the aggregate content, fine content, cement-aggregate ratio and coarse-to-fine aggregate ratio were taken as controlling factors. Results show that similar materials have a moderate range of parameters, steady performance, convenient preparation and affordable cost; the content of aggregates and fines are the two critical controlling factors that influence the bulk density; the cohesion is largely determined by the cement-aggregate ratio; the elastic modulus is primarily influenced by aggregate content; and all the factors also exert certain controlling effects on the internal friction angle and permeability coefficient. Furthermore, the regulating effects of silicone oil, liquid paraffin, glycerol and petrolatum on the hydro-mechanical properties of similar materials were investigated. The bulk density is positively correlated with the additive amount of glycerol, and the elastic modulus has a negative correlation with petrolatum or liquid paraffin content. The cohesion increases almost linearly with increasing additive amount of silicone oil and petrolatum, whereas four regulators were unable to regulate the internal friction angle of similar materials. The permeability coefficient sharply decreases with the increasing amount of the silicone oil, liquid paraffin and petrolatum. Lastly, the similar materials were applied to complete the excavation seepage model test in Bahe Tunnel of Xi'an Metro Line 9, it was revealed that groundwater seepage and excavation disturbance together possess the water and sand gushing as well as liner deterioration.

Keywords: Similar materials, Metro tunnel, Orthogonal test, Range analysis, Solid-fluid coupling

1 INTRODUCTION

A special kind of geologic body called as cobble stratum is formed with diverse genesis, complex structure and mixed soil and rock during the Quaternary Period, which is widely distributed in many cities such as Beijing, Chengdu and Xi'an in China. In the past few years, with the rapid development of

subway construction, there has been a boom in metro tunnels employing the shield tunnelling method through cobble stratum and water-rich conditions. Particularly for underwater shield tunnels, due to the coupling effect between groundwater seepage and excavation disturbance, the excessive deformation of the formation, water and sand gushing from the excavation surface, instability and

*Corresponding author: zanwb@chd.edu.cn

surface collapse frequently occur (Du et al., 2019; Shi et al., 2021; Wang et al., 2023). For the avoidance and treatment of the foregoing catastrophes, it is hence essential theoretically and practically to study the evolution laws of seepage and stress fields during the excavation process of underwater shield tunnels.

The main research approaches utilized to investigate the mechanism of seepage-induced disasters involve theoretical analysis, numerical simulation and model testing. As a tried-and-true method for resolving challenging geotechnical engineering issues, the geo-mechanical model test can truly reproduce the actual engineering geological and hydrogeological conditions and gather the multi-field information of the entire process of disaster evolution. However, similar materials must concurrently satisfy the similarity criteria of seepage, stress and deformation conditions in the solid-fluid coupling model test (Bai et al., 2020; Chen et al., 2015). Thus, the development of similar materials with a high degree of similarity, reliability and steady performance is a pre-requirement.

The choice of basic materials and material proportions are the key factors that determine the physical and mechanical properties of similar materials. Scholars have carried out numerous investigations utilizing various raw materials to generate a similar material that satisfies the test requirements. Considering the critical influence of mineral composition on the physical and mechanical properties of rock, Lu et al. (2022) and Cui et al. (2022) used standard sand, kaolinite powder, illite powder, ordinary Portland cement, gypsum and iron powder to synthesize the similar materials of white sandstone and red mudstone, which can provide a reference for similar material preparation of other rocks. Luo et al. (2023) developed the similar materials applicable to model tests of reef limestone marine environment, which was composed of the foaming agent, powdered talc, sea sand, cement, gypsum and air-entraining agent. To apply the strength-reduction method to model test, a similar material composed of paraffin wax, quartz sand, and barite powder was developed to simulate the quantitative strength-reduction by temperature change (Kong et al., 2023). To resolve the related problems caused by leakage water of a tunnel in a karst area, Tian et al. (2018) used the fine sand (2 mm in diameter), cement (P.C32.5), clay, barite powder and water mixture as the similar material for limestone, and analyzed the effects of size of cave, inclination of joint plane, distance between cave and tunnel, precipitation, and loading on the pore pressure, soil pressure and displacement.

Although some achievements have been made in the development of similar materials and their simulation testing methodologies, most of them are focused on rock or soil mass and research on the creation and use of similar materials for solid-fluid coupling model experiments in cobble stratum is still rare. Additionally, a great deal of literature merely

addresses how to manufacture materials similar to the desired rock and soil based on their own experience and the model's requirements, and research on the regulation of material's physico-mechanical and hydraulic properties is neglected. Therefore, it is an urgent need for systematic research and development on solid-fluid coupling similar materials in cobble stratum.

Based on the investigations of fundamental constituents of similar materials, this paper selected quartz sand with different mesh sizes as the aggregate material, barite powder as the fine material, gypsum as the binder, silicone oil, liquid paraffin, glycerol, petrolatum as the regulator. Through a large number of proportioning experiments, we developed a solid-fluid coupling similar material for cobble stratum and it has a moderate range of parameters, steady performance, convenient preparation and affordable cost. Finally, the similar materials were applied to the excavation seepage model test of Bahe Tunnel in Xi'an Metro Line 9, and the evolution laws of stress and seepage field of the surrounding rock were revealed.

2 SIMILARITY PRINCIPLES

The similarity principles serve as the theoretical basis for conducting model experiments as well as the prerequisite for generating similar materials for model experiments. For underwater shield tunnels, the similarity of geometric, boundary, stress conditions and hydraulic performance must be fulfilled together. The similarity principles are often derived with dimensional analysis, fundamental elasticity equations and solid-fluid coupling theory.

The similarity ratio (C) is the ratio of the same physical variables for the prototype and the model. According to the dimensional analysis method, the similarity ratio of dimensionless physical quantities is 1, and the similarity ratio of the physical quantities of the same dimension is equal. The formula is as follows:

$$\begin{cases} C_\varepsilon = C_\mu = C_\varphi = 1 \\ C_E = C_\sigma = C_c \end{cases} \quad (1)$$

Where ε is strain, μ is Poisson's ratio, φ is internal friction angle, E is elastic modulus, σ is stress, and c is cohesion.

The equilibrium equations for the prototype and the model are:

$$\begin{cases} (\sigma_{ij,i})_p + (f_i)_p = 0 \\ (\sigma_{ij,i})_m + (f_i)_m = 0 \end{cases} \quad (2)$$

Where $(\sigma_{ij,i})_p$ and $(\sigma_{ij,i})_m$ are the stress tensor for the prototype and model, $(f_i)_p$ and $(f_i)_m$ are the volume force tensor for the prototype and model.

The following relationship can be deduced from the equilibrium equations.

$$\frac{C_\gamma C_L}{C_\sigma} = 1 \quad (3)$$

Based on the physical, geometrical equations, as well as the stress and displacement boundary conditions, the following relationship can be derived.

$$\begin{cases} C_\delta = C_e C_L \\ C_\sigma = C_E C_e \end{cases} \quad (4)$$

The relationship between the model and the prototype variables can be deduced by the solid-fluid coupling mathematical model with a continuous medium, i.e., the seepage equation and the effective stress equation are as follows (Huang et al., 2023):

$$\begin{cases} K_x \frac{\partial^2 P}{\partial^2 x} + K_y \frac{\partial^2 P}{\partial^2 y} + K_z \frac{\partial^2 P}{\partial^2 z} = S \frac{\partial P}{\partial t} + \frac{\partial e}{\partial t} + W \\ \sigma_{ij} = \bar{\sigma}_{ij} + \alpha \delta P \end{cases} \quad (5)$$

Where K_x , K_y , K_z are the permeability coefficients for the x , y , z directions and $K_x=K_y=K_z$, P is the water pressure, S stands for the water storage coefficient, e is the volume strain, W is the source and sink term, σ_{ij} is the total stress tensor, $\bar{\sigma}_{ij}$ is the effective stress tensor, α is the coefficient of Biot effective stress and δ is the Kronker notation.

Based on the seepage equation, the effective stress equation and the equilibrium equation, the similar ratio of the permeability coefficient can be deduced as follows.

$$C_K = \frac{\sqrt{C_L}}{C_\gamma} \quad (6)$$

Where C_K is the similarity ratio of the permeability coefficient, C_L is the similarity ratio of the length, and C_γ is the similarity ratio of the bulk density.

3 MATERIALS AND METHODS

3.1 Raw materials

The research object of this similar material simulation experiment is the cobble stratum, which is composed of cobbles, gravel and sand with significantly varied particle sizes. It has the characteristics of coarse particle overlapping, fine particle filling, soil cementation and high permeability. To accurately

recreate the sand and water outburst process, the following characteristics are required to be included for new similar materials. (1) Similar materials are manufactured from a mixture of coarse and fine aggregates that guarantee an appropriate framework and porosity. (2) The material has stable physical, mechanical and chemical properties that are not easily influenced by environmental factors including time or temperature. (3) Similar materials should have a wide range of permeability coefficients and excellent adaptability in terms of hydrological properties. (4) The mechanical parameters of the material (e.g., cohesion, angle of internal friction, etc.) vary greatly with the proportions of its composition, facilitating the simulation of complicated and changing geological environments. (5) The materials should be convenient to prepare, mix and shape, as well as simple to maintain with an efficient manufacturing procedure. (6) The materials have a wide range of sources, low cost, and are non-toxic and harmless.

Based on the principles of similar material selection outlined above, the primary goals for making similar materials are overall control and sub-item modification. Since it has stable physical and mechanical characteristics and is not water-insoluble, selecting quartz sand with a 6–8 mesh, 10–20 mesh and 70–140 mesh as aggregates can accurately simulate the complex and diverse grading composition of surrounding rocks. Barite powder with a high specific gravity and high compaction is chosen as the counterweight material, which can be capable of regulating the material's specific gravity. Gypsum is used as the cementing agent because it is simple to use, quick to mold, weak to cement and can more effectively regulate the strength of similar materials. Silicone oil, liquid paraffin, glycerin and petrolatum are sequentially utilized as modifiers to regulate one or several specific parameters and have little or no impact on other parameters.

3.2 Experimental design

The orthogonal test is a powerful test approach suitable for multiple factors and levels, which can minimize the number of tests and improve the uniformity of the distribution of test points. Based on the preliminary results of pre-experiment, as well as combined with previous research experience on solid-fluid coupling similar materials, it can be acknowledged that the quantity and particle size of quartz sand, barite powder content and cement-aggregate ratio are all significant factors impacting the material's mechanical and hydraulic properties. In this orthogonal experimental design of similar material proportioning, the aggregate content (i.e., quartz sand content) was chosen as Factor A, the fines content (i.e., barite powder content) was chosen as Factor B, the cement-aggregate ratio (i.e., the ratio of the gypsum to quartz sand content) was chosen as Factor C, and the coarse-to-fine aggregate ratio (i.e., the ratio of the quartz sand

content of the 6-8 and 10-20 mesh to the quartz sand content of 70-140 mesh) was selected as Factor D.

Since this experiment requires a wide range of similar material parameters to be regulated with high precision, each factor is set to a fairly large number of five levels, and the design of the orthogonal test for similar materials is shown in Table 1. The standard orthogonal table $L_{25}(5^6)$ with 6 factors and 5 levels was adopted, and a total of 25 groups of similar materials with different proportions are presented.

Since the regulators used in the similar materials simulation experiments of solid-fluid coupling must be non-hydrophilic, four kinds of materials (i.e., silicone oil, liquid paraffin, glycerol and petrolatum) were selected after reviewing a substantial amount of information on solid-fluid coupling similar materials. On the basis of the above 25 sets of orthogonal tests, the effects of four types of regulators and their additive amount (i.e., 2%, 3%, 4%, 6% and 8%) on the mechanical and hydraulic parameters of similar materials were further studied by employing the single-factor test method.

Table 1. Orthogonal experiments for similar materials.

Level number	Factor A	Factor B	Factor C	Factor D
1	0.20	0.04	2%	0.25:1
2	0.35	0.08	4%	0.5:1
3	0.50	0.12	6%	1:1
4	0.65	0.16	8%	2:1
5	0.80	0.20	10%	4:1

3.3 Experimental test

The physical quantities measured in this test include the material's density, elastic modulus, cohesion, internal friction angle, and permeability coefficient. When configuring the similar materials, the quartz sand, barite powder and gypsum powder were firstly mixed, then the weighed water used for mixing was added and finally the appropriate regulators were provided to complete the mixing process until the combining material was homogeneous. The process of preparing the specimens of similar materials was shown in Figure 1.

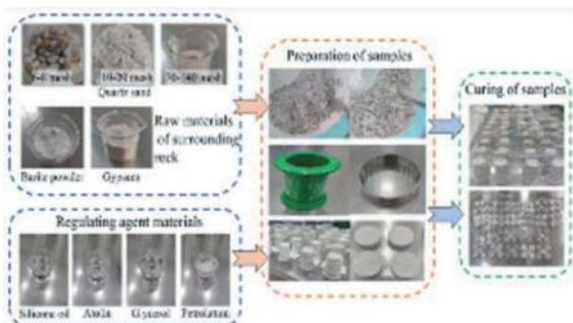

Figure 1. The procedures of preparing the specimens.

A double-opening mold with diameter of 50 mm and height of 100 mm was used to make the cylindrical specimens. The uniaxial compression test was conducted on an electro-hydraulic servo universal testing machine, as shown in Figure 2(a). The specimen was loaded at a displacement rate of 0.02 mm/min along the axial direction. The ultimate failure patterns of the specimen included X-shaped shear failure, single-slope shear failure and tensile failure (see Figure 2(b)). The full stress-strain curve of specimens was obtained, and its slope of the elastic phase was the elastic modulus E .

The cohesive force (c) and internal friction angle (ϕ) of similar materials were determined by ZJ-4K strain-type direct shear apparatus. The specimens of $\phi 61.8 \text{ mm} \times 20 \text{ mm}$ were made by standard ring cutters and were saturated by filling the shear box with water. The direct shear tests were carried out under different vertical pressures of 100 kPa, 200 kPa, 300 kPa and 400 kPa as shown in Figure 2(c). The parameters of shear strength were calculated as follows:

$$\tau = c + \sigma \tan \phi \quad (7)$$

Where τ is the shear force, σ is the vertical pressure.

The permeability coefficient (K) is an important indicator that synthesizes the hydraulic properties of similar materials. Because the permeability coefficient of cobble stratum is commonly large, the TST-70 constant head permeameter was employed to measure the specimen's permeability coefficient as shown in Figure 2(d). The permeability coefficient was calculated as follows.

$$\begin{cases} K_T = \frac{QL}{Ah_t} \\ K_{20} = \frac{q_T}{\eta_{20}} \end{cases} \quad (8)$$

Where K_T is the permeability coefficient of specimen at T Celsius degrees, Q is the volume flow at the time period t , L is the height difference between two pressure measuring holes, A is the test cross-section area, H is the difference in average water level, t is the time, K_{20} is the permeability coefficient of

Figure 2. Physico-mechanical tests of similar materials.

specimen at 20 Celsius degrees, η_T is the dynamic viscosity of water at T Celsius degrees and η_{20} is the dynamic viscosity of water at 20 Celsius degrees.

4 RESULTS AND ANALYSIS

4.1 Test results of similar material

The physical quantities of materials including bulk density, modulus of elasticity, cohesion, internal friction angle and permeability coefficient were measured by cutting ring, uniaxial compression test, direct shear test and constant head permeability test. The test results of 25 groups of similar material specimens were listed in Table 3. It can be observed that the variation range of similar material parameters is 16.5-21.1 kN/m³ in bulk density, 3.14-4.63 MPa in elastic modulus, 0.007-0.529 kPa in cohesion, 19.6-38.7° in internal friction angle and 0.003-2.02 cm/s in permeability coefficient. Compared with previous research on the similar materials of geo-mechanical model test, the newly-developed similar materials have a wide range of physical, mechanical and hydraulic parameters and better satisfy the requirements for similar physical modeling tests in cobble formations. Additionally, in accordance with the demands for specific

Table 2. Test results for similar material parameters.

Number	Bulk density (kN/m ³)	Elastic modulus (MPa)	Cohesion (kPa)	Internal friction angle (°)	Permeability coefficient (cm/s)

projects, we can flexibly modify the proportions of similar materials to customize the similar materials of solid-flow coupling model test.

4.2 Sensitivity analysis involved in parameters

In this section, range analysis method was utilized to examine the sensitivity of the test results because it has the advantages of simple calculation, an intuitive image and ease of understanding. The magnitude of the extreme difference illustrates the extent to which a specific component influences the material's critical characteristics. The effects of each component of similar materials on parameters including bulk density, elastic modulus, cohesion, internal friction angle and permeability coefficient will be analysed as shown in Figure 3.

It can be seen from Figure 3(a) that the extreme deviations of factors A and B are the largest, whereas those are close and small for factors C and D. This indicates that the two critical controlling factors are aggregate content and fines content, both of which have a significant impact on the sensitivity of bulk density. Figure 3(b) presented the distribution of each factor's impact on elastic modulus. It is noticeable that the factor A has the greatest extreme deviations, while the extreme deviations of the other three factors are close and smaller. This shows that the aggregate content is the main factor that has a significant impact on elastic modulus sensitivity. As shown in Figure 3-(c), the extreme difference of the factor C is much greater than that of other three factors. This means that the cement-aggregate ratio is the most important factor deciding cohesion and its effect on the sensitivity of cohesion is significant. As shown in Figure 3(d), it can be observed that the extreme difference in skeleton content is the biggest, followed by the fines content, which is close to the coarse-to-fine aggregate ratio, and the extreme difference in cement-aggregate ratio is the smallest. In summary, the internal friction angle of similar materials varies significantly with the increasing levels of each factor. Figure 3(e) illustrated each factor's effect on the permeability coefficient. The sensitivity of the permeability coefficient to each factor is in descending order as follows: skeleton content, coarse-to-fine skeleton ratio, fines content and cement-aggregate ratio. Specifically, the permeability coefficients of similar materials increase with increasing coarse-to-fine skeleton ratio, while decreasing with an increase of skeleton content, fines content and cement-aggregate ratio.

4.3 Effect analysis of the regulators

To further investigate the regulating effect of different types of regulators and their additive amount on the physical, mechanical and hydraulic parameters of similar materials, Group 9 was chosen from 25 sets of orthogonal tests, and silicone oil, liquid paraffin, glycerin and petroleum jelly were added at 2%, 3%, 4%, 6% and 8% of the total mass, respectively.

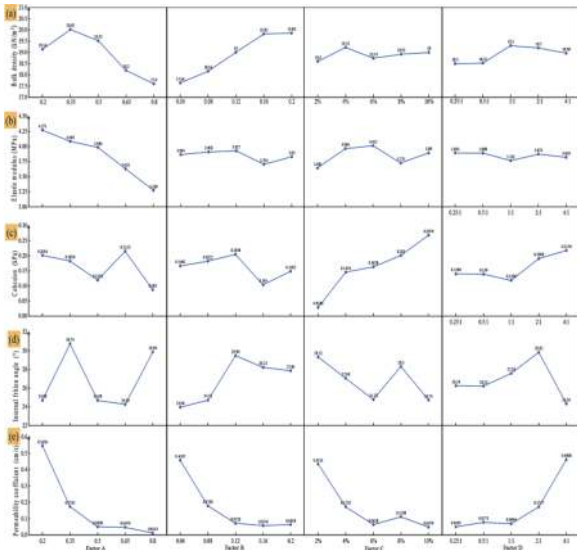

Figure 3. Sensitivity analysis of factors influencing the parameters of similar materials.

The specimen fabrication with the additive regulators and parameter testing were identical to those of the orthogonal test mentioned previously, and the test results are shown in Figure 4.

It can be observed from Figure 4(a) that the bulk density of similar materials is significantly influenced by glycerol, and it gradually increases with the increase of glycerol content. Silicone oil, liquid paraffin and petroleum have a little impact on the bulk density of similar materials, and it presents a fluctuating pattern with the increasing amount of added regulator. As seen in Figure 4(b), liquid paraffin and petroleum have an enormous effect on the elastic modulus of similar materials, yet silicone oil and glycerin have only a minor impact. When more liquid paraffin or petroleum is added, the elastic modulus of similar materials decreases. As shown in Figure 4(c), silicone oil, glycerin and petroleum have a significant effect on the cohesion of similar materials, but liquid paraffin has a negligible impact. With the increase of added glycerol, the cohesion of similar materials shows fluctuating changes, which will not be analyzed in detail. The cohesion of similar materials gradually increases because the amount of silicone oil or petroleum jelly added increases. As illustrated in Figure 4(d), it is difficult to regulate the internal friction angle of similar material even though any of the four regulators was used. Combined with the aforementioned results of the orthogonal test, the skeleton content, fines content and coarse-to-fine skeleton ratio all have a great effect on the internal friction angle of similar materials. It is pointed out that the particle gradation of the materials has a decisive role in the internal friction angle. It can be seen from Figure 4(e) that the permeability coefficient of similar materials is less influenced by glycerol, while silicone oil, liquid paraffin and

petroleum have a significant influence on the permeability coefficients of similar materials. With increasing additions of the three regulators (i.e., silicone oil, liquid paraffin and petroleum), the permeability coefficient of similar materials sharply decreases.

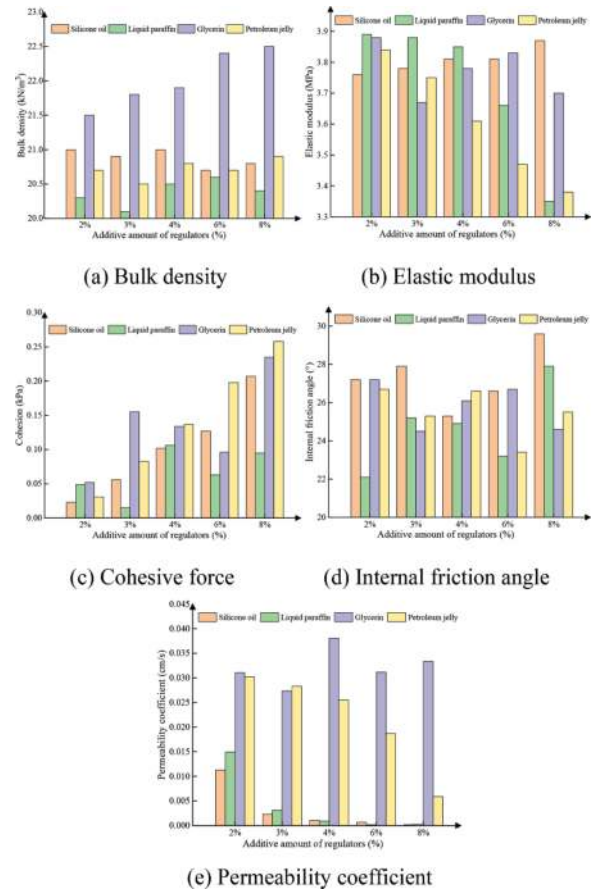

Figure 4. Effects of four types of regulators and their additive amount on similar material parameters.

5 APPLICATION OF SIMILAR MATERIAL SIMULATION

5.1 Overview of similar simulation experiments

Shield tunneling method was employed in Xi'an Metro Line 9 to cross the Ba River between Xiangwang Station and Baliu 2nd Road Station. The diameter of the shield tunnel is 6.0 m, and the depth of the tunnel ranges from 10.0 m to 24.9 m. The left and right tunnels together pass through 124 meters of full-section cobble layer, which has high permeability coefficients, poor stratigraphic stability, complicated constructing circumstances and frequent water and sand outbursts. The process of shield tunneling produces considerable head pressure in the tunnel face, resulting in soil eruption at the screw conveyor, shield tail breakdowns and great increase in safety risk as shown in Figure 5.

Figure 5. Schematic diagram of underwater shield tunneling in Xi'an Metro Line 9.

To simulate the response of the seepage and stress fields of the surrounding rock during the process of shield tunnelling under the hydro-mechanical coupling effect, a water storage tank with a volume of 1 m^3 was set up above the side of the model box to fulfil the requirements of water pressure and quantity for the experiment. Based on the dimension of model box ($1.5 \text{ m} \times 0.5 \text{ m} \times 2.0 \text{ m}$) used in this paper, the geometric and bulk density similarity ratio of the model test were determined to be $1/40$ and 1 , respectively. Based on the similarity criterion Eq. (1) (3)(4)(6), the similarity ratios of other relevant parameters can be calculated as follows.

$$\begin{cases} C_\varepsilon = C_\mu = C_\varphi = 1 \\ C_E = C_\sigma = C_\delta = C_c = 40 \\ C_K = 6.32 \end{cases} \quad (9)$$

The physical variables measured in this test included pore water pressure, lining strain and surrounding rock stress. The model test device, sensors and data acquisition system are presented in Figure 6. The pore water pressure was measured by DMKY-1 high-precision micro pore water pressure meter with a diameter of 15.8 mm and a height of 21 mm . The lining strain was measured by pasting welding-free strain gauges on the inner and outer surfaces of the PMMA tube, and the dimensions of strain gauges were 10 mm by 5.5 mm . The surrounding rock stress was measured using DMTY-type miniature earth pressure box with a diameter of 16 mm and a thickness of 4.8 mm . All measurement data was recorded by DM-YB 1860 dynamic and static resistance strain instrument.

Figure 6. Model test device and monitoring instruments.

5.2 Determination of similar material proportions

Based on a large quantities of material proportioning tests described previously, the similar material

proportions employed in this model test were provided in Table 3. The physical and mechanical parameters of the model and prototype surrounding rock were shown in Table 4.

Table 3. Proportioning of similar materials.

Item	Quartz sand (mesh)			Barite powder	Gypsum	Liquid paraffin
	70~140	10~20	6~8			
Percent	21.24%	42.48%	14.71%	19.61%	1.96%	1.8%

Table 4. Material parameters of the model and prototype.

Material	γ (kN/m ³)	E (MPa)	c (kPa)	φ (°)	K_r (cm/s)
Model	19.8	3.9075	0.0885	33.7	0.00274
Prototype	20.3	147	0.10	36.0	0.09259

Since the structural safety of the lining depends heavily on its flexural capacities, flexural stiffness is hence the key factor to be taken into account when designing for model similarity. According to the principle of bending stiffness equivalence, the lining of the model and prototype tunnel should have similar bending stiffness under the conditions of transverse bending, and their thicknesses should satisfy the following equation.

$$E_m I_m = n^{-3} E_p I_p \quad (10)$$

Where E_m is the elastic modulus of model lining, I_m is the moment of inertia of cross-section of model lining, n is the similarity ratio, E_p is the elastic modulus of prototype lining, I_p is the moment of inertia of cross-section of prototype lining.

In the practical engineering, C30 reinforced concrete tube were used with an elastic modulus of 30 GPa and a thickness of 30 cm . Thereby, the customized Plexiglas tube has a thickness of 1.5 cm and an elastic modulus of 3.75 GPa , which is calculated by Eq. (10). Additionally, the diameter of the Plexiglas tube employed was 15 cm based on the geometric similarity ratio.

5.3 Test procedures and results

Figure 7 illustrated the detailed test procedures for this model experiment. (i) For better sealing and waterproofing, the contact surface between the model box frame and toughened glass was evenly coated with glass adhesive; the waterproof geotextile was laid at the bottom of the model box as shown in Figure 7(a). (ii) As shown in Figure 7(b), firstly, weigh and mix the solid raw materials based on the proportion of similar materials; then, mix the liquid

paraffin with the water; finally, recombine the previously mixed solid components with the freshly mixed liquid paraffin. (iii) The well-mixed model material was filled and compacted in layers to a height of 10 cm per layer as shown in Figure 7(c). (iv) Repeat steps (ii) and (iii) until filling to the reserved tunnel hole, insert the PVC pre-embedded pipe and adhere foam waterproofing tape as shown in Figure 7(d). (v) As shown in Figure 7(e), installing the micro earth pressure box and pore water pressure gauge when filling to the corresponding measurement points. (vi) After the whole model filling was completed, the soil was saturated for 24 hours as shown in Figure 7(f). (vii) Through the gradual removal of the previously buried PVC pipe and the insertion of the organic glass pipe, this experiment reproduces the excavation and support procedure for shield tunnels.

Figure 7. The test procedures for this model experiment.

Figure 8(a) demonstrates the dynamic change curve of osmotic pressure at each measurement point during tunnel excavation and water level variation. As can be observed, the osmotic pressure of each measurement point shows obvious drastic fluctuations due to tunnel excavation and supporting effects, particularly for WS1 nearby the surface and WS5 close to the tunnel border. After that, the osmotic pressure of the surrounding rock exhibits a fluctuating increase when the water level rises. Figure 8(b) shows the dynamic variation curves of vertical stress at each measurement point during tunnel excavation and water level change. During the excavation and support stage, the vertical stress of the surrounding rock shows a fluctuating type of reduction, i.e., the radial stress relaxation phenomenon. Afterwards, the vertical stress of the surrounding rock increased in a stepwise manner as the water level continued to increase. Figure 8(c) illustrates the dynamic variation curves of horizontal stress at each measurement point during tunnel excavation and water level change. It can be seen that the horizontal stress of surrounding rock sharply increases influenced by the disturbing effects of tunnel excavation and support, i.e., the phenomenon of circumferential stress arching. After then, the horizontal stress of the surrounding rock slightly increased as the water level continued to rise.

(a) Osmotic pressure

(b) Vertical stress

(c) Horizontal stress

Figure 8. Multiple information of surrounding rock.

The internal force of the model lining can be measured by applying circular resistance strain gauges symmetrically to the inner and outer sides of the lining. The axial force and bending moment of the lining can be calculated by Eq. (11) and Eq. (12), respectively.

$$N = \frac{1}{2}E(\varepsilon_1 + \varepsilon_2)gbh \quad (11)$$

$$M = \frac{1}{2}E(\varepsilon_1 - \varepsilon_2)gbh^2 \quad (12)$$

Where N is the axial force of the model lining, M is the bending moments of the model lining, E is the elastic modulus of model lining, ε_1 and ε_2 are the inner and outer strain of the model lining, b is the unit length (1 m) and h is the lining thickness.

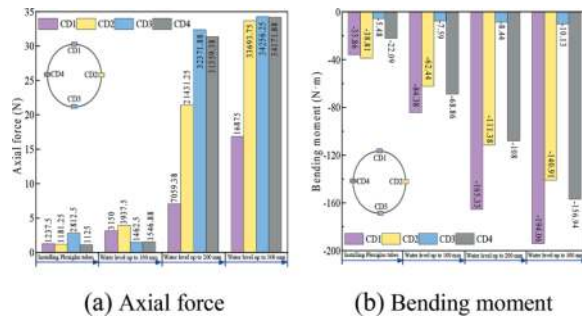

Figure 9. Structure internal force of the model lining.

Figure 9 shows the variations of axial force and bending moment of the lining structure during tunnel excavation disturbance and water level change. At the stages of initial excavation, support and water level up to 100 mm, the axial forces and bending moments of the lining structure were typically low, but they suddenly increased as the water level continued to be greater than 200 mm. In summary, it is obvious that the excavation disturbance and water level changes have significant effects on the distribution of osmotic pressure, surrounding rock stress and internal force of lining structure. Groundwater seepage and excavation disturbance together possess the effect of causing tunnel water and sand gushing as well as liner deterioration.

6 CONCLUSIONS

The similar materials composed of quartz sand with different mesh size, barite powder, gypsum, silicone oil, liquid paraffin, glycerol and petrolatum have a moderate range of parameters, steady performance, convenient preparation and affordable cost. When they were applied to complete the excavation seepage model test in Bahe Tunnel of Xi'an Metro Line 9, it was revealed that groundwater seepage and excavation disturbance together possess the water and sand gushing as well as liner deterioration. This can provide

material basis for obtaining good test results and serve as a valuable reference for the selection of solid-fluid coupling similar materials for physical modeling test.

Study on the deformation and stress law of single shell lining in subsea rock tunnels

Wenbo Zhang

China Railway Academy Co., Ltd., Chengdu, China

ABSTRACT: This paper focuses on investigating the performance of a single-layer lining in practical tunnel engineering applications. The study utilizes a test section of a single-layer lining in the Huangdao segment of the Jiaozhou Bay Second Tunnel, China's longest subsea road tunnel. The engineering research aims to validate the effectiveness of a single-layer lining in hard rock tunnel engineering, particularly under grade 3 surrounding rock conditions. The research delves into the mechanical contact characteristics of the anchor-type single-layer lining structure. It also examines the deformation and laws of force governing the interaction between the single-layer lining and the surrounding rock, as well as the overall stability of the support structure. Experimental results indicate that the anchor-type single-layer lining exhibits excellent adhesion and integration with the surrounding rock, with force and deformation remaining within safe allowable limits. The application of a single-layer lining in hard rock tunnels is deemed feasible for ensuring engineering quality and safety. The support structure's operational performance proves reliable, making it suitable for widespread application and promotion in practical engineering.

Keywords: Hard Rock Tunnel, Single-Layer Lining, Force, Deformation

1 INTRODUCTION

The single-layer lining, introduced in the 1970s as a tunnel support system ^[1], has witnessed significant technological advancements in recent decades. With the refinement of shotcrete construction technology and improved performance quality, its application has proliferated. Nordic countries, including Norway, Sweden, Finland, and others, have widely embraced anchor and shotcrete support as a permanent solution in various tunnel and underground engineering projects, including road tunnels, railway tunnels, subways, underground factories, and sports facilities. Beyond the Nordic region, countries such as Canada, the United States, Brazil, and Chile, along with a notable presence in Asia, particularly in Singapore and Hong Kong, have adopted this method. Additionally, it finds applications in Australia's road and subway tunnels ^[2]. The construction of shotcrete single-layer lining stands out for its simplicity, eliminating the need for lining trolleys and the laborious installation of geotextiles and waterproof boards. This streamlined construction process not only facilitates easy quality control but also significantly reduces project costs. In geological conditions suitable for its application, the shotcrete single-layer lining demonstrates outstanding promotional value.

In the 1960s, the Cheng-Kun Railway in China successfully employed shotcrete with anchor rod single-

layer lining technology in tunnels featuring favorable surrounding rock conditions. Similarly, the Shantou liquefied petroleum gas storage project utilized shotcrete and anchor rod single-layer lining support technology in several tunnels ^[3]. Notably, the auxiliary adit, spanning a length of 1220m, for the Qinling Tunnel on the Xikang Railway applied shotcrete steel fiber concrete for its single-layer lining ^[4]. The Gaopeng Gou Tunnel also incorporated 289m of shotcrete steel fiber concrete as a single-layer lining ^[5]. The Kuanshi Expressway Xiaotuanshan Tunnel employed 30m of wet spray steel fiber and mixed fiber high-performance concrete for its single-layer permanent lining ^[6]. Single-layer lining was applied in specific segments of the ventilation adit for the Xiaokou Expressway Extra-long Tunnel ^[7], the ventilation adit for the Baoyi Expressway Hongyanshi Tunnel ^[8], and the ventilation adit #1 for the Hanglan Expressway Motianling Extra-long Tunnel ^[9].

In recent years, China has made notable strides in the research on single-layer lining, including both field applications and a theoretical understanding of the physical properties of lining structures. Yunhua Zhu conducted an analysis of the support structure and surrounding rock stability of wet-sprayed steel fiber concrete single-layer lining using the finite element method ^[10]. Yilun Zou et al. delved into the mechanical properties of single-layer lining in high-stress tunnels, employing numerical calculations based on the Hoek-Brown criteria ^[11]. Jianjun Wu

et al. scrutinized the mechanical characteristics of the single-layer lining structure and the stability of surrounding rock in the context of the Heiwu Railway Dabieshan Tunnel [12]. Yisan Deng et al. undertook a comprehensive study on the application of waterproof single-layer lining in the Qingdao Metro [13]. Guoping Du et al. contributed research on the stability of fiber concrete single-layer lining in tunnels, with a specific focus on the forces involved in the working process, including anchor rods, fiber concrete, and their interaction with the surrounding rock [14].

In summary, the aforementioned scholars have conducted extensive studies on the stability characteristics of single-layer lining and its applications in underground engineering. Building upon this existing body of research, the current paper undertakes on-site experiments to investigate the application of single-layer lining with the surrounding rock in hard rock tunnels. The study also examines the deformation and laws of force governing the interaction between single-layer lining and the surrounding rock. The results obtained from these experiments offer valuable references for related engineering projects.

2 PROJECT OVERVIEW

The Jiaozhou Bay Second Subsea Tunnel, strategically positioned between the existing Jiaozhou Bay Tunnel and the Jiaozhou Bay Bridge, serves as a vital cross-sea passage linking the primary urban area of Qingdao on the east bank with the West Coast New Area. The total length of the main line spans 17.48 kilometers, with the tunnel section covering 14.37 kilometers (10.02 kilometers underwater and 4.35 kilometers on land). This tunnel stands as the longest subsea road tunnel in China, plunging to a maximum depth of 115 meters below sea level. As part of the preliminary work for the second tunnel, the Huangdao inclined shaft extends over a total length of 1111 meters. It is comprised of an open-cut section measuring 69 meters and an underground excavation section spanning 942 meters. The cross-section takes on a horseshoe shape, and post-lining, the net width of the bottom surface is 7.0 meters, with a central height of 7.7 meters.

3 FIELD EXPERIMENT

3.1 Test section support parameters

The inclined shaft section of the Jiaozhou Bay Second Subsea Tunnel at the Huangdao end, spanning from X1DK0+650 to X1DK0+710, is buried deep and transitions into the underwater section, situated in mildly weathered rock. This segment exhibits local development of joint fractures, and overall stability is deemed satisfactory. While structural fractures with water may be present, the groundwater level remains relatively

low. The surrounding rock is classified as level III, with full-section excavation being employed. Key support parameters are detailed in Table 1.

Table 1. Experimental section support parameters.

Content	Parameter Indicators

3.2 Experimental plan

For a comprehensive understanding of the mechanical changes and deformations in the surrounding rock and support structure post-excavation, it is imperative to select representative sections with typical observation points within the test section. Gathering mechanical data from deformation gauges at these chosen sections enables the assessment of the safety and stability of the tunnel structure. In this experiment, three representative sections were selected, and the milestones and test items are outlined in Table 2. The experiment focuses on anchor rod axial force contact pressure between surrounding rock and shotcrete, and shotcrete stress measurement points. These were strategically placed in areas with significant stress variations, including the crown, arch shoulder, and sidewall. The sensor arrangement is detailed in Table 1. To comprehend the coordinated deformation of the surrounding rock and tunnel structure, deformation measurement points were positioned at the crown and sidewall locations. Each measurement point at these locations was inserted into both the surrounding rock and the shotcrete, as depicted in Figure 2.

Table 2. Test section mileage calculation items.

Measure Section Mileage	Measurement Items	Sensors
DK0+655	Anchor Rod Tension	Rebar
DK0+682	Contact Pressure between Surrounding Rock and Shotcrete	Gauge Pressure Box
DK0+705	Stress in Shotcrete	Concrete
	Deformation of Surrounding Rock and Lining	Strain Gauge

Figure 2. Arrangement of deformation measurement points in the experimental section.

Table 3. Anchor rod tension test results.

Position		Left wall	Left arch foot	Arch top center	Right arch foot	Right wall
DK0	0.5m	13.21	4.55	0.82	0.59	10.31
+655	1.5m	0.29	1.17	0.02	0.77	0.94
	2.5m	-0.22	1.22	0.83	0.81	1.17
DK0	0.5m	75.35	3.35	0.62	-0.06	6.02
+682	1.5m	35.58	1.85	-0.15	-0.22	1.44
	2.5m	-7.8	0.49	0.1	0.14	0.65
DK0	0.5m	0.29	0.91	1.03	-0.35	-0.39
+705	1.5m	-0.08	0.37	0.38	-0.14	0.71
	2.5m	0.09	0.65	-	-0.36	0.02

Note: The axial force of the anchor rod with a “-” value indicates compression, while “+” indicates tension, units “kN”.

3.3 Test results analysis

(1) Anchor Rod Axial Force

Within the test section, $\phi 22$ multiple corrosion-resistant anchor rods, each with a length of 3 meters, were employed. Five testing points were strategically selected for each section, encompassing the middle of the crown, two arch shoulders (approximately 5.5 meters from the bottom plate), two side-walls (approximately 2.5 meters from the bottom plate), or two arch feet (approximately 5 meters from the bottom plate). The detailed test results are presented in Table 3.

Figure 3. DK0+655 left wall anchor rod axial force.

Figure 4. DK0+655 right wall anchor rod axial force.

Figure 5. DK0+682 left wall anchor rod axial force.

Test Results Analysis:

➤ The maximum anchor rod axial force recorded in the test section is 75.35 kN, which falls below the ultimate tensile force of the anchor rod body (170 kN). Notably, force values predominantly hover in the range of -1 to +1 kN, suggesting minimal or negligible force impact on these anchor rods due to the surrounding rock. These measured values are

primarily attributed to shrinkage during the solidification and hardening process of the cement mortar.

- The anchor rods in the test section generally exhibit tension, with axial force variations observed in three distinct stages over time. There is a rapid increase stage in the initial 1-3 days post-construction, where axial force values typically reach 40%-60% of the final stable values. This is followed by a slow fluctuating increase stage spanning the 10-18 days post-construction, with axial force values approaching the final stable values. The final stage involves axial force stabilization after 15-20 days of construction.
- Considering the distribution of anchor rod axial force, there is a decrease with increasing depth. The force is more pronounced at individual points from a depth of 0.5m to 1.5m, becoming less noticeable at a depth of 2.5m. This suggests that the 0.5m point is within an area where the surrounding rock experiences larger displacement towards the tunnel. It can be inferred that the generally widespread loose zone of the surrounding rock in the test section ranges from 0.5m to 1m, locally extending to 1.5m. Combining this with the loose zone of the surrounding rock, it can be concluded that the depth of anchor rod anchoring into the surrounding rock's elastic-plastic zone is between 1m and 2m.
- In the DK0+655 and DK0+682 sections, the left sidewall displays more developed joint fractures and slightly lower integrity. The maximum measured points for anchor rod axial force align with these fractured areas, indicating that the anchor rod forces are appropriate for the geological conditions. The results imply that in sections with developed joint fractures and fractured surrounding rock, the anchoring effect of the anchor rod becomes evident.

(2) Contact Pressure between Surrounding Rock and Lining

The focus of this experiment was to assess the variation in contact pressure between the surrounding rock and the lining. Five measurement points were strategically arranged at each section, covering the crown, arch feet (left and right sides), and sidewalls (left and right sides). Detailed test results are presented in Table 4.

Table 4. Contact pressure test results of rock mass and lining.

Location	Mileage		
	DK0+655	DK0+682	DK0+705
Left wall	24.08	21.12	7.23
Left arch foot	13.39	7.67	2.18
Arch top center	17.61	12.82	2.10
Right arch foot	9.99	8.00	12.02
Right wall	9.99	1.47	4.99

Note: Contact pressure with a “+” value indicates compression, while a “-” value indicates tension, units “kPa”.

Figure 6. Distribution of contact pressure between rock mass and lining in DK0+655 section.

Figure 7. Distribution of contact pressure between rock mass and lining in DK0+682 section.

Figure 8. Distribution of contact pressure between rock mass and lining in DK0+705 section.

Analysis of Surrounding Rock and Lining Contact Pressure Results:

- The contact pressure between the surrounding rock and shotcrete in the test section registers compressive stress, ranging from 1.47 kPa to 24.08 kPa. The maximum contact pressure is

Figure 9. Contact pressure distribution in DK0+655 section.

Figure 10. Contact pressure distribution in DK0+682 section.

Figure 11. Contact pressure distribution in DK0+705 section.

24.08 kPa for the DK0+655 section, 21.12 kPa for the DK0+682 section, and 12.02 kPa for the DK0+705 section. All absolute values remain below the theoretically calculated design values, indicating a sufficient safety margin in the support structure.

- The temporal variation in contact pressure between the surrounding rock and lining unfolds in three stages. There is an early rapid increase stage within 6-8 days post-shotcrete construction, where contact stress values typically reach 60%-80% of the final stable values. Subsequently, a slow fluctuation stage transpires in the 10-20 days post-construction, characterized by continued contact stress fluctuation—some areas exhibit a slow increasing trend, while others show a slow decreasing trend (linked to the redistribution of surrounding rock pressure). The final stage involves contact stress stabilization after 20-25 days of shotcrete construction.

- The distribution of contact pressure at each section aligns well with geological conditions and locations where anchor rod axial force is prominent. The left sidewalls of the DK0+655 and DK0+682 sections, marked by more developed joint fractures and a more fractured rock mass, exhibit significantly higher contact pressures between the surrounding rock and lining. Experimental results indicate that in areas with a more fractured rock mass, the synergistic deformation release of surrounding rock pressure by shotcrete with steel fiber and the lining is evident. This underscores the effective support provided by the single-layer lining system comprised of anchor rods and shotcrete with steel fiber.

(3) Shotcrete Stress

This experiment focused on monitoring the circumferential internal stress of the lining layer. Five measurement points were strategically arranged at each section, covering the crown, arch feet (left and right sides), and sidewalls (left and right sides). Sensors were embedded within the steel fiber concrete, and the detailed test results are presented in Table 5.

Table 5. Shotcrete stress test results (MPa).

Location	Mileage		
	DK0+655	DK0+682	DK0+705
Left wall	0.41	-1.02	0.25
Left arch foot	-0.97	0.51	-
Arch top center	0.82	0.68	-1.33
Right arch foot	-2.43	-0.14	0.54
Right wall	0.69	0.07	-0.26

Note: Shotcrete Stress with a “+” value indicates compression, while a “-” value indicates tension, unit “MPa”.

Figure 12. Concrete stress at section DK0+655.

Analysis of Shotcrete Stress Results:

- The maximum compressive stress value in the circumferential direction of the resprayed layer in the test section is 2.43 MPa, falling below the design value of 19.1 MPa for the compressive strength of C40 concrete. Similarly, the maximum tensile stress value in the circumferential direction is 0.82

Figure 13. Concrete stress at section DK0+682.

Figure 14. Concrete stress at section DK0+705.

MPa, below the design value of 1.71 MPa for the tensile strength of C40 concrete. These results affirm the safety of the support strength of the shotcrete with steel fiber in the test section.

- Among the measured points, 57% exhibit tensile stress, while 43% show compressive stress. Initially, most points display compressive stress post-shotcrete, gradually transitioning into tensile stress. As shotcrete with steel fiber provides support, internal stresses are generated in the axial and radial directions due to surrounding rock pressure and support resistance, influencing the tangential (circumferential) stress values. Additionally, contact pressure between the resprayed layer and the initial spray layer on the outer side of the resprayed layer can impact internal stress test values.
- Examining the stress change temporal diagram, the evolution of internal stress in the shotcrete lining unfolds in three stages: an early rapid development stage within 6-8 days post-shotcrete construction, a slow fluctuating development stage in 10-25 days post-construction, and a stage where shotcrete stress tends to stabilize after 20-25 days of shotcrete construction (with some stress points exhibiting certain fluctuations after 25 days).
- The locations of the maximum internal stress values vary among sections, and stress values on the left and right sides of the same section display an asymmetrical state. This discrepancy is attributed to differing integrity and deformation

of the surrounding rock in various locations, resulting in varying internal stresses generated by the resistance of the shotcrete to the surrounding rock. This underscores the highly effective supporting role played by the resprayed layer.

(4) Deformation of Surrounding Rock and Lining

Deformation monitoring points were strategically positioned on the left and right sidewalls and the crown of the tunnel. At each location, measurement points were established on both the initial support and the surrounding rock to gauge horizontal convergence and settlement of the surrounding rock and lining structure. Notably, three points were selected for settlement measurements at the crown, and one set of convergence measurement lines was chosen for sidewall convergence. Internal measurement points in the surrounding rock were placed at a depth of at least 10cm and not in contact with the shotcrete. Similarly, internal measurement points in the initial support were positioned at a depth not less than 10cm. The detailed test results are presented in Table 6.

Table 6. Deformation test results of surrounding rock and lining in the test section.

Mileage	Location	Arch Crown Settlement		Side Wall Convergence	
		Surrounding Rock	Lining	Surrounding Rock	Lining
DK0+655	Left	-2.20	-4.40	-1.2	-3.2
	Mid	-3.40	-4.00		
	Right	-3.20	-3.70		
DK0+682	Left	-1.90	-3.50	-0.4	-0.8
	Mid	-1.50	-2.60		
	Right	-0.60	-4.10		
DK0+705	Left	-0.70	-2.60	-1.2	-2.4
	Mid	-0.90	-2.90		
	Right	-0.70	-3.30		

Note: “-” values for the arch crown indicate settlement, and “-” values for convergence indicate convergence, unit “mm”.

Figure 15. Settlement of surrounding rock and lining arch section at DK0+655.

Figure 16. Settlement of surrounding rock and lining arch section at DK0+682.

Figure 17. Settlement of surrounding rock and lining arch section at DK0+705.

Figure 18. Convergence of surrounding rock and lining side walls in the test section.

Figure 19. Cumulative deformation distribution of surrounding rock and lining in the test section.

Analysis of Surrounding Rock and Lining Deformation Results:

- The deformation values and deformation rates observed in the test section for the surrounding rock and lining are relatively small, all falling within the design control standards. The average change rates of the surrounding rock crown and convergence range from -0.02 to -0.11 mm/d and -0.02 to -0.05 mm/d, respectively. Similarly, the average change rates of the lining crown and convergence fall within the ranges of -0.12 to -0.17 mm/d and -0.03 to -0.11 mm/d, respectively. These values adhere to the criteria for basic stability of deformation (rate < 0.2 mm/d).
- Surrounding rock deformation values span from +1 mm to -2 mm, constituting approximately 75% of the total measurement points, with an average cumulative change of -1.49 mm. In contrast, lining deformation ranges from -2 mm to -5 mm, encompassing about 90% of the total measurement points, with an average cumulative change of -3.1 mm. The cumulative deformation of the shotcrete with steel fiber lining surpasses that of the surrounding rock.
- The joint stability of the shotcrete with steel fiber concrete single-layer lining and the surrounding rock is deemed satisfactory. The surrounding rock generally stabilizes its deformation trend 3-5 days after initial data collection, while the lining typically stabilizes its deformation trend 10-15 days after initial data collection. Importantly, the deformation of the surrounding rock stabilizes earlier than the deformation of the lining.

4 CONCLUSIONS AND OUTLOOK

The performance of the single-layer lining support system proves to be excellent for maintaining the stability of the rock surrounding the tunnel. The analysis results lead to the following conclusions:

- (1) In areas where joints and fractures in the surrounding rock are more developed and fragmented, the anchor support demonstrates significant effectiveness. The distribution of anchor forces aligns with the surrounding loosened rock. The measured contact pressure between the surrounding rock and the lining is relatively small, indicating the safety of the anchor-sprayed support system in the test section. Contact pressure distribution correlates with the condition of the surrounding rock, with higher pressures observed in areas with more fragmented rock. The variation of 60% to 80% of contact pressure occurs 6 to 8 days after the construction of the secondary spray

layer, stabilizing after 20 to 25 days of construction.

- (2) The stress distribution of the sprayed steel fiber-reinforced concrete lining is irregular, signifying that the lining resists the deformation of the surrounding rock and generates different internal stresses. This underscores the effective supporting role of sprayed steel fiber-reinforced concrete. The surface of the sprayed lining exhibits no cracks, and the circumferential tensile/compressive stresses fall within allowable limits, affirming the safety of the sprayed steel fiber-reinforced concrete support strength.
- (3) The synergy of deformation between the sprayed steel fiber-reinforced concrete lining and the surrounding rock is satisfactory, with relatively small deformation. The surrounding rock generally stabilizes its trend 3 to 5 days after the initial data collection, while the lining stabilizes its trend 10 to 15 days after the initial data collection. This indicates that the support system of anchor + sprayed steel fiber-reinforced concrete effectively controls deformation, providing robust support.

In summary, the experimental results affirm the feasibility of a single-layer lining under hard rock conditions, ensuring the quality and safety of tunnel engineering. The support structure demonstrates reliable working characteristics and can be widely applied and promoted in the mainline engineering of the Jiaozhou Bay Second Subsea Tunnel and similar projects

ABSTRACT: The fracturing of brittle rocks under loading involves an internal energy conversion process within the system. Acoustic emission (AE) and infrared radiation (IR) energy, as two forms of energy, are correlated with the elastic strain energy and dissipation energy of brittle rocks during uniaxial loading. This study introduced an infrared radiation index for the average cumulative radiation energy increment (Δ ACRE) based on Stefan-Boltzmann law. AE cumulative Absolute energy and Δ ACRE of the samples during loading were obtained separately using AE and infrared thermography systems. The mathematical model for coupling elastic strain energy with Δ ACRE, dissipated energy with acoustic emission energy were derived and created. The causes of rock failure under loading were explained from an energy perspective. Based on the theory of energy dissipation, a quantitative analysis index Radiant-AE Energy Ratio (REAER) for rock failure was proposed. It is defined as the ratio between Δ ACRE and AE absolute energy, which can be used to predict and identify rock failure and obtain precursor points of failure. This study offers a novel approach to predict rock burst disasters.

Keywords: brittle rock, strain energy, acoustic emission, infrared thermography, precursors of failure

1 INTRODUCTION

Rock bursts often occur during mining, tunnel excavation, and underground construction processes. Due to its sudden, destructive, and unpredictable characteristics, rock burst has become a serious disaster for production and safety. Rock burst is a phenomenon that rock mass releases a large amount of energy instantaneously along the excavation unloading surface (He et al., 2005). Rock is the main carrier of rock burst. Therefore, understanding the evolution process of strain energy during rock deformation and failure at different load stages is of great significance

for obtaining precursor indicators of rock bursts and achieving stability monitoring and disaster warning in engineering projects (Zhou et al., 2018).

When rocks are damaged, strain energy is released in the form of elastic waves and heat. Elastic waves propagate rapidly and generate acoustic emission (AE) phenomena (Meng et al., 2014). Heat is transferred from the interior of the rock to the surface, forming an infrared radiation signal (IR). Therefore, the AE and IR characteristics of rocks during damage can help determine the strain energy evolution process during rock deformation and failure (Sun et al., 2017). Previous research on the evolution of AE and

*Corresponding author: 2211056@tongji.edu.cn

IR characteristics during rock loading has achieved many important results. Lin et al. (Lin et al., 2015) examined the mechanisms of crack propagation and failure in granite with defects during uniaxial compression. Li et al. (Li et al., 2010) explored the spatiotemporal evolution of acoustic emission events in both granite and marble. Zhang et al. (Zhang et al., 2018) investigated the failure patterns of anisotropic shale in Brazilian splitting tests, utilizing acoustic emission parameters. Cui (Cui et al., 1993) and Grinzato et al. (Grinzato et al., 2004) studied the thermal radiation characteristics of rocks under load. Wu et al. (Wu et al., 1998) discovered three types of abnormal rock failure characteristics using thermal radiation to study the precursors of rock failure.

However, the relationship between the strain energy under rock loading and the true infrared radiation energy (thermal energy) and acoustic emission energy (mechanical energy) is still unclear. In addition, some scholars have proposed some indicators for determining rock failure precursors based on AE and IR characteristics. Cao et al. (Cao et al., 2020) proposed a quantitative analysis index of energy dissipation infrared radiation ratio (EDIRR). Using the inflection point of EDIRR from horizontal to rapid growth as a precursor point for rock failure. Wu et al. (Wu et al., 2021) used the inflection point of AE cumulative count curve from horizontal to rapid growth as a precursor point for rock failure. However, the monitoring methods used are relatively single, and there are not many studies combining AE with IR. Moreover, the current methods for predicting rock failure are mostly based on observing the trend of changes in indicators, which cannot intuitively and quickly confirm the precursor points of rock failure.

Based on this, this article uses a combination of AE and IR methods to explain the failure process of rocks from the perspectives of infrared radiation energy (thermal energy) and acoustic emission energy, and proposes a new index for efficiently identifying precursor points of rock failure. The research results provide new ideas for predicting the occurrence of rock disasters.

2 EXPERIMENTAL SECTION

2.1 Sample preparation

In this study, representative red sandstone samples collected from Hunan Province, China were used. The rectangular size samples having a dimension of $50 \times 50 \times 100$ mm were prepared with high geometric integrity from the same red sandstone block. The faces of the samples were carefully polished to avoid the end non-parallelism and to control parallelism within 0.2 mm. The processed red sandstone is shown in Figure 1(a). Rock samples were divided into 2 groups and each group contain 6 samples. All group samples were kept in laboratory at a room temperature for 48 hours.

2.2 Experimental equipment

The rock loading experiment was conducted on a single axis servo rigid testing machine WDW-600 having maximum loading capacity up to 600 kN. The loading rate is 0.15mm/min. The surface temperature of the samples was obtained using a Fotric 618C-L29 IR imager with a resolution of 640×480 pixels and a wavelength range of 7.5–14 μm . The capture frame rate of the IR imager is 25 FPS. The AE parameters were obtained using a PCI-2 AE data-acquisition system with a host, 2 signal amplifiers, and 2 AE sensors. The sensor model is R15 α and can monitor AE signals with a frequency of 50–400 kHz. The entire testing system is shown in Figure 1b.

Figure 1. The figures of red sandstone samples (a) and testing system (b).

3 RESULTS AND DISCUSSION

3.1 Energy evolution process

Assuming that the compression deformation process of rocks is carried out in a closed system and there is no energy exchange with the outside world. So, the energy change of the system can be obtained from the first law of thermodynamics:

$$U = U^d + U^e \quad (1)$$

Where, U is the total strain energy (J), representing all the energy during the entire process, which can be calculated from the area between the sample stress-strain curve and the coordinate axis; U^e is the elastic strain energy (J), which is the energy stored during rock deformation; U^d is the dissipated strain energy (J), which can be obtained by the difference between the U^e and the total strain energy U .

Figure 2 shows the relationship of dissipated strain energy and elastic strain energy. According to the study by Zhang et al. (Zhang et al., 2019), the U^e stored during uniaxial loading of rocks can be obtained by formula (2).

$$U^e = \frac{1}{2E_u} \sigma^2 \quad (2)$$

Where, E_u is the unloading elastic modulus; for the convenience of calculation, the elastic modulus is usually used instead of E_u . The elastic modulus in this article is the slope of the linear stage of the stress-strain curve.

Figure 2. The relationship of dissipated strain energy and elastic strain energy in stress-strain curve.

Figure 3 shows the stress-strain curves and energy evolution-strain curves of the red sandstone samples. It can be clearly seen that as the strain increases, the stress, total strain energy, elastic strain energy, and dissipated strain energy all show an upward trend. According to the changes in stress-strain curves, the uniaxial loading process of red sandstone can be divided into three stages: compaction stage, elastic stage, and brittle failure stage. During the compaction stage, a portion of the input energy provided by the loading machine is converted into elastic strain energy and stored by the rock, while a portion of the energy is released as the primary pores inside the rock are compacted and destroyed. Therefore, the elastic strain energy and dissipated strain energy at this stage slowly increase, and the stored elastic strain energy is much higher than the dissipated strain energy. In the stage of elastic, all the input energy of the loading machine is converted into the elastic strain energy of the rock. Moreover, there are no small cracks or energy dissipation inside the rock, so the dissipated strain energy of the rock remains unchanged. In the stage of brittle failure, the elastic strain energy stored in rocks is rapidly released and converted into dissipated energy.

Figure 3. The strain energy evolution curves of red sandstone during uniaxial loading.

3.2 Infrared Radiation Energy (IRE)

All objects above absolute zero emit infrared radiation, and its radiation intensity is closely related to material properties and temperature states. During the loading process, the rock generates heat under external forces and emits infrared radiation outward. By using an infrared thermal imager, the temperature

state of rocks can be obtained, thereby calculating the IRE. According to thermodynamics, it can be known that the radiation capacity of the red sandstone follows the Stefan–Boltzmann law (Ulhoa et al., 2019). Considering the radiation characteristics of objects, the infrared radiation energy can be calculated using the following formula:

$$IRE(t) = A\varepsilon\sigma\Delta tT^4(t) \quad (3)$$

Where, $E(t)$ is the IRE; ε is the emissivity of the red sandstone, $\varepsilon \approx 0.909$; σ is the Stefan–Boltzmann constant, $\sigma = 5.67 \times 10^{-8} \text{ W}/(\text{m}^2 \cdot \text{K}^4)$; T is the average temperature of the red sandstone; A is the area; Δt is the time interval in seconds.

If the IRE corresponding to time t is $IRE(t)$ in the rock loading process, then the variation of the IRE from time t to time $t-1$ is:

$$\Delta IRE = A\varepsilon\sigma\Delta T^4(t)\Delta t \quad (4)$$

The average cumulative radiation energy increment during the entire loading process of red sandstone is:

$$\Delta ACRE = \sum_{t_0}^t \Delta IRE(t) \quad (5)$$

According to the above equation, the $\Delta ACRE$ during the entire loading process of red sandstone samples is calculated and plotted in Figure 4. It can be clearly seen that $\Delta ACRE$ of the sample increases with increasing stress. As the stress has a control effect on IR (Ma et al., 2019), the reduction of rock peak strength will inevitably lead to the change of maximum $\Delta ACRE$ amplitude.

Figure 4. The $\Delta ACRE$ curves of red sandstone during uniaxial loading.

The relationship of $\Delta ACRE$ with stress and elastic strain energy during uniaxial loading of rock are shown in Figure 5. The correlation coefficient is more than 0.85 shows a strong linear relationship between $\Delta ACRE$ with stress. The correlation coefficient is more than 0.90 shows a strong cubic polynomial relationship between $\Delta ACRE$ with elastic strain energy. The fitting equations are listed in Table 1.

3.3 AE absolute energy

When the rock is damaged, the strain energy is released in the form of elastic wave, and the elastic

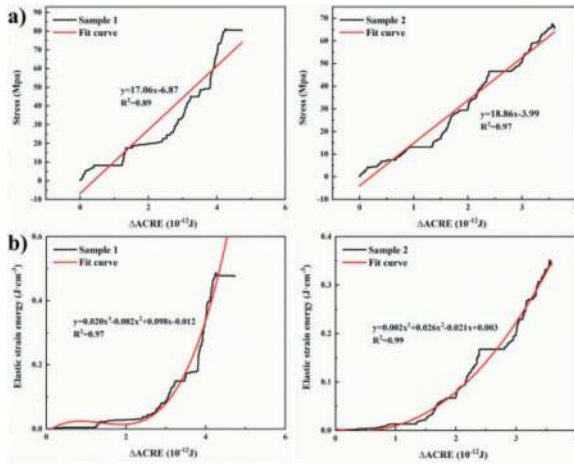

Figure 5. The relationship of Δ ACRE with stress (a) and elastic strain energy (b) during uniaxial loading of samples.

Table 1. The relationship of Δ ACRE with stress and elastic strain energy during uniaxial loading of samples.

Sample	Relationship equation(Δ ACRE-stress)	R ²
1	$y=17.06x-6.87$	0.89
2	$y=18.86x-3.99$	0.97
Sample	Relationship equation (Δ ACRE- elastic strain energy)	R ²
1	$y=0.020x^3-0.082x^2+0.098x-0.012$	0.97
2	$y=0.002x^3+0.026x^2-0.021x+0.003$	0.99

wave propagates rapidly and produces acoustic emission. Therefore, the AE characteristics of rock during loading are helpful to determine the failure law. Figure 6 illustrates the waveform characteristic of AE signals (Geng et al., 2017). Absolute Energy is the time integral of the square of the signal voltage at the sensor before any amplification, divided by a 10k Ω impedance and expressed in aJ (attojoules, 1aJ=10⁻¹⁸J). The corresponding physical energy formula is:

$$E = \frac{U^2}{R} \cdot t \quad (6)$$

Absolute energy is not affected by pre gain and can be compared intuitively with energy in physics.

Figure 7 presents the stress-time curves, AE absolute energy and accumulated AE absolute energy of the red sandstone samples. Higher AE energy is associated with more severe rock damage. As shown in Figure 8, the failure process of red sandstone also can be divided into three stages according to AE absolute energy. During the compaction stage (I), microcracks inside the rock rupture and generate a small amount of AE signals, and the accumulated absolute energy slowly increases. In the stage of elastic (II), There is no AE signal inside the rock, and the accumulated AE absolute energy remains basically unchanged. In the stage of brittle failure

Figure 6. The waveform characteristic of AE signals.

(III), the rock undergoes severe damage, generating many AE signals, and the accumulated AE absolute energy increases exponentially.

Figure 7. The stress-time, AE absolute energy-time and accumulated AE absolute energy-time curves of the red sandstone samples.

The accumulated AE absolute energy and dissipated energy during the entire loading process of red sandstone samples is calculated and plotted in Figure 8. It can be clearly seen that accumulated AE absolute energy and dissipated energy have the same growth trend over time. It can be interpreted that a part of the dissipated energy is emitted in the form of stress waves.

Figure 8. The accumulated AE absolute energy and dissipated energy during the entire loading process of red sandstone samples.

3.4 Radiation-AE energy Ratio (REAER)

During the process of rock loading, the increase of elastic strain energy is the process of energy storage in the rock. Its maximum value represents the maximum energy that a rock can store. Continuing to increase the load will result in the release of elastic strain energy. At this point, the elastic strain energy sharply decreases. Dissipated strain energy is the energy dissipated throughout the entire process of

a rock, which remains basically unchanged in the early stage and exhibits an exponential upward trend after reaching the maximum load. The elastic strain energy of rocks is fully transformed into dissipated strain energy. Therefore, the ratio of elastic strain energy to dissipated strain energy can be used as an indicator to predict rock failure. Using the time corresponding to the maximum ratio as the precursor point for failure. According to the research in the previous chapter, it can be seen that $\Delta ACRE$ can replace elastic strain energy, and AE absolute energy can replace dissipated strain energy. Therefore, the ratio of elastic strain energy to dissipated strain energy can be converted into the ratio of $\Delta ACRE$ to AE absolute energy, which can be more conveniently and quickly measured in engineering practice.

Using indicator REAER can monitor the process of rock failure under loading in real-time. The calculation formula is:

$$REAER = \frac{\Delta ACRE}{\sum AE \text{ absolute energy}} \quad (7)$$

The REAER and stress curves of red sandstone samples under loading conditions are shown in Figure 9. The characteristics variation of REAER curves for rock samples are basically the same. During the compaction and elasticity stages, the REAER of the sample continuously rises to its maximum value. This indicates the beginning of the rock failure stage. During the failure stage, the REAER value continuously decreases until the samples are destroyed. The maximum REAER value of rocks can be considered as a precursor point for rock failure, and the decreasing stage after the maximum REAER value can be used as the criterion to monitor rock failure and instability.

Figure 9. The REAER evolution curves of samples during uniaxial loading.

The failure time, precursor of failure, and leading failure time of rock samples are listed in Table 2. The failure time of sample 1 is 1510 s, the precursor of failure is 1325 s, which 185 s ahead of the failure time. The failure time of sample 2 is 1401 s, the precursor of failure is 1103 s, which 298 s ahead of the failure time. The failure time of sample 3 is 1540 s, the precursor of failure is 1311 s, which 229 s ahead of the failure time. The failure time of sample 4 is 1567 s, the precursor of failure is 1396 s, which 171

s ahead of the failure time. The average leading time reached 220s.

Table 2. The failure time, precursor of failure, and leading failure time of rock samples.

Sample	Failure time /(s)	Precursor of failure /(s)	Leading failure time/(s)
1	1510	1325	185
2	1401	1103	298

4 CONCLUSIONS

This study conducted uniaxial compression tests on red sandstone samples, monitored and analysed the IR and AE characteristics of the rocks to study its failure process. The main conclusions are as follows.

- (1) According to the first law of thermodynamics, the energy evolution process during rock loading is analysed. The strain energy during the rock loading process is mainly composed of elastic strain energy and dissipated strain energy. The elastic strain energy undergoes three stages: gentle-rise-sharp decrease, and the dissipative strain energy undergoes three stages: slow rise-constant-sharp increase. Corresponds to the process of rock failure.
- (2) According to Stefan-Boltzmann law, the indicator $\Delta ACRE$ is proposed to reflect the change of stress and elastic strain energy of rock during loading. There is a linear function between stress with $\Delta ACRE$. There is a cubic polynomial relationship between $\Delta ACRE$ with elastic strain energy.
- (3) The cumulative AE absolute energy during rock loading is calculated. Compared with the dissipated strain energy, it is found that they have the same change trend, and the dissipated strain energy can be replaced by the cumulative AE absolute energy.
- (4) A quantitative analysis index of the REAER was introduced, which can be used to predict violent rock failures intuitively and quickly.
- (5) This study not only solves the characterization problem of elastic strain energy and dissipative strain energy during rock loading, but also combines IR with AE, which is more conducive to monitoring and warning of rock failure.

BIM Modelling & reality capture in underground drill and blast caverns

Pedro Rey Antón*, Ivo Jose Ferreira Teixeira, Alessandra Barbetta, Bruna Bezerra Vieira & Fernando Abreu

ACCIONA Construction Brazil

ABSTRACT: Line 6 of São Paulo Metro is a design-build megaproject integrating the simultaneous construction of more than 15 km of TBM tunnel, 15 stations, 17 shafts and around 2km of non-mechanized tunnels and a train yard. The project has been implemented in a consolidated and complex urban environment in the central area of the city, and the northern part of the line was carried out on a granitic hard rock formation under very complex geotechnical conditions, this required the use of drill and blast methods to be excavated. The drill and blast stations concept are based in deep large diameter shafts and caverns, strongly relying on the observational method and toolbox measures, which generates great coordination challenges because of the strict and diverse construction tolerances. Therefore the combination of the use of point clouds (generated “in loco” by the survey department) and BIM models was chosen to be able to control and adapt the excavations while coordinating it with other disciplines: civil (primary and secondary lining), architecture, MEP, systems, subcontractors... For the nature of the “fast track” construction method, and the fact it is a design-build project, a lively communication and constant feedback was created between the construction and the design models through federated models, that is, between the technical office and the construction site. Thanks to this channel, it has been possible to optimize the decision-making process and to perform overall corrective actions in a shorter time span, improving and adapting the original designs, construction methods and generating shorter delays than may have taken place with a traditional method.

Keywords: BIM, Point Clouds, Drill&Blast, decision-making process, Design&Build, Reality Capture

1 INTRODUCTION

Line 6 of São Paulo metro is currently one of the most challenging projects worldwide. Its design-build megaproject integrates the simultaneous construction of more than 15 km of TBM tunnel, 2 km of non-mechanized tunnels, 15 underground stations, 17 shafts and emergency exit points, and large train yard. Its twenty-two trains in operation and two electric substations serve the line. It is important to highlight that while the line faces challenges related with the construction integration within the complex city of São Paulo, a focus is always given to the development of peripheral regions and communities it crosses.

For this article, João Paulo I station will serve as an example (both explanatory and illustrative) on the implementation of the project in three other similar stations and conceptually throughout the line.

The future João Paulo I station encompasses 39.50 m diameter and 41.30 m deep shaft in its underground component, with two 200 m² platform tunnels

around 64 meters and 30 meters extension each. The surface of the shafts is around 727 m AOD (Above Ordnance Datum), while the excavation is completed at the 688.8 m level. The station is integrated in a highly dense urban area combining high-rise buildings and small houses in the near vicinity as well as a main artery road and water/drainage infrastructure. All in all, the vibration and excavation control are taken as essential to allow a safe and continuous construction process.

This paper focuses on how BIM methodology and entire processes were established and ran since the early design through the full construction cycle. Emphasis is given on how the Terrestrial Laser Scanning (TLS) point clouds generated from the site were integrated to the BIM models design, adapted construction of BIM models and models from other disciplines in such cases. Through these federated models (design and construction), mitigations, adaptations and improvements were studied and implemented daily through this methodology, adapting the excavation procedures where needed to comply with the strict tolerances.

2 GEOLOGIC AND GEOTECHNICAL ASPECTS

As mentioned previously, due to the particularities of the São Paulo geology the northern part of São Paulo line 6, which is the focus herein is implemented in a heterogenous granitic hard rock formation.

The geology of the João Paulo I station is integrated in the geological context of the intrusive granitoids of the Precambrian Basis covered by quaternary sediments. This granitoids are classified as homogeneous to porphyroids, thin to very coarse and light to heavy gray and red. The relatively high resistance to weathering generates superficial rock elevations and most of the areas are not covered by tertiary sediments having only residual soil below the quaternary deposits.

While the residual soils tend to be essentially soft soils in terms of geotechnical behaviour, the granite due to its formation and weathering patterns present a broad array of Rock Mass Rating (RMR) values, but nevertheless always demanding the use of drill and blast techniques to proceed with the excavation in a reasonable time scale.

2.1 Local geology and geotechnical profile

In the station area the stratigraphy can be divided in two major ground types: soil and rock. The soil type can be further divided in two different horizons, the upper one related with quaternary deposits which thickness ranges from 2.0 to 5.0 m and the deeper one with residual soil of granite origin encompassing all three levels of alteration (mature, young, saprolite) and up to 10.0 m thicknesses. Within the residual soil

Figure 1. 3D schematic geological model study.

the frequency of boulders is high some of them reaching metric proportions.

In terms of rock excavation two main sub-divisions having different geomechanical behavior were identified. The first one is categorized as small layer of weathered granite (GIra) and is associated with Class V and low Class IV-, while the second category and the vast majority is defined as granite (GI) sub-divided in the remaining RMR classes (IV+ to I).

The rock top in the region is quite irregular, its starting level ranging from 724 mAOD up to 709 mAOD, while up to 10m level difference was identified in the shaft location. The water table is almost at the surface level.

The granite was categorized with a UCS ranging from 34 to 128 MPa and an average of 73 MPa recognizing the need to use drill and blast techniques in the shaft excavation. Additionally, television data from the boreholes allowed an estimation of stereographic projection to identify several main discontinuity families which has a critical aspect of the overbreak probability during the tunnel excavation.

By such a type of geology the selected station concept requires a large diameter shaft which would be excavated in both soil and rock layers intertwined with two caverns which would be fully excavated in rock.

2.2 Excavation concept and construction sequence

The shaft excavation concept was divided in three types: i) full soil excavation, ii) transition where some part of the shaft would be in soil and rock, and iii) full rock ground. All three types the excavation was partialized by the application of a shotcrete primary lining reinforced with steel mesh in the soft soil and transition ground type and macrofibre in the rock part.

To improve the stability conditions and generate a watertight barrier in the soil layer a perimetral ground treatment made by secant jet grouting (JGv) columns was performed. The JGv was designed to have a variable length in accordance with the rock top.

The advancement in the soil-rock transition was predicted to be slower and more complex as the progress rates in rock are much lower than in the soil which requires laborious and carefully controlled drill and blast sequence and the fact that flyrock at such surface level is hazardous. The solution was to create independence between the level where the excavation in the soil would take place and where the rock would still be excavated, meaning that the soil and rock would be excavated in different steps inside the transition area. The remaining excavation of the shaft would be completely carried out in rock and was carried out using the drill and blast method with rock bolts applied as needed in accordance with the local stability conditions.

The tunnel excavation would be performed fully in rock, having a partialization based in crown, bench and invert. A conjugation of shotcreted macrofibre

reinforced primary lining, rockbolts, lattice girders, pipe umbrella, etc. could be used in view of the local conditions and rock behaviour and predicted in the tool box measures defined in the design criteria.

2.2.1 *Blasting schemes and tunnel excavation*

The blasting scheme is a central aspect of the drill and blast methodology. It is always a game of trade-offs, especially in urban areas where vibration limitation is severe and damage to the infrastructures in the surrounding area is not allowed.

The blasting scheme concept was based on the combination of two aspects:

- I) smooth blasting and
- II) tight net of blastholes with different activation speeds. Additionally small powder factors would be used even with a considerable total amount of explosives.

The “smooth blasting” technique was originated in Sweden after 1950 and consists in the performance of a tight “line drilling” with holes quite close to each other with reduced loading. The objective of this technique is to keep the excavation line as close to the theoretical as possible, minimize overbreak and vibration. The drilling was performed with ‘jumbo’ and/or pneumatic drilling rig. The explosive type used was packaged emulsion with high water resistance.

While a tremendous effort was made in the blasting schemes to minimize overbreak, lining reinforcements and related issues, the likelihood of its existence in the existing geology was quite high, which could generate a relevant problem in the future in terms of “invading” the space needed for the secondary lining, architecture, MEP, systems, etc.

In order to avoid such problems, which would be translated in costs and time overrun, the implementation of BIM with the 3D scanning since the excavation phase was performed generating specific action plans for each specialty to adapt its design as needed or perform additional civil works to correct the clash. (Bieniawski, 1989) (Teixeira et al., 2023)

3 METHODOLOGY

3.1 *Building information management*

Building Information Modeling (BIM) combines policies, technology and process which altogether constitute a “methodology to manage the essential building design and project data in digital format throughout the building’s lifecycle”. (Penttilä, 2006)

BIM tools have been increasingly incorporated into collaborative design and modelling processes, with the promise of substantive benefits for the efficiency of the design process. (Hardin & McCool, 2009) This methodology has quickly transformed the way infrastructures and buildings are conceived, designed, constructed, and operated. Although the first concepts of BIM date back to the early concepts

of researching in parametric modeling imagined in USA and Europe in late 1970s and early 1980s, the Architecture-Engineering-Construction (AEC) industry practically started to implement it in projects as of the mid-2000s. (Eastman, et al., 2011).

BIM models developed under this methodology contain in their development the geometrical data, and non-geometric data as well. In addition, the following concepts will be achieved: an improved and optimized collaboration, intelligent documentation, access to a single source of information and distributed access and retrieval of building data and high-quality project outcome through enhanced performance analysis, as well as multidisciplinary planning and coordination. (Fischer & Kunz, 2004) (Haymaker et al., 2005) (Haymaker & Suter, 2006) Given the complexity of both the urban and geotechnical aspects, a series of models and studies of the area and the site were carried out where the station was to be built.

3.2 *Design and built project*

It is important to note that São Paulo line 6 project is carried out under the design-built project contract typology. Its design is carried out at the same time as the construction, which is known as “fast-tracking”. Normally the construction project is delivered by the traditional method, wherein all activities begin on completion of their predecessors. However, we have become accustomed for some time on seeing the “fast-track” method used on large, complex projects. Fast-tracking consists of carrying out activities, initially considered sequential, in parallel, overlapping their performance. It is considered one of the three most common techniques of scheduling compression or acceleration. Thus, some amount of overlap occurs in this method between pairs of activities such as design and construction. For both project development and construction, a series of BIM models have been developed for each of the disciplines that make up the project.

The main advantage of the design-build approach is that it can implement the orderly intersection and close coordination of work at various stages through the simultaneous performance of design and construction tasks. The success of design projects depends on the quality of the available information. However, unlike crashing and substitution of activities, which usually directly increase project costs, overlapping activities are considered to increase project risk due to increased potential for change and/or rework (Ruby, 1978) (Van der Werf, 2003) which can lead to increased costs and problems such as schedule delay, cost overrun, and quality failure. (Wang & Feng, 2023) (Fazio et al., 1988).

Because of this complexity, decision was made to align the BIM models to the different phases of the project based on the total rework and complexity they generate. A favorable overlap strategy generates the required time savings, while considering both critical and non-critical activities and following the

critical path or adapting to changes if a new critical path emerges.

The use of these BIM models in both design and construction integrated with point clouds application has been used previously and validated in achieving optimization of the schedule of real-world projects.

Therefore, always aligned to the fact that it is a fast-track project, the choice was to combine the use of Terrestrial Laser Scanning point clouds (generated “in loco” by the survey department) and BIM models to be able to control the blasting performance while coordinating it with other disciplines: civil (primary and secondary lining), architecture, MEP, systems, subcontractors... Due to the nature of the construction method and the fact that it is a design-build project, a lively communication and constant feedback was created between the construction and the design models, and between the technical office and the construction site.

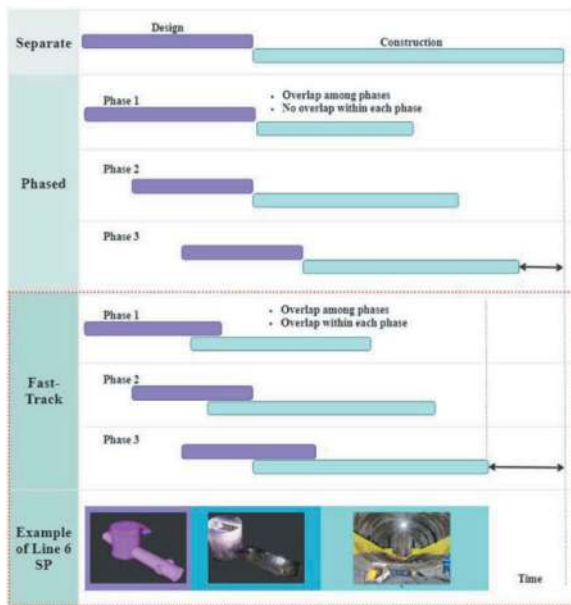

Figure 2. Design/Construction interaction schemes.

3.3 Overview of laser scanning

Terrestrial Laser Scanning (TLS) is a new technology that offers the possibility of creating 3D images in a fast way, with high definition and high density of surfaces and built elements.

Looking at it from a practical and economic point of view, this technology has proven to have the ideal characteristics for the incorporation of its use in construction works in general and especially in infrastructure, applying it in multiple uses and providing great benefits. Specifically in the case of tunnel works, it is used by surveyors’ teams for surface modelling, profiling, volume calculation and work control. As a result, TLS use has increased even more in this type of projects, however, little has evolved to date in its use in combination with other technologies.

Simplifying the concepts of 3D terrestrial laser scanning very much, in terms of operation and instrument design, it can be perceived as a total station equipped with a servo mechanism and a reflectorless EDM. (Kotsis et al., 2005) In operating mode, the system measurement method takes averages under the system of taking points at a predetermined horizontal and vertical directions controlled by the instrument’s control unit. (Lichti et al., 2000) In this way, a large number of points in space, 3D points, are obtained, which are combined by performing the process several times. This set of points is known as a “point cloud”. The laser scanner gives the option to place these points in spatial coordinates, with a minimum margin of error. (Berger et al., 2016)

Continuing with this cycle, several point clouds are executed and geo-referenced by least squares-based technique called “Fuzzy Joint”, so that they can be joined together between subsequent scan positions performed. Finally, this technique uses overlapped volumes between neighbouring point clouds allowing a full volumetric surface to arise. (Kotsis et al., 2005)

Figure 3. João Paulo I station points cloud.

4 BIM MODELLING & REALITY CAPTURE ON LINE 6

4.1 Model creation

Based on the project requirements and baseline information, conceptual BIM models were developed in the early stages of the project by the architectural designer and analysed and validated by the structural and geotechnical designer in conjugation

with the construction company's technical team. For the development, the BIM models were designed in a way that: i) considered both the design of the project itself, ii) particularities of its construction methodology, iii) information for the subsequent use and iv) maintenance in the life cycle of the asset.

Once it was developed and adapted to the needs and requirements of the project, geotechnical and structural designers created the internal and external structural models, based on the architectural models and the construction needs mentioned above. Special emphasis was given to the models of the excavation/primary structures in view of the construction schedule of the project. The designers' models were coordinated to ensure a seamless and integrated design. At the same time the other designers, especially MEP disciplines, such as HVAC (wet and dry), plumbing, electrical, strain signalling, lighting, or fire protection, started to analyse these models and implement their own design models. Once they were developed, they were also coordinated and retrofitted to the Architecture and Structures models, adapting, and making changes to them as well in an iterative process. The information models already developed includes architectural components, engineering systems for structures, MEP services, as well as details of cross-cutting. In addition, given the fast-track nature of the project, the subcontractors were also brought in at a much earlier stage of the project to ensure the correct functionality and constructability of the project, as well as optimizations. This led them to also developing their own models from the design of the different disciplines, also entering these co-ordination processes at the very beginning.

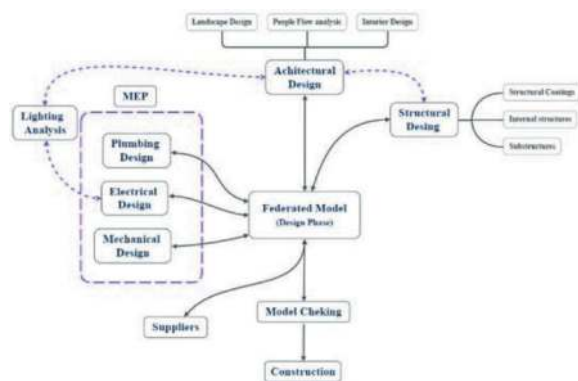

Figure 4. BIM models process. design phase.

Given the magnitude and complexity of the project, the need to introduce multiple BIM uses was prominent. These BIM uses are updated according to the needs required by the work and the construction progress. (Rey & Sedó, 2022)

In such a large project, it is important to analyse and develop the necessary BIM uses, at each site and each case, depending on the necessities of the construction units, different disciplines, work methodologies, etc. The following diagram shows the

BIM uses that have been performed to João Paulo I station:

Figure 5. BIM uses.

4.2 Model coordination

In this type of large complex construction projects involving multiple parties such as contractors, suppliers and designers proper (model) coordination is fundamental. Many activities are carried out simultaneously, which can generate variations and compatibility issues due to construction, errors, omissions and misunderstandings leading to undesirable results that oblige the need to carry out the rework.

Rework has been a primary cause of cost and schedule overruns in large construction projects (Hegazy et al., 2011). The use of BIM models therefore had to be aligned in all phases linking design and construction aiming at mitigating those reworks. At the start of a project, it could be seen how all the work resides in the backlog of work to be performed. Once the project started to be on track and progressed in its construction, the pace of work is determined while the first objectives are performed. (Cooper, 1993)

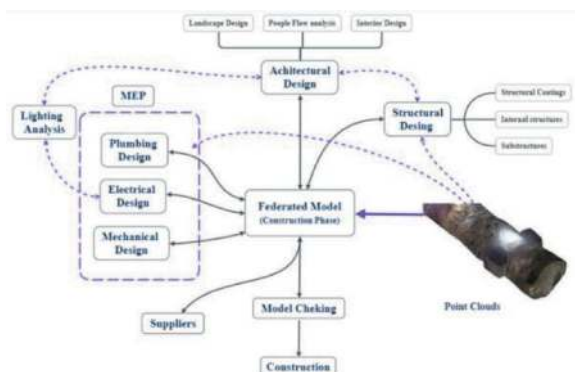

Figure 6. BIM models process. Construction phase.

4.3 Federated model & point clouds model

In addition, as explained in the geology section, due to the intrinsic characteristics of the blasting operations, imperfections in the excavation contour would occur in a positive or negative way (overbreak and underbreak). Corrections performed afterwards, especially underbreak correction would cause impact in the schedule as the excavation cycle would not be able to flow.

Thus, the need arose to align the design models according with each specific discipline tolerance, while the construction is carried out almost in “day by day” basis. To allow this, the decision was to have “point clouds” of the performed excavation contour generating realistic topographic models of the construction, that were immediately federated with the design models, thus being able to see the changes from the performance versus the theoretical designed.

In essence, if any change in the design was necessary both for technical and tolerance issues (secondary lining thickness for example), as well as to meet the minimum space requirements of the other disciplines, the federated model would be a decision-making channel and the fundamental workplace to align all the aspects of the construction.

The fractional value of quality determines the portion of the work being done to enter the pool of work really performed, which will never again require the re-doing. The remaining one will need some rework, but during the time that rework remains in a pool which we term “undiscovered rework”, work that contains as-yet-undetected errors and is therefore perceived as being performed. (Cooper, 1993)

The creation of this federated model combines the point clouds giving the input of the construction at the moment, together with the design models from the different disciplines these constructability problems was shown also these variations that needed to be eventually “solved”.

These types of errors/imperfections natural to this kind of work are traditionally detected “downstream” of the activities and are usually perceived much later. Usually, by then, the dependent jobs have already incorporated and assimilated these issues generating technical and qualitative deviations. Afterwards the level of effort and resources needed to mitigate them are quite high and represent a cost and time overrun that can be quite impactful on such a design and build projects. Sometimes these re-processing are performed again, looping into this cycle of reprocessing once or in additional subsequent times. (Cooper, 1993)

However, they were perceived at a earlier stage in this exercise allowing the proper implementation at each moment of measures to be taken and/or changes to be made. The use of BIM design-build models makes it possible to perceive these hypothetical reworks in advance and to adapt them to accurately re-create, forecast and diagnose the performance in the Project.

Figure 7. Federated BIM model with point clouds model.

Finally, an additional innovation is the capacity of the technical office to input site relevant data that federates with the rest of the models, while carrying the major responsibility of specialties model coordination. Of course, the prevalence of these work models (realistic – “as-built”) over the rest is a sine qua non condition when it comes to coordinating all the disciplines.

5 JOÃO PAULO I EXAMPLE

The concrete case of the deep underground João Paulo I station provides the opportunity to showcase the innovative BIM methodology implemented in São Paulo line 6, as is detailed below with specific examples of the applications carried out on it.

Two major integrations work were carried almost concomitantly while the excavation advances:

- i) the first one was to validate and simulate the possible ground improvements and/or lining reinforcements and their impact on the viability of the architecture, systems, and system subcontractors.
- ii) the second one was the integration of the point cloud with the spaces resulting from blasting excavation. The most significant case was an important overbreak and underbreak. For this particular item, as explained, modeling certain tolerances and spaceproofing was required, while minimizing the rework such as the excavation of underbreaks that could be “incorporated” in the secondary lining.

Figure 8. João Paulo I Federated BIM model.

Successful fast-track projects require timely, clear, and high-quality information to be provided to the construction team by the design team. In order to achieve this information on time and on the desired quality, usually the different disciplines involved in the design overlap and optimize each other. This results in the need for bi-directional exchange of information between the dependent design disciplines, sponsored by the point clouds.

Figure 9. Overbreaks and underbreaks analysis BIM models.

Other case example of this concepts could be seen in the evacuation lateral niches built in the João Paulo I station. Originally these structures were not deemed to be needed and were not foreseen in the overall cavern geometry. Thus, there was an important geotechnical and structural limitation on the sizing and shaping of this lateral tunnel.

While the cavern excavation was already in progress a general task force was done to design and implement such structures in order to deliver a solution that could be still excavated while the main cavern was constructed.

In addition to the strict structural and geotechnic requirements, aspects such as tolerances, headers, escape routes, air extraction, etc., were needed to be taken into account and so decision was to model the space proofing of those points to be able to coordinate, study and consider alternatives; until a coordinated model was achieved, which was finally implemented, and adapted as the blasting was carried out and the scanning was federated and coordinated with the rest of the disciplines, which required further adjustments.

Figure 10. João Paulo I federated BIM model.

In the example of this station, it was made abundantly clear that the discovery of potential rework earlier and immediately avoids a large part of the program-wide disruption, especially in development time impacts. Another advantage of this linkage of design (or construction) models and point clouds models was the possibility of obtaining quantities and measurements, both underbreak and overbreak, which allowed the optimization in construction as well as decisions based on these direct costs.

Figure 11. Federated model: structural BIM models & point clouds model.

Finally, it is worth mentioning that in this graphic part, obtaining images of the construction progress at any given moment in conjunction with the design models has helped a lot in the dissemination and clarity of problems, understanding, changes and progress of the work; thus the coordination of the project and its disciplines and the various (and diverse) agents that participate in it become more dynamic, collaborative and manageable.

6 CONCLUSIONS

In this paper we have presented an approach on how the use of point clouds generated on site, federated to the design models, which has allowed us to quantify and mitigate the impact of rework on construction projects.

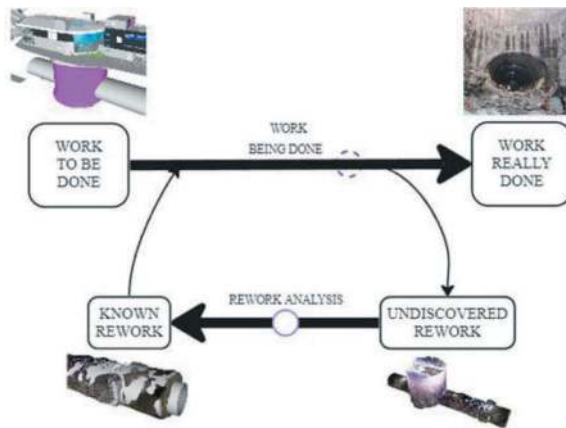

Figure 12. Line 6 - São paulo metro rework cycle.

The use of reality captured for project coordination adds value to the analysis process, since it allows the integration between the construction work and the design in time. Project awareness improves all those involved, since reality captured is a 3D representation of a survey carried out in the field, thus allowing visualization of all the built elements. This allows monitoring the excavation, enabling for example, the verification, quantification, interpretation and mitigation of overbreaks and underbreaks to the extent that there is sufficient space, according to multidisciplinary needs. Additionally, it provides the capacity to visualize the impact of the project changes as well as to extract quantities of the impact of these changes (both positive and negative) and to record rework amount as negative percentage completed of affected activities on the rework dates.

With all this Laser Scanning point clouds and BIM models federation exercise, a complete connection between construction and design, and between the construction site and BIM models, has been performed. This establishes a full collaborative platform, going from design to work and transcending to

the subcontractors; having in real time their interaction with the work performed, being able to coordinate and readjust.

Figure 13. Federated model: structural BIM models & point clouds model.

In summary, this methodology has been exemplary to optimize the decision-making process, based in quantities, and to perform overall corrective actions in a shorter time span, improving and adapting the original designs, generating shorter delays than those taking place in a traditional method.

Matteo Giani
Pini Group SA, Lugano, Switzerland

ABSTRACT: The Sotra Link Project (SLP) is one of Norway’s priority infrastructure projects. It includes the design, construction, financing, maintenance of several underground and surface structures between Sotra island and the city of Bergen. Among them: 23 tunnel portals, 12.5 km of tunnels and a 900 m-long suspension bridge. This paper deals with the application of BIM approach from the Early Design to the Detail Design of tunnels. The benefits of adopting BIM methodology are shown, and consist mainly of: i) better handling of clashes and inconsistencies; ii) better understanding of effective design choices, resulting in a reduction of errors; iii) better communication between different design teams; iv) a greater level of accuracy, ensuring SLP manageability in each design phase. The evidence of the advantages of BIM approach, also in the Construction Phase, is illustrated. In particular, the focus will be on the excavation of the western portal of Kolltveit tunnel and the first stretch of the Kolltveit tunnel with its technical peculiarities. The result of the excavation compared to the theoretical 3D models will also be shown. The SLP contract was awarded in September 2021 and it is currently in the Construction Phase, while the infrastructure will be opened to traffic in 2027.

Keywords: Building Information Modelling, Tunneling, Computational design, Parametric design, Underground structures, Project database, Rock Support

1 INTRODUCTION

The application of BIM methodology in the design and management of a complex infrastructure project is becoming increasingly relevant and essential to ensure the quality of the project, as well as its manageability over time.

The BIM approach is based on the use of three-dimensional, digital BIM models containing both geometric data and information, which are “comprehensive” and “consistent” and work as a centralized source of data. The adoption of BIM in big civil engineering projects has proved to bring important advantages, among them: a general reduction of design errors, better checking of clashes, better management of the construction and maintenance phases (Barbieri et al., 2023). The current paper deals with the adoption of BIM methodology for a complex

infrastructure project in Norway, focusing on the solutions and advantages of BIM in tunnel design and construction.

2 THE SOTRA LINK PROJECT: GENERAL OVERVIEW

The Sotra Link Project (SLP) is a key infrastructure project in the western county of Vestland, Norway. It includes the design, construction, operation and maintenance of a road system connecting the city of Bergen with the island of Sotra. The link includes 9 km of highway, a 900 m-long suspension bridge, 12.5 km of tunnels (Kolltveit, Straume, Knarrevika, Drotningstveit), 19 roads and pedestrian underpasses, 23 tunnel portals, 22 bridges and viaducts, and 14 km of pedestrian and bicycle paths (Figure 1).

*Corresponding author: Guido.Barbieri@pini.group

The Norwegian Public Roads Administration (NPRA) awarded the Public-Private-Partnership (PPP) contract to design, build and operate the project to the “Sotra Link” company (that outsourced the design and construction to the “Sotra Link Construction Joint Venture” SLCJV) in 2021, for a total value of about 2 billion €.

In accordance with the NPRA’s BIM guidelines, the BIM approach was adopted for the design process of the entire project (Barbieri et al., 2023).

Figure 1. SLP: rendering of the new bridge (NPRA, 2021).

2.1 Adoption of BIM in the project

The adoption of BIM methodology in the SLP is mentioned in the tender documents, where it is clearly stated that the project must be based on BIM models. The models must have a “maturity level” of 3 or higher, as defined in UK’s “Government Construction Strategy” documents (BIM Industry Working Group, 2011). This means that the use of BIM models is that of an integrated database that functions as the main source of information of the entire project.

2.1.1 BIM strategy: The BIM Execution Plan (BEP)

Implementing a BIM approach in a complex infrastructure project such as the SLP requires a common strategy and a set of rules for the creation and delivery of digital models. The BIM Execution Plan (BEP) is the main document that provides the framework for the BIM project development, in order to meet the Employer’s Information Requirements (EIR) requested by the final client of the project (the NPRA). The BEP is prepared by SLCJV with the cooperation of the design team and lays the foundation for collaboration in the BIM project, explaining how project information is managed by each party, the roles and responsibilities of each party, and the exchange of data between parties (ISO 19650-2, 2018). To ensure efficient and comprehensive management of project information, the BEP defines a “BIM Information Strategy”, which establishes the framework that enables the delivery and exchange of project information. This

strategy is based on an Object Breakdown Structure (OBS), which organizes project data into hierarchical levels (Area, Discipline, etc.; Figure 2).

Responsibility of the BIM and technical coordination for each area is assigned to a specific design company (called a “task team” in the BEP). The exchange of data between task teams during the design phase, as well as coordination and communication between teams, takes place on a digital platform, the Common Data Environment (CDE), which enables collaboration among the various project teams and parties.

Figure 2. OBS structure of the SLP: project Areas.

In the SLP, the CDE consists of several interconnected platforms. Autodesk Construction Cloud (ACC) is the main part of the CDE where all project data is stored: the various task teams produce BIM models containing the data for a specific OBS and deliver it on ACC for review and validation. The “federation” of BIM models is one of the main advantages of BIM methodology, since it allows for the combination of models from different disciplines into a single, comprehensive model of the project (Shivasami et al., 2023). In the SLP, the federation of models follows the OBS structure: each team creates several “Container Models” that link together BIM models related to a certain Area; these container models are then combined into a single “federated” model (the “Coordination Model”), which allows for continuous coordination and inter-disciplinary verification of design data for the entire project.

2.1.2 Pini Group’s responsibilities in the project

As one of the task teams of the SLP, Pini Group is currently responsible for the design of roads, bridges and structures (together with teams from other companies), as well as for the design of all tunnels in the project, which are located in Areas 02 (Kolltveit), 04 (Straume), 06 (Knarrvika) and 10 (Drotningstvik). These activities mainly concern the geologic characterization of the site, structural/geotechnical design of the tunnels and creation of the BIM models, together with activities on site.

3 THE ADOPTION OF BIM FOR TUNNEL DESIGN

The implementation of BIM methodology for the underground structures in the SLP was based on the integration of all the project data within a centralized project database, consisting of the BIM models and related documentation (drawings and reports), linked together following the Object Breakdown Structure.

To achieve this aim, an integrated processing workflow was set up. The data produced by the various teams of each discipline (geology, geotechnical-structural engineering, road design, etc.) were processed by the BIM Team and integrated in the BIM models. The workflow structure using iterative and automated subprocesses ensured that any changes in design data were quickly integrated into the models.

The data processing workflow is based on the following phases (Figure 3):

1. Production of inputs (geological, geotechnical, structural and road data);
2. Data pre-processing;
3. Implementation of processed data into the BIM models;
4. Upload of BIM models (including the Container Models) to the CDE (ACC) for final review and validation by SLCJV.

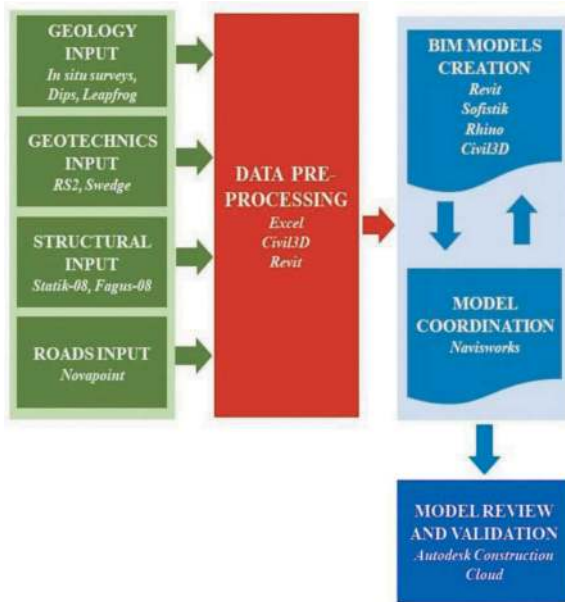

Figure 3. Data processing workflow.

3.1 Data creation and processing

The inputs for the BIM models consisted of data belonging to the various sub-disciplines of the underground works design, mainly geological, geotechnical and structural data. These data were integrated into the BIM models to create a consistent database, which served as the basis for continuous quality control of the design.

3.1.1 Input data

Geological studies of site conditions resulted in a geological model consisting of homogeneous units, depending on the estimated “Q-value” of the rock masses (Barbieri et al., 2023). This model was created with the support of specialized software, including Leapfrog, which made it possible to produce a 3D model of the main geological units, as well as the position of boreholes and faults, for each project area (Figure 4).

Based on this geological model, homogeneous “rock classes” were then defined along the tunnel alignments, with each class associated with a specific type of “rock support”. In the context of the retaining works, tunnel portals and underground structures, the input data for the BIM models (i.e. rock support, shotcrete, bolts, spiling, grouting, formwork geometry, steel reinforcement) were provided by the designers on the basis of Finite Element calculations (Barbieri et al., 2024).

Figure 4. Geological 3D model of Area 10 (Drotningstvik).

3.1.2 Data processing for BIM models implementation

Input data to be implemented in BIM models are provided in a variety of file formats (Excel spreadsheets, CAD drawings, etc.) that must be processed to be transformed into information that can be directly used to create BIM models.

The integration of design data into the BIM model is one of the main challenges of an integrated BIM project. For the underground works of the project, the workflow adopted is synthetically shown in Figure 5 and is divided into two phases: a pre-processing of the “raw” data into a form that can be implemented in the BIM environment; and the model creation, which integrates this data into the model.

3.2 BIM model creation

The second phase of data implementation into digital models is the creation of the BIM models on the basis of pre-processed data. For the underground works of

the SLP, the BIM platform used was Autodesk Revit 2023, along with special plugins dedicated to infrastructure modelling (Sofistik Bridge + Infrastructure Modeler), visual programming environment used for script creation (Dynamo Revit), and the Rhino.Inside plugin, that allowed an interoperability with the powerful CAD software Rhinoceros and its specific visual programming environment, Grasshopper.

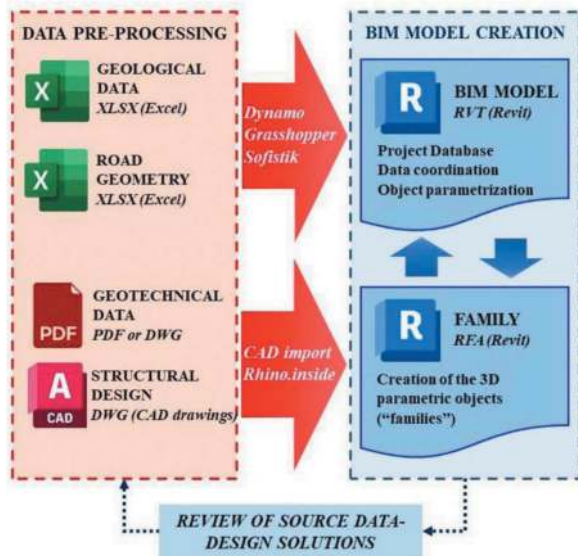

Figure 5. BIM model implementation workflow.

The creation of the BIM models was performed following a strategy consisting mainly of two processes:

1. Creation of classes of parametric objects (“families”) in the Revit BIM software environment, which are then used by dedicated Revit plugins to automatically create structural elements along road alignments, following the inputs provided (this was mainly done for the structures of tunnel tubes and ramps);
2. Automatic creation of model elements and implementation of alphanumeric information in the models, through scripts created ad hoc (using Dynamo and Grasshopper).

3.2.1 Parametric model components: The families

Parametric objects are the basis of the creation of a digital BIM model of a built environment. Model objects are defined as three-dimensional components representing a specific construction element, which contain data attributes and parametric rules (Sacks et al., 2018). A database of families (i.e., classes of digital objects) was created in the BIM software environment, based on pre-processed design data (in many cases, CAD drawings were imported into a view within the BIM software, to create the family and its parametric rules efficiently). The behaviour of individual instances of these families is governed by

parameters that can be manipulated to create a 3D component that faithfully represents the actual construction element.

3.2.2 Automated modelling workflows

Parametric families allow the implementation of semi-automated or fully automated modelling workflows, thanks to the parametric nature of these digital objects. Once the library of families has been prepared, the creation of BIM models can be done efficiently, either using scripts created ad hoc, or through specific BIM software plugins that automatically create instances of the families following the pre-processed input data.

In the case of the rock support bolts for tunnel portals, for example, the position and orientation of the bolts are governed by parametric entities within the bolt family (such as adaptive points, numerical parameters for bolt inclination, etc.) After importing the digital model of the rock cut surfaces of the portals, through scripts made with Dynamo and Grasshopper, a set of reference lines was automatically created from the intersection of the laying plans of the bolts and the excavation surfaces. Another Dynamo script was used to create the bolts along the lines, with the desired spacing and bolt inclination according to the design specifications (Figure 6).

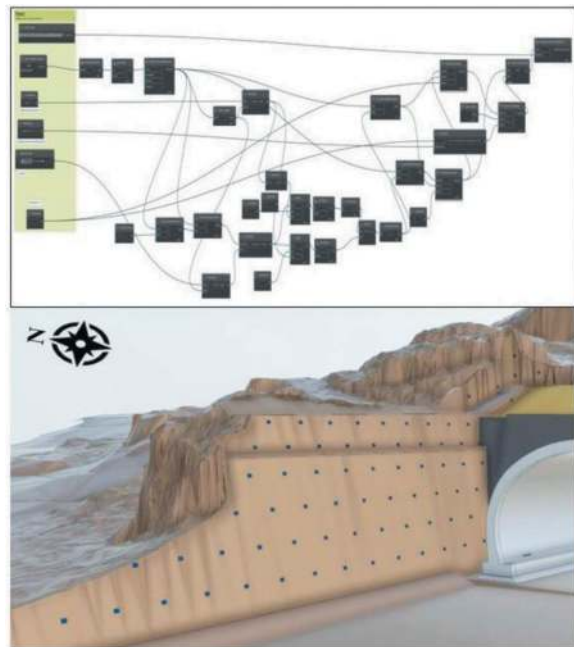

Figure 6. Automated creation of the bolts with Dynamo (Dynamo script; rock support bolts, Kolltveit West portals).

3.2.3 Parametric modelling of tunnel tubes

The BIM approach to infrastructure design is proven appropriate when modelling long structures running along an alignment. In this case, parametric cross sections of the various structural components of the tunnel tubes can be extruded to create the BIM model (Sacks et al., 2018). The initial step in creating the

tunnel tube models was to define a set of parametric families, one for each rock class support. The families contain parameters that control the characteristics of the rock support layer, such as bolt spacing and shotcrete thickness. The values of these parameters were set for each rock support class, following the structural indications and according to the adopted excavation method (“drill and blast”). Once the library of families was ready, the Sofistik Bridge Modeller plugin for Revit enabled the automatic creation of each rock support section of the tunnel. The plugin extruded the parametric cross-section families of each structural component of the rock support (shotcrete, bolts, spiles, shotcrete ribs) following the inputs, which consisted of the stations defining the rock support classes and the road geometry data (Figure 7).

Figure 7. Parametric cross-section family of the rock support of the tube (class IVa); BIM model of the Drotningstvik tunnel tube rock support, with rock support classes shown in false colors.

3.2.4 Automated implementation of object attributes

A fundamental feature of the BIM model is that objects not only have a three-dimensional representation, but also carry with them attributes and properties in alphanumeric format, within specific information parameters (Figure 8). The information content of the BIM model is also referred to as LOI, “Level Of Information” of the model and its objects. According to the client’s requirements, BIM models are the basis for the construction and maintenance phases of the project. This means that the models must contain all the information needed to manage the various phases of the project. More specifically, the model must allow quantity extraction for the BoQ, and model objects must have special attributes that allow 4D and 5D analysis to be performed on the models.

GEO-B10_Bolteplate-type_Bolt-Plate-Type_[mm]	100210x210

Figure 8. Information parameters of a rock support bolt (BIM model of the Kolltveit West portals rock support).

Due to the large number of objects in a model (up to about 12,000 elements for the rock support models of the tubes), an automated implementation of the LOI in model elements was required. The “parametrization” of the models (i.e., populating the object parameters with related information) required the use of scripts created ad hoc within the visual programming environments (Dynamo, Grasshopper). To make automation possible, some specific object properties (such as the object’s “family name”) must follow a codification that allows the use of databases (Excel spreadsheets), containing tables that associate each family with a set of parameter values to be populated in the model objects (Figure 9). The information contained in the database can then be automatically implemented in the parameters of the model objects with a specific Dynamo script (Rich et al., 2023). In this way, the information content of the models can be quickly updated whenever there is a change in the design data.

4 MODEL FEDERATION AND COORDINATION

Model federation is performed following the hierarchy of container models described in the BEP. The federation process is scheduled every week, to have a constantly updated database of the project.

4.1 Model federation

The overall coordination of each project Area is assigned to a specific Area Coordinator, who is the designer (task team) responsible for that Area. Among the responsibilities of the Area Coordinator is the weekly creation of the Area Coordination Model, following the BIM Cycle described in the BEP.

The Area Coordination Model consists of multiple Container Discipline Models, one per designer: each designer creates the Container Discipline Model related to a certain Area by merging all the BIM models related to the disciplines assigned to the designer in that Area. After the Container Discipline Models are uploaded to the CDE (ACC), each Area Coordinator creates the federated Coordination Model as a composition of all the Area's Discipline Container Models, plus the Area's Container Base Model (the model of the Area's existing context). The typical structure of the Area Coordination Model is shown in Figure 10.

The individual BIM models are also regularly uploaded to the CDE for review and validation by the SLCJV. As stated in the BEP, the deliverable BIM models must be in open format (IFC) to enable model interoperability. The models are also georeferenced to allow them to be properly combined in the coordination software environment (Navisworks or Solibri) and on the digital platforms of the CDE.

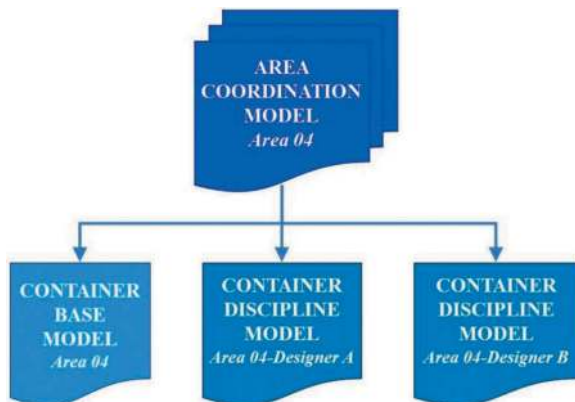

Figure 10. Structure of an Area Coordination Model.

4.2 Model coordination and check

Once created, the Area Coordination Models on ACC are combined into a single complete Coordination Model of the entire SLP. This final model is shared on another digital platform of the CDE, BIMcollab, where the project Coordination Model can be inspected and validated by SLCJV and the final client (Figure 11).

One of the main advantages of BIM methodology is the possibility to inspect and verify multiple disciplines in the same model (Shivasami et al., 2023). The Coordination Model on BIMCollab allows for verification of interference between different disciplines, as well as notification of design problems to designers via BIMCollab's "issue" tool, or through the creation of BCF files. This enable designers to adjust their

design choices in a timely manner and resolve disciplinary interferences, thus reducing the possibility of problems during the construction phase.

Figure 11. Project Coordination Model (Kolltveit tunnel).

5 BIM AND CONSTRUCTION PHASE

In May 2023, the first tunnel of the SLP, the Kolltveit tunnel, began its construction phase, starting from the West portals (Figure 12). In July 2023, the first blasting was carried out at the West portals of Kolltveit tunnel for the west-bound tube.

Figure 12. Kolltveit tunnel, West portals: the construction site in July 2023.

BIM models have proven useful for communication between the design team and the construction team on site and for measuring consistency with the design as the work progressed. Due to local variations in geology from geological prognosis, construction deviations on site were applied in some cases to accommodate unforeseen conditions.

For instance, during the excavation of the West portals of the Kolltveit tunnel, on-site surveys were

carried out with advanced instrumentation and procedures (laser scanning) that enabled the creation of three-dimensional point cloud models of the completed works.

These point clouds files were imported into the model coordination software and then combined with the design BIM models, to verify the adequacy of the built portal pit to the design model. The overlaying of the design BIM model and the point cloud of the finished portal pit is shown in Figure 13. The construction generally followed the design indications in the model, with some variations (especially in the rock cut between the two portals). The westbound and eastbound Kolltveit tunnels also followed the design indication without major variations.

In addition, the use of the point cloud obtained from the laser scanning of the inner lining of the existing old Kolltveit tunnel, which runs close to the new Kolltveit tunnels, allowed the check of the clearance distance between the two infrastructures, in order to make proper design assessments of the impact of tunnel excavation on the existing tunnel.

Figure 13. Coordination between the cloud point model and the BIM model of the design phase: Kolltveit tunnel, West portals.

6 CONCLUSIONS

This paper presented a summary of the main aspects of the implementation of BIM methodology in a complex infrastructure project, focusing on the design and construction of underground structures. Compared with a traditional design process based on 2D drawings and non-integrated project data management, the BIM approach for underground works proved to bring several significant improvements in both the design and construction phases. Despite the initial effort to implement BIM-based procedures within the design team, the benefits of BIM became evident as the design phase progressed. The creation of a single comprehensive digital model of the project that worked as single “source of truth” allowed for more precise control of clashes between disciplines and more efficient resolution of design issues. Collaborative workflows on the shared digital platform enabled better communication between task teams

and between the design team and the client, reducing the possibility of errors and radical construction variations on site. Moreover, the implementation of information in models (LOI) allowed immediate extraction of project quantities from the models, enabling rapid BoQ updating, and formed the basis for accurate 4D and 5D analysis. In conclusion, the application of BIM methodology to infrastructure projects, despite the initial investment by all parties in terms of intense training, has proven to create a more integrated and collaborative approach to infrastructure, with benefits in terms of increased productivity, reduction of costs due to errors, and improved communication between the stakeholders of the project.

The design and BIM activities of the SLP are currently on schedule. The design phase is scheduled to be completed in 2024, and the infrastructure is expected to be completed in 2027.

INFRA-BIM interoperability for Tunnel Renewal

Maurizio Catapano*, Andrea Poli & Roberto Roncoroni
Tecne Autostrade per l'Italia, Milano, Italy

Ana Reis
Tecne Systra-SWS Advanced Tunneling, Torino, Italy

ABSTRACT: BIM methodology is today the driving force behind an ongoing revolution in the Engineering and Construction sector. In parallel with studies on new tunnels, the engineering company TECNE, part of Gruppo Autostrade per l'Italia (Gruppo ASPI), is implementing the so-called Tunnel Renewal Strategy which aims to propose a new approach to Tunnel Rehabilitation Works. Within this framework, TECNE is developing a proprietary BIM approach to the Design of modernization of existing tunnels based on an interoperable workflow. As the studies cover existing tunnels, the BIM approach depends on the input data available (for example endoscopic video surveys, laser scanner surveys, historical documentation). The BIM project is then developed in different phases according to construction sequence: from the demolition of portions of the existing lining up to the reconstruction phase. This Project & Construction Information Model becomes the basis on which it is then possible to implement the Asset Information Model for Facility Management according to the Asset Information Requirements identified jointly with the concessionaire of the Italian Highway aiming to prototype a digital twin in the perspective of better maintenance planning and integrated infrastructure management.

Keywords: Tunneling, BIM, INFRA-BIM, Tunnel Renewal, Interoperability

1 INTRODUCTION

The Italian motorway network has mainly developed between the 1960s and 1970s. By the end of the 1970s, about 70% of the tunnels of the current ASPI network had been opened to traffic, with an overall development of about 55% of the current network (Tecne, 2023).

Therefore, in compliance with the Italian Guidelines for the management and classification of the risk of existing tunnels, the external linings of the tunnels are subject to surveys. The surveys conducted have shown different types of defects affecting portions of the surface area of the tunnels. Therefore, a project is necessary for the implementation of specific structural renewal interventions on the linings.

Rehabilitation consisted of repairing the interior structure, adding a fire-rated wall to comply with modern standards, optimizing the track alignment, and redesigning the drainage, ventilation and electrical systems.

The purpose of this paper is to present an interoperability workflow for the application of the Infra-Building Information Modelling (I-BIM) methodology during the design of rehabilitation of existing tunnels for Italian Highways.

Figure 1. Tunnels of the current ASPI network.

*Corresponding author: maurizio.catapano@tecneautostrade.it

In the IT field, interoperability is conceived as the ability of a system (software) or an information product (hardware) to exchange data, semantic structures and services with other systems and products, in a reliable and resource-optimising manner, with the aim of ensuring interaction between non-homogeneous systems and platforms and reuse of data by them.

The BIM methodology relies on the above principle, as it is based on an approach grounded on:

- the collaboration between the different players involved;
- information management in a sharing environment.

2 TUNNEL RENEWAL STRATEGY

The objective of ASPI Network's Tunnel Renewal Strategy is the extension of tunnel linings' life cycle (i.e., additional 50 years) through the construction of new, structurally autonomous shell structures, replacing the original linings and ensuring suitable performance in case of seismic events. Given the need to minimise the impact on motorway traffic, the implementation of the programme requires innovative technical and technological solutions, i.e. the optimization of structural interventions, the automation and speeding up of operations, the maximization of work productivity and flexibility in terms of sites and logistics in order to allow rapid work site start-up and dismantling, by only closing at night time.

The TRS defines ASPI's strategic approach to address the modernization and renewal plan of the motorway asset, with specific reference to tunnels (about 600 tunnel-tubes on the network), in an organized manner. The TRS aims at the renewal of the design life of tunnels, by meeting a series of key requirements for the works and through the management of network operations, with a view to identifying the most suitable design solutions according to specific traffic conditions as well as the conditions of relevant work sites.

The main requirements defined in the TRS context are:

- safety for operation (in case of alternation of works/ operation and/or works when there is traffic);
- safety for workers (protection, mechanization);
- minimization of impact on traffic (protection, mechanization);
- prompt intervention (mechanization);
- high structural performance (pre-casting operations, high-performing concrete mix, etc.);
- installation of an effective and durable waterproofing system;
- sustainability (asset preservation, recycling, use of vehicles with low environmental impact, materials with low carbon footprint);
- standardization of solutions.

The TRS design solutions are based on the construction of a new lining that is structurally independent from the original one, which shall be partially demolished, without the reduction of the inner profile of the tube or even with an increase of the profile itself in order to ensure compliance with the minimum cross section necessary as established by the regulations in force. A first view of the basic principles characterizing typological intervention in tunnel lining renewal in terms of structural solutions and construction processes is provided herein.

As mentioned above, any intervention requires the demolition of original linings to the minimum extent necessary for the insertion of a new shell to preserve tunnels' outline, while safeguarding the structural integrity of the residual portion that shall act as a temporary support in the transition period preceding the construction of new linings. To this end, one of the main conditions identifying the application context is the state of stress of existing linings. The presence of compression in existing linings due to the state of stress associated with their selfweight determines the definition of a design intervention.

Demolition may be then carried out by means of low-impact technological solutions, such as milling and hydro-demolition. These methods, also considering that demolition is only partial, offer several benefits in terms of reduction/minimization of the workload that would otherwise be required for rock mass consolidation and support in case full demolition of the crown was to be carried out.

Tunnels covered by the structural renovation plan are generally characterized by the absence of linings waterproofing system, which is typical of ASPI network tunnels built before 1980. Crown and walls were casted directly in contact with the adjoining rock mass, with the possible prior installation of temporary supports.

In order to contribute to the durability of new linings, a waterproofing membrane combined with a compensating geotextile layer between the existing residual concrete lining and the newly built one shall then be inserted. However, the whole sealing system shall guarantee the preservation of the original drainage conditions around the cavity, in order to avoid any possible hydraulic overloading as a result of the intervention or of any changes in the hydrogeological setting established over the years. The insertion of the waterproofing and geotextile layer between the new lining and the original one may result in a slip under shear action.

Because of this possibility and due to the basic design hypothesis of a complete performance decay - in the long run - of the residual portion of the original concrete lining and of any temporary supports installed during the excavation of the tunnel, the total static autonomy of the new lining shall be a priority. Therefore, the latter shall ensure that all the safety requirements needed in the long term and in the various project scenarios (including the seismic one), regardless

of the residual resistant contribution of the existing lining, are met (Mazzola et al., 2023).

3 BIM INTEROPERABILITY FRAMEWORK

TECNE, part of Gruppo Autostrade per l'Italia, has decided to implement the BIM process for the rehabilitation of existing tunnels, providing guidelines on the main documental and technical properties on which the model is based and has chosen to require the production of BIM models in the design and construction phase.

3.1 *Italian legislation and building information modeling*

Interoperability has become increasingly important in recent years. Starting from 2016, where the old public procurement code, under Legislative Decree 50/2016, in Art. 23, par. 13, mentioned the use of interoperable platforms through non-proprietary open formats at the discretion of the Contracting Authorities for new assets, as well as for renovation, upgrading or variants, with priority given to complex works, the use of electronic methods and tools. This guideline was conceived in order not to hinder competition between technology providers and the involvement of specific projects among designers.

Less than 2 years later, the legislator decided to attach more importance to the concept of interoperability; therefore, the Ministry of Infrastructure and Transport issued Ministerial Decree 560/2017 to define the mandatory introduction of the BIM methodology in public procurement. Article 4 of the Decree is fully dedicated to interoperability, requiring Contracting Authorities to use interoperable platforms through non-proprietary open formats, where data must remain connected to multidimensional object-oriented models, as well as being retrievable at any stage and by any operator during the design, construction and management of the intervention, according to open and non-proprietary digital formats.

In 2021, under the 'Governance of the National Recovery and Resilience Plan and Initial Measures to Strengthen Administrative Structures and Speed up and Streamline Procedures' the Ministry of Sustainable Infrastructures and Mobility was required to adopt an autonomous ministerial decree providing for rules and technical specifications for the use of specific electronic methods and tools such as modelling methods for construction and infrastructure in procedures relating to public investments partially or fully financed with the resources provided for by the NRP and the NPCI and the programmes co-financed by the European Union Structural Funds, which was to coordinate with M.D. 560/2017, while remaining separate from it.

Ministerial Decree 312/2021 was therefore introduced, not to alter Article 4 of Ministerial Decree 560/2017, but to transform the term "multidimensional models" into "disciplinary information models

and multidimensional aggregates" bringing the concept of interoperability applied to the BIM methodology even closer.

Even the most recent piece of legislation, Legislative Decree 36/2023 for the implementation of Article 1 of Law no. 78, delegating the government in terms of public contracts, in addition to confirming the existing regulatory framework on the subject, it also extends the obligation of interoperability not only to the use of platforms through open formats, but it also requires specific guidelines concerning data and information exchange methods, the provisions relating to the maintenance of the interoperability criteria of the information tools over time, the maintenance of the interoperability characteristics of the information models, the interoperability between works accounting documents and the recording of the controls carried out by the Works Management with the information models.

All the above clearly shows that, over the past seven years, interoperability has evolved considerably, becoming part of the primary objectives of companies wishing to improve and streamline their working procedures based on collaboration facilitated by the exchange of information.

3.2 *Digitalization goals and OpenBIM workflow for existing tunnels*

Since its establishment, Tecne has understood the huge potential of working through the exchange of data and information to make the most of systems and applications chosen based upon its performance requirements.

Furthermore, the legislative framework has over time embraced this trend, especially in those contexts requiring the adoption of digital construction information management methods and tools, in relation to each individual technical-administrative procedure within the contracting authority, for the awarding and execution of public works, services and supply contracts and to ensure maintenance and management of the entire life cycle of the property or infrastructure asset, up to its decommissioning.

Based on the above considerations, Tecne has implemented and invested in OpenBIM tools and expertise, as the method provides a universal approach that fosters collaboration during design, construction and commissioning phases of building construction based on open standards and workflows, capable of:

- promoting a transparent workflow;
- providing a common language;
- providing durable data that can be used throughout the life cycle of the asset.

BIM methodology and tools are designed to facilitate the interoperability of different disciplines, through a system based on open formats (.IFC, .

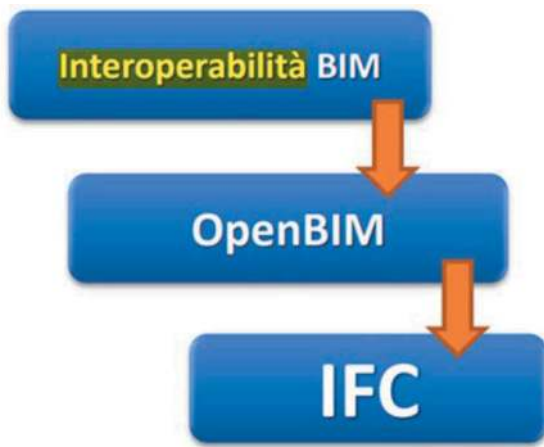

Figure 2. Interoperable workflow based on industry foundation classes format.

BCF, .LandXML, .shp, etc.) that involves every area of engineering from the earliest design stages.

Ensuring a neutral and efficient transfer of information between different disciplines and professionals is now possible thanks to an open format capable of preserving the modelling know-how while maintaining the graphic and alphanumeric information content of the model.

The most popular open formats in BIM modelling are IFC and Land XML.

In order to guarantee interoperability in its processes, Tecne immediately adopted the IFC standard in accordance with the scheme of ISO 16739 and developed its own classification system, associating each type of object with a specific IFC class, distinguishing by discipline and modelling application respecting their specific characteristics.

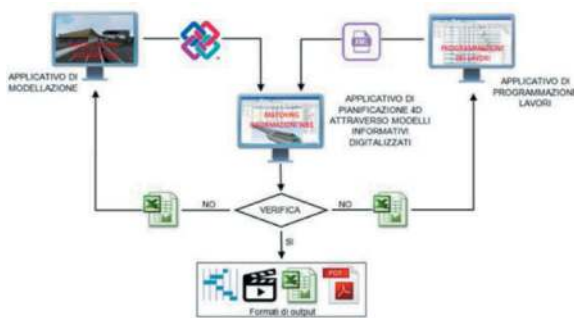

Figure 3. Interoperable workflow with BIM authoring software and work schedule.

Moreover, the company organised its information database by standardising the Property Sets to ensure the transparency and uniqueness of the information transferred in the open format according to the following operational flow:

- breakdown of the project and standardisation of WBS codes;

- compilation of the Property Set by coding each object in the information model;
- transfer of information from the native format to the interoperable IFC (Industry Foundation Classes, ISO 16739-1:2020) format;
- verification and validation of assigned codes through coordination activities (model checking);

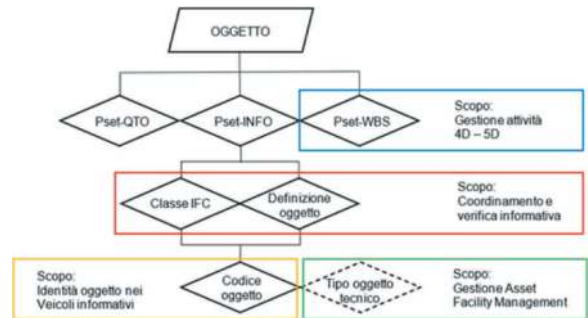

Figure 4. Property set classification for model checking, 4D, 5D and facility management.

The challenge addressed by Tecne is to manage all information assets by applying the processes of verification and coordination (3D), time planning of works (4D) and parametric computation (5D), through information conveyed exclusively by transferring data in open formats according to the diagram in the figure below.

The main data useful to guarantee an information interconnection between processes are retrieved from a well-organised and controlled structure of codes at the various WBS levels assigned to each object, where the structure of any other application (e.g. work programme) must perfectly match the data found within the models, respecting the coding system of the WBS levels and their sequential order.

Such information management is conceived to meet the needs of different BIM uses and must necessarily be subject to a strict verification process of the data structured and organised according to an information flow that Tecne has developed through the support of issues management platforms that allow information exchange by synchronising the information through another type of open format, the BCF (BIM Collaboration Format).

Figure 5. BIM collaboration format for model checking.

The whole co-ordination activity is managed according to a circular flow where the queries stemming from the analysis and verification of the project (so-called Issues) are collected in digital reports (BCFs) via the

Co-ordination software, which in turn generates information exchange according to the steps below:

- the coordination software synchronises the Issues on the information exchange platform through the open BCF format, a true interoperable information carrier. Here, the issues are visualised and commented on by all the operators involved in the project;
- the information exchange platform is then used to download the issues to the modelling software to execute the queries;
- once the operator's queries have been answered, the Issues are again uploaded to the information exchange platform;
- the co-ordination software retrieves the information from the platform and analyses it again, keeping track of all comments.

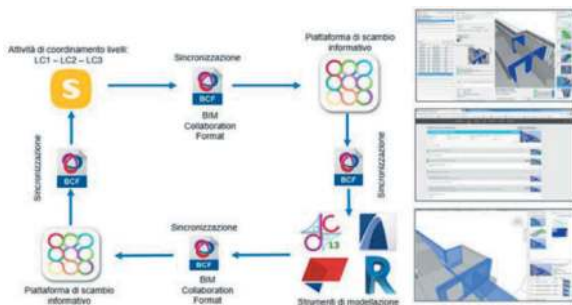

Figure 6. Circular flow of coordination activity and design management.

3.3 Case study

In the case studies different interventions design solutions were developed following the BIM methodology. Interventions solutions for Tunnel renewal or structural reinforcement lining that can include voids fillings on the back of the crown, rock bolts, partial or total demolition of the lining, waterproofing and drainage collection system, installation of steel mesh reinforcement, on-site casting of the new lining and/or lowering the road platform.

As a first step, models for the existing state of the tunnel were developed (model containing information about the different cross sections, portals and voids and compress stress model). In compliance with the design solution, the demolition model is developed. Here, the demolition of the lining and sidewalks were designed accordingly with the solutions for the lining rebuilt, as well as the interventions model with all the information and representation of the design solution such as filling of the voids, rock bolts, proposed lining, steel reinforcement mesh, waterproofing and drainage collection system.

For the development of the information models a workflow has been created with a central 3D tunnel model (OTD), capable of connecting with other models such as civil, geological, geotechnical, and steel and concrete (see Figure 7).

This workflow was created with the purpose of connecting all the disciplines involved in the project, so when receiving new input all the disciplines can update simultaneously and be connected.

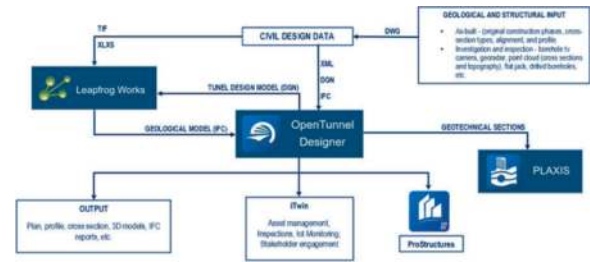

Figure 7. Workflow for the model and design of interventions for tunnel renewal.

The project starts with the analyses of the input data coming from the as-built (original construction phases, cross section types), inspection and investigation (point cloud topography, borehole tv camera, flat jacks, drilled boreholes, defects schedules, etc.). This data is entered in an editable file (xlsx, tif or dwg) in such a way as to allow it to be imported into the modelling softwares and draft models that can provide support for the design of interventions.

The analyses of the existing road and tunnel (tunnel minimum clearance verification) and the reconstruction of tunnel alignments and profiles are performed with a civil software (Civil3D). All the information coming from the civil software is imported as a xml, dgn and IFC file into the 3d tunnel model.

All the data regarding borehole tv camera, flat jacks and topography from the investigations are imported into geologic software (Leapfrog works) as an xlsx file and tif file. This data is used to create a model of the voids that can exist on the back of the crown and to create a flat jack model that shows the concrete compress stress along the tunnel (see Figures 8 and 9).

Figure 8. Voids model (Leapfrog works).

Figure 9. Flat jacks and voids model (Leapfrog works).

The tunnel model can be imported in Leapfrog in a way to have information regarding the tunnel theoretical intrados and extrados.

The models (voids and compress stress models) and topography created in the geologic model are exported in IFC in a way that, in the Tunnel BIM model, the soil meshes, and the voids model will be referenced.

Figure 12. Tunnel renewal model.

Figure 10. Existing model.

In the tunnel BIM model (OTD), templates of the cross section that contain information about theoretical excavations, sub excavations, lining parts reinforcements and material are created. Templates for MEP elements can also be created, such as hydraulic elements for the drainage and collection of the water coming from the rock mass (see Figure 13).

Figure 11. Demolition model.

Figure 13. Waterproofing and drainage collection system solution.

Each modelled object is assigned to a WBS levels code to meet the needs of different BIM uses (4D, 5D, 6D) and the verification process.

In the Tunnel BIM model (OTD) analytical sections are created and exported along with the soil into a geotechnical software (PLAXIS 2D), automatically

with scripting files. The geometric tunnel information and reinforcements and soil material are exported into geotechnical software to proceed with the geotechnical verification (see Figures 14).

Figure 14. Staged construction for the geotechnical verification (PLAXIS 2D).

In parallel, the tunnel units that were modeled in the tunnel BIM model (OTD) are referenced in the steel and concrete software (ProStructures) where the steel bars and detailed elements of the lining steel mesh reinforcement are drafted (see Figure 15).

Figure 15. Steel reinforcement mesh model (ProStructures).

From the tunnel BIM model and steel and concrete model plans, profiles, cross sections, reports, schedules, tables etc. are extracted for the project deliverables.

The main software (OTD) creates a model that can be updated into the cloud and be used for different scenarios such as asset management, inspections, IoT monitoring and stakeholder engagement.

4 CONCLUSIONS AND FUTURE WORKS

The application of Building Information Modelling (BIM) in tunnelling projects is nowadays considered the best option as it allows improving design quality, construction schedule and budget by easily

implementing many operations. The nature of design-build projects necessitates the use of a smart system able to handle a high volume of data in an efficient way.

BIM procedures can be implemented in Gruppo ASPI to facilitate design, construction and operation processes to form a reliable basis for decisions.

Operating according to the principles of interoperability through open formats only is a difficult and challenging choice, as it can call into question well-consolidated and apparently functioning processes until it is time to deal with a public procurement authority that has reached a level of digital maturity in line with the increasingly interoperability-oriented legal provisions.

Once the choice has been made, and, after better consolidating the whole process, the advantages will become tangible, along with a new awareness of the neutral format as the only form of interoperability capable of ensuring fair data control and validation, a standard that is independent of software house formats and that implicitly ensures the reuse of data over time.

Contracting authorities will soon be required to keep data accessible for a long time avoiding the risks stemming from the relentless evolution of proprietary formats. Moreover, in their role as public bodies, they will be required to make their tenders accessible to as many bidders as possible.

Finally, not to be underestimated is the condition for users and public administrations to freely invest in the technology considered to be the best available option, thus minimising their investments and costs.

Finally, in terms of future works, Gruppo ASPI aims to develop an integrated digital twin for each asset which can be used for managing multiple types of tunnelling data in a comprehensive way by creating a digital twin of the tunnelling project.

China Railway 14th Bureau Group Mega Shield Engineering Co., Ltd

ABSTRACT: In response to the welding needs of cutterheads used in tunnel construction, a cutterhead welding mobile robot has been developed to fulfill the demand for efficient and reliable welding processes. Conventional manual welding methods are time-consuming, labor-intensive, and prone to quality issues and safety hazards. The introduction of welding mobile robots facilitates the automation of the welding process, enhancing precision, efficiency, and ensuring worker safety. The design of the tunnel boring machines (TBM) cutterhead welding mobile robot involves several key steps. Firstly, an analysis of the welding requirements and working conditions for cutterheads used in shield tunneling is conducted. This analysis takes into account material properties, joint configurations, welding parameters, and spatial constraints. Based on this analysis, the mechanical structure, control system, and welding tools of the robot are designed and optimized. Specialized algorithms are developed for weld seam recognition, path planning, motion control, and welding parameter optimization. By utilizing precise visual recognition, path planning, and motion control algorithms, the robot accurately positions itself and ensures consistent welding on cutterhead joints. The design of the TBM cutterhead welding mobile robot holds significant research value. The automation of the welding process has improved welding quality, productivity, and worker safety. Ongoing research aims to further optimize the robot's design and control algorithms, ultimately enhancing its performance and expanding its applications within the tunnel construction industry.

Keywords: Mobile welding robot, Path planning, Weld seam recognition, Welding parameter optimization, Tunnel boring machines cutterhead

1 INTRODUCTION

With the development of industrialization and technological advancements, robotic welding technology has found widespread applications across various industries. It's particularly indispensable in the field of heavy machinery manufacturing. Compared to traditional manual welding, utilizing welding robots in welding tasks not only saves labor costs but also enhances welding efficiency and quality, meeting the diverse requirements of different sectors.

The development of welding robot technology has gone through three stages: teach and playback, low intelligence, and high intelligence [1]. The earliest teach and playback robots executed pre-taught programs for repetitive tasks, demanding high consistency in welding but lacking adaptability. Low

intelligence welding robots integrated various sensing technologies, offering some environmental awareness. They could adjust welding paths and parameters based on the actual workpiece conditions, thus improving welding quality. High intelligence welding robots, enabled by digital manufacturing systems and advanced technologies, achieve full welding process automation. This includes scanning, 3D modeling, weld seam recognition, path planning, real-time tracking, and monitoring. Currently, teach and playback and low intelligence welding robot technologies are well-established and widely used in welding applications. In contrast, high intelligence welding robot systems are still in their infancy, with less maturity, limited scope, and higher costs. Nonetheless, they are crucial for realizing the automation, flexibility, and

*Corresponding author: jl_mao@shiep.edu.cn

intelligence of welding manufacturing, representing the inevitable future trend in welding [2].

Tunnel boring machines (TBM) are specialized construction machinery used for underground tunnel excavation, primarily designed for creating tunnels beneath the earth's surface. The key component driving these machines is the cutterhead of the TBM, which plays a pivotal role in the tunneling process [3]. In the manufacturing of the cutterhead, the welding process is extensive. Traditional manual welding methods are not only time-consuming but also lead to lower welding efficiency and quality. Moreover, they pose potential health hazards to the welding operators. To address these challenges [4], this paper introduces a welding system tailored for cutterhead welding in TBM [5], [6]. Utilizing robotic welding offers several advantages. Firstly, it significantly enhances production efficiency and welding speed, ensuring high reliability with the ability to operate continuously, thus guaranteeing welding quality. Secondly, it ensures superior welding quality with a pleasing surface finish, eliminating issues associated with uneven manual welding and reducing the dependence on the skill level of the welder. Finally, robot welding is well-suited for repetitive tasks, often requiring minimal human intervention beyond material supply and monitoring. In the multi-layer and multi-pass welding process of shield tunneling cutterheads, without the support of a vision system, it would typically demand repeated teaching, manual intervention, and could not handle complex groove configurations to ensure weld quality during different layers and passes [7]. Therefore, there's a necessity to introduce intelligent vision-based welding robots to further recognize weld seams.

However, traditional weld seam recognition systems face several challenges, including sensitivity to lighting and environmental conditions, difficulty handling complex weld seams, high real-time demands, the need for manual setup and calibration, and complex data processing requirements [8], [9]. These issues are particularly pronounced in complex tasks such as multi-layer and multi-pass welding. As a result, the field of intelligent welding is increasingly inclined towards utilizing intelligent vision systems, incorporating deep learning neural networks and advanced image processing techniques [10]. These emerging technologies have the potential to overcome the limitations of traditional systems and enhance the accuracy and efficiency of weld seam recognition.

In light of the shortcomings of various conventional approaches, this paper introduces an intelligent vision-based autonomous welding robot with weld seam recognition capabilities. It offers a significant enhancement in welding efficiency and quality for TBM cutterheads. Through a vision system, the robot can instantaneously identify information about weld seam position, shape, and groove, enabling autonomous welding path planning. Consequently, this greatly enhances welding efficiency and quality.

2 BACKGROUND OF MOBILE WELDING SYSTEMS IN TBM CUTTERHEAD WELDING

In the context of TBM cutterhead welding, facing the challenges of massive cutterheads and complex multi-layer, multi-pass welding tasks, the adoption of a mobile welding robot system has become a crucial solution. The background of this project involves the manufacturing and installation of TBM cutterheads, as well as cutterhead cutterbox assembly. Factors such as the enormous size of the cutterhead, multi-piece assembly, various welding bevels, and welding materials increase the complexity and difficulty of welding.

Firstly, the massive dimensions and thickness of the cutterhead necessitate a multi-layer, multi-pass welding process performed by welding robots. The welding robot system must precisely control the movement of the welding torch to ensure welding quality and consistency.

Secondly, various welding bevels need to be considered. In TBM cutterheads, the main bevel types include X-type, Y-type, and K-type. X-type welds are primarily located at thinner cross seams where the cutterheads are joined; Y-type welds are mainly found at the outer edges of the cutterheads, where the steel plates are thicker; K-type welds are predominantly located at the auxiliary support steel plates on the cutterhead's arms that contact the center section of the steel plate [11].

Additionally, considering the scale of the cutterhead, the robot system must have efficient welding capabilities to complete the work within a limited timeframe. The cutterhead's surface can be complex and uneven, so the system needs to accurately control the path to adapt to various surfaces. Since the final size of the cutterhead is massive, the robot system needs to be mounted on a track on the ground to move along the cutterhead's surface for welding.

In conclusion, TBM cutterheads involve complex welding tasks and massive workpiece dimensions, requiring a highly precise welding robot system to accomplish them. This system must not only possess welding capabilities but also take into account factors such as robot motion control, path planning, environmental installation, and welding process parameters to ensure the cutterhead welding is completed smoothly and meets high-quality welding standards. Based on the welding requirements and project background mentioned above, it is advisable to set up a ground track welding experimental platform for various technical tests. The anticipated preview of the final welding project's outcome is shown in Figure 1.

3 TBM CUTTERHEAD MOBILE WELDING ROBOT SYSTEM

The Cutterhead Mobile Welding System developed in this project primarily consists of five main components: the robot body, the visual module, the ground track electrical control system, the welding kit, and

Figure 1. Welding preview image of the TBM cutterhead mobile welding robot.

the welding control software. These components work in synergy to accomplish specific welding tasks. They communicate and exchange data via the Ethernet IP protocol to facilitate functions like arm swinging, visual recognition, precise point control of the ground track system, digital twinning, and the ultimate analysis of welding seam quality. The system's detailed composition is illustrated in Figure 2.

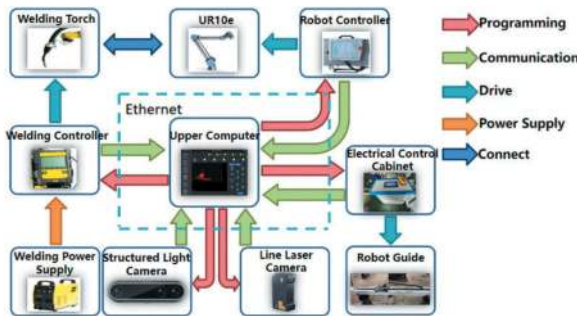

Figure 2. Structure diagram of the mobile welding system.

3.1 Robot

The welding robot body uses the UR10e six-axis industrial robot produced by Universal Robots. It serves as the primary motion platform within the welding system and is programmed and developed using URscript language. The robotic arm executes movements based on received welding trajectories. The robot's end-effector, the welding gun, moves to various positions on the workpiece as directed by the robot's motion. Additionally, the robot can receive control commands from the upper-level computer interface. The robotic arm operates alongside human workers in the same workspace and can flexibly adjust its position and orientation to adapt to various working scenarios and requirements. Furthermore, it possesses reconfigurable and programmable capabilities, allowing it to perform different types of tasks.

3.2 Visual recognition module

The vision module consists of two main components: the structured light camera and the line laser scan camera. The structured light camera is primarily responsible for coarse welding seam recognition, while the line laser scan camera handles fine seam recognition. For Rough Identification, the structured light camera, specifically the Silver Bull R-132 structured light camera, captures RGB-D images of the welding scene. These images are processed using the CenterNet neural network, enabling rapid and accurate identification of the approximate welding seam location. For Precise Identification, the system utilizes the DeepVision SR-7900 line laser scan camera to generate point cloud images. These point cloud images are further processed by mapping depth information to grayscale images using a linear relationship. The Marr-Hildreth edge detection method is applied to identify the welding seam's edges and create bounding boxes, ultimately extracting detailed welding seam data. This dual-camera system provides comprehensive visual data for precise welding seam recognition, ensuring high-quality welding results.

3.3 Welding kit

The welding kit primarily includes a welder, wire feeder, welding gun, and a nozzle cleaning station. The welder employs an Esab welding power source, equipped with overheat, under-voltage, and over-voltage protection mechanisms. It is suitable for various light, medium, and heavy-duty MIG/MAG applications. Standard features encompass built-in optimization curves, arc current, and voltage control, gas checking, 2-step/4-step arc initiation, and inductance adjustment. These functionalities reduce setup time, facilitating high-quality welding results. The Esab wire feeder is an integral component of the welding robot system, responsible for supplying the welding wire to the welding gun. As welding wire serves as the filling material during the welding process, precise control via the wire feeder ensures accurate delivery of the wire to the weld seam, enhancing the automation and precision of the welding process. The TRM605W welding gun is employed for melting the electrode material and forming the weld seam during the welding process. This welding gun employs electric current to heat and melt the electrode material, filling the weld joint with molten metal, establishing a robust connection. The pneumatic welding nozzle cleaner utilizes the SC220ASE model. This essential auxiliary device is mainly utilized for removing slag and impurities from the welding gun nozzle and torch head during the welding process. Its role is to maintain the welding gun in optimal working condition, ensuring welding quality and efficiency.

3.4 Electrical system

The electrical control system for the ground track consists of a PLC, ground track modules, servo motors, and associated low-voltage electrical components. The main control PLC used in this system is the Delta DVP-32EH. The primary function of the PLC is to receive, interpret, and execute commands from the upper-level human-machine interface (HMI). These commands encompass settings related to the robot base, including movement, speed, and positioning parameters. The PLC is also interconnected with the servo system to ensure precise positioning and motion control of the robot base. The servo system comprises servo motors, encoders, and servo drives. The servo motor is responsible for driving the motion of the robot base, while the encoder continuously monitors the base's position in real-time. The servo drive adjusts the operational state of the servo motor based on commands from the PLC, enabling high-precision positioning and motion control. Additionally, the electrical system incorporates an upper-level HMI with a touchscreen interface. This interface allows operators to send commands to the PLC via touch inputs, enabling actions such as setting welding positions. It can also provide fault alerts for potential issues that may occur during the operation.

3.5 Human-machine interaction application software

The welding software section primarily consists of our self-developed digital twin system and weld seam quality analysis software, as shown in Figure 3.

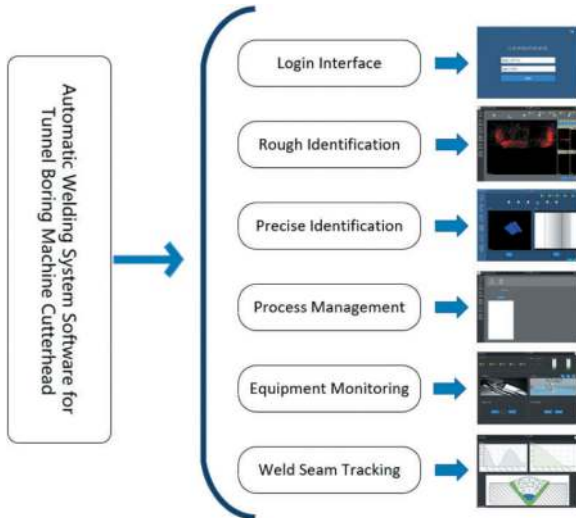

Figure 3. Welding software function overview.

The digital twin system can run synchronously with the actual welding robot. It monitors the welding robot's working status, position, speed, and welding parameters in real-time through sensors and real-time data collection. This allows operators to observe the welding process in real-time on a computer, enhancing control over the welding

work. Furthermore, it provides real-time status information for the mobile welding robot, including welding progress, working speed, welding temperature, and other critical parameters, enabling operators to detect and address potential issues promptly, ensuring welding quality. Lastly, the weld seam quality analysis software facilitates a detailed post-weld analysis. This includes welding quality assessment, welding defect detection, and a review of welding parameters. Operators can use this data to refine the welding process and reduce defect rates.

4 THE IMPLEMENTATION OF KEY TECHNOLOGIES IN MOBILE WELDING SYSTEMS

4.1 Weld seam recognition via multimodal fusion

The system's core comprises two critical visual systems: a structured light camera and a line laser scanning camera. These two cameras work in synergy, providing the robot with highly accurate welding environment perception and task planning through advanced computer vision techniques. Firstly, the project utilizes two different types of cameras, including the structured light camera for rough welding seam position detection, and the line laser scanning camera for more precise three-dimensional groove data acquisition.

4.1.1 Implementation of rough identification

The Rough Identification is performed by the structured light camera. This camera is responsible for capturing RGB-D images of the welding area. The images are transmitted to the upper computer and analyzed using the Centernet convolutional neural network to detect the approximate position of the weld seam [12]. Features processed by residual blocks are readjusted using Channel and Spatial Attention Mechanism (CBAM) (as shown in Figure 4 to reweight the features in both spatial and channel dimensions. These reweighted features are then fused with the features from the decoding layer, allowing the network to make full use of effective features and enhance detection accuracy [13]. The specific process is as follows:

$$\begin{cases} F' = M_C(F) \otimes F \\ F'' = M_S(F') \otimes F' \end{cases} \quad (1)$$

where F is Characteristics of the input; F' is the channel attention and the input features are multiplied by elements to get new features; M_C is the summed result activated by Sigmoid to obtain one-dimensional channel attention; F'' is the resulting 2D spatial attention multiplied by the feature map F' by element to obtain a feature map weighted in both the channel and spatial domains; M_S new features F' are subjected to global maximum pooling and mean pooling by space, and the

resulting 2D vectors are spliced and subjected to convolution and Sigmoid activation operations to obtain the 2D spatial attention.

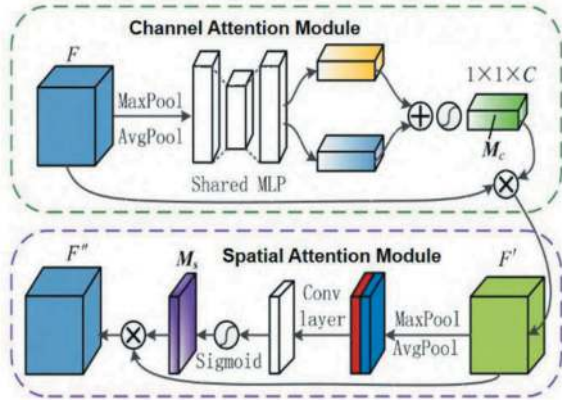

Figure 4. Channel and spatial attention module.

This step is crucial as it provides approximate coordinates and features of the welding area for subsequent tasks. Next, based on the output from the structured light camera, the robot's motion path is planned. This path planning not only ensures that the robot can accurately reach the welding position but also avoids any potential obstacles to ensure safety. The process of Rough Identification is illustrated in Figure 5.

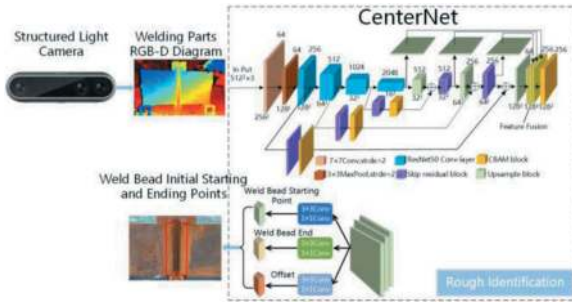

Figure 5. The rough identification process.

4.1.2 Precise identification implementation

Precise Identification is achieved through the intervention of a line laser scanning camera. This camera is responsible for high-precision three-dimensional groove data scanning. The scanning is performed using a line laser camera, followed by direct-pass filtering. Simultaneously, it generates a depth-mapped grayscale image and establishes a 3D-2D coordinate index. Subsequently, threshold segmentation is applied to the depth-mapped grayscale image, followed by further morphological processing. Marr-Hildreth edge detection method is then employed to obtain the two-dimensional coordinates of the weld seam [14].

The Marr-Hildreth steps are as follows:

(1) Gaussian filtering:

Gaussian filtering is used to smooth images and reduce the impact of noise. Define $I'(x, y)$ as the

result of applying a Gaussian filter $G(x, y)$ to the input image $I(x, y)$:

$$I'(x, y) = I(x, y) * G(x, y) \quad (2)$$

where $*$ represents the convolution operation.

(2) Laplace operator:

The Laplace operator is used to detect edges in an image. Define $E(x, y)$ as the edge strength image obtained by applying the Laplacian operator $L(x, y)$ to the smoothed image $I'(x, y)$:

$$E(x, y) = L(x, y) * I'(x, y) \quad (3)$$

where $*$ represents the convolution operation.

(3) Zero-crossing detection:

Zero-crossing detection is used to determine the location of edges. In the context of the edge strength image $E(x, y)$, edge points are determined by comparing the edge strengths of neighboring pixels.

The detected 2D coordinates are combined with the 3D-2D coordinate index previously generated by the low-pass filter. The features of the weld groove are extracted using slope analysis. Once the precise characteristics of the groove are obtained, the upper computer begins the multi-layer, multi-pass welding planning. The Precise Identification process is illustrated in Figure 6.

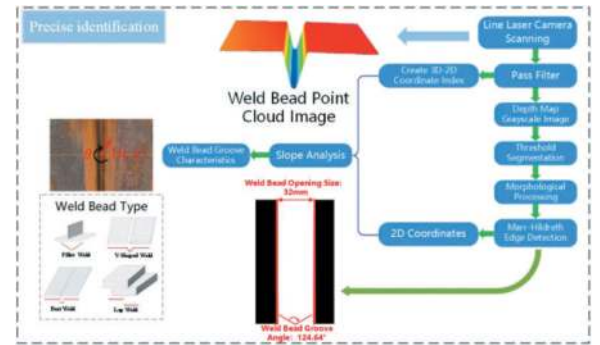

Figure 6. The precise identification process.

4.2 Calculation of multi-layer multi-pass welding groove layer parameters

Based on the point cloud data processed from the previous seam recognition step using structured light and line laser scanning, as well as the seam path information, the multi-layer and multi-pass welding path for the robot is planned. Before planning the multi-layer and multi-pass welding, it's essential to determine the seam layout method. There are generally two layout methods: one is the equal-area seam layout, where each seam has the same cross-sectional area. The other layout is the equal-height layout, where each layer of seams has the same height. Each method has its own advantages and disadvantages [15]. In this system, the equal-height seam layout method is selected for planning and design from the perspective of heat input for each layer of seams.

Next, taking the example of multi-layer and multi-pass welding with a flat butt V-groove, after each pass, there will be some welding deformation in the groove. To minimize the deformation caused by the previous pass, it's essential to adjust the welding sequence appropriately. This adjustment is made to balance the heat input at both ends of the groove and reduce the distortion caused by uneven heat input. Typically, there are two welding sequences to consider. In the left pattern, welding proceeds from left to right, which can lead to the accumulation of heat on one side of the workpiece in a short time, potentially causing distortion at one end of the workpiece. In the right pattern, welding begins on both sides before proceeding to the center. This sequence ensures good fusion between the left and right seams and the sidewalls of the workpiece, while also promoting the evenness of the weld layers. However, this sequence may require the robot to travel a distance without welding, leading to a slight reduction in work efficiency. A comparison of these two welding sequences is depicted in Figure 7.

Figure 7. Welding sequence classification.

For the sake of analysis, during the pre-planning process, the cross-sections of the fill welds are simplified into three shapes: triangles, trapezoids, and rhombuses. If a layer has only one weld seam, its cross-section is a triangle. If there are n seams in a layer, the last one is a trapezoid, while the first $n-1$ seams are rhombuses, where n is greater than 1 [16]. The planning is illustrated in Figure 8.

Figure 8. Welding plan.

In the case of the equal-height weld seam layout, where the height of each weld seam is the same in every layer, the steps to determine the position of a single weld seam are as follows. Define h as the height of each weld layer:

$$h = \frac{H}{n} \quad (4)$$

where H represents the groove height/plate thickness, and n represents the number of weld seam

layers. According to the triangle theorem, the width W_i of the i th layer can be determined as follows, and the width W_{i-1} of the $(i-1)$ th layer is as follows:

$$\begin{cases} W_i = \frac{(i \cdot h)^2}{\cos^2(\frac{\theta}{2})} \cdot \sin \theta \\ W_{i-1} = \frac{((i-1) \cdot h)^2}{\cos^2(\frac{\theta}{2})} \cdot \sin \theta \end{cases} \quad (5)$$

where θ is the groove angle. Based on the equal-height cross-section of the V-groove, A is defined as the length of the diamond-shaped side of the weld seam in each layer:

$$A = \frac{h}{\sin(\frac{\pi}{2} - \frac{\theta}{2})} \quad (6)$$

The entire cross-section of the weld seam in each layer can be approximated as a trapezoid, where S_T is defined as the area of the trapezoid and can be expressed as follows:

$$S_T = \frac{(W_i + W_{i-1}) \cdot h}{2} \quad (7)$$

The parameter S_T is obtained from the above equation. Define T as the number of weld seams in each layer, with the calculation formula provided as follows:

$$T = \left(\frac{S_T}{A \cdot h} \right) + i \cdot \frac{S_T}{A \cdot h} \quad (8)$$

Define B_T as the length of the lower base of the small trapezoid in the last weld seam of each layer, with the calculation formula provided as follows:

$$B_T = W_{i-1} - \left(\left(\frac{S_T}{A \cdot h} \right) \cdot A \right) \quad (9)$$

By applying all of the above formulas, the necessary parameters for weld seam spatial coordinates can be determined. Coordinates of the spatial position of the j -th weld channel in the i -th layer x_{ij} , y_{ij} , z_{ij} , is:

$$\begin{cases} x_{ij} = (x_0 - H_{i-1} \cdot \tan \frac{\theta}{2}) + (A \cdot j) + (B_T \cdot j) \\ y_{ij} = y_0 \\ z_{ij} = z_0 + H_{i-1} \end{cases} \quad (10)$$

Based on the analysis of weld bead arrangement described above, the spatial coordinates for each weld bead in every layer can be calculated. UR robot's offset instructions are used for programming and planning. The main approach is to obtain the start and end positions of the weld bead in the first layer based on visual information and plate data. Then, the offset instructions are used to assign positions for other weld beads and introduce any necessary deviation compensation. Additionally, adjustments are made to the welding torch's orientation during the welding process. This significantly reduces the number of teaching iterations in the welding process and enhances welding efficiency.

4.3 Motion planning for multi-layer and multi-pass welding

Welding paths and trajectory planning are paramount to ensuring the quality of weld seams. To perform arc-shaped motions, typically, three points are required: two endpoints and one intermediate point. These three points determine a spatial plane, which is used for trajectory planning in that plane. Connecting these three points involves two segments of cubic polynomials. It's essential to ensure that the velocity and acceleration are continuous at the intermediate point to avoid sudden changes in velocity, which would otherwise require infinite acceleration. Increasing acceleration in robot control leads to higher drive currents. Therefore, continuity at the intermediate point is crucial [17]. Assuming that the initial time for each segment of the cubic spline is $t=0$, and the final time is $t=t_f$ ($i=1, 2$). Define θ_0 as the initial point, θ_v as the middle point, θ_g as the final point, $\theta_1(t)$ as the first segment of the cubic spline, and $\theta_2(t)$ as the second segment of the cubic spline:

$$\begin{cases} \theta_1(t) = a_{10} + a_{11}t + a_{12}t^2 + a_{13}t^3 \\ \theta_2(t) = a_{20} + a_{21}t + a_{22}t^2 + a_{23}t^3 \end{cases} \quad (11)$$

Applying constraint conditions for each trajectory segment, with the initial velocity and final velocity of each segment being zero, the velocity at the intermediate point [18], and ensuring acceleration continuity, eight constraints can be established as shown in the following equation:

$$\begin{cases} \theta_0 = a_{10} \\ \theta_v = a_{10} + a_{11}t_{f1} + a_{12}t_{f1}^2 + a_{13}t_{f1}^3 \\ \theta_v = a_{20} \\ \theta_g = a_{20} + a_{21}t_{f2} + a_{22}t_{f2}^2 + a_{23}t_{f2}^3 \\ 0 = a_{11} \\ 0 = a_{21} + 2a_{22}t_{f2} + 3a_{23}t_{f2}^2 \\ a_{11} + 2a_{12}t_{f1} + 3a_{13}t_{f1}^2 = a_{21} \\ 2a_{12} + 6a_{13}t_{f1} = 2a_{22} \end{cases} \quad (12)$$

From the eight constraint conditions represented by the eight equations (the first two equations are position constraint conditions for the first segment, the third and fourth equations are position constraint conditions for the second segment, the fifth and sixth equations are constraints for initial and final velocities being 0, and the seventh and eighth equations represent the continuity of velocity and acceleration at the intermediate point) [19], a linear equation system is established with the unknown coefficients, which can be solved to obtain the coefficients for the two segments of the cubic polynomial as follows:

$$\begin{cases} a_{10} = \theta_0 \\ a_{11} = 0 \\ a_{12} = \frac{12\theta_v - 3\theta_g - 9\theta_0}{4t_f^2} \\ a_{13} = \frac{-8\theta_v + 3\theta_g + 5\theta_0}{4t_f^3} \\ a_{20} = \theta_v \\ a_{21} = \frac{3\theta_g - 3\theta_0}{4t_f} \\ a_{22} = \frac{-12\theta_v + 6\theta_g + 6\theta_0}{4t_f^2} \\ a_{23} = \frac{8\theta_v - 5\theta_g - 3\theta_0}{4t_f^3} \end{cases} \quad (13)$$

Following the interpolation algorithm described above, the robot's path and trajectory can be planned, including motions such as the crescent-shaped swing in the welding process of curved or circular weld seams.

5 VERIFICATION OF EXPERIMENTAL RESULTS

In order to verify the stability and reliability of the multi-layer multi-pass welding system, a series of multiple experimental tests were conducted. These experiments focused on different aspects of the system, mainly including the function of the self-developed welding software, the selection of welding process parameters, the effect of visual recognition of weld passes, and the effect of multi-layer multi-pass welding. An experimental test bed was built to conduct experiments on the key functions mentioned above. The results of these experiments will verify the feasibility and stability of the system, as well as help in the further optimization of the system parameters and algorithms and the subsequent upgrading or secondary development, etc., in order to meet various welding scenarios and process requirements. The welding experiment platform is shown in Figure 9.

5.1 Welding software feature

The welding software contains the following functions: Rough Identification image display, Precise Identification image display, weld tracking interface, welding parameter monitoring interface and weld quality analysis interface. The main functions are shown in Figure 10.

5.2 Welding process selection

Welding process parameters have been repeatedly experimental testing were derived priming layer, filler layer, as well as the cover layer of the required welding current, welding arc voltage and shielding gas flow. Specific as shown in Table 1.

Figure 9. Mobile welding robot experiment platform.

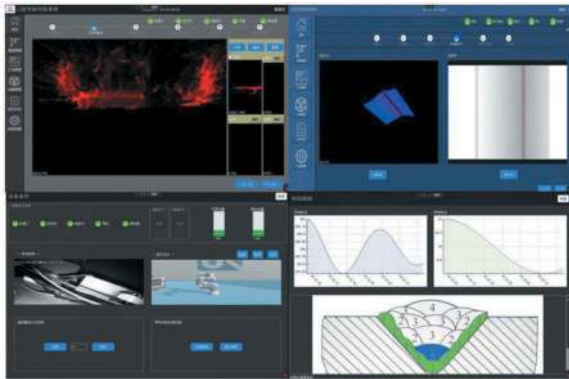

Figure 10. Welding software function demonstration.

Table 1. Welding process parameter table.

weld line	Welding Current/A	Welding Voltage/V	Gas Flow/L*min ⁻¹
underlayer	220-250	25-28	25
filler layer	260-280	30-31	25
covering layer	240-260	28-30	25

5.3 Weld seam recognition results

Structured light cameras and line laser scanning cameras play a crucial role in accurate positioning and bevel measurement during the welding process. In the validation session, a series of identification and measurement experiments will be conducted. First, the positioning accuracy of the structured light camera will be evaluated to ensure its reliability in identifying the weld location. Next, a line laser scanning camera will be utilized to acquire bevel data

and verify its accuracy. The validation results are shown below.

Figure 11. Rough identification and precise identification results.

5.4 Multi-layer multi-pass welding results

In order to verify the welding effect of the system, welding experiments were carried out on the welded plates. The material of the welded structure is Q345B carbon steel with a thickness of about 80mm, which is welded by flat butt welding. Using MAG active gas shielded welding method for physical welding experiments. The welding process is smooth and without anomalies, and the weld filler is uniform. The experimental welds can meet the requirements of the field process. Finally, the Welding results are shown in Figure 12.

Figure 12. Multi-layer and Multi-pass Weld Seam Results.

6 CONCLUSIONS

- (1) Through the use of precise path planning and motion control algorithms, the robot is able to accurately position and weld consistently on the cutter head. Automation of the welding process improves weld quality and reduces variability compared to manual welding.
- (2) The use of mobile robots increases productivity by reducing downtime and enabling continuous operations.
- (3) Implementing welding mobile robots also improves worker safety by reducing worker exposure to hazardous welding environments.
- (4) By automating the welding process, the technology improves weld quality, productivity and worker safety. Ongoing research aims to optimize the robot's design and control algorithms, ultimately improving its performance and expanding its applications in the tunnel construction industry.

Guangdong Provincial Highway Construction co., Guangzhou, China

Jian Liu*

Shen-Zhong Link Management Center, Zhongshan, China

ABSTRACT: The transportation infrastructure still holds a vast market with substantial demand, but the traditional construction methods are increasingly insufficient to cater to the evolving landscape of information technology development. Facing the opportunities and challenges of global technological innovation and application, as well as the requirements of high-quality transportation infrastructure, many countries, such as the United States, Germany and China etc, have introduced national policies aimed at advancing digital and intelligent manufacturing. To successfully build a 5-kilometer-long steel-shell immersed tunnel with eight lanes in both directions, it requires many innovations in manufacturing and construction equipment. These include the implementation of four intelligent manufacturing lines and an intelligent management system for steel tube manufacturing, the use of intelligent pouring robots for self-compacting concrete pouring, the employ of intelligent trolleys for moving an immersed element of 80,000 tons, a floating and installation vessel, and an underwater 3D intelligent gravel foundation leveling system. Through a series of innovative approaches, the project has manufactured and installed all 32 elements, along with a final closure. Notably, the lateral accuracy of approximately 50% of the immersed elements has been maintained within 10mm. Digital and intelligent construction methods have proven to enhance manufacturing and construction quality, reduce safety risks, improve construction efficiency, reduce labor costs, and provide a benchmark for future infrastructure projects.

Keywords: Digital construction, Intelligent manufacturing, Concrete pouring, Floating installation, 3D leveling, Integrated vessel

1 BACKGROUND

1.1 *Digital and intelligent construction technology for the infrastructure*

The transportation infrastructure construction industry, one of the largest industries in the world, has been notably slow to adopt standardization and digital and intelligent innovations. In the recent 35 years of global economic and technological development, the application rate of technologies such as Building Information Modeling (BIM) and intelligent manufacturing in the construction field has only reached 60% (including building construction)^[123]. In contrast, in the past few years, the utilization of advanced technologies such as cloud computing, intelligent equipment, big data, the Internet, and 5G has surpassed 90%.

In 2015, China introduced the “Made in China 2025” strategy, aimed at enhancing quality and

efficiency by accelerating the integration of new-generation information technology with the manufacturing industry. Based on this status quo, the broad prospects for the development of digital and intelligent technologies, point out the direction for future transportation.

At present, China has made significant advancements in cross-sea infrastructure construction technology. The Hong Kong-Zhuhai-Macao (HZM) Bridge, which opened to traffic in 2018, is characterized by its “large-scale, standardization, industrialization, and assembly” approach. However, the infrastructure industry still faces the challenge of integrating digital and intelligent construction technologies with traditional equipment. National major cross-sea projects are urgently needed to drive advancements in “industrialization, digitization, and intelligence” and modern engineering technologies. This will enhance China’s

infrastructure construction in the digital and intelligent era.

1.2 Shen-Zhong Link introduction

The Shen-Zhong fixed sea link across the Pearl River estuary in China is currently under construction, with an expected opening to traffic in 2024. Connecting Shenzhen in the east with the cities of Zhongshan and Guangzhou Nansha in the west (shown in Figure 1), the 24km link spans over and under the world's busiest shipping channels. It features a suspension bridge with a main span of 1,666m, a cable-stayed bridge with a main span of 580m, and transitions on two man-made islands into a 5km long immersed tunnel and a 485m cut-and-cover section extending from the east landfall near Shenzhen (shown in Figure 2).

Figure 1. Project location.

The link comprises a four-lane highway in each direction, for a total of eight lanes, with a special element of six lanes in each direction. It is designed for a traffic speed of 100km/hr and has a design life of 100 years. The immersed tunnel consists of 32 elements, each measuring 10.6m in height, 46m in width, and 165/123m in length, with a 2.2m long closure joint.

Figure 2. Main structures.

2 INTELLIGENT MANUFACTURING SYSTEM FOR STEEL SHELLS

2.1 Challenges

The total amount of steel used for the 32 tubes reaches 320,000 tons, averaging 10,000 tons per tube. The steel plate structure is a composite design,

featuring inner and outer panels as the primary flexural elements, along with transverse and longitudinal diaphragms as the main shear components. All these elements are secured together using stiffeners and welding joints (shown in Figure 3). The cumulative length of the weld seams for a single tube section reaches 270,000m. The components required for traffic engineering, electromechanical facilities and other reserved and embedded facilities amount to 32,000 per tube.

Figure 3. Local details for steel shell.

The geometric tolerance in steel shell manufacturing is set at 10mm between two ends, surpassing the precision requirements of steel box girders and the shipbuilding industry. The inner and outer side panels of the main structure are made of Q420C, with a maximum thickness of 40mm, and the transverse bulkheads constructed from Q390C, with a maximum thickness of 30mm.

To satisfy the overall construction schedule, it was necessary to manufacture one tube per month. Traditional manual fabrication methods for the steel structure proved inadequate for meeting the demands of large-scale, high-efficiency, and high-quality construction required for the Shen-Zhong Link project.

2.2 Four-lines and one-system

To promote the convergence of the shipbuilding and transportation industries, a steel shell small segment workshop, a digitized medium segment piggybacking, and an automated large segment assembly production line were studied and developed. Among these, the small segment intelligent manufacturing workshop takes center stage and is referred to as the “four-lines and one-system” intelligent manufacturing production system. This system encompasses a plate/profile intelligent cutting production line, a sheet intelligent welding production line (shown in Figure 4), a block intelligent welding production line, an intelligent painting production line, and an information

management control system. Together, these components enable the intelligent manufacturing of steel shell tubes, enhancing the manufacturing quality and efficiency, and driving technological advancement in both China's transportation and shipbuilding industries.

Figure 4. Intelligent welding line.

2.3 Achievement

- (1) The utilization rate of steel plates reached 96%, resulting in a savings of 3,436 tons of steel and a total cost reduction of 39.22 million yuan.
- (2) The steel intelligent cutting production line improved efficiency and precision in cutting. This led to a total reduction of 594 labor hours required for grinding and repairs per standard tube, equating to a remarkable saving of 19,008 hours for all 32 tubes.
- (3) The intelligent welding production line demonstrated a marked improvement in the efficiency and quality of sheet body welding, resulting in a reduction of approximately 192.5 labor hours for grinding and repairs per standard tube. For all 32 tubes, this translated to a substantial saving of 6,160 labor hours.
- (4) The block intelligent welding production line made notable strides in both efficiency and welding quality for block assembly. The weld seams were consistently well-formed without the need for additional grinding. In comparison to manual welding, each standard tube can reduce the grinding processing time by about 197.87 hours, resulting in a total saving of 6,331.84 hours for all 32 tubes.
- (5) The construction of the intelligent painting workshop for small segments led to a significant improvement in painting quality and efficiency. A centralized control system enabled remote control for automatic sandblasting and paint spraying, increasing sandblasting efficiency by 50% when compared to manual methods.

3 INTELLIGENT CONCRETE POURING ROBOT

3.1 Challenges

Each tube requires a substantial volume of self-compacting concrete, totaling $28,000\text{m}^3$. This places stringent demands on the concrete's working performance, quality stability, casting process, and precise control of pouring speed. Notably, a strict requirement dictates that the gap between the steel panel and the concrete surface must not exceed 5mm, with a heightened sensitivity to temperature.

Traditional pouring equipment heavily relies on manual labor and lacks precision in controlling pouring stop times, often leading to overflows. Additionally, manual measurements are used to control the height of the concrete surface, hindering real-time monitoring and, consequently, compromising the quality of self-compacting concrete pouring. Moreover, traditional pouring equipment requires leveling the tube surface as it moves, which is further complicated by the presence of numerous vent holes, pouring holes, and fixtures on the tube's surface.

3.2 Concrete pouring robot

To guarantee the quality of concrete pouring, a self-compacting concrete pouring robot and a control system were studied and developed. These intelligent pouring robots, equipped with various sensors (including temperature sensors, locators, and concrete level rangefinders), are capable of automatic concrete distribution and precise control of the pouring process, ensuring high-quality and controlled pouring speeds.

Based on the BIM technologies, intelligent sensing and Internet of Things technologies, an information management system for the whole process of the concrete pouring was developed. This system covers concrete production, transportation, pouring and testing, and harnesses big data for informed decision-making. It enables real-time monitoring, record-keeping, rapid defect identification, and automatic report generation, and enhances the overall quality of concrete pouring while promoting efficiency. (shown in Figure 5&Figure 6).

Figure 5. System control room.

Figure 6. Intelligent pouring robot.

3.3 Achievement

- (1) The project has completed the concrete pouring for all the tubes. And the working and mechanical properties of self-compacting concrete for each tube, have met the specified requirements.
- (2) Through comprehensive testing, it has been confirmed that the gap between the top surface of the concrete and the inner face of the panel of nearly 2,000 compartments aligns with the project requirements. And the waste rate is only 0.4%. This achievement highlights the project's exceptional levels of automation, pouring quality, and on-site waste rate control.

4 TUBE TRANSPORTATION SYSTEM

4.1 Challenges

After the concrete pouring process, each element weighs around 80,000 tons. To meet the requirement of producing one tube per month, the freshly poured tube needs to be transported to the outfitting area within one day to make space for the next one. This involves a transportation distance of up to 220m. Traditionally, a sliding method was employed to move giant components, each weighing over ten thousand tons, such as the 56,000 tons tube of the Oresund Strait Tunnel and the 76,000 tons tube of the HZM Bridge.

However, the equipment used for sliding was both complex and unwieldy to operate. It was challenging to control axis deviation, resulting in low construction efficiency and high operating costs.

4.2 Digital transportation system

The immersed element transportation system consists of 200 hydraulic trolleys equipped with wheel rails, each with a maximum load capacity of 800 tons. These trolleys are organized longitudinally into four rows, with each row containing 50 units (shown in Figure 7).

The development of intelligent horizontal transportation equipment and its control system has greatly improved the efficiency of longitudinally moving an 80,000-ton tube. This system features fixed-distance synchronous movement, precise point-to-point parking, self-correction capabilities, self-leveling support, adaptability, and a maximum full-load moving speed of no less than 1m/min.

Figure 7. Transportation trolley.

To achieve self-balance during the transportation of heavy tubes and minimize the impact of uneven track surfaces on tube deformation, a hydraulic three-point support system is utilized. After conducting a risk analysis, to ensure a smooth transportation process and reduce the effects of hydraulic support system faults, two oil circuits, labeled A and B, were implemented. This configuration accounts for potential oil circuit leakage at specific support points in extreme situations. An additional jack is required to support the original weight, necessitating that the entire transportation equipment be able to handle loads up to 2 times the margin (i.e. a maximum load capacity of 160,000 tons).

This system effectively replaces sliding friction with rolling friction, which reduces the friction resistance during the transportation of tube joints. This, in turn, significantly reduces energy consumption while eliminating the need for sliding plates and lubricating oil. At the same time, a control system has been developed, reducing the demand for construction personnel and improving the working environment, resulting in reduced construction costs.

4.3 Achievement

- (1) Compared to the pushing method involving sliding plates, the number of workers performing each operation has been reduced from 34 to 21. For a single tube, this reduction in labor costs amounts to 78,000 yuan, while management costs are lowered by 300,000 yuan, and consumables expenses are reduced by 690,000 yuan. The cumulative cost saving per tube totals 1 million yuan, achieving considerable economic benefits.
- (2) The transportation distance for a single tube is 220m, and the time is shortened from 7 days of

the HZM sliding technology to 4 hours. This significant reduction in time greatly shortens the overall construction period.

5 INTEGRATED FLOATING AND INSTALLATION VESSEL

5.1 Challenges

Restricted by the on-site conditions, the construction of immersed elements faces a series of technical challenges. These include transporting the elements over long distance (up to 50 kilometers) with a total weight of 80,000 tons, long-distance lateral towing (up to 5 kilometers), and dealing with high cross-current velocities along the foundation trench. Additionally, precision control is required for the deep-water element immersion and docking, especially under the complex conditions of hydro-logical sediments.

The traditional floating and installation methods are inadequate for meeting the requirements of this project. Consequently, the equipment and installation processes for the 32 tubes must meet exceptionally high standards.

5.2 Integrated vessel

Relying on the project, systematic research has been conducted on an integrated vessel for self-propelled transportation, the integrated construction process of floating and the installation of the immersed elements. The development of this vessel hinged on achieving functional integration, merging ship and tube elements, integrating structures, and consolidating power systems. This approach successfully addressed pivotal technical challenges, including ship-element connection technology, automatic trajectory control, resistance to cross-currents, precise positioning of the ship-tube interface, and safety risks during long-distance floating. As a result of these innovations, the efficiency of the floating and installation process more than doubled when compared to traditional technology (shown in Figure 8 & Figure 9).

Figure 8. Integrated vessel.

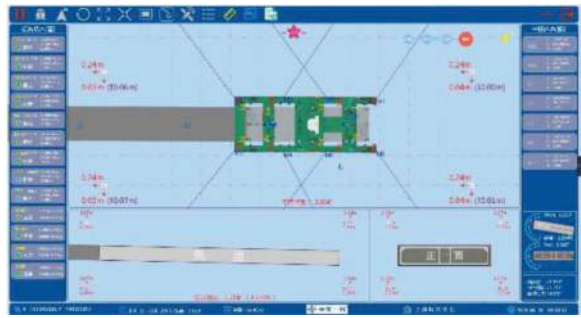

Figure 9. Control system for installation.

5.3 Achievement

- (1) The world's first integrated vessel completed the deep-sea precision docking for 22 elements, with approximately 50% of the elements being installed with a lateral deviation of less than 10mm, significantly surpassing the construction standard of 50mm.
- (2) This vessel established a groundbreaking element installation pace of one per month, thanks to a systematic overhaul of the immersed element floating and installation process.
- (3) The vessel's capabilities included a cruising speed of up to 4 knots per hour, 360° in-situ rotation, and a resistance to cross-current of 1.6 knots.
- (4) The vessel managed to reduce the required dredging volume by 15 million cubic meters, thereby enhancing docking accuracy.

6 UNDERWATER 3D INTELLIGENT GRAVEL FOUNDATION LEVELING SYSTEM

6.1 Challenges

The pre-paving method for the foundation of immersed tunnel construction has high precision, fast paving speed, and strong quality controllability. The underwater gravel foundation paving and leveling are pivotal technologies in the construction of immersed tunnels.

To accommodate the structural characteristics of immersed tunnels, characterized by their ultra-wide span, variable width, large curvature, deep burial, and demand for high work efficiency, it is crucial to minimize the structural dimensions of the leveling frame. This minimization helps reduce the overall scale and draft depth of the vessel, which is more conducive to maintaining control over the frame's deformation.

6.2 Gravel leveling system

The 3D intelligent leveling and dredging vessel is composed of underwater gravel foundation bedding leveling equipment integrated into the working ship (shown in Figure 10). It encompasses vehicle devices, pile leg devices, a leveling funnel, a base frame structure, an electric control system, a measurement and

control system, as well as a skid pipe. The leveling control center, located on the working ship, manages information exchange and control through fiber optic and specialized network transmission cables. The whole process of underwater gravel foundation leveling is characterized by intelligence and full automation.

Figure 10. Diagram of 3D intelligent leveling and dredging vessel

6.3 Achievement

- (1) Combined with single-beam self-scanning, and verified through underwater probing by multi-beam scanning, it is evident that the surface of the gravel base is smooth, the ridges and furrows are clear, and the leveling precision meets the requirements of $\pm 40\text{mm}$.
- (2) The width of the top of the gravel ridge measures no less than 1.8m, in compliance with the design specifications.
- (3) The qualification rate has reached an impressive 98%, exceeding the design requirement of 95%.
- (4) Excluding considerations for the entry and exit of the working ship, the leveling of 2 widths can

be completed within a single day, aligning with the construction requirements.

- (5) Post-immersion measurements for the placement of tubes confirm the elevation control system's authenticity and reliability, underscoring the practicality and effectiveness of the split-width method.

7 CONCLUSIONS

The Shen-Zhong Link immersed tunnel represents a groundbreaking engineering feat, being the world's first two-way eight-lane steel-shell concrete tunnel. This project has presented numerous technological challenges, especially tube manufacturing and immersion for engineers. Through innovation approaches, all 32 elements and one closure joint were successfully installed. The integration of digitized and intelligent equipment played a pivotal role in enhancing the construction process, ultimately improving project quality. Digital and intelligent construction methods have not only elevated the quality of manufacturing and construction, but also mitigated safety risks, boosted construction efficiency, reduced labor costs, and established a benchmark for future infrastructure projects.

Digital strategies-driven optimization of infrastructure maintenance: The case study of the rehabilitation of a disused tunnel in northern Italy

Federico Foria*, Emanuele Moschetti & Mario Calicchio
ETS Srl, Via Benedetto Croce, Rome, Italy

Vlad Grigoras & Burak Boyaci
Bentley Systems, Incorporated, Exton

ABSTRACT: In recent years, the planning and design of existing structures have become critical points within civil engineering and infrastructure management. As structures are often built based on design conditions that may no longer align with their current capacity, there is a need to ensure their preservation and meet modern requirements. Building Information Modeling (BIM) has emerged as a valuable solution to addressing these challenges. By utilizing BIM, a technology and methodology that enables comprehensive digital representation of the infra-structure, designers have now the capability to easily identify and mitigate critical points from the early stages of design by using a best practice engineering approach and clash detection technology. In a specific case study, ETS has undertaken the responsibility for conducting the rehabilitation of a disused tunnel with masonry lining in a harbour area. The intervention is within the framework of the connection between the historic harbour of Genoa (Parco Rugna/Bettolo) and Bivio Fegino. The design process has been carried out with digital strategies for infrastructure maintenance that are very fast and minimally invasive. A new tunnel modelling and design solution, OpenTunnel Designer, has been utilized to digitally model and analyze the existing tunnels. Starting from the digital geometric survey, it becomes feasible to generate precise digital replicas of actual structures. This process not only encompasses the replication of the physical elements but also extends to the digitalization of the construction process itself. As a result, a comprehensive digital twin of the infrastructure is created. By adopting this approach, ETS can streamline the assessment and rehabilitation process, ensuring that the historic tunnel meets modern safety standards and preserving its integrity.

1 INTRODUCTION

1.1 *State of the art*

Infrastructures play a key role in a social and economic life of a country and their strategic value needs to be protected by a solid and reliable plan of maintenance.

The lifespan of tunnel infrastructures is even more longer than other type of structure, and the managing of their aging effects must be a priority for infrastructure owners.

Inspections and diagnosis on structure are the tools in hands of operators that can ensure the asset is guaranteeing safety and structural integrity during the entire operational phase: by a dedicated plan of investigations on infrastructures, it is possible to

manage works and repairs that may be necessary, and verify they are finally effective.

Today standard practise is still based on skills and experience of operators, often equipped only with technical sheets to be filled with analogical information based on each country standards and code. The outcome of the tunnel inspection is usually composed of survey of defects made by a set of photos linked to a location along the tunnel, for the final evaluation for hazard assessment and intervention planning.

This type of analogic approach can lead to the emergence of problems related to data interpretation, human error, inaccuracies in positioning, and insufficient information obtained during inspection, limiting the reliability and reproducibility of the analysis and, most important, invalidating part of the risk assessment.

*Corresponding author: Federico.foria@etsingegneria.it

Moreover, the need to run the inspection works during nighttime and in a rush mode, to reduce the impact on traffic, brings to an increase of risks for workers on the line.

This investigation method, beside the outdated practice compared to nowadays technology, is still the state of the art, it doesn't meet the modern requirement of the civil engineering management and, even worst, a large set of infrastructures worldwide are not checked at all.

As a reference, in China the number of construction accidents shows a rising trend in tunnel projects over the past decade, and it can bring to a public concern in using the infrastructure. Qihu et al. (2016, Qihu et. al) proposed several ways to overcome this problem, including the implementation of the risk management plan by using IT solutions for early warning systems.

1.2 Innovation

To overcome old methodologies in latest period the use of BIM technology and the possibility to work on the digital twin of the structure is becoming always more important in the infrastructures field, especially in the operation and maintenance area, as reported also by Qiuchen Lu et al. (2020, Qiuchen Lu et al.).

The implementation of BIM technology requires a framework able to manage the information and to assess the risk management, in order to express its full potential. This is the background used by ETS to implement MIRET approach (Management and Identification of the Risk for Existing Tunnels), to reach the digitalization of the risk management assessment of existing tunnels. The digitalization of the process starts since the beginning of the data acquisition thanks to a mobile mapping instrument developed by ETS and named ARCHITA.

ARCHITA is equipped with a set of instruments like georadar, thermal camera, tunnel scan, laser scanner and lighting system, and it can run an inspection at a speed of 15 to 30 km/h, aiming to a minimization of the time for traffic disruption, increasing of operators safety and improvement of back-office capabilities.

Use of digitalization in the management of asset is a key to improve the infrastructure safety during lifetime, because authorities and operators can base their decisions on more reliable, objective and trusted data, shared in real time with all the actors involved with the workflow. This type of process can also improve the safety of workers on the line.

In the framework of the digitalization for the realization of the Information Modelling (BIM) ETS specialists decided to test the OpenTunnel Designer developed by Bentley Systems (for tunnel modelling) and Leapfrog (for soil modelling) developed by Seequent. Outcomes from this software for digitally model and analyze the existing tunnels, are described in this paper with the case study of the rehabilitation of disused tunnel between the historic harbour of Genoa and Bivio Fegino in Italy, performed by ETS.

2 INTEGRATED APPROACH

The entire method for the improvement of the management of infrastructures safety is an integration of technologies that gives rise to an interweaving of best practices and modern approaches, starting from on-site inspection phase, analysis of data, use of digital representation of the infrastructures, decisions making phase and planning of further inspections.

Also with the help of BIM technology, MIRET approach is able identify and mitigate critical points of the risk management, while using Archita, the elaboration of digital information becomes easier and reliable.

Since BIM approach comes from the field of building structures type, and it is not always applicable to line infrastructures, an innovative tool, OpenTunnel Designer, was used in the process to overcome some gaps related to the digitalization of a line element, like the tunnel.

2.1 MIRET

To improve the efficiency and safety of infrastructural works, it's fundamental having tools that can allow proper management and identification of the priorities due to their potential manifestation. The availability and management of information relating to the entire lifecycle of an infrastructural asset may be the innovative element, particularly from a strategic perspective, for infrastructure managers. ETS has started investing in a new approach for the manipulation of the survey-inspection data to get a more objective and dynamic diagnostic, maintenance, and risk assessment to manage existing tunnels (Foria, Ferraro, et al., 2021).

MIRET approaches the analysis of the existing tunnels by focusing on an integrated workflow capable of connecting and manipulating survey-inspection data for diagnostics, maintenance and priorities assessment for the management of existing tunnels.

By repeating the process over time, it is possible to have constant monitoring of the work with the advantage of knowing the infrastructure conditions during its lifetime.

Figure 1. MIRET puzzle chart (Foria, Ferraro, et al., 2021).

2.2 BIM workflow

Building Information Modeling (BIM) is a complex system of procedures and technologies to manage building processes.

BIM methodologies, when applied to infrastructure (Infrastructure Building Information Modelling, I-BIM), can offer digital information management, and therefore in a manner that is more effective and can also be used with large-scale infrastructural assets. These methodologies can be successfully applied with considerable advantages in terms of cost reduction and improved management of both material and professional resources (Ciccone *et al.*, 2022).

This process aims to fill and implement the information of the as-built model, through inspection, digitalization and diagnosis of infrastructures to obtain a digital model of the work.

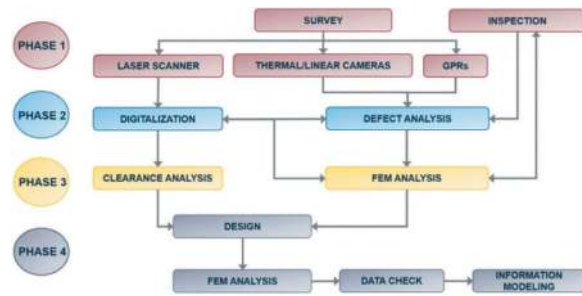

Figure 2. MIRET workflow from survey and inspection to information modelling.

2.3 Opentunnel designer

OpenTunnel Designer has been tailored to improve decisions taking process by being able to combine, organize, and manage geotechnical and existing conditions data quickly and accurately. It makes possible to work with soil strata and linear infrastructure data, as well as reference road, rail corridors and bridge structures. Its capabilities include modelling the full excavation shape, excavation tracks, tunnel lining (conventional and TBM type), reinforcements and interior objects. Native modelling tools help you save design time, by making automatic updates as a result of any change made to the tunnel template or alignment geometry. The entire modelling process is done with built-in parametric tools that do not require the use of visual scripting for parametrization, handling complex geometry or geometry transfer from road/rail civil software.

ETS chooses to adopt this workflow early and it also contributed to his development. The process is used for the digitalization and analysis of data for MIRET methodology the progression in machines' computational power allows solutions devised within the artificial intelligence (AI) framework, efficiently applying the knowledge learnt to the collected data.

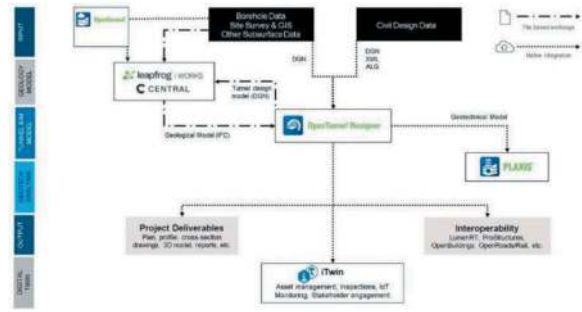

Figure 3. Bentley tunnel design solution workflow.

3 CASE STUDY: DISUSED TUNNEL IN GENOA

ETS, in the framework of the connection between the historical harbour of Genoa, in the “parco Rugno” port terminal, and the “Ex Bivio S. Limbania” worked on the rehabilitation of the existing and disused tunnel (Galleria Molo Nuovo) with masonry lining. ETS specialists chose the MIRET approach with the tool provided by Bentley Systems to achieve digitalized, and reliable model of the tunnel.

Building Information Modelling (BIM) is a process that brings data, models and information together, with the goal of coordinating between the different participants in the building process, reducing risk and increasing efficiency. When applied to infrastructure, BIM methods can offer effective digital information management for large-scale infrastructural assets, such as rail tunnels, especially where it is required to capture large amounts of digital information to create an accurate ‘as-built’ model of the asset in its current state.

Figure 4. Tunnel point cloud model (left) and extracted typical cross section (right).

The project’s first phase involved conducting a laser scan of the tunnel interior and then extracting tunnel cross-sections from the point cloud at each point of interest. Using thermal scanning the approximate lining thickness has been identified along the tunnel length.

Using OpenTunnel Designer native tools, the as-built tunnel cross-sections have been created and used for modelling the initial state of the tunnel. The modelling starts by creating a 2D cross section that contains all the necessary elements for creating the 3D model starting with tunnel lining, reinforcement and auxiliary objects. Using the initial point cloud file and the georeferencing capabilities, one can verify if the created BIM model follows the scanned geometry of the actual asset.

Figure 5. As built tunnel section (left) and as built tunnel BIM model (right).

By utilizing intelligent parametric constrained cross-section geometry, 3D models can be updated dynamically, resulting in a significant reduction in modelling time by up to 50% and drafting time by up to 70%.

Based on the proposed design data, the intervention works have been modelled taking into consideration all required design elements. One critical step during the design of intervention works was the assessment of the soil-structure interaction that has been determined using the geotechnical analyzer, PLAXIS. OpenTunnel Designer is able to automatically create design models for PLAXIS 2D/3D using the information from the physical model. This is a great advantage for geotechnical engineers that now can focus on geotechnical analyses and not on creating input geometry for different cases of design.

Figure 6. Proposed tunnel section (left) and proposed tunnel BIM model (right).

Improving global infrastructure is vital in tackling climate change, environmental issues, sustaining economies, and enhancing the standard of living. Developing and maintaining a digital twin of a physical asset can be highly beneficial in tunnel renovation and maintenance, and it helps us towards achieving these significant sustainability targets. It was therefore possible to create a digital twin of an existing asset by leveraging the iTwin platform capabilities. Using iTwin Experience the users connect engineering, spatial, and enterprise data in one place to better understand the project characteristics and mitigate risk early on from the first stages of design.

One key component in any construction project is represented by the continuous monitorization of different critical elements that have a high impact on the stability of the structure. iTwin IoT platform enables users to seamlessly incorporate data collected by IoT sensors and condition monitoring devices across infrastructure networks, to measure and visualize changes in asset condition, location, or performance, to optimize processes and/or interventions during construction, operations, and maintenance. By securely incorporating real-time data at scale from

hundreds of sensor types, iTwin IoT increases the value of engineering and geotechnical data.

Figure 7. The digital twin of the existing asset with modeled intervention works on iTwin platform.

4 CONCLUSIONS

Digitalization is always more a strategic tool for the improvement of the safety of the infrastructures, and in some cases is also becoming a requirement for calls and competitions.

BIM is a well known tool able to create a digital twin of a structure, but OpenTunnel Designer, a new innovative tool from Bentley Systems, is the game changer tool for infrastructure as tunnels.

The integrated approach of this technology together with MIRET method and ARCHITA instrumentation, developed by ETS srl, gives the possibility to reach the goal of a solid and reliable risk management for existing tunnels maintenance.

Together with the safety improvement, this approach can facilitate the work by reducing the modelling time up to 50%, the drafting time up to 70%, and the 3D geotechnical modelling up to 80%.

Finally, the strict collaboration between different disciplines like geotechnical, drafters and others, combined with the availability of data from the first stage of the project, is a key point for a reliable, reproducible and safe risk management process.

Intelligent technologies and applications on TBM tunnel construction

Weishe Guo*, Kairong Hong & Pan Gao

China Railway Tunnel Group Guangzhou, Guangdong, China

Fengyuan Li

State Key Laboratory of Shield machine and Boring Technology, Zhengzhou, Henan, China

ABSTRACT: In the field of TBM tunneling construction, China Railway Tunnel Group (CRTG) has carried out the exploration and application of intelligent technology including ‘one network’, ‘one platform’ and ‘six applications’. More specifically, ‘one network’ refers to one industrial internet of TBM tunnelling construction, which is built by exploring the interconnection of construction equipment and developing an intelligent equipment acquisition terminal for equipment group in tunnel construction based on IoT technology, in order to standardise the digital interface between different equipment. ‘One platform’ refers to a TBM tunnelling database to standardise the data format, developed through exploring the interaction and fusion of heterogeneous data from multiple sources in tunnel construction, which forms the groundworks for machine learning. Finally, ‘Six applications’ refers to: (1) intelligent interconnection and collaboration of equipment group in TBM tunnel construction based on IoT technology; (2) intelligent TBM tunnelling based on big data and machine learning; (3) online intelligent detection and diagnosis of TBM status based on sensing and communication technologies; (4) Intelligent assembly of arc components based on automatic measurement and obstacle avoidance perception technology; (5) Intelligent assembly of middle partition wall based on machine vision and automatic measurement technology; (6) non-destructive rapid detection and intelligent identification of tunnel structures based on air-coupled radar, 3D scanning and machine vision technology.

The application of the aforementioned intelligent technologies in the Shanghai Urban Railway Airport Connecting Line Lot 11 Project had achieved the reduction of the number of operating personnel by 18 people per shift and the increase of production efficiency by 16%, and the average advance rate of 460 m/month for a 14 m diameter TBM.

Keywords: TBM Tunnelling, intelligent technology, big data, intelligent tunnelling, Internet of Things (IoT), collaboration

1 INTRODUCTION

By 2022, many tunnels have been built in China, including about 25,000 kilometres of railway tunnels [1], about 22,000 kilometres of highway tunnels [2], about 10,000 kilometres of urban metro tunnels [3], and about 47,000 kilometres of water conservancy/hydropower tunnels and other kinds [4]. At present, infrastructure construction still plays a pivotal role in China’s national economy, however, the overall situation of the global economy is not optimistic, and China commits to achieve “Peak Carbon Dioxide Emissions” in 2030 and “Carbon Neutrality” in 2060, all of which have generated an urgent demand for industrial transformation and upgrading and high-quality development [5].

With the rapid aging of China’s social population, resulting in the difficulty of construction companies in recruiting workers, the general trend of transformation

of technology and production method has forced the tunnelling industry to apply intelligent technology[6] and carry out intelligent construction [7].

In this paper, the ways to enhance the level of intelligent TBM tunnel construction are introduced, focusing on “one network, one platform, and six applications”, the role of intelligent technologies in TBM tunnel construction is discussed based on engineering practice, and the prospect and trend of tunnel construction technologies are shared.

2 WAYS TO ENHANCE THE LEVEL OF INTELLIGENT TBM TUNNEL CONSTRUCTION

Normally, the tunnel construction methods include drilling and blasting method [8], TBM method [9], cut-and-cover method and immersed tube method

*Corresponding author: 112899002@qq.com

[10], among which drilling and blasting method and TBM method are the most common.

TBM method is a fully mechanized construction method. The way to improve its intelligent construction level is to make prior knowledge algorithmization [11-12], and to integrate Internet of Things(IOT) technology, with Big Data technology and artificial intelligence technology (AI) on the basis of mechanization construction, and then gradually realize intelligent construction. The path to improve the level of intelligent TBM tunnel construction is shown in Figure 1.

Figure 1. Path to improve the level of TBM tunnel intelligent construction.

3 OVERVIEW OF THE APPLICATION IN PROJECTS

“One network, one platform, and six applications” are the result of a R&D project that has been carried out by CRTG and the Shanghai Rail Transit Airport Link Line Lot 11 is the first demonstration project.

The Shanghai Rail Transit Airport Link Line is an urban railway connecting Shanghai Hongqiao Airport and Pudong Airport with a operation speed of 160Km/h. After completion, the transit time between Hongqiao Airport and Pudong Airport will be shortened from the current 2h to 40min.

The Lot 11 of the airport line is located near Lingkong Road, Chuansha Town, Pudong District, Shanghai. The project scope of works includes a TBM launching shaft in Lingkong Road and a tunnel section in length of 4.721km from Lingkong Road to Resort Station, which is excavated by an air-cushion slurry balance TBM with a diameter of 14.04m. The tunnel internal structures adopting prefabricated assembly design is shown in Figure 2. Among them, the size of three-hole arc-shaped components is 9.5 m × 2.834 m × 2m and the weight is 33.6 t; the size of the middle partition wall is 9.116 m × 0.4m × 2 m and the weight is 22.65 t.

4 “ONE NETWORK, ONE PLATFORM AND SIX APPLICATIONS” IN TBM CONSTRUCTION

4.1 “One network” - industrial internet of TBM tunnel construction

By applying IoT technology, CRTG research team broke through the barriers of multi-type, multi-

Figure 2. Layout of Shanghai rail transit airport connecting line project.

protocol and multi-data of engineering equipment used in TBM tunnel construction, developed a series of intelligent acquisition terminals, and created an end-edge-cloud collaborative industrial internet of TBM tunnel construction [13].

In view of the multiple types and multiple protocols of TBM construction equipment, the team solved the problem of equipment adaptive access, developed a series of intelligent acquisition terminals suitable for edge-cloud collaborative processing, and realized the real-time acquisition of PLC data of TBM tunnel group equipment.

For the structured data of TBM mainframe and group equipment, the OPC protocol was adopted to unify ontology models and data interfaces; for semi-structured or unstructured resource data such as geological data and design documents, digitization and vectorization were performed; the fusion of multi-source heterogeneous tunnel construction data was realized, and the big data dictionary was formed.

Based on 5G technology, the end-edge-cloud network architecture was adopted, the data was initially cleaned, processed, denoised, VPN-encrypted and sent to the big data center in the cloud, and the industrial Internet for TBM tunnel intelligent construction was constructed, realizing the data acquisition, fusion and governance of all the elements of TBM construction. The structure of industrial Internet for TBM construction is shown in Figure 3.

Figure 3. The structure of industrial internet for TBM construction.

4.2 “One platform” – a TBM construction big data platform

Based on the industrial Internet structure of TBM construction, a TBM construction big data platform

has been built by adopting Hadoop distributed big data cluster technology architecture and open-source databases such as Hbase and advanced stream processing platforms like Kafka. The data lake governance storage architecture is adopted to process the massive data, which realizes the fusion of multi-source heterogeneous data such as TBM engineering geological, construction environment, group equipment, tunnel structure and so on.

The file security encryption and filtering system is developed in the Platform, which realizes the isolation of client application data. The data calling authority rules solves the problem of customer data privacy and realizes data security, sharing and interaction based on data lake architecture.

The industrial big data platform has the functions of storage, cleaning, and application, from which was developed a system of intelligent monitoring, comprehensive analysis, collaborative management and intelligent application. See Figure 4 for the big data platform for TBM projects. The platform services 590 more projects and accumulates sample data of 152T, which provides the data base and primary platform for the industry.

Figure 4. Big data platform of TBM construction.

4.3 “Six applications”

4.3.1 Application 1: Intelligent interconnection and collaborative management of equipment group for TBM tunnel construction

Based on TBM industrial internet, the intelligent interconnection and collaborative management of equipment group including TBM host, arc-shaped components assembly robot, partition wall assembly robot, material transport locomotive, vertical lifting equipment, slurry treatment equipment, etc, has been achieved.

Based on data governance and fusion technology combined with TBM construction characteristics, the intelligent monitoring of equipment group operation data, comprehensive analysis of parameters, cooperative management and control, navigating tunnelling, and monitoring and command, the cooperative operation of equipment group in TBM construction has been realized, which improves tunnelling efficiency, enhances equipment risk avoidance ability and enhances the comprehensive utility of equipment group.

This application has significantly reduced equipment failure rate and improved equipment use efficiency. By applying this system, the equipment operation and maintenance personnel have been reduced by 5 persons in Shanghai Railway Airport Line Project, and the utilization rate of equipment has been increased by 10% and the construction production efficiency has been increased by 16%.

4.3.2 Application 2: Intelligent tunnelling driven by mechanism-data hybrid

Intelligent tunnelling is an artificial intelligence algorithm model that is trained by massive big data such as TBM tunnelling data, equipment data and engineering geological data. After training in the cloud computing center, the intelligent tunnelling model is

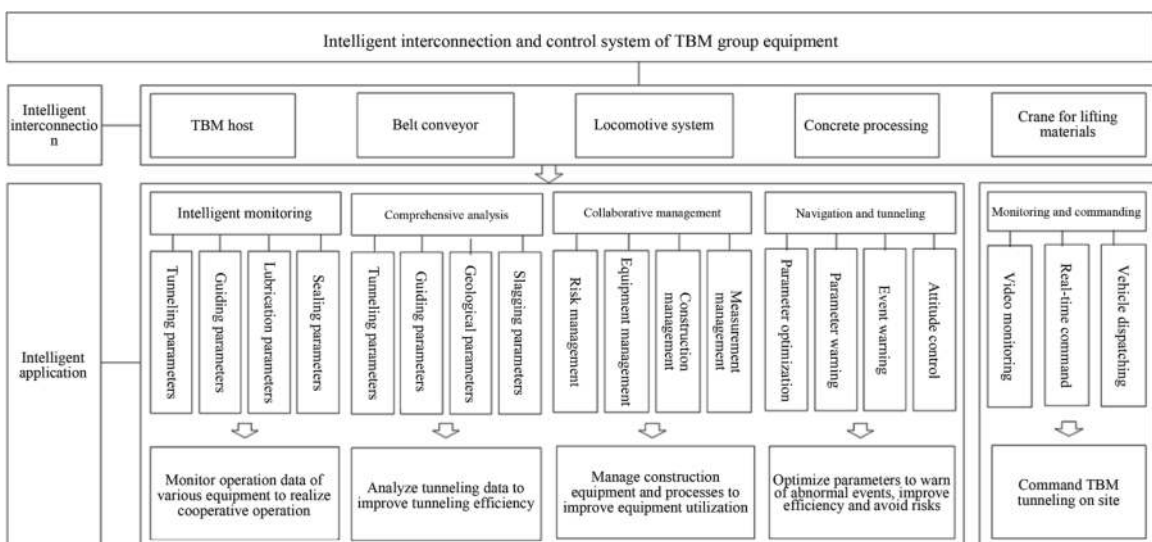

Figure 5. Intelligent interconnection and management system.

deployed on the edge server near the TBM machine [14], and the edge server completes the related calculation and inference tasks with extremely high speed, and then instructs the control terminal to execute tunnelling operations.

The specific principle and process are as follows: Real-time tunnelling data, equipment data and engineering geological data during TBM tunnelling are uploaded to TBM big data platform; and the active tunnelling model, tunnelling parameter recommendation model, attitude control model, abnormal event warning model are trained and managed by the big data platform (see Figure 6 - technical route of TBM active parameter prediction).

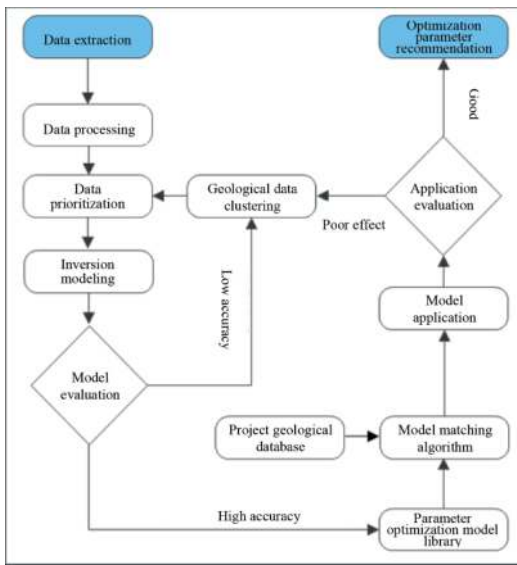

Figure 6. Technical route of TBM active parameter prediction.

After the effect of the relevant intelligent model is verified, it is deployed to the edge server, which provides the TBM control terminal with extremely low-latency intelligent model data service which is not limited by the bandwidth of the communication operators. During intelligent tunnelling, the edge server calculates the relevant intelligent model and immediately transmits the recommended parameters and commands to the control terminal; the control terminal perceived the TBM equipment parameter data in real time in an all-round way, and the edge server carries out lightweight processing on the data and uploads it to the big data platform. This process was repeated continuously in the intelligent tunneling to obtain stable and controllable tunneling parameters and optimal attitude.

The cloud is responsible for the training of intelligent algorithm models, edge for the deployment and feedback of intelligent algorithms, and the end for control and execution. The core of cloud-edge-end architecture is in the cloud, the key is in the edge, and the control is in the end.

The TBM intelligent tunnelling system based on big data was applied to the Shanghai Railway

Airport Line Project, and the TBM tunnelling is “under surveillance but unmanned”, which reduced two TBM operators per shift. The overall technical route of intelligent tunnelling is shown in Figure 7.

Figure 7. The overall technical route of intelligent tunnelling.

Currently, the algorithm model of intelligent tunnelling is trained by similar historic data and parameter, especially the similar geological data at same region. The research work of combining tunnel advance geological forecast data and historical tunnelling data to train intelligent tunnelling algorithm model is in progress.

4.3.3 Application 3: Real-time online monitoring and diagnosis of TBM equipment status

TBM is highly-integrated large equipment, and manual inspection and offline detection can no longer meet its daily maintenance needs. As more TBMs are put into use, real-time on-line monitoring and diagnosis of equipment status is becoming more and more important. Based on sensing communication technology, CRTG develops real-time on-line system for monitoring and diagnosis Principle of TBM status on-line monitoring system is shown in Figure 8.

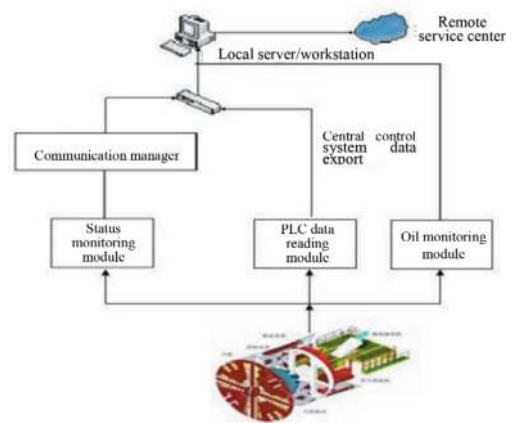

Figure 8. Principle of TBM status on-line monitoring system.

The system can realize automatic acquisition and analysis of (1) vibration, temperature, cutter head torque, bearing running time and other parameters of hydraulic pump unit, main bearing and gear reducer;

(2) viscosity, density, dielectric constant, moisture and laser particle of hydraulic oil; (3) viscosity, moisture, metal particle and laser particle of gear oil.

Based on the big data of TBM operation status, it is feasible to carry out the analysis of equipment operation status, risk and failure early warning and equipment operation trend, etc. The system can protect TBM avoid major losses caused by the damage of core components under complex condition. Figure 9 is the deployment and operation diagram of TBM status online detection system.

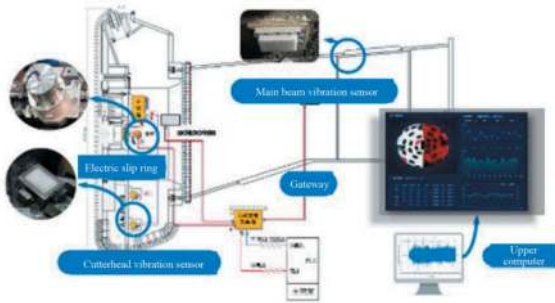

Figure 9. The deployment and operation diagram of TBM status online detection system.

4.3.4 Application 4: Intelligent assembly of arc components based on automatic measurement and obstacle avoidance perception technology

The arc-shaped components assembling robot is designed as double-frame structure of main frame and auxiliary frame. The robot consists of main frame, auxiliary frame, fine-tuning platform, hydraulic system and intelligent control system (see Figure-10). Overall dimension is $6530 \times 3200 \times 2609\text{mm}$ and the weight is 35t. Artificial intelligence technologies such as automatic measurement, obstacle avoidance perception and intelligent algorithm are applied in the robot. Automatic assembly can be realized by only pushing the button.

Figure 10. The frame structure of arc-shaped components assembly robot.

The assembly accuracy can be precise to millimeter. Only one person is needed for the operation of the robot, which saves 4 people compared with the traditional assembly. The on-site assembly operation is shown in Figure 11.

Figure 11. Arc-shaped components assembly robot on-site operation.

4.3.5 Application 5: Intelligent assembly of middle partition wall based on machine vision and automatic measurement technology

The middle partition wall assembly robot is designed as stretchable portal structure, which is composed of main frame, grasping mechanism, stretchable mechanism, rotating mechanism, conveying mechanism, walking system, hydraulic system, intelligent control system and working platform (see Figure-12). The robot is designed as walk-through type with large headroom. The overall size is $11576 \times 4350 \times 6185\text{mm}$, which allows construction vehicles to cross. The dead weight of the robot is 80t.

Figure 12. Structure of middle partition wall assembly robot.

Artificial intelligence technologies such as machine vision, automatic measurement and intelligent algorithm are applied in the robot. Only by pushing one button, it will automatically start matching holes, grasping and rotation, which realizes algorithm decision-making and automatic assembly.

The assembly accuracy can be precise to millimeter. Only one person is needed for the operation of the robot, which is 10 times higher in efficiency, and saves 7 people compared with the traditional cast-in-situ operation. The on-site assembly operation is shown in Figure 13.

4.3.6 Application 6: Rapid non-destructive intelligent detection of tunnel structural health

The system integrates non-contact multi-channel air-coupled ground penetrating radar, machine vision inspection and 3D laser scanning, which can realize rapid non-destructive detection and intelligent

Figure 13. Partition wall assembly robot on-site operation.

identification of internal damages, apparent damages, geometric and spatial deformation of tunnel lining structures. The intelligent comprehensive detection vehicle is shown in Figure 14.

Figure 14. Intelligent comprehensive detection tunnel vehicle.

Comprehensive detection efficiency of air-coupled ground penetrating radar system is 10 ~ 40km/h, which is efficient to detect internal damages of tunnel structures by non-contact detection with detection distance of 0.5~4.5 m.

The machine vision technology can provide a lining crack recognition accuracy of 0.2mm, lining split recognition accuracy of 3mm × 3mm, and water leakage recognition accuracy of 20mm × 20mm; while the 3D laser scanning technology can provide a leakage recognition accuracy of ≤ 20mm × 20mm and a ranging accuracy of ± 1mm. By adopting the modular design, the inspection cabin of the intelligent inspection equipment can be mounted on a vehicle chassis, a railroad flat car and other carriers to perform non-destructive quality testing during the entire life cycle of railroads, highways, urban rail transit and other projects. Figure 15 are the on-site operation of TBM tunnel structure detection.

5 SUMMARY OF APPLICATION EFFECT

The above intelligent applications have been applied and verified in the Shanghai Airport Link Line Project, which have achieved the reduction of manpower, increase in efficiency and safety assurance.

Figure 15. On-site operation of TBM tunnel structure detection.

5.1 Reduction of operators

The application of Equipment Group Interconnection Collaborative Management System for TBM tunneling has reduced 6 personnels for equipment operation and maintenance; by using the intelligent tunnelling system, the number of operators is reduced from 3 to 1; 3 operators are reduced after using arc-shaped components assembly robot and 7 operators are reduced after using partition wall assembly robot. A total of 18 operators are reduced in Shanghai Airport Line Project through the above applications. The advantages of intelligent construction technology compared with traditional construction technology are shown in Table 1 below:

5.2 Efficiency improvement

These applications have improved the production efficiency of the project by 16% in the Shanghai Airport Line Project. Among them, the equipment group interconnection collaborative management system improves equipment utilization rate by 10%; Compared with the traditional assembly process, the efficiency of the arc-shaped components assembly robot is improved by 3 times; Compared with the traditional operation, the efficiency of the middle partition wall assembly robot is increased by 10 times.

5.3 Precision and quality

According to statistics, the accuracy of the tunnel axis after the application of intelligent tunnelling system is significantly improved, as shown in Figure 16; After the application of arc-shaped components and middle partition wall assembly robots, the construction accuracy has been improved from centimeter level to millimeter level compared with the traditional operation method.

Table 1. Comparison of the advantages of intelligent construction technology over traditional construction technology.

Type	Number of workers per shift				Construction Efficiency				Construction Accuracy
	Equipment Operation and Maintenance Management	Tunneling System Operation	construction of arc components	construction of middle partition wall	Equipment utilization rate/%	Average Monthly Progress/m/month	construction time for arc components/min	construction time for middle partition wall/min	Tunnel Alignment Deviation/mm
Traditional Construction	9	3	4	8	75.2	360	60	386	±50mm
Intelligent construction	3	1	1	1	85.1	420m	22	38	Less than ±10mm

Figure 16. Line chart comparing axis control of intelligent tunneling and manual tunneling.

5.4 Economic benefits

After the application of the research results in the Shanghai rail transit airport Link line lot 11, the cumulative economic benefits of 22.98 million RMB have been generated. Among them, labor cost savings of 5.06 million RMB, TBM equipment savings of 16.2 million RMB, water and electricity savings of 1.72 million RMB. After applying intelligent construction technology, the savings in various direct costs are shown in Table 2 as follows.

6 CONCLUSION AND DISCUSSION

In the current situation of global economic development, it is a general trend to study and explore the

less human or even unmanned in the construction process by applying the new generation of information technology.

6.1 Application of intelligent technology and developing intelligent construction is the direction of the high-quality development of tunnel industry

It is an inevitable trend of society to upgrade construction from mechanization to intelligence. Intelligent construction can improve productivity and realize high efficiency, high quality, energy saving and emission reduction, which is the direction of high-quality development in the industry. The main driving force of the intelligent transformation and upgrading for tunnel construction to intelligence comes from both external and internal aspects. In external aspect, with the rapid development of digital information and intelligent technology and technology spillover, as well as national demands on industrial transformation and high-quality development, the tunnel industry is driven to achieve digital transformation and intelligent construction. In internal aspect, the slowdown of global economic growth, the increasingly fierce market competition, and the aging population have forced the industry itself to take the initiative to develop intelligent construction. In

Table 2. Direct cost savings after applying intelligent construction technology.

Type	Details	Unit Price	Quantity	Subtotal/RMB
labor costs	equipment operation and maintenance management	15000 RMB/month	6person×2.5month	22.5
	construction of arc components	500 RMB/day	3person×296day +4person×83day	61
	construction of middle partition wall	500 RMB/day	7person×118day +8person×98day	80.5
	tunneling system operation	25000 RMB/month	2person×12month	60
	material management	8000 RMB/month	2person×24month	38.4
	project management personnel salary	15000 RMB/month	65person×2.5-month	243.75
TBM equipment rent costs	/	21600 RMB/m	10m×75day	1620
water and electricity costs	/	23000 RMB/day	75day	172.5
total	/			2298.65

this course, enterprises with long-term vision and quick action will take the lead and lay the foundation for their invincible position.

6.2 *“Prefabrication + assembly + interconnection and collaboration based on big data” will become the construction trend*

TBM tunnel can provide favorable innate conditions for intelligent construction, while tunnelling by drilling and blasting with relatively simple geological conditions are also relatively ideal scenes for intelligent construction. The prefabrication of components in factory base on digitalization, and rapid intelligent assembly on site, and the realization of assembly line operation will become the trend of tunnel construction.

6.3 *Intelligent construction will inject new vitality into the tunnelling industry and promote industry upgrading*

In the foreseeable future, tunnel construction will realize the transformation from roughness to precision, from more labor to few or even none, from low-efficiency and high-consumption to high-efficiency and low-consumption. The iterative upgrading of machine learning based on engineering big data will inject enormous vitality into the tunneling industry.

Final words: The Big data platform of TBM construction is definitely an open platform that can be used by the worldwide tunnelling community, including manufacturer, contractor, designer, engineers. And we know that although the application research of intelligent technology in TBM tunnel construction has made some achievements, there is still a significant gap between realizing the goal of TBM tunnel intelligent construction. In order to accelerate the development progress, we are eager to have more TBM equipment connected to the Big data platform of TBM construction. We will provide mature intelligent applications for each connected TBM, such as assisted navigation tunnelling, abnormal event warning, intelligent monitoring, comprehensive analysis, collaborative management, etc.

ABSTRACT: As an essential infrastructure for urban construction and development, rail transit engineering is currently experiencing rapid growth. Considering the future development of cities, shield tunnel construction for urban rail transit is becoming increasingly common. With urban development, the underground environment has become more complex, posing uncertainties for shield tunnel construction, such as intricate geology, underground municipal pipelines, existing underground structures, and operational urban rail lines. Effectively and safely conducting shield tunnel construction has become one of significant challenges in metro engineering. This paper explores a fine management approach for urban rail transit shield tunnel construction using Building Information modelling (BIM) technology. Firstly, BIM technology is applied to integrate various elements along the urban rail transit alignment, creating a comprehensive spatial model for shield tunnel excavation. Then, based on relevant BIM standards and mapping rules, real-time parameters and construction status are linked to the BIM model to facilitate dynamic monitoring of the shield tunnel construction progress. Furthermore, a self-developed BIM-based shield tunnel construction management platform is proposed. This platform advances the “one-map” control of shield tunnel construction in the metro network, and enables remote real-time monitoring of the construction status in a 3D environment. The platform has been applied in the construction and management of Shenzhen Metro Phase IV and its adjustment project, facilitating shield tunnel construction and management in a collaborative 3D environment. This advancement enhances the visualization and digitization of shield tunnel construction, ensuring the quality and efficiency of metro construction, and empowering high-quality urban development.

Keywords: rail transit engineering, shield tunnel construction, BIM (Building Information Modelling), fine management

1 INTRODUCTION

Rail transit engineering is an important infrastructure for city development. The world's first metro project can be traced back to London, United Kingdom, in the year 1863, marking its existence for over 160 years. Across the globe, numerous countries are vigorously advancing their rail transit projects. Considering the city development and the evolution of modern rail transit technologies, an increasing number

of cities, particularly those economically developed, are adopting shield technique for the tunnel construction project. The use of shield tunnelling construction can facilitate mechanization and standardization in construction, expediting construction progress. Nevertheless, there are still several issues.

- (1) The underground environment is complex, characterized by non-uniform distribution of various geological layers, especially unfavorable

*Corresponding author: 24428412@qq.com

geological conditions, posing significant risks to shield tunnelling construction. Moreover, the presence of pre-existing underground structures and intricate underground pipeline networks in urban areas complicates data collection efforts.

- (2) The real-time management of shield tunnelling construction presents difficulties. The existing shield tunnel management systems often use two-dimensional representations and charts to display shield tunnelling construction data. The complex and confined underground environment of shield tunnelling makes data transmission challenging, leading to data issues related to timeliness.
- (3) Predicting risks in shield tunnelling construction is challenging. Shield tunnelling construction is dynamic, understanding construction parameters and their development trends typically relies on human expertise, demanding a high level of professional competence.
- (4) The aging staff problem in shield tunnelling construction is becoming increasingly severe. The aging problem is profoundly affecting the labor supply-demand structure across various industries, particularly labor-intensive construction industry. It is difficult for aging workforce in shield tunnelling construction to adapt to new technologies and methods.

According to statistics as shown by China Association of Metros (2023), as of the end of 2022, there were 55 cities with operational rail transit systems in mainland China, covering a total distance of 10,287.45 kilometers. Additionally, 50 cities have ongoing rail transit projects. Among them, 98.409 kilometers of rail transit lines are in the construction process in Shenzhen. Furthermore, Shenzhen has received approval for the Fifth Phase of its metro plan, comprising 11 lines, approximately 185.6 kilometers in length. Considering the international index that a network length of 400 kilometers is recognized as a world-class metro, Shenzhen has become the city with a world-class metro.

Facing such a large-scale rail transit construction, the efficient advancement of shield tunnelling operations has become one of the critical challenges in the rail transit engineering. In recent years, Shenzhen Metro has integrated Building Information Modelling (BIM) technology throughout the entire lifecycle of the rail transit engineering. It has also used BIM technology for the fine management of shield tunnelling construction in rail transit engineering. Taking the BIM model as the foundation, various elements along rail transit lines both above and below ground were integrated, and then a three-dimensional (3D), information-rich, and interactive space was developed for shield tunnelling construction. Furthermore, Shenzhen Metro has developed a fine management platform for shield tunnelling construction.

2 LITERATURE REVIEW

In addressing the aforementioned issues, researchers and engineers have undertaken studies and practical efforts for shield tunnelling construction.

- (1) Concerning the shield tunnelling excavation model, researchers have explored automated modelling methods for shield tunnelling through using software products such as Revit (Yu et al., 2018) and Bentley (Liu, 2019). Li et al. (2020) employed BIM technology to establish a Tunnel Boring Machine (TBM) information model, including personnel distribution, material transport, and structural layout, and other information. They integrated this model with geological and TBM data to assess shield tunnelling construction risks, visualize risk levels, and aid in risk assessment. Borrmann et al. (2015) employed a BIM+GIS (Geographic Information System) approach to research the semantic modelling method for shield tunnels at different scales, providing a data foundation for macro and micro-level analysis in shield tunnelling management.
- (2) In terms of shield tunnelling construction control, Stascheit et al. (2018) studied BIM applications in the design and construction phases of shield tunnelling projects, proposing a construction management and control method based on 3D visualization, digital component-level integration, and multiple data sets. Kiseok et al. (2022) conducted analyses and simulations to optimize shield tunnelling management, considering some aspects such as geological analysis, tunnel curve optimization, and shield envelope surfaces within a BIM-based environment.
- (3) Regarding shield tunnelling construction risks, Marco et al. (2023) improved shield tunnelling construction management through the use of a four-dimensional (4D) BIM environment and a safety rule set comprising seven indicators. Zhao et al. (2019) addressed the impact of shield tunnelling construction on surrounding structures. They employed BIM technology and automated detection to analyze deformations after shield tunnelling construction.
- (4) As for shield tunnelling construction management platforms, some comprehensive tunnel engineering information systems have been established to collect and manage data throughout the lifecycle. Lin et al. (2018) extended a unified shield tunnel information model based on IFC (Industry Foundation Classes) schema, encompassing data related to tunnel geology, structure, alignment, construction, monitoring and defects. Yu et al. (2016) applied sensor devices for real-time data collection and management, constructing a BIM-based 3D visualization tunnel construction management system. This system enabled dynamic and intelligent

monitoring of materials, equipment, personnel, progress, quality, and safety throughout the entire construction process.

In summary, research and practical applications of BIM technology in shield tunnelling construction have made significant progress. However, there is still relatively limited exploration in the comprehensive and intelligent scenarios through BIM-based environment and BIM data.

3 OVERALL SCHEME OF THE BIM-BASED FINE MANAGEMENT FOR SHIELD TUNNELLING IN RAIL TRANSIT

In response to the aforementioned challenges in shield tunnelling construction management, this study aims at building an integrated 3D space with multi-type data for shield tunnelling construction. A fine management platform for shield tunnelling construction was also developed. This platform refines the management units of rail transit shield tunnelling to meet the demands of various business scenarios. The technical framework and data flow for management are detailed in the following sections.

3.1 Technical framework

In this research, a BIM-based fine management technical framework of rail transit shield tunnelling was constructed according to four levels (as illustrated in Figure 1): foundational layer, technical layer, platform layer, and application layer, along with two mechanisms, namely, the standardization and security mechanisms.

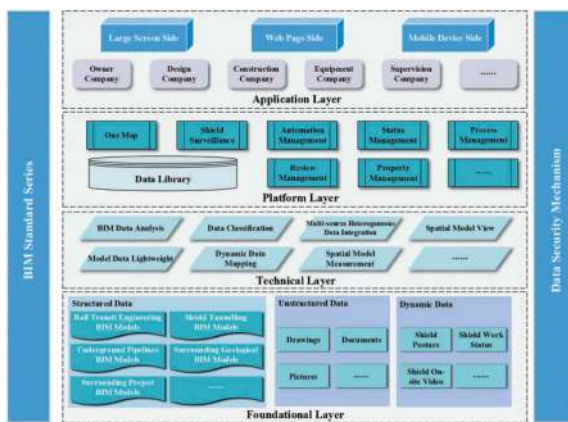

Figure 1. BIM-based fine management technical framework of rail transit shield tunnelling.

3.1.1 Foundational layer

The shield tunnelling construction involves surrounding environmental data and its own excavation parameters. Based on data status, it can be categorized into static data and dynamic data. Static data can further be divided into structured data and unstructured data. Structured data primarily includes BIM models of metro stations and tunnels, as well as

models of the surrounding geological features and underground pipelines. Dynamic data primarily consists of shield tunnelling monitoring parameters, shield posture and work status during the tunnelling construction. Before shield tunnelling construction, comprehensive collection of above-ground and underground elements provides an accurate data foundation for the fine management of shield tunnelling.

3.1.2 Technical layer

The value of BIM technology extends beyond 3D visualization, it also encompasses data computation and analysis. Therefore, data-level processing and analysis of BIM models are necessary. Focusing on the requirements of shield tunnelling management, this layer primarily investigates techniques such as data classification, BIM data parsing, integration of heterogeneous data, spatial model measurement, and develops relevant algorithms and technical engines. This allows for fine management of shield tunnelling construction at the data level.

3.1.3 Platform layer

An independent fine management platform of rail transit shield tunnelling was developed. It integrates diverse data from various sources into a database, and contains several management modules such as property management, process management and review management. This platform supports the integration of shield tunnelling construction data from multiple rail transit lines, enabling overall control at the network level.

3.1.4 Application layer

With the user authorization, various stakeholders in rail transit engineering, including construction, design, equipment, and other units, can collaboratively manage shield tunnelling on a unified BIM platform. To meet the demands of shield tunnelling construction management across various scenarios, three interfaces have been developed: a large-screen command center, a web-based management portal, and a mobile management application. Specifically, the large-screen command center is designed to meet the requirements of network-level shield tunnel management scenarios, enabling comprehensive oversight, remote command capabilities, and precise control.

3.1.5 Mechanism

In the BIM-based fine management process of rail transit shield tunnelling throughout the entire lifecycle, one fundamental task is the integration of BIM model data from the surrounding environment of tunnel projects. To ensure the standardization and uniformity of BIM model data, a series of rail transit engineering BIM standards have been developed, covering aspects like classification and coding, modelling, delivery, and application. Additionally, the mechanism for data security during BIM applications in rail transit

engineering has been established. Measures such as user authorization, data encryption and decryption, and data tracing are implemented to safeguard data security of shield tunnelling management in the rail transit.

3.2 Management process

Any accidents involving shield tunnelling equipment during the excavation process can lead to significant economic losses. To ensure the safety, reliability, and compliance of shield tunnelling construction in the tunnel project, an access and management mechanism for shield tunnelling equipment has been established. This mechanism covers the entire process from equipment selection to shield tunnelling excavation management, and ultimately to tunnel breakthrough and equipment removal. The primary management process is illustrated in Figure 2.

Figure 2. Fine management process and data flow of shield tunnelling construction.

3.2.1 Shield machine selection

As shown by Song et al. (2022), the selection of shield machines should take into account the characteristics of the engineering project, while ensuring construction safety and project quality, and meeting project deadlines. The primary reference indicators for shield machine selection are the geological and hydrogeological conditions. Typically, in soft geological conditions such as gravelly cohesive soil or soil-like highly weathered mixed granite, considering factors like water height and burial depth, it is recommended to use a slurry balance shield machine. In geological conditions comprising sand layers, silt layers, and other adverse conditions, especially with a high water table, a slurry shield machine is recommended. In cases where the geology is characterized by variable hardness or long stretches of hard rock, an Earth Pressure and TBM Dual-Mode Shield Machine is advisable.

3.2.2 Shield machine access review

The platform is responsible for the submission of specialized schemes that evaluate shield machine

selection and adaptability, as well as reliability analysis. This process also involves the selection of expert reviewers and other shield machine documents. Prior to the shield machine access review, relevant companies should collect geological survey data and data related to the surrounding environment along the alignment, including existing structures, above-ground and underground structures, pipelines, rivers, etc. This data is then uploaded to the platform, providing a virtual 3D environment for expert reviewers during the shield machine access review. This approach helps address challenges in data collection and presentation during shield tunnelling construction. After expert review and approval of the specialized scheme, the shield machine access permit is issued by the relevant management authorities.

3.2.3 Shield machine inspection

Shield machine inspection includes both factory inspection and on-site inspection, with expert participation if necessary. Key aspects of shield machine inspection include the inspection of shield body, cutter head, segment assembly machine, grouting system, and electrical system.

3.2.4 Shield tunnelling construction control

According to the requirements of the route design, the construction unit conducts shield tunnelling and segment assembly according to the plan. Utilizing the design line profile and geological information, the construction unit can simulate and analyze the shield tunnelling route, initiating automatic shield machine excavation. During the excavation, real-time monitoring of shield machine excavation status and parameters is achieved through the shield tunnelling fine management platform. Automatic warnings are triggered if excavation parameters deviate from the normal range.

4 INTEGRATION OF HETEROGENEOUS DATA SOURCES AND CONSTRUCTION OF 3D SPACE FOR SHIELD TUNNELLING

When rail transit projects are built in the underground areas of the bustling zone, there are some problems that need to be addressed, including geology (especially adverse geological formations), underground municipal pipelines, underground structures, and existing subway and railway projects. These data sources often belong to different ownership entities, making management interface complex. To ensure the safe and effective excavation of shield tunnelling in such environments, it is crucial to integrate different information along the alignment of tunnel projects. This method can serve as a technical foundation for shield tunnelling construction optimizing, risk mitigation, and other critical aspects of the project.

4.1 Integration of several heterogeneous data sources

The surrounding environment data relevant to shield tunnelling construction can be categorized into different types, as shown in Table 1.

Table 1. Surrounding environment data of shield tunnelling construction.

Type	Description	Model Depth
Geology	According to borehole data of field survey, the geological model is simulated by interpolation algorithm.	L3.0 (G3/N)
Underground pipelines	Underground pipelines are created according to drawings of different types.	L2.0 (G2/N2)
Surrounding projects	Based on the collected data, models are created according to different building types, such as existing rail transit lines, existing building foundations, and other existing municipal infrastructure.	L2.0 (G2/N1)

4.1.1 Information integration

To develop the effective shield tunnelling method and tunnel construction strategy, it is crucial to consider the conditions along the rail transit alignment. Factors such as the geological and geophysical attributes along the alignment, the distribution of adverse geological conditions, types and dimensions of underground pipelines, and the structural characteristics of existing structures all play a significant role in the shield tunnelling construction. To address issues related to inaccurate, incomplete, and non-standard information along the subway alignment, some attribute information templates were established for geology, underground pipelines, and existing structures. Each participating party is required to collect relevant data and submit to the proposed platform.

4.1.2 Model standardization

Before integrating surrounding environment data for shield tunnelling construction, it is essential to generate this data according to uniform standards and specifications. Since there were no standardized guidelines for building geological models, Shenzhen Metro has developed a technical guideline to standardize geological model outcomes. Through this guideline, issues related to the non-standardization and inconsistency of model data, especially for underground pipelines and geological surveys, have been resolved. This not only accumulates standardized urban underground digital assets but also leverages the value of BIM data, improves data reusability, and avoids redundant modelling during shield tunnelling construction. This is particularly

valuable for the construction of new lines, where existing geological and underground pipeline data can assist in construction management.

4.1.3 Depth adequacy

While there is a high requirement for the depth of tunnel project models in shield tunnelling applications, the surrounding environment models have relatively lower depth requirements. Considering the data application requirements, the depth of surrounding environment models can be appropriately reduced. This is shown in Table 1. For instance, the depth requirement for modelling geological formations due to adverse geological risks can be designated as L3.0, whereas for underground pipelines and nearby existing structures, which only need to exhibit certain geometric characteristics, the model depth for underground pipelines and existing structures can be L2.0. It should be noted that the model depth L1.0-L4.0 employs the expression method specified in the Chinese national standard “Building Information Model Design and Delivery Standard (GB/T 51301-2018),” which is equivalent to LOD 100-LOD 500. By specifying suitable model depths, it not only resolves the issue of varying model depths by different people but also ensures the efficient operation of the BIM platform.

Additionally, by developing data interfaces, monitoring parameters from the shield tunnelling construction can be transmitted to the shield tunnelling fine management platform. This addresses challenges related to transferring data in closed and limited spaces, assisting in the dynamic control management.

4.2 3D space of shield tunnelling construction

Based on a unified spatial coordinate system, above-ground and underground model data within the impact range of shield tunnelling construction need to be integrated, constructing a 3D space for shield tunnelling construction, as shown in Figure 3. This 3D space transforms the traditional 2D approach of shield tunnel management, addressing challenges related to complex interference relationships and management difficulties. It makes shield tunnelling construction more precise and more visual.

Figure 3. 3D space of shield tunnelling construction.

4.2.1 Above-ground and underground visualized space

Using BIM models as the foundation, this space encompasses various elements of the rail transit project's above-ground and underground components, including geological models, underground pipeline models, and surrounding structure models. It creates a 3D space for monitoring and managing shield tunnelling construction. Project managers can use this visualized space to assess the status of shield tunnelling and potential risks, aiding in optimizing project adjustments. To meet requirements of visible view and data loading, techniques like Level of Detail (LOD) and incremental loading are employed to display elements as needed, meeting the management demands within the 3D space.

4.2.2 Integrated space with all information

The 3D space of shield tunnelling integrates various information not only in breadth but also in depth. For example, attributes like stratum numbers, moisture content, porosity, and compressibility modulus of geological bodies are added in the geological model. For underground pipelines, the parameters such as pipeline type, diameter, and material are stored in the model. By integrating comprehensive information in the 3D space, it provides a basis for accurate analysis and prediction of shield tunnelling construction.

4.2.3 Structured and computable space

To precisely determine the spatial relationships between the shield tunnelling location and potential risks within the 3D space, measurements techniques for 3D space were studied. The parameters need to be measured include the shield machine's burial depth, the distance between shield machine's cutterhead and building foundations, and the distance between shield machine and adverse geological conditions. Through techniques like capturing the nearest points in the model and calculating distances between two points, a computable 3D space is formed. As shown in Figure 3, it allows for the measurement of the shield machine's burial depth and analysis of spatial relationships between the shield machine and different geological layers.

5 BIM-BASED FINE MANAGEMENT PLATFORM FOR RAIL TRANSIT SHIELD TUNNELLING CONSTRUCTION

To meet the requirements of fine management in shield tunnelling construction, a BIM-based fine management platform for rail transit shield tunnelling construction was developed (hereinafter referred to as the BIM platform). This platform provides technical support for collaborative, digital, and three-dimensional shield tunnelling construction operations for various participating companies. Its main application scenarios are as follows.

5.1 Data classification and visualization

In the shield tunnelling management process, data from various participants or of different types needs to be collected, resulting in a wide variety of data sources and formats. To address issues such as unclear data classification, non-standard data representation, and inconsistent integration, a data center was established within the proposed BIM platform. Data is imported after undergoing data cleaning, classified and graded, and a common foundational database for the entire shield tunnelling process was established (as illustrated in Figure 4). It promotes the uniform creation, use, and presentation of shield tunnelling management data.

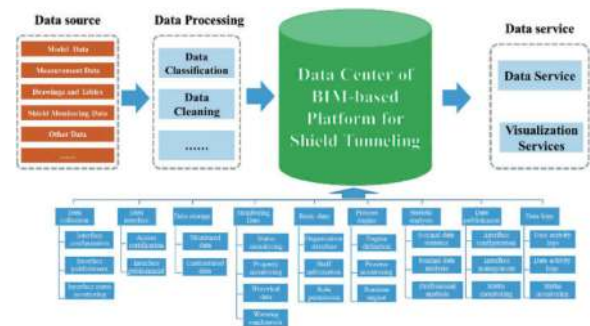

Figure 4. Data classification of data center of fine Management platform for shield tunnelling.

During the shield tunnelling process, data is not limited to the project itself but also relates to the surrounding environment. Relevant data for shield tunnelling management can be categorized into structured data (such as BIM model data) and unstructured data (such as documents and drawings). The parsed BIM models can be divided into geometric information and attribute information, which are stored separately to enhance visualization and data service capabilities. The shield tunnelling process is dynamic, and it requires real-time data storage, such as shield posture, excavation parameters, etc. Historical data storage and data anomaly alert mechanisms can be established after collecting enough data. Maintaining historical data provides a basis for shield control during excavation, while the data anomaly alert mechanism promptly detects shield tunnelling construction issues, allowing for adjustments and optimizations based on historical data to mitigate risks. This research achieves the 3D view of the tunnel project, the dynamical display of shield tunnelling status and parameters, which is beneficial in addressing issues related to two-dimensional management and lagging status updates.

5.2 "One Map" of shield tunnelling construction

There may be multiple metro lines under simultaneous construction in the city. Each line's shield tunnelling progress varies, requiring a more scientific and rational approach of network-level shield

tunnelling construction management to avoid impacting the overall quality and progress of the rail transit network. In Shenzhen, there are 12 metro lines under construction in 2023. With the commencement of construction for Shenzhen Metro Phase V, even more lines will be simultaneously constructed. Managing such many shield tunnelling machines simultaneously poses significant challenges.

To address data integration challenges in network-level shield tunnelling management, this study utilized the SuperMap's GIS system as the foundation, and integrated the status of shield tunnelling construction for various railway lines within the "One Map", along with real-time construction data from the sites. By comparing the progress and excavation status of shield tunnelling, it assisted managers in making informed resource allocations for different railway lines, ensuring their smooth progress. Additionally, the "One Map" compiled statistics on risk issues associated with shield tunnelling across all railway lines, aiding project participants in timely risk mitigation. Through the "One Map" approach, it achieved network-level management of shield tunnelling construction from city-wide aspect, as shown in Figure 5.

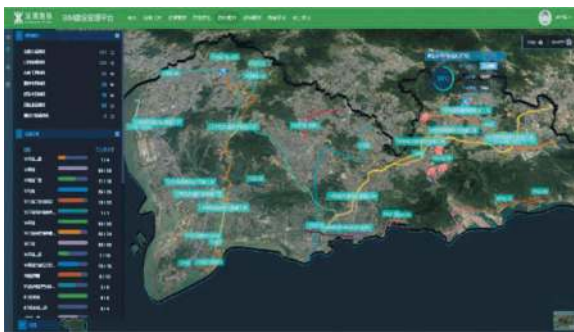

Figure 5. "One Map" of shield tunnelling construction.

To address the macro and micro-level data integration challenges in network-level shield tunnelling construction, GIS and BIM data fusion technology was studied in this paper. It allowed for the rapid transition between GIS data and BIM data through the "One Map". Shield tunnel manager can pinpoint the location of shield tunnelling on specific metro lines, review the progress of the tunnel project, and analyze the interference relationships between surface and subsurface elements within the shield tunnelling range. This facilitates remote control and collaborative management of shield tunnelling construction.

5.3 Automatic shield tunnelling

Traditional shield tunnelling excavation and segment assembly plans often require manual calculations based on the design metro line. These processes are highly specialized. The underground construction

environment is complex. If there is a deviation from the tunnel's intended alignment, it usually requires a complete redesign based on the original line, which can be time-consuming. To address these issues, an intelligent shield tunnelling technology based on the design route was developed. To analyze the differences among the design line, shield tunnelling line and segment formation line, a predictive model based on shield tunnelling parameters is being developed, using the tunnel project model. This research also involves studying automatic control technology for the shield tunnelling machine system in conjunction with shield tunnelling parameters. The ultimate goal is to establish an intelligent shield tunnelling solution that innovates the tunnelling management approach.

In practical projects, a pilot test of automatic control for the shield tunnel machine has been conducted. The test has shown that under steady-state conditions, the accuracy of shield advance speed control is within ± 5 mm/min, the accuracy of soil pressure in the silo is within ± 0.1 bar, and the accuracy of shield posture deviation control is within ± 3 mm. Figure 6 displays the deviation curves of the main parameters when the shield tunnel machine is in automatic control mode. In the figure, it can be observed that when the predetermined line was used as an input parameter, and the geological conditions along the metro line was applied as boundary conditions, the shield tunnel machine could advance along the spatial line effectively based on the predictive model of shield tunnelling parameters. Additionally, the primary parameters of the shield tunnel machine remain stable in this state.

Figure 6. Deviation curve of measurement values and set values of main parameters in shield tunnelling automatic control.

5.4 Shield tunnelling surveillance

Status of shield tunnelling machines in different metro lines varies. There are still many problems to be solved, such as data integration difficulties, low visualization, and delayed information transmission, especially during high-risk construction phases like

shield tunnelling construction under existing structures, crossing critical areas, or starting & receiving of shield tunnelling machine. To ensure the safety of shield tunnelling construction and to respond promptly to emergencies, real-time monitoring of shield tunnelling construction is necessary. This study integrates technologies including BIM, AR (Augmented Reality), IoT (Internet of Things), video surveillance, and cloud services to establish an “online + offline” shield tunnelling surveillance mode. Using BIM models as the base, a virtual space of shield tunnelling construction was created in this mode, replicating the construction site at the 1:1 scale. Information is fed back through sensors, surveillance videos, and other media, enabling real-time monitoring of construction status and boring parameters of shield tunnelling. Combining the surrounding environmental conditions presented in 3D space, it intelligently senses construction risks and provides warning alerts through the interaction of AR video and voice, realizing a dual safety surveillance mechanism in the “online + offline” mode.

During the construction, there may be issues like water gushing in the screw machine. Through on-site monitoring and video analysis, a neural network model based on time series analysis was developed, and technology integration of AI (Artificial intelligence) and video was studied for intelligent identification. To identify water gushing issue, its principle is to determine the visual characteristics of object falling at the muck chute. As a result, an online warning system was developed for real-time alerts, reducing risks such as excess spoil discharge and ground collapse.

6 APPLICATION ANALYSIS

6.1 Data integration

Since 2019, Shenzhen Metro has been comprehensively promoting the application of BIM technology in Phase Four and Phase Four Adjustment projects. In the initial stages, a series of BIM standards were developed based on project experience, which standardize BIM applications in various project phases. Currently, standardized BIM digital assets have been accumulated, including geological models along metro lines covering 264.92 km, precise real-world models covering 234 km², and multiple underground municipal pipelines models along metro lines. These digital assets provide a rich data foundation for constructing the 3D space for shield tunnelling construction. To ensure the uniformity of BIM applications in various business scenarios and facilitate collaboration management on a unified platform, the proposed BIM-based fine management platform for rail transit shield tunnelling construction was embedded in the BIM-based comprehensive application platform, which was independently developed by Shenzhen Metro.

6.2 Access review for shield tunnelling machine

To establish a standardized access review mechanism for shield tunnelling machine, Shenzhen Metro has researched and published the “Access Review Management Measures for Shield Tunnelling Machine in Shenzhen Metro”. These measures have been embedded within the proposed BIM platform for shield tunnelling management. Before the access review of shield tunnelling machine, participating companies are required to collect information related to geological conditions, underground pipelines, and surrounding structures along the metro line, following the relevant BIM standards. They are then expected to create 3D models and upload to the BIM platform. Through using this information to construct a 3D space for shield tunnelling construction, the platform provides technical support to access review. Based on information concerning geological conditions, underground pipelines, and building structures, the construction company can rapidly assess potential risks during shield tunnelling excavation. This enables them to develop secure and efficient shield tunnelling construction plans.

6.3 Shield tunnelling construction handover

In traditional handover procedures for shield tunnelling construction, project managers primarily rely on 2D drawings for technical explanations. It needs highly specialized knowledge to understand complex space relationship and construction technology. Shenzhen Metro has been actively promoting the application of forward-design BIM models during the construction phase, pioneering the use of the 3D-based drawing set in the rail transit field. By using a 3D visual representation, shield tunnelling construction plans and critical milestones can be displayed for construction staff. This approach addresses issues related to inconsistent understanding of the plans, non-intuitive plan representations, and difficulties in grasping spatial relationships. Simultaneously, through binding the staff information to the segments, it can distribute responsibilities to individuals for ensuring the quality of segment assembly. This has led to the implementation of a “real name system” for managing approximately 200,000 segments (approximately 300 km) during shield tunnelling construction.

6.4 Shield tunnelling intelligent management

During shield tunnelling construction, the shield tunnelling system transmits real-time excavation status, excavation parameters, and monitoring videos to the BIM platform. Project managers can remotely monitor the shield tunnelling progress, providing a basis for on-site control and resource allocation. Figure 7 illustrates the excavation progress of the tunnel project between Moon Road Station and East Zhou Road Station of Line 13 North Extension. Managers can also

access monitoring cameras at different locations on the shield tunnelling site, observing on-site construction operations and monitoring excavation parameters. In case of data anomalies, early warning alerts are triggered, enabling intelligent risk assessment in shield tunnelling construction and hazard mitigation.

Currently, Shenzhen Metro realizes the real time monitoring of 399 shield tunnelling machines across ongoing projects, ensuring “One Map” management of shield tunnelling. Within the “One Map”, the real-time monitoring of key excavation parameters is achieved, and warnings for anomaly indicators such as excavation volume, assembly speed, and soil pressure fluctuations can be automatically reminded. It has accumulated to 2,100 warnings, leading to an 80% reduction in ground collapse rates among tunnel projects.

Figure 7. Fine management of shield tunnelling based on 3D space.

7 CONCLUSIONS

As a critical infrastructure for the city, rail transit engineering has experienced rapid growth in recent years alongside city development. In this paper, the fine management of rail transit shield tunnelling construction was studied based on BIM technology, and a BIM-based fine management platform has been independently developed. This proposed platform integrates diverse and heterogeneous data sources related to shield tunnelling construction, including geology, underground pipelines, and structures. It constructs a computable 3D space for shield tunnelling, providing a data foundation for optimizing and adjusting construction plans. By utilizing structured data from BIM models and real-time excavation data, the “online + offline” shield tunnelling surveillance mode and the shield tunnelling automation mode have been developed.

The achievements have been comprehensively applied to Shenzhen Metro Phase Four and Phase Four Adjustment projects, validating the feasibility and effectiveness. This can serve as a reference for other cities looking to refine their management of shield tunnelling projects.

As Shenzhen Metro Phase Five is about to start, the proposed fine management platform for shield tunnelling construction will be used in more projects. To further enhance its intelligence,

efficiency and precision, the future research and applications will focus on the following areas: a) Integration of more comprehensive and abundant urban underground space information; b) Innovation in the application of BIM+5G technology in shield tunnelling for data transmission; c) Deepening the study of the coupling relationship between shield tunnelling 3D space and design line.

Innovative design and practice of full life cycle of complex underground engineering equipment based on digital twin

Feixiang Liu*

China Railway Construction Heavy Industry Corporation Limited, Changsha Hunan, China

ABSTRACT: Digital twin is one of the key enabling technologies to implement intelligent construction. According to the characteristics of complex and changeable service environment of typical underground engineering equipment, highly personalized customization and high complexity of equipment itself, based on the continuous pursuit of the digital goal of “stuffing the product into computer, moving the workshop onto computer and building the tunnel on computer”, the technological advancement path from digital mock-up to digital twin of underground engineering equipment was put forward. Through the study of key technologies such as high-fidelity modeling and simulation, high-confidence prediction and optimization, and high-real-time data interaction based on digital twin, a new mode of independent innovation design throughout the whole life cycle of complex underground engineering equipment was established. Based on the actual demand, this paper discussed the “three elements” of digital twinning application of underground engineering equipment, described the implementation framework of digital twin, carried out the practice of digital twin technology in the field of large-scale and complex underground engineering equipment, and explored a new way to improve the key service performance of major equipment.

Keywords: Digital twin, Digital, Underground engineering equipment, Full life cycle

1 INTRODUCTION

With the rapid development of a new round of scientific and technological revolution and industrial transformation, the world is in a stage of great transformation from the industrial age to the digital age. The digital economy has become a hotspot for global economic development, and the United States, the United Kingdom, the European Union and other countries have successively put forward digital economy strategies^[1]. Promoting the integrated development of digital economy and real economy has become a consensus among governments and industrial circles. Either the National Strategic Plan for Advanced Manufacturing developed by the United States^[2], or “Industry 4.0” proposed by Germany^[3] or “Made in China 2025 strategy” has taken intelligent manufacturing integrating digitization, networking and intelligence as the core of the new round of scientific and technological revolution, and at the same time intelligent manufacturing has become the common development trend of the world’s manufacturing industry at present. The key to intelligent manufacturing lies in the interconnection and integration of the manufacturing information world and the physical world, and the two-way interaction between real world and virtual world based on digital twin provides an effective means^[4]. More and more

academics and industrialists have regarded digital twin as one of the key enabling technologies to practice intelligent manufacturing^[5].

In 2003, Professor Michael Grieves from the University of Michigan in the United States put forward the idea of “virtual digital representation equivalent to physical products”, which was officially named as digital twin in 2011^[6]. The United States Air Force and NASA adopted this concept and applied it in aircraft design (such as F-15), health assessment, damage prediction, etc.^{[7][8]}. In recent years, the coverage on research and application of digital twin technology has grown exponentially^[9]. In October 2019, the United States Navy built the first digital twin for USS Abraham Lincoln^[10]; in March 2020, the United States Air Force announced that it was using digital twin technology to safeguard the network security of GPS 2R satellite^[10]; the aero-engine enterprises in the United Kingdom and Russia also plan to complete the introduction of digital twin technology in the near future^[11]; and domestic aerospace, shipping, machinery, water conservancy and hydropower and other industries are also increasing their attention to digital twin technology year by year^{[12]-[15]}. Some mines and coal mine boring machines, etc. have begun to introduce digital twin technology to realize intelligent construction and management^[16]. Moreover, digital

*Corresponding author: wangyongsheng@crchi.com

twin has also been included in the national strategic planning^[17]. In April 2020, the National Development and Reform Commission and the Office of the Central Cyberspace Affairs Commission printed and issued the *Implementation Plan on Promoting the “Cloud Application, Data Empowerment and Artificial Intelligence” Action to Cultivate New Economic Development*, juxtaposing digital twin with big data, artificial intelligence, 5G, etc. The State-owned Assets Supervision and Administration Commission of the State Council issued the *Notice on Accelerating the Digital Transformation of State-owned Enterprises* in August 2020, which clearly requires the state-owned manufacturing enterprises to enhance the design and manufacturing level based on digital twin in their digital transformation.

According to the applicable criteria for digital twin proposed by Tao Fei and other scholars^[5], the products with high single product value, complex system and process, extreme operating environment and other characteristics are suitable for the application of digital twin, while large-scale complex underground engineering equipment with complicated and changeable service environment and a high degree of personalized customization is highly consistent with the applicable criteria for digital twin. In view of the technical challenges faced by the development of underground engineering equipment, this paper first puts forward the advancement path of digital technology from digital mock-up to digital twin for underground engineering equipment, then introduces the key technologies of digital twin and a new model of independent innovation design based on digital twin throughout the full life cycle of underground engineering equipment, and finally expounds the application value of digital twin technology in solving the technical problems faced by underground engineering equipment through some practical application cases. Based on the requirements of underground engineering equipment, this paper discusses the “three elements” in digital twin application, describes the implementation framework of digital twin technology for underground engineering equipment, and preliminarily realizes the successful verification and practice of digital twin system in the field of large-scale underground engineering equipment in China, thus exploring a new way to improve the core competitiveness of major equipment in China.

2 DIGITAL TECHNOLOGY IS THE ONLY WAY TO DEVELOP UNDERGROUND ENGINEERING EQUIPMENT TECHNOLOGY

2.1 *Technical challenges faced by the development of underground engineering equipment*

After long-term investment in research and development, China’s underground engineering equipment has embarked on the road of independent

development and made major breakthroughs in key technical bottleneck areas such as main bearings. However, it still faces the following technical challenges:

- (1) Difficulty in coupling analysis between equipment and complex and changeable geological environment. Underground engineering equipment has high technical complexity, high interdisciplinary degree and high system integration. The coupling between the equipment system and the geological environment is nonlinear, unstable and unpredictable. Based on the above factors, it is difficult for traditional methods to accurately analyze and optimize the performance of underground engineering equipment in a complex geological environment.
- (2) Difficulty in real-time perception and interaction of man-machine-environment. Underground engineering equipment has a high degree of personalization, user attention and participation. It belongs to a typical “multilateral” project such as simultaneous implementation of survey, design and manufacturing, and its development process requires multi-party coordination. However, due to the lack of virtual-real space synchronous mapping and other technologies in extremely harsh service environment, it is impossible to obtain the real status information of equipment in time, and it is difficult to realize man-machine-environment interaction.
- (3) Difficulty in accurate prediction and matching of equipment performance. The construction of underground engineering equipment in a complex and changeable high-risk service environment often faces the problems such as unpredictable geological types, life performance and sudden failures, and the “complex mechanism and difficult traceability” of failures result in high risk and high consumption during construction, which greatly limits the service performance of underground engineering equipment.

In view of the above-mentioned technical challenges faced by underground engineering equipment, it is difficult for traditional design ideas and methods to fully support independent innovation and development of products. The independent innovation and development of underground engineering equipment must take a digital way of forward design.

Figure 1. Construction environment diagram of underground engineering equipment.

2.2 Construction of digital system for underground engineering equipment

CRCHI has long been committed to the construction of enterprise digital system for high-end complex underground engineering equipment^[18]. In 2016, it put forward the digital strategic conception of “stuffing the product into computer, moving the workshop onto computer and building the tunnel on computer”, continuously promoted the digital and intelligent upgrading including R&D design, production and manufacturing, marketing service, supply chain, finance, management and operation, promoted the construction and implementation of digital projects such as CAX, CAPP, PLM, ERP, MES and high-performance computing center, and provided a digital environment for the application of digital mock-up and digital twin technology in the R&D design, production and manufacturing stages of products. Meanwhile, CRCHI has also established a product big data platform. By cooperating with multiple underground tunnel construction control business centers, it has developed an IoT platform for underground construction equipment, and connected the underground engineering equipment produced by CRCHI or even third-party equipment to this platform, basically realizing remote monitoring of real-time status information of equipment and intelligent construction assistance and providing network and data support for the application of digital twin technology in the operation and maintenance stage of products.

Figure 2. Digitalization objective pursued by CRCHI.

2.3 From digital prototype of underground engineering equipment to digital twin

According to the definitions specified in GB/T 26100-2010^[19], digital mock-up (DMU) not only reflects the geometric attributes of product objects, but also reflects the functions and performance of product objects in at least a certain field. This paper describes the different development stages of digital mock-up for underground engineering equipment in combination with the elaboration on the evolution process of digital mock-up in Reference^[20], as shown in Figure 3. The digital mock-up of underground engineering equipment gradually evolves into one containing functions and physical properties from 2D to 3D in the primary stage with product structure (organizational relationship) and

attributes added; moreover, it also reflects real manufacturing information such as production and manufacturing deviation, thus forming a complete engineering design process containing real physical product data. However, due to the lack of data interaction feedback with the manufacturing/service process of physical entities, digital mock-up fails to form a closed loop for iterative design optimization based on real data and cannot solve the problems such as coupling between geological environment and equipment, equipment performance/failure prediction under actual working conditions, intelligent decision-making optimization, etc., seriously restricting the independent innovative design of underground engineering equipment. Therefore, it is necessary to realize data interaction and integration between digital mock-up and physical entity with the help of digital twin technology.

Figure 3. Development stage of Digital Mock-Up (DMU) for underground engineering equipment.

At present, digital twin has no fixed technical system, mode and method^[5], and the understanding of digital twin is also different and constantly evolving. The author believes that digital mock-up is a defined ideal product, which reflects human consciousness. Enterprises manufacture the physical products according to digital mock-up, while digital twin describe physical product, which is a combination of digital mock-up and physical entity. Therefore, the digital twin of underground engineering equipment should at least start from “digital mock-up with increased manufacturing information”, and the real physical information of physical products is added to the digital mock-

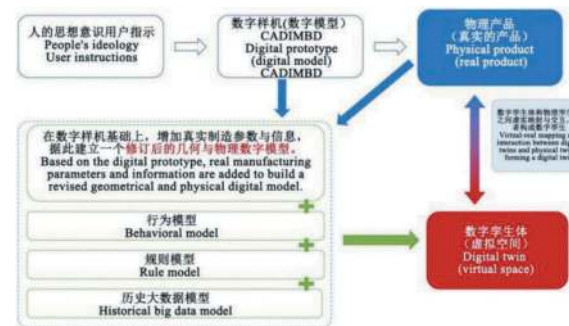

Figure 4. Underground engineering equipment from digital Mock-up to digital twin.

up through sensors, so as to form data interaction and integration between physical product and digital mock-up and realize virtual-real mapping and virtual-real synchronization. Meanwhile, an operation mechanism of virtual-real mutual improvement and mutual iterative update between physical product and digital mock-up has been established through digital twin.

3 INDEPENDENT INNOVATIVE DESIGN OF UNDERGROUND ENGINEERING EQUIPMENT BASED ON DIGITAL TWIN

For complex products, Grieves et al.^[6] gave the definition of digital twin: Digital twin is a set of virtual information structures that comprehensively describe potentially produced or actually manufactured products from micro-atomic level to macro-geometrical level. The best result of building a digital twin is that any information that can be obtained by testing the actually manufactured product can also be obtained from its digital twin. However, with the current technology and computing power, it is difficult to realize the digital twin defined above at this stage. In other words, it is difficult to realize a digital twin that can fully map the physical product in real time. Physical product can only be mapped from the required dimension and perspective. Therefore, the application of digital twin can only be obtained from the required dimension and perspective. It can be seen from the definition that the role of digital twin runs through the full life cycle of product such as R&D design, production and manufacturing, operation and maintenance, etc., but it serves the product mainly in the operation and maintenance stage. Based on digital twin, we can obtain the equipment operation condition, predict its service life through simulation and then iteratively optimize the design to form a new model of independent innovative design for the full life cycle of underground engineering equipment and realize the following functions.

3.1 Operation simulation based on digital twin

The digital twin can be used to accurately simulate the operation process, behavior and status of underground engineering equipment integrated with the complex service environment in real time. By taking TBM as an example, based on the digital twin of TBM products and tunnel construction environment, it can fully simulate the complex operation process of TBM under arbitrary extreme working conditions and constrained load conditions in virtual environment, analyze and predict the status behavior and task execution success rate of TBM, etc., providing reliable basis for TBM modification before formal service and task execution and decision-making after service.

Figure 5. Operation simulation based on digital twin.

3.2 Health prediction based on digital twin

Through the simulation of digital twin and the real-time data collected by sensors, the health status of underground engineering equipment can be diagnosed and predicted to provide guarantee for the safe operation of underground engineering equipment. The underground engineering equipment usually shows the following behaviors during operation: predictable behavior and unpredictable behavior. Predictable behavior is divided into predictable desired behavior and predictable undesired behavior, with the former being a desirable outcome. Unpredictable behavior is also divided into unpredictable desired behavior and unpredictable undesired behavior. The latter belongs to a behavior that needs to be eliminated, which not only seriously affects the normal operation of equipment, but also causes safety accidents of people and equipment. The most important purpose of building a digital twin is to repeatedly simulate operation and accurately predict in virtual space and eliminate the “unpredictable undesired behavior” during the development, operation and maintenance of underground engineering equipment to the greatest extent, thus avoiding unknown catastrophic problems.

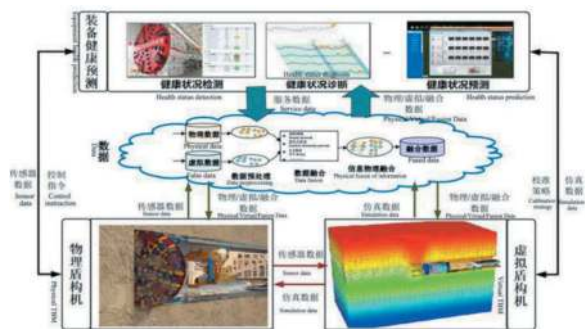

Figure 6. Health prediction based on digital twin.

3.3 Iterative optimization based on digital twin

Another important function of digital twin for underground engineering equipment is reflected in the iterative optimization of product life cycle. As shown in Figure 7, sensors collect and sense the status of

physical entity and transmit the data to the virtual twin, and then the virtual twin conducts analysis/reasoning/diagnosis and makes independent decisions to drive the physical entity to accurately execute and optimize the operation scheme, and gradually improve the use value and system stability of the product, thus forming a closed-loop iterative optimization of product life cycle^[21]. On the other hand, the data based on digital twin as well as analysis/reasoning/diagnosis results can be fully applied to the development of next generation products, thus realizing iterative optimization of cross-generation products.

Figure 7. Iterative optimization based on digital twin.

4 KEY TECHNOLOGIES OF DIGITAL TWIN FOR UNDERGROUND ENGINEERING EQUIPMENT AND IMPLEMENTATION FRAMEWORK

4.1 Key technologies of digital twin requiring breakthroughs for underground engineering equipment

4.1.1 High-fidelity modeling and simulation technology

High-fidelity modeling and simulation is the model data basis for building the digital twin of a product^[20]. The simulation of digital mock-up is based on the ideally defined DMU, which only plays a guiding role. The simulation of digital twin is based on real physical product, and it is necessary to achieve the fidelity of modeling and simulation with real physical product and real environment. Therefore, the high-fidelity modeling and simulation technology is regarded as an important milestone to realize the digital twin of products, which is also an important feature that distinguishes the digital twin from the digital mock-up. In order to realize high-fidelity modeling and simulation of complex underground engineering equipment, the author believes that there are at least three aspects requiring breakthroughs: mechanical coupling analysis between equipment and rock, soil, etc; full-element modeling and simulation of multiple scales at the complete machine level, component level and part level as well as multiple physical fields such as mechanical, electrical and hydraulic; interface development and real-time data interaction between simulation software for different disciplines.

4.1.2 High-confidence simulation prediction technology

One of the important functions of high-fidelity simulation model is to predict its performance and function before the physical prototype is produced, so as to guide design and obtain improved optimization scheme; predict product failure and health status in the operation and maintenance stage of physical prototype, and eliminate unpredictable undesired behavior in advance. The construction environment of underground engineering equipment is highly complex, random and uncertain, and the coupling between equipment and complex and changeable environment makes the high-confidence simulation prediction full of technical challenges while considering the multiple elements such as geological environment and equipment performance. At present, there is no precedent in the industry.

4.1.3 High real-time data interaction technology

High real-time data interaction is the material basis for the virtual-real integration of digital twin and physical entity^[20]. Mass data will be generated during the manufacturing and construction of underground engineering equipment. Due to the high complexity of the equipment itself, various types of data and extremely harsh construction environment, it is often difficult to collect data on site, integrate heterogeneous data, transmit data in real time, etc. How to realize data acquisition, analysis and control of physical products of underground engineering equipment, as well as high real-time data interaction and application with digital twin is also a key technology requiring breakthroughs.

4.2 Implementation framework of digital twin technology for underground engineering equipment

4.2.1 "Three elements" for implementation of digital twin technology

As a complex cutting-edge technology, digital twin contains multiple elements. In summary, the core elements are "model, data and software", among which model is the core, data is the foundation and software is the carrier, all of which complement each other. In terms of models, there are the mechanism models including mathematics/physics/chemistry, function, design and analysis, such as GIS/CAE-based coupled simulation model for geology and TBM, and then data analysis models including machine learning model, empirical model and fault model obtained from data acquisition and big data analysis, such as optimization model for muck improvement parameters of Shield Machine based on big data. The comprehensive application of mechanism models and data analysis models constitutes the model source of digital twin. In terms of data, there are the basic model data such as CAX model data and then the physical data collected by sensors.

Both models and data need to be implemented by software. Finally, the whole digital twin technology framework is built with model + data + software as the core elements.

Figure 8. "Three elements" of digital twin.

4.2.2 Implementation framework of digital twin technology for underground engineering equipment

The digital thread is regarded as a communication channel for the evolution of product models at all stages. It relies on the business system throughout the product life cycle (as shown in Figure 9), covering various links such as product conception, design, supply chain, manufacturing and delivery. The data from each link, department and system are not isolated but shared through collection, transmission, integration and fusion. Throughout the product life cycle, the digital thread provides access, integration and conversion capabilities for the digital twin of products. Its goal is to run through the product life cycle and value chain, realize comprehensive traceability, information interaction and value chain collaboration, and build a digital environment for the implementation of digital twin technology for underground engineering equipment.

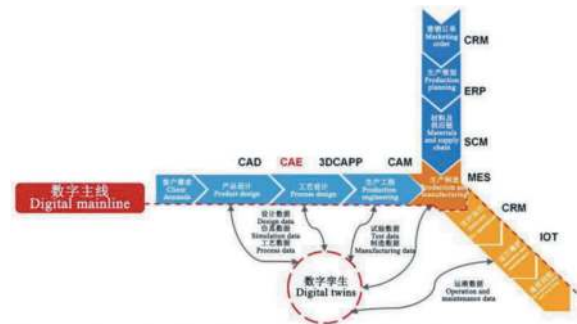

Figure 9. Digital twin implementation basis: Digital thread.

Based on the above analysis, this paper proposes an implementation framework of digital twin technology for underground engineering equipment, which is divided into three aspects: data support, digital mock-up and digital twin platform (providing model and software support) and engineering application, as shown in Figure 10. Digital support consists of a product layer, an acquisition layer and a data layer. PLM, SCADA, MES and collaborative management platform of big data are used to complete the data acquisition and transmission in design, manufacturing, operation and maintenance stages of equipment, providing data support for digital mock-

up and digital twin platform. The digital mock-up and digital twin platform consists of a technology layer, a model layer and a software layer. Based on the full life cycle data of underground engineering equipment, the mechanism/non-mechanism models required for digital mock-up and digital twin of underground engineering equipment are constructed by carrying out technical research such as modeling, simulation, prediction and optimization, and the development of digital mock-up software platform and digital twin system of underground engineering equipment is completed, so as to carry out application verification in major national projects such as plateau railway.

Figure 10. Implementation framework of digital twin technology for underground engineering equipment.

5 INNOVATIVE APPLICATION PRACTICE OF DIGITAL TWIN FOR UNDERGROUND ENGINEERING EQUIPMENT

In view of a series of technical challenges such as difficulty in coupling analysis between equipment and complex geological environment, difficulty in real-time perception and interaction of man-machine-environment, and difficulty in accurate prediction and matching of equipment performance caused by the complex and changeable service environment of underground engineering equipment, highly personalized customization and high complexity of equipment itself, CRCHI has set up a technical breakthrough team through industry-university-research cooperation relying on national key research and development projects, taken the lead in breaking through the integrated modeling and simulation technology of large-scale underground engineering equipment and complex geological environment, established an efficient order reduction method for multi-physical field coupling model, overcome the accurate mirroring technology of digital twin driven by construction data online in real time, and independently developed the digital twin system for underground engineering equipment (as shown in Figure 11), covering various types of equipment products such as shield machine, drill jumbo, driving and bolting integration equipment, so as to realize real-time perception feedback and

dynamic decision optimization during equipment construction based on digital twin.

Figure 11. Digital twin system of shield equipment and its functions.

The above technological achievements and digital twin systems have taken the lead in demonstration application in more than ten major projects such as urban subway, plateau railway and large mine, effectively preventing various potential risks in the process of equipment design, manufacturing and service, and significantly improving equipment performance and construction efficiency. The specific application of digital twin in the field of underground engineering equipment is illustrated by two cases below.

Case 1: Real-time prediction of geological environment based on digital twin. In view of the need to obtain geological information in front of the excavation face of shield equipment in time during the construction of a metro project to guide construction optimization, the geotechnical type identification technology based on local tangent space alignment of shield machine operating parameters and Xgboost fusion is studied, and the mapping relationship between historical operation data (cutterhead torque, thrust, etc.) of shield equipment and geological information in front of the excavation face (surrounding rock grade, etc.) is explored by LTSA algorithm. A data-driven high-precision prediction model for geological types of shield equipment construction is developed and integrated into the digital twin system. On this basis, the geological prediction model is driven by the field operation data of shield equipment to realize real-time prediction of geological types and real-time early warning of geological risks.

During the application verification of this metro project, a total of 335 rings were tunneled by the shield equipment. By comparing the real-time prediction results of digital twin system with the on-site sampling test results, the correct number of rings for geological type prediction was 303, with an accuracy rate of 90.4%, which provided strong support for the construction scheme of this metro project to match the geological environment and for making timely adjustment and optimization.

Figure 12. Real-time prediction of geological environment based on digital twin.

Case 2: Intelligent construction of drill jumbo based on digital twin. Aiming at the engineering problems such as over-excavation and under-excavation of working face caused by poor consistency of spatial error distribution in drilling positioning of drill jumbo, we have established the kinematic inverse solution, dynamics and system simulation models of drill jumbo boom, developed the boom deformation compensation algorithm and model order reduction technology to solve the technical difficulties such as poor consistency of spatial error distribution in drilling positioning of drill jumbo construction and difficulty in meeting the high real-time requirements of digital twin, researched the digital twin system for operation and maintenance stage of drill jumbo, and conducted data interaction with enterprise big data platform. In the promoted application of a new plateau railway tunnel, based on the digital twin system, the synchronous action of twin model remotely driven by the actual operation posture parameters (angle, cylinder stroke, etc.) of the boom and the real-time prediction and optimization of boom motion trajectory are realized, and the on-site construction is guided by the feedback control instructions of the twin system. The field measurement data shows that the average deviation between the actual hole position coordinates in automatic drilling of boom and the target hole position coordinates in the blasthole diagram is 4.8 cm, and the construction efficiency of drill jumbo using digital twin system in the same section is increased by 21.5%.

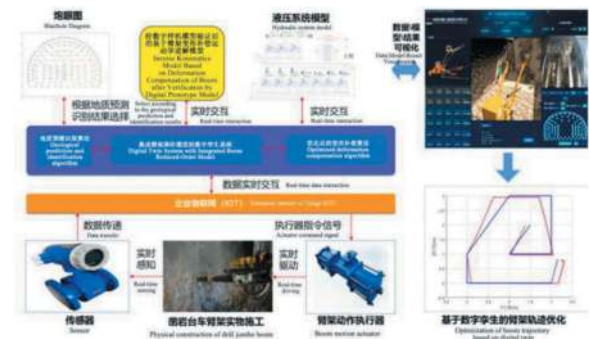

Figure 13. Intelligent construction technology route of drill jumbo based on digital twin.

6 CONCLUSION

- (1) In view of the technical challenges faced by the development of underground engineering equipment and in combination with the digitalization process of CRCHI, this paper expounds the advancement path from digital mock-up to digital twin, and proposes a new model of innovative design for the full life cycle of underground engineering based on digital twin.
- (2) Furthermore, centered on the key technologies requiring breakthroughs in the application of digital twin for underground engineering equipment and the three elements of “model, data and software”, the implementation framework of digital twin technology for underground engineering equipment based on the digital thread is formulated, and the development of digital mock-up and digital twin system for underground engineering equipment is completed.
- (3) Through the practical engineering application of digital twin technology for typical complex underground engineering equipment such as TBM, drill jumbo and all-in-one tunneling and anchoring machine, the bottleneck problems such as equipment performance prediction, early warning of construction risks and dynamic decision optimization in complex geological environment faced by underground engineering equipment have been preliminarily overcome, and a closed-loop feedback innovation mechanism based on digital twin throughout the life cycle of underground engineering equipment has been formed to provide a typical demonstration for the promoted application of digital twin technology in large-scale equipment manufacturing industry.

ABSTRACT: With the development of information technology, automation and artificial intelligence technology, intelligent construction has gradually become the inevitable direction of tunnel engineering development. In order to guide the development of intelligent construction of railway shield tunnel, this paper summarizes the practical experience of intelligent construction of railway tunnel in China and absorbs the latest scientific research achievements of intelligent construction of various industries at home and abroad, and puts forward the principles and objectives of intelligent construction of railway shield tunnel, starting from tunnel survey, design, construction and construction management. The basic requirements, implementation plan and details of intelligent shield tunnel construction are clarified, the classification method and standard of intelligent shield tunnel construction are formulated, and the evaluation system of intelligent railway shield tunnel construction is constructed. At the same time, the composition and function of the visual intelligent management platform of railway shield tunnel are introduced in detail, which provides a hierarchical and step-by-step realization path for intelligent shield tunnel construction. It provides a broad space for the practice of new technologies, new methods, new equipment and new ideas in intelligent tunnel construction.

Keywords: Railway shield tunnel, Intelligent construction, Grading Method, Intelligent management platform

1 INTRODUCTION

With the rapid development of 5G communication technology and AI technology in China, the shield technology is perfecting the adaptability of tunnel construction in different geological conditions and different working conditions, and the continuous improvement of labor cost, the share of tunnel shield (including TBM) construction in railway tunnel construction is gradually increasing, and it may become the mainstream of tunnel construction in our country in the future. According to statistics, by the end of 2021, there are a total of 31 railway shield tunnels in operation or under construction in China, with a total of 303km, and 40 railway tunnels planned to be constructed with the shield method, with a total of 387 km. Shield construction is a factory operation in

which segments are prefabricated in the factory, excavation, support, lining and transportation are organized according to the assembly line. With a high degree of mechanization, it has the basis and advantages of intelligent construction. Therefore, research on intelligent construction technology of shield tunnel is of great significance for promoting intelligent and unmanned tunnel construction.

Qinghuayuan Tunnel of Beijing-Zhang High-Speed Railway is located in a densely built area of the city with a complex construction environment. In order to solve the problem of safe passage of large-diameter shield tunnel in dense buildings, China Railway Engineering Design and Consulting Group Co., LTD., together with Beijing Jiaotong University, China Railway 14th Bureau Group Co., LTD., China Academy of Railway Sciences and other units,

*Corresponding author: liujianyou2008@qq.com

carried out the research on intelligent construction technology of shield tunnel. The fully prefabricated assembly technology of shield tunnel has been formed, the intelligent assembly equipment has been developed, the visual intelligent management platform of shield tunnel has been developed, and the intelligent construction technology system of shield tunnel has been established.

In order to unify the technical standards for intelligent construction of railway shield tunnel, commissioned by China National Railway Group Co., LTD., China Railway Engineering Design and Consulting Group Co., LTD., chaired the preparation of Technical Guide for Intelligent Construction of Railway Shield Tunnel, which proposed classification methods and standards for intelligent construction of shield tunnel, laying a foundation for improving the intelligent construction level of railway shield tunnel.

This study clearly puts forward the principles and objectives of intelligent shield tunnel construction, and puts forward requirements for intelligent construction of railway shield tunnel from four aspects: survey, design, construction and construction management. In each aspect, the key process links as technical indicators, according to its degree of intelligence, divided into three levels, respectively, basic intelligence (level I), intermediate intelligence (level II) and advanced intelligence (level III). Therefore, the evaluation index system of shield tunnel intelligent construction is established, and on the basis of the research, the method and process of intelligent evaluation for the whole shield tunnel project are put forward.

2 THE BASIC MEANING OF INTELLIGENT CONSTRUCTION OF SHIELD TUNNEL

Intelligent construction of shield tunnel is to apply advanced technologies such as BIM, GIS, digital twin, visualization, artificial intelligence, 5G communication, prefabrication and assembly to the whole process of shield tunnel construction, and comprehensively improve the digitization, information and automation of shield tunnel in survey, design, construction and construction management. Intelligent decisions and responses should be made to various working conditions and construction risks to achieve safe, quality, rapid and efficient completion of tunnel construction tasks.

According to the actual situation and needs of the project, the intelligent level of the survey, design and construction of the shield tunnel should be predetermined before commencement, and the intelligent results should be evaluated during and after completion.

The intelligent construction level of shield tunnel can be determined according to construction objectives, construction conditions, tunnel characteristics, surrounding environment and other factors. Finally, the intelligent construction of shield tunnel should establish a visual intelligent management platform to

realize the centralized and unified management of visualization, digitalization and intelligence in survey, design and construction.

3 THE BASIC REQUIREMENTS OF INTELLIGENT CONSTRUCTION OF SHIELD TUNNEL

3.1 *Survey requirement*

The overall survey work of intelligent construction of shield tunnel should meet the needs of the corresponding intelligent construction grade and provide basic geological data for each process of intelligent construction. The intelligence level and selection index of shield tunnel intelligent construction survey at each stage should be determined according to the actual situation and needs of the project, and the survey work at each stage should be based on the characteristics of shield method and the requirements of intelligent construction grade, so as to provide information support for predicting the impact of engineering activities on the surrounding environment. At the same time, the geological parameters required should be obtained according to the selection of the survey intelligence index and grade in each stage of the survey, so as to meet the needs of intelligent design and construction. The depth of work in each stage of reconnaissance, preliminary test, fixed test, supplementary test and construction survey is gradually increased from the front to the back, and the depth of the corresponding design stage is also gradually increased, and the survey accuracy of the survey work corresponds to the intelligence level, and the unnecessary selection of too high intelligence level in the early stage increases the unnecessary work burden. If the intelligent construction of shield tunnel has special requirements and needs to formulate detailed information model, special investigation or special research should be carried out.

In the investigation of intelligent construction of shield tunnel, the investigation plan and implementation rules should be formulated according to the site, surrounding environment, engineering characteristics and intelligent construction scheme, the geological conditions should be ascertained more accurately, the investigation data should be digitized and a 3D visual information model should be formed, whose scope, form and accuracy should meet the requirements of the predetermined intelligent construction level of investigation.

3.2 *Design requirement*

The intelligence level of the intelligent construction design division shall be determined in the feasibility study stage, the intelligent index of the intelligent construction design division shall be determined in the preliminary design stage, and the design scheme and implementation rules shall be formulated and implemented in accordance with the construction drawing stage. The construction mode of factory

prefabrication and on-site assembly should be adopted preferentially for the main body and auxiliary structure of shield tunnel, which is conducive to realizing the goal of intelligent construction. The influences of embedment depth, geology, surrounding environment, construction technology and other factors should be considered for the main prefabricated components of shield tunnel, and the structural strength, stiffness and stability should be calculated according to the construction stage and the normal use stage.

The intelligent design of shield tunnel should provide the three-dimensional model of prefabricated structure and the selection of shield machine to meet the requirements of the corresponding intelligent construction grade. Intelligent construction design of shield tunnel should adopt BIM forward design, and the accuracy of BIM forward design can meet the requirements of corresponding intelligent construction level, and establish a visual intelligent management platform.

3.3 Construction requirement

The intelligent index and grade of the intelligent construction division shall be determined comprehensively by the design unit according to the actual situation and needs of the project, and the construction unit shall, according to the implementation plan of intelligent construction, prepare the implementation rules for intelligent tunneling of the shield tunnel, allocate the necessary machinery (shield) equipment, and equip with intelligent construction software and relevant personnel. The intelligent tunneling construction of shield tunnel should include the matching of tunneling speed and construction group, geological conditions, deformation of risk source, the matching of palm surface pressure and ground deformation, and the linkage of tunneling and advance geological prediction. At the same time, it is necessary to determine the type of shield machine and its supporting equipment, as well as the shield machine starting, receiving and driving scheme. The implementation indicators of the intelligent construction scheme should be reasonably selected according to the project and the actual situation of the surrounding area, and it is not necessarily necessary to select all of them. The implementation rules of intelligent tunneling of shield tunnel should improve the process flow, realization means and control standards.

Finally, the intelligent tunneling construction of shield tunnel should establish the system of tunneling direction perception, comparison analysis of application groups, geological and risk source analysis, ground deformation analysis, advance geological prediction, and include it in the visual intelligent management platform.

3.4 Management requirement

The intelligence level of the construction and management division shall be comprehensively evaluated according to the indicators of monitoring measurement

and risk control. The intelligent objective of monitoring and measurement should be determined according to the characteristics of the tunnel, construction conditions, surrounding environment and other factors. The requirements of intelligent monitoring and measurement level should be determined in the feasibility study or preliminary design stage, and the type of monitoring and measurement project, the number of sections and the layout method should be determined. An analysis and evaluation system should be established for intelligent monitoring and measurement, and it should be incorporated into a visual intelligent management platform. The statistical function of the data analysis and evaluation system should compare the data directly representing the tunnel state with the over-limit value specified by the existing code or the designed overlimit value to evaluate the tunnel state. The data analysis function of the analysis and evaluation system should realize the charting analysis of the data, and the data directly representing the tunnel state should be displayed through the temporal graphs and spatial distribution charts of stress, strain and displacement. The data analysis function of the analysis and evaluation system should carry out regression analysis on the temporal curve and predict the development trend. For different construction stages, segmental regression should be used for temporal curve fitting.

The risk management and control of intelligent construction of shield tunnel should be carried out in four stages: feasibility study, preliminary design, construction drawing and construction, and the corresponding intelligent indicators and levels should be selected according to the actual situation in each stage. Intelligent risk management and control should be based on monitoring data and combined with other intelligent functions to achieve intelligent risk assessment and dynamic control of construction process risks, and incorporated into the visual intelligent management platform.

4 CLASSIFICATION METHOD OF INTELLIGENT CONSTRUCTION OF SHIELD TUNNEL

Intelligent construction of shield tunnel is to make full use of BIM, GIS technology, digital twin, visualization technology, artificial intelligence technology, 5G communication technology, prefabrication and assembly and other advanced technologies, combined with shield machine. Intelligent objectives of shield tunnel should be determined according to tunnel construction objectives, construction conditions, tunnel characteristics, surrounding environment and other factors, and the overall intelligence of shield tunnel intelligent construction should be initially classified. Then, combined with the overall intelligent construction grade determined in the preliminary design stage, the intelligent level of four divisions (survey, design, construction and management) of shield tunnel intelligent construction should

be determined. Intelligent tunnel construction can be divided into I, II and III levels. Level I intelligence is the basic intelligence, should achieve automatic data upload, automatic sorting, manual analysis, manual decision, manual operation; Level II intelligence is intermediate intelligence, should achieve automatic data upload, automatic sorting, automatic analysis, automatic advice, assist manual decision-making, manual operation; Level III intelligence is advanced intelligence, should achieve automatic data upload, collation, analysis, automatic decision-making and operation.

The intelligent classification standard of shield tunnel is established based on the current technological development status, and the intelligent classification index and standard need to be adjusted according to the future development of artificial intelligence, communication, visualization, construction machinery, machine equipment and other technologies.

4.1 Survey classification method

Eight indicators are used to assess the intelligence level of intelligent survey work of intelligent shield tunnel construction. According to the technical accuracy and intelligence perfection of each single indicator, its intelligence level is divided into I, II and III levels. The survey results must be displayed in a three-dimensional digital information model to meet the needs of intelligence in subsequent stages, as shown in Table 1.

4.2 Design classification method

The intelligent evaluation of shield tunnel design division adopts 9 indicators. In addition to the traditional items such as shield machine type selection and structural design, intelligent segment design, BIM design and intelligent control design of tunneling process are highlighted, especially the specific

Table 1. Intelligent classification of shield tunnel investigation.

Serial number	Classification index	Level I	Level II	Level III
1	Remote sensing geological interpretation	The mapping scale is 1:50,000, and the spatial resolution should not be less than 10m.	The mapping scale is 1:50,000, and the spatial resolution should not be less than 5m.	The mapping scale is 1:50,000, and the spatial resolution should not be less than 1m.
2	Engineering geological mapping	Engineering geology and hydrogeology mapping should meet the accuracy of 1:10,000 topographic map.	Engineering geology and hydrogeology mapping should meet the accuracy of 1:2,000 topographic map.	Engineering geology and hydrogeology mapping should meet the accuracy of 1:500 topographic map.
3	Existing facility survey	Mainly identify the use of existing buildings (structures), geological diseases, foundation forms, foundation buried depth, etc., the numerical deviation shall not exceed 5m.	Mainly identify the use of existing buildings (structures), geological diseases, foundation forms, foundation buried depth, etc., the numerical deviation shall not exceed 2m.	Mainly identify the use of existing buildings (structures), geological diseases, foundation forms, foundation buried depth, etc., the numerical deviation shall not exceed 0.5m.
4	Stratigraphic lithology and stratigraphic boundary	The accuracy of the decision should not be less than 50%	The accuracy of the decision should not be less than 60%	The accuracy of the decision should not be less than 70%
5	Underground voids and obstacles	The accuracy of the decision should not be less than 50%	The accuracy of the decision should not be less than 60%	The accuracy of the decision should not be less than 70%
6	In-situ testing of formation physical property parameters	The accuracy of the decision should not be less than 50%	The accuracy of the decision should not be less than 60%	The accuracy of the decision should not be less than 70%
7	The physical parameters of formation were tested in laboratory	The accuracy of the decision should not be less than 60%	The accuracy of the decision should not be less than 70%	The accuracy of the decision should not be less than 80%
8	Survey results (required)	The three-dimensional geological information model is established, and includes information such as stratum number, stratum lithology, stratum boundary, geological time, degree of weathering, weathering boundary, basic bearing capacity, conventional parameters, groundwater development degree, type, surface water and groundwater erosiveness, bad geology, special soil and soil.	The three-dimensional geological information model is established, and includes information such as stratum number, stratum lithology, stratum boundary, geological time, weathering degree, weathering boundary, basic bearing capacity, conventional parameters, moisture degree, density state, groundwater development degree and type, surface water and groundwater erosiveness, bad geology, special soil, underground pipeline, etc.	Establish a 3D geological information model, which includes stratum number, stratum lithology, stratum boundary, geological time, weathering degree, weathering boundary, basic bearing capacity, conventional parameters, moisture degree, compaction state, geological origin, lithology description, groundwater development degree and type. Information of surface water and groundwater erosion, bad geology, special soil, underground pipelines, surrounding structures, etc.

Table 2. Intelligent classification of shield tunnel design.

Serial number	Single index	Level I	Level II	Level III
1	Single and double hole selection	Manual comparison	Program assisted manual selection	Intelligent comparison
2	Prefabricated structure (Required)	segment	Segment, rail structure	Segment, subrail structure, accessory structure, track structure
3	Intelligent design of segment structure	Automatically determine the wedge amount, automatically draw the ring three-dimensional map	Automatic wedge measurement, automatic segmentation, automatic drawing of three-dimensional segment segmentation	Automatic determination of wedge, automatic segmentation, automatic determination of detailed structure, automatic drawing of the three-dimensional structure of the segment
4	Intelligent design of shield tunnel profile	Automatic mapping of geology, mileage, slope; Automatic determination of segment type and auxiliary measures	Automatic mapping of geology, mileage, slope; Automatic determination of segment type, auxiliary measures, palm surface pressure, synchronous grouting pressure	Automatic mapping of geology, mileage, slope; Automatic determination of segment type, auxiliary measures, palm face pressure, synchronous grouting pressure, risk type and grade
5	Structural calculation	Three-dimensional structure calculation considering buried depth and geology	Three-dimensional structure calculation considering buried depth, geology and surrounding environment	Fine structure calculation considering burial depth, geology, surrounding environment and construction technology
6	BIM Design (Required)	Lines, strata, sections	Line, stratum, section, segment segmentation	Line, formation, section, segment segmentation, connection, reinforcement, waterproof and other details of the model
7	Dynamic design	Manual dynamic selection of palm surface pressure, synchronous grouting pressure, driving speed and other driving parameters, as well as risk measures	The program assisted the manual decision of the driving parameters such as palm surface pressure, synchronous grouting pressure, driving speed, and risk measures	The program intelligently decides the driving parameters such as the face pressure, synchronous grouting pressure, driving speed and risk measures
8	Shield machine selection	The software provides a list of shield machine types corresponding to the stratum, and manual selection	The software provides the list of shield machine types corresponding to strata, analyzes the pertinence and advantages and disadvantages, puts forward selection suggestions, and makes selection decisions manually	Software automatic analysis intelligent decision selection
9	Visual Intelligent Management Platform (Required)	Two-dimensional information display, shield real-time monitoring, construction video monitoring, monitoring data upload	3D information presentation, monitoring data and construction response prediction	Information display, forecast, dynamic feedback and information construction

requirements for intelligent visual intelligent management platform are put forward. Similarly, according to the degree of intelligence perfection, the intelligence level of each indicator is divided into I, II and III levels, as shown in Table 2.

4.3 Construction classification method

Construction is the core link of shield tunnel construction, which has many procedures, complex technology and high technical precision, and is a key part of intelligent construction. The construction process is further divided into five parts: shield equipment, component prefabrication, transportation and lifting, excavation construction, and prefabricated parts assembly. Each part is then divided into I, II and III levels according to its technical details or key

process sequence as an evaluation index. Limited by space, only prefabricated parts assembly is taken as an example to illustrate the specific situation of intelligent classification, as shown in Table 3.

4.4 Management classification method

The intelligence level of the construction and management division shall be comprehensively evaluated according to the indicators of monitoring measurement and risk control.

- (1) Monitoring and measurement of shield tunnel
The intelligence level of shield tunnel monitoring measurement can be divided into I, II and III levels according to 12 indicators, as shown in Table 4.

Table 3. Intelligent classification of shield tunnel prefabricated parts assembly.

Serial number	Classification index	Level I	Level II	Level III
1	Segment identification and selection	Manual selection, manual confirmation	Automatic selection, manual confirmation	Automatic selection and confirmation
2	Segment structure assembly	Manual detection of segment gap, misalignment, manual remote control adjustment assembly	Automatic detection of segment gap, misalignment, manual remote control adjustment assembly	Automatic detection of segment gap wrong table, automatic adjustment assembly
3	Positioning of underrail structure and auxiliary structure	Manual measurements assist positioning	Laser positioning	Automatic identification and positioning
4	Assembly of underrail structure and auxiliary structure	Mechanical manual auxiliary assembly	Manual remote control mechanical assembly	Mechanical automatic assembly
5	Underrail structure grouting	Manual grouting, manual testing	Mechanical grouting, manual testing	Mechanical grouting, automatic testing

Table 4. Intelligent classification of shield tunnel risk management and control.

Serial number	Classification index	Level I	Level II	Level III
1	Working well component stress #	Automatic measurement; Manual collection; Manual upload	Automatic measurement; Automatic collection; Manual upload	Automatic measurement; Automatic collection; Automatic upload
2	Formation deformation #	Automatic measurement; Manual collection; Manual upload	Automatic measurement; Automatic collection; Manual upload	Automatic measurement; Automatic collection; Automatic upload
3	Pressure behind segment #	Automatic measurement; Manual collection; Manual upload	Automatic measurement; Automatic collection; Manual upload	Automatic measurement; Automatic collection; Automatic upload
4	Segment reinforcement stress #	Automatic measurement; Manual collection; Manual upload	Automatic measurement; Automatic collection; Manual upload	Automatic measurement; Automatic collection; Automatic upload
5	Segment stress #	Automatic measurement; Manual collection; Manual upload	Automatic measurement; Automatic collection; Manual upload	Automatic measurement; Automatic collection; Automatic upload

9	Deformation of structures (building)*	Manual measurement; Manual collection; Manual upload	Automatic measurement; Automatic collection; Manual upload	Automatic measurement; Automatic collection; Automatic upload
10	Tunnel deformation *	Manual measurement; Manual collection; Manual upload	Automatic measurement; Automatic collection; Manual upload	Automatic measurement; Automatic collection; Automatic upload
11	Work well deformation *	Manual measurement; Manual collection; Manual upload	Automatic measurement; Automatic collection; Manual upload	Automatic measurement; Automatic collection; Automatic upload
12	Analysis and evaluation system	Data statistics, early warning	Data statistics, early warning and analysis	Data statistics, early warning, analysis and recommendations

Table 5. Intelligent classification of shield tunnel risk management and control.

Serial number	Classification index	Level I	Level II	Level III
1	Risk identification	The program automatically identifies single-factor risks	The program automatically identifies single-factor risks and multi-factor combination risks	The program automatically identifies single factor risk and multi-factor combination risk, and gives the probability of risk occurrence
2	Risk classification	Manual classification	Program aided manual grading	Automatic program grading
3	Risk counter-measure	The program automatically puts forward a list of risk countermeasures and makes decisions manually	The program automatically puts forward risk countermeasures and suggestions, and makes decisions manually	The program automatically puts forward risk countermeasures and analyzes the effect of risk control

(2) Risk control of shield tunnel

The intelligence level of shield tunnel risk management and control can be divided into I, II and III levels according to three indicators, as shown in Table 5.

5 INTELLIGENT SHIELD TUNNEL CONSTRUCTION VISUAL INTELLIGENT MANAGEMENT PLATFORM

Visual intelligent management platform refers to a visual network management platform for collaborative operation and intelligent decision-making based on a unified information cloud platform and a variety of intelligent information integration methods to achieve intelligent construction of railway shield tunnel. At present, the existing railway tunnel construction management system is mainly for construction units. The visual intelligent management platform is a visual unified network management platform of multi-professional cooperation established by applying BIM technology, and carries out systematic management of intelligent tunnel construction. This platform can realize the real-time display of various horizontal profile information, construction video, monitoring data, shield machine parameters, surrounding environment monitoring and other projects; Construction management can optimize and adjust the tunneling parameters, construction organization and risk response measures of shield tunneling machine on this platform. Construction management can carry out progress control, inspection and pricing, quality acceptance and other work on this platform; After the completion of the project, the platform can be used as the basic platform for maintenance and management.

The visual intelligent management platform can realize a series of intelligent requirements, such as: real-time display of the construction progress of each shield machine, detailed record of the comparison between the preset progress and the actual

progress of shield construction and the overall completion, statistical analysis of the progress information, and output visual graphics and corresponding reports, as shown in Figure 1. The construction progress indicators of each shield machine can be set within the scope of management authority, and the early warning can be achieved through information push when the progress is abnormal, as shown in Figure 1. The construction parameters of each shield machine in the construction process are displayed in real time, and the manager can realize the remote real-time monitoring of the shield construction process. In the form of time period, the data of material consumption, efficacy, number of advancing rings and mileage in the shield construction process are counted and queried, and can be output in the form of reports. It can upload and download the settlement data of the measuring point, support the query of the accumulated settlement amount and settlement rate curve of single point settlement and multiple settlement points, and output it in the form of a report to push the abnormal data. Empirical formula method, artificial intelligence method, big data processing method and refined numerical modeling methods can be used to analyze the whole process of shield construction based on engineering geological data, construction parameters and monitoring data, so as to obtain the prediction and early warning value of formation deformation during construction and feedback adjustment of later shield construction and a series of reinforcement measures. The plane and section influence areas of risk sources at all levels in each shield section can be displayed by plane plan or three-dimensional model.

Finally, after the completion of the shield tunnel, the construction unit should organize the design, construction, supervision and other units to evaluate the intelligent results. The result evaluation should include the overall intelligent evaluation of the project, as well as the intelligent evaluation of each branch of survey, design, construction and construction management. The scope and items of intelligent results acceptance shall be accepted and evaluated

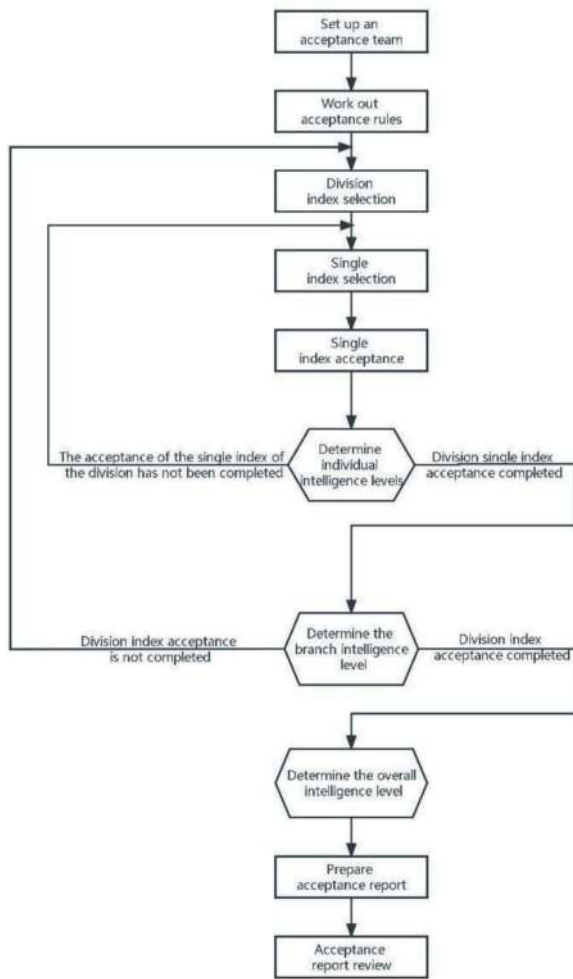

Figure 1. Acceptance process of intelligent achievement of shield tunnel.

item by item according to the intelligent construction implementation plan determined at the construction drawing stage. The acceptance of intelligent results should include the intelligent evaluation indicators proposed in the implementation plan of intelligent construction. The acceptance of intelligent results can be divided into three levels: comprehensive index, partial index and single index. The intelligent management platform can form acceptance reports and transfer them to operation and maintenance. The acceptance of intelligent results should first evaluate the intelligence level of a single index, and comprehensively evaluate the intelligence level of the division index based on all the individual indicators of the division, and comprehensively evaluate the overall intelligence level of the project based on the intelligence level of all the divisions. The acceptance process is shown in Figure 1.

6 ECONOMIC BENEFIT ANALYSIS

The expected increase in the cost of intelligent construction of shield tunnel is mainly reflected in the

survey, design, equipment, component prefabrication, transportation and lifting, excavation construction, assembly construction, monitoring and risk control, etc. The increased cost is mainly used for equipment transformation and software development.

The intelligent realization of shield tunnel can greatly reduce labor consumption and save labor cost. Improve the construction efficiency and reduce the construction period; Improve construction safety and reduce accident risk; Improve construction quality and increase quality benefit; Improve the working environment and increase environmental benefits.

To sum up, equipment transformation and software development in the early stage of intelligent construction of shield tunnel will increase a certain cost, but in the later stage, huge benefits will be achieved by reducing labor, improving efficiency, ensuring safety, improving quality and improving the environment, and the overall benefits will far exceed the increased costs.

7 CONCLUSION AND PROSPECT

This paper puts forward the idea of intelligent classification of railway shield tunnel for the first time, puts forward the principles and objectives of intelligent construction of shield tunnel, establishes the evaluation system and evaluation method of intelligent construction, and establishes the classification standard of intelligent construction of shield tunnel. The basic requirements of intelligent construction survey, design and construction of shield tunnel are clarified. This paper mainly discusses the following points:

- (1) The basic requirements, implementation schemes and detailed rules of four sub-divisions of intelligent construction of railway shield tunnel, namely, survey, design, construction and construction management are discussed in detail.
- (2) The classification method of intelligent construction of railway shield tunnel is proposed, and the intelligent classification evaluation system and evaluation standard are constructed.
- (3) Establish an intelligent management platform, realize the visualization of intelligent construction, and carry out systematic management of intelligent tunnel construction.

This paper discusses in detail the basic requirements, implementation plans and rules of the four branches of intelligent construction of railway shield tunnel: survey, design, construction and construction management, summarizes the intelligent classification method of intelligent construction of shield tunnel, establishes a visual intelligent management platform, and provides a broad space for the practice of new technologies, new methods, new equipment and new ideas in intelligent construction of tunnel.

The interface between construction site and Tunnel Information Model: The case of the Brenner Base Tunnel

David Marini* & Giuseppe Venditti
BBT SE, Bolzano, Italy

ABSTRACT: The Brenner Base Tunnel is a complex tunnel system and it will require a suitable virtual twin once it becomes operational. In order to achieve this, a Tunnel Information Model of the underground civil works under construction was created, showing the final linings for both mechanised and D&B excavated sections. The correct identification of the level of information required and close cooperation with the construction site are essential elements for this type of virtual reconstruction. A case of synergistic collaboration with the construction phase is seen, for example, with regard to TBM excavation, in which information from the boring machine itself is used for the installed rings. The purpose of this abstract is to present the Information Model approach used for the Brenner Base Tunnel, a strategic project for the future of Europe and the longest underground railway project in the world upon its completion.

Keywords: Brenner Base Tunnel, Tunnel Information Model, TBM excavation, complex tunnel system

1 INTRODUCTION

The Brenner Base Tunnel (BBT) is a flat railway tunnel that connects two States and is the central part of the new Munich-Verona railway corridor, along the extended Scandinavian-Mediterranean corridor within the European

TEN-T transport network. It stretches between Innsbruck (Austria) and Fortezza (Italy) for a total length of 64 km (including the Innsbruck bypass) and will be the longest underground railway link in the world.

The BBT is a complex system of tunnels with a total length of almost 230 km, of which more than 160 km have been completed to date, the main works being the two-line tunnels and the exploratory tunnel (see Figure 1).

It will offer a viable alternative for freight transport and will create a new travel opportunity for passenger traffic.

It is truly a European project, as is shown by the strong confidence the European institutions have shown in this infrastructure project. To date, the European Union has already allocated more than € 1.6 billion to the project, covering 50% of the costs for design and exploration activities and 40% of the costs for construction activities.

Thanks to the new € 700 million tranche of European funding from the Connecting Europe Facility

(CEF) European co-financing programme, which BBT SE was able to access following the positive assessment from the European Commission within a recently published call for tenders, all project costs are now borne equally by the European Union (50%) and the two states of Italy and Austria (25% each). The implementation of innovative and forward-looking systems, such as a Tunnel Information Model (TIM) contributed to the positive assessment on the part of the European Commission.

2 OBJECTIVE OF THE TUNNEL INFORMATION MODEL

The objective of the Information Model of the Brenner Base Tunnel project is the digital and information management of the railway infrastructure including civil works, railway superstructure and technological equipment. The Tunnel Information Model (TIM) is methodically integrated into the documentation system of civil and technological works with a transnational view of the project. This requires the setting up of a Project Information Model (PIM), developed during the design (see Figure 2) and construction phases of the different construction lots.

In this specific case, then, we have a TIM generated by the uniform management of information and

*Corresponding author: david.marini@bbs-se.com

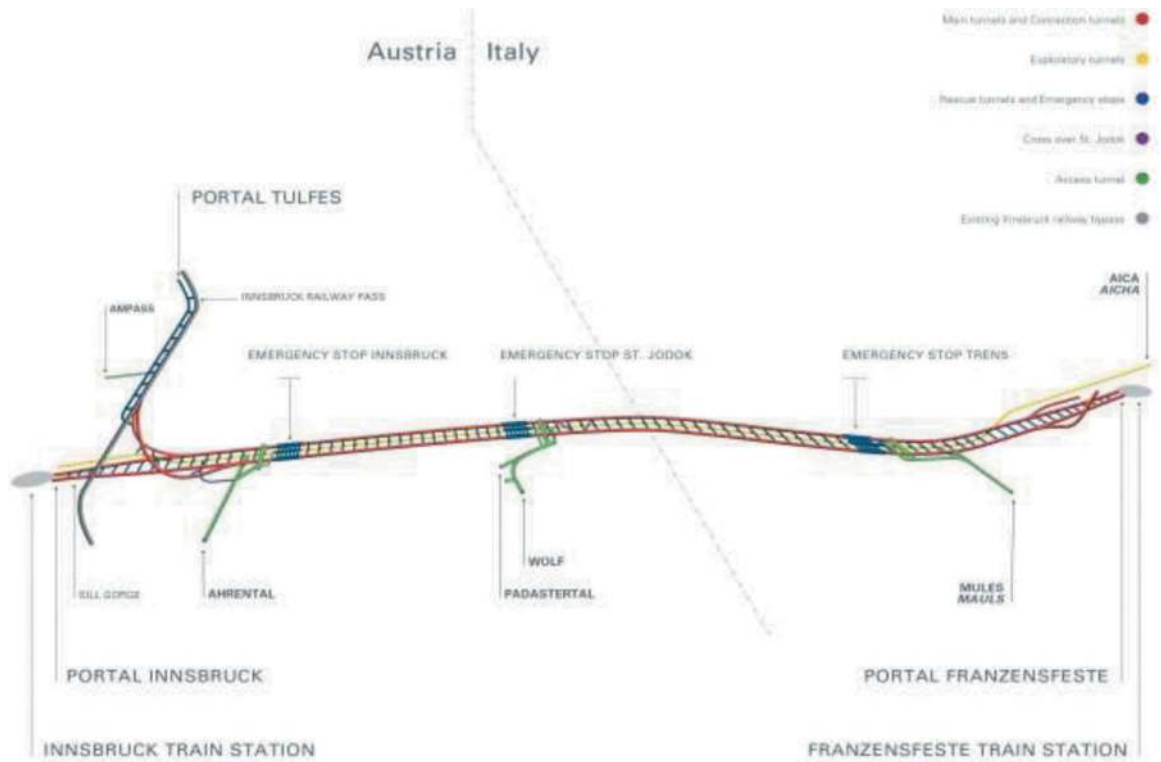

Figure 1. Diagram of the Brenner base tunnel system.

Figure 2. Emergency stop model.

data for the railway outfitting and railway operation phase. The methods applied for the BBT comply with the latest regulatory developments for BIM in Italy and Austria. The consequent improvement in transnational communications also improves and increases the transparency and quality of the project.

The comprehensive and unified management of information and data on the main tunnels leads in the long term to optimised maintenance and fewer breakdowns due to continuous preventive maintenance, as well as fewer disruptions to rail traffic during the operational phase.

3 THE CONSTRUCTION SITE

The construction of the Brenner Base Tunnel requires a careful choice of type sections able to support the stresses induced by excavation. In particular, depending on the excavation method, a final lining consisting of a ring of prefabricated tubbing rings and/or a final lining of cast-in-place concrete is used (see Figure 3).

Figure 3. Final lining, change from single track to double track.

Sections excavated with conventional methods require the final cast-in-place lining with a suitable waterproofing and drainage system.

In excavations with conventional methods, the installed waterproofing system consists, from the outside of:

- levelling layer for the waterproofing;
- dimpled membrane drainage elements supporting the geotextile protection layer;
- protective geotextile with a minimum weight (of 900 g/m²);
- waterproofing sheathing in polyvinylchloride PVC-P or composite geotextile^o (see Figure 4);
- PVC protection membrane (or protective layers in the reverse arch);
- Internal and external PVC-P transition strips and elastomer waterstops with steel side seams.

Figure 4. Waterproofing of the dome area for conventional excavation sections.

Depending on the type of structural element, the stretch of the tunnel and the concrete exposure class, stretches excavated using conventional methods mainly require the use of the following compressive strength classes:

- foundations, base slab and invert: C30/37 – C32/40.
- dome: C30/37.
- precast concrete segmental rings: C50/60.

The main components of the concrete used are briefly described below:

- Cement: given the need to guarantee the durability of the work for 200 years, extremely high-performance mixes have been developed to guarantee very low permeability and high resistance to carbonation and chemical attack. Among the various exposure classes, special care was devoted to designing the mixes that must guarantee resistance to sulphate attack, which may only contain cement with a typical maximum content in clinker of 0% C3A (Tetracalcium Aluminate), which can therefore be defined as free of C3A.
- Additives: additives are provided to further increase the performance of the concrete.

- Aggregates: in the Brenner Base Tunnel project, particular importance was given to the environmental impact of producing aggregates to be recycled. If the excavated rock meets the necessary suitability requirements, it is screened and processed in crushing plants.

The prevention of chemical attacks on the concrete has been a particular area of interest. Depending on the type of structural element and the chemical composition and reactivity of the groundwater, assessed in terms of sulphate content, pH, aggressiveness, ammonium content, mercury content and water hardness, exposure classes (XA1, XA2, XA3) which are resistant to chemical attack has been used.

In particular, with reference to the chemical parameters listed above, ranges of values were identified and, based on expectations, a minimum exposure class was associated with each of them. The overall exposure class of the concrete is chosen based on the class associated with the most restrictive parameter.

For sections with emergency evacuation features, highly fire-resistant concrete (CF-ERF) has been used. In addition to the characteristics specified for ordinary concrete in the executive design, the mixture has a polypropylene fibre content. The addition of fibres provides a stiffer and more viscous consistency which can generally be evened out by adding fluidifying additives.

For mechanised excavation in Italy, the lining in the main tunnels consists of a universal type ring composed of 6 ordinary elements plus a keystone. Longitudinally, the tubing rings are approximately 1.75 m long and 45 cm thick (see Figure 5). The introduction of a universal ring meant the adoption of a monolithic element was created, thus reducing the risk of openings between the joints and guaranteeing better sealing against water infiltration, with a consequent increase in overall performance.

Figure 5. Tunnel lining with universal tubing rings.

For increased precision in installing the tubing ring linings, PVC guide bars were installed in the

longitudinal connections between the rings. In order to waterproof the longitudinal joints and the areas between the individual rings of the lining, seals with elastomeric profiles were installed, where necessary, both on the inside and on the outside of the tubing ring. The longitudinal connection and the alignment between the rings are ensured by means of longitudinal connectors. The connection systems are equally spaced along the circumference and positioned in the middle of the thickness of the tubing rings.

With regard to the main tunnels, the characteristics of the concrete change depending on whether the tubing ring is a base slab tubing ring or part of the ring system. In particular: for the base slab tubing rings the concrete class C30/37, exposure class XC3/XA1, maximum aggregate size 22 mm and slump S4 is used; for the tubing rings which are part of the ring system the concrete class C50/60, exposure class XC4/XA2, maximum aggregate size 22 mm and slump S4 is used.

Along the sections excavated by TBM, performance-related and geometric requirements have shown the advisability of using a so-called double lining, i.e. consisting of precast concrete segmental rings and a final concrete lining. Double lining is foreseen in fault zones, in areas where groundwater is particularly aggressive, and in sections that play an important role in case of emergency evacuations (emergency stops, etc.).

4 THE FINAL CIVIL WORKS WITHIN THE MODEL

The different typological sections were developed in such a way as to obtain parametric 3D extrusions that could in turn be used in a versatile manner for the various tunnel sections.

To better meet operational requirements, the modelling was divided into global modelling and typological modelling. Global modelling shows what was actually executed on site and is reported in a unitary federated file (see Figures 6 and 7).

Figure 6. Federated as-built model of the construction lot isarco river underpass.

The global models, besides being a real representation of the finished product, contain specific information on the finished works, such as start and end of casting progressions, mixed-design used, performance characteristics of the cast concrete with the pertinent exposure classes for the different types of works (dome, inverted arch, etc.), non-conformities, technical changes and hyperlinks to the technical documents saved on BBT SE's CDE (see Figure 8). Geological, geotechnical and monitoring information is also present in the global model.

For a better representation of the details of the various section types of the final lining, type models were created which do not contain site-specific details (such as the start and end chainages contained in the global model) but more construction-specific details, such as waterstops, waterproofing layers, geotextiles, etc. (see Figure 9).

Figure 7. Federated as-built model of the construction lot Mules 2-3 between Mezzaselva and Mules.

Figure 8. Example of global model with an overlay of the laser scan performed on site.

Figure 9. Typological model of the mechanized excavation model.

More specifically, from the modelling of two-dimensional families using generic metric models, we move on to nesting within the generic metric model, using two adaptive points and two reference points. With adaptive points, the sections on the route can be extruded based on the chainages and thus the actual geographical coordinates, whereas with reference points the sections on the route can be seen with the proper rotations.

The adaptive families themselves contain the shared parameters as stipulated by the pertinent level of information needs (see Figure 10).

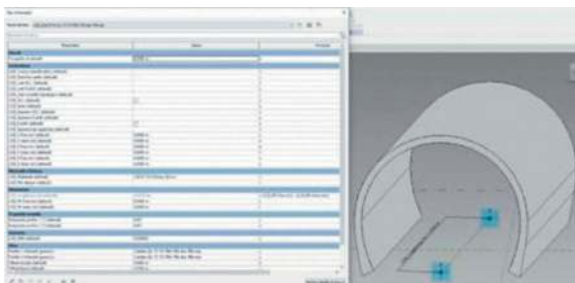

Figure 10. Parametric family pertaining to the dome, for excavation with conventional methods.

In this way, in the adaptive model family, it is possible to assign length and rotation parameters for both two-dimensional profiles, parameters which in turn are calculated directly by visual programming scripts according to the coordinates of the route and with respect to the actual casting lengths executed on site.

Having obtained the three-dimensional sections of each individual element necessary to obtain the federated model (domes, arches, walls, intermediate slabs, side fills, sub-bases, ground and platform pipes, gravel), the modelling of the tunnel sections proceeds by automating the process through visual programming codes.

In this particular case, the code:

- imports the x, y, z coordinates of individual cast sections;
- creation of adaptive points on which to create the segments;
- calculation of the rotations of the start and end profiles of each single cast element;
- extrusion of the ring segment casting as a function of the start and end chainages with the standard section used on site;
- populating the information attributes and document set in each element as required by the level of information need.

For the mechanised excavation of the line tunnels of construction lot H61 Mules 2-3, the type of machine adopted is a double shield TBM, with an excavation diameter of approximately 10.7 m for a section of approximately 14 km for each machine.

The positioning of each individual ring element has been respected, keeping to the assembly diagrams provided for by the project and consistent with the positioning data from the machine's navigation system (VMT). The main data concerns the position of keystone element A. Knowing the position of the key segment from the VMT and knowing the number of possible positions (19 assembly schemes from the design for the line tunnels), it was possible to determine the positions of the remaining ring elements analytically, by automating everything through visual programming scripts (see Figure 11).

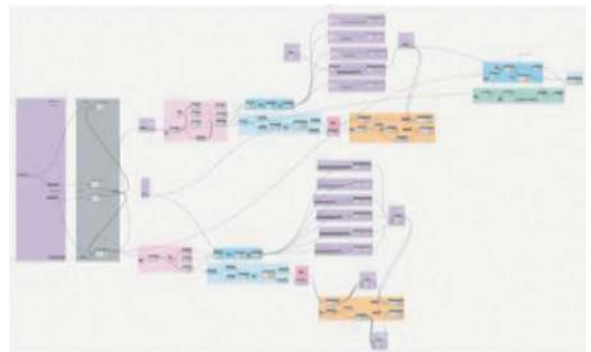

Figure 11. Overview of the script for generating a local model.

Knowing the coordinates of the route and the position of the ring segments and knowing the number of rings between two chainages, modelling proceeded using dedicated scripts according to the route and the related populating of information and document set as per the level of information need (see Figure 12).

Figure 12. Diagram of precast concrete segmental rings positioning.

For each individual precast concrete segment, for information purposes, its identification code was included as parametric information in the digital model, which allows to trace the production history (see Figure 13).

Figure 13. 6+1 prefabricated segments forming a ring.

5 TECHNOLOGICAL EQUIPMENT AS PART OF THE MODEL

Technological equipment will also play an important role in the Brenner Base Tunnel project in BIM modelling. The information management plan currently drawn up for the final design phase provides clear information on the requirements for the railway superstructure, the electric traction systems, the command and control systems, the mechanical systems, etc. (see Figure 14).

BBT SE's goal is to achieve a unified and complete model which contains both the specialised models for the civil works and specific systems, and the information related to technological equipment.

Figure 14. Modelling the railway infrastructure in the open-air section.

6 THE SYNERGETIC FLOW OF DATA TO/FROM THE CONSTRUCTION SITE

The different information requirements included in the model are identified a priori according to the requirements that arise both during the construction phase of the work as well as during its operation, differentiated for sections built using conventional and mechanised excavation methods, and included in the pertinent information and documentation set.

Thanks to the modelling of the individual concrete cast segments and the precast concrete segmental rings installed by the boring machine, the individual non-conformities (NC) are introduced in the exact detection position, as well as technical modification requests received during construction.

This document set than can be viewed in the modelis connected to the Common Data Environment (CDE) of the project.

A case of synergetic collaboration with the construction phase becomes particularly efficient with regard to the advancement of the TBMs. In the ring segments installed by the TBM, an information set from the excavating machine itself is recorded. These include both information sets in relation to position data (progression, position of the ring segment, etc.), as well as physical and mechanical parameters recorded directly by the tunnel boring machine during excavation (see Figure 15).

Figure 15. TPC command and control screen of the TBM in the Mules 2-3 lot.

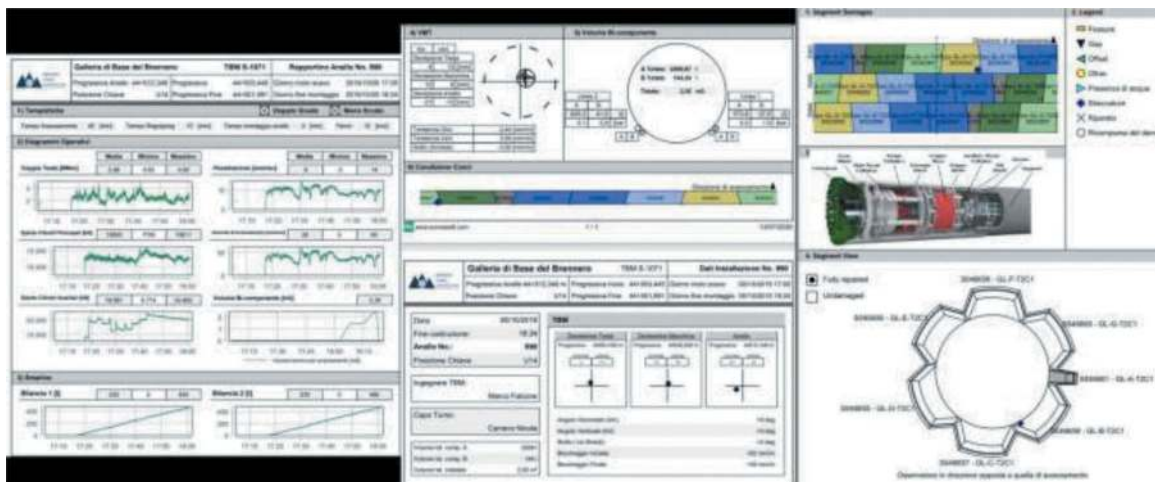

Figure 16. Ring report of a precast concrete segmental ring.

These parameters, acquired approximately every three seconds by the TBM, constitute an effective system for monitoring the condition of the rock mass. Therefore, they are of importance within the project information model. These parameters can be seen in the ring report in the model, and they include: head torque (MNm), penetration (mm/revolution), average spoil weight (t), pea gravel quantity (m^3), horizontal and vertical ring deviation (mm), main and auxiliary cylinder thrust (kN), excavation speed (mm/min) (see Figure 16).

In addition, machine parameters trends are cross-referenced with data from point surveys to define their behaviour as a function of geology. Therefore, in the specific case of the mechanised excavation of the Exploratory Tunnel, the modelling of the TBM segments is supported by the input of reports from the advance drilling.

Core drilling is carried out in the most geologically, geomechanically and hydrogeologically critical portions of the route.

In addition to forward drilling surveys, reports from tunnel face mapping are also put into the model. Geological documentation, which consists of surveys, is of fundamental importance in interpreting some of the measurements that are recorded by TBMs.

The tunnel face mapping carried out on site provides the RMR (Rock Mass Rating) index, always included in the TIM for each chainage survey, which allows the rock to be classified through a score after analysing certain parameters (see Figure 17).

Figure 17. Excavation tunnel face mapping report.

The synergetic flow of data to and from the construction site leads to other information needs, including, by way of example:

- strain-gauge bar monitoring: measurements of deformation/strain on the first-phase lining (shotcrete and ribs) using 5 pairs of vibrating-wire strain-gauge bars welded to the ribs and embedded in the shotcrete;
- load cell monitoring: measurement of deformation/strain on the first-phase lining (shotcrete and ribs), by means of 2 load cells placed below the base of the ribs;
- bolt load sensor monitoring: measurement of the deformations of the rock mass on the contour of the excavation using five radially arranged bolt load sensors;
- convergence monitoring: convergence of 5 reflective targets on temporary shotcrete lining or 2 targets on footings.

All of these data flow into the level of information need, depending on the specific works and the section of the tunnel, according to the latest standards, including ISO 19650 and EN 17412.

7 CONCLUSIONS

For strategic infrastructures such as the Brenner Base Tunnel, a Tunnel Information Model is essential for easier management of the innumerable data generated during construction which can thus be consulted over time, and such a model is also easy to use. In this way, the history of the structure can be tracked throughout its life cycle, which is an effective tool during the operational phase.

ACKNOWLEDGMENTS

We would like to express our sincere thanks to BBT SE CEOs Gilberto Cardola and Martin Gradnitzer, both for their willingness to share the technical experience of the Project and their support of our

active participation in international events in our sector. Our thanks also go to Lisa Terzariol for the translation of this article.

Integrated design of precast concrete linings for mechanized tunnels

Alessandro Menozzi*, Beatrice Tiberi, Daniele Maturi & Roberto Comini
SYSTRA SWS, Trento, Italy

ABSTRACT: Nowadays, metro tunnels represent probably the most sustainable solution for an efficient and environmental-friendly urban transportation, ensuring an optimized use of available land and fostering the development of green livable cities. In this context, mechanized tunnel has become one of the best construction practices, guaranteeing high productivity, safe working environment and small induced surface settlements causing minimal damage to existing buildings.

Considering the cutting-edge digital technologies rapidly evolving in the world of civil infrastructures, an innovative approach has been conceived for the integrated design of precast segmental linings. The developed tool uses basic input data like tunnel alignment and diameter, segments layout and geotechnical profile, to generate the BIM tunnel geometry and the required FEM/DEM structural and geotechnical models. This paper presents the meaningful case study of Grand Paris Metro Line 14, Lot 4, which implements this integrated design strategy and provides an optimized metro tunnel design, overcoming the typical limitations of traditional approaches.

Keywords: BIM technologies, Segmental Lining, Mechanized Excavation, Advanced Simulation

1 INTRODUCTION

Mechanized excavation represents one of the most reliable solutions for tunnels in urban environment. As a matter of fact, this technology is a “unicum” in the world of civil infrastructures, due to the industrialization and standardization of the implemented processes (i.e., segments prefabrication, transportation and installation, TBM driving parameters, implementation of innovative accessories). Furthermore, compared to conventional excavation, TBM-driven tunnels radically reduce construction time, guaranteeing not only a safe and confined working environment, but also an effective quality control.

The integrity of TBM-excavated tunnels mainly relies on their segmental lining, which is obtained by a sequential arrangement of concrete segments adopting a staggered layout for longitudinal joints, in order to guarantee overall stability of the system. This specific structural arrangement activates the typical behavior of reciprocal structures, studied for the first time by Leonardo da Vinci about 500 years ago (Da Vinci, 1519; Da Vinci, 1505).

In this context, an accurate design is fundamental to achieve the expected results in terms of organization and economy of the whole construction process. As in all industrial productions, in fact, the manufacture of segmental lining components is turning into a more and more standardized and refined production chain, implying a non-stop research for time and cost optimizations.

Nowadays, engineers are thus required even more than in the past for a 360-degree integrated knowledge not limited to structural and geotechnical design, but extending to fabrication stages and associated cutting-edge technologies fostering a continuous improvement in the quality and efficiency of the entire process.

1.1 *Traditional design approaches*

The conventional design of tunnel linings has traditionally followed two main approaches (Figure 1): the continuum model and the unidimensional model (hereinafter referred to as “geotechnical” and “structural” models).

The former simulates ground behavior by means of 2D plate elements and concrete lining via continuous beam elements with appropriate axial and bending stiffness. Often, these models also implement contact elements to manage ground-structure interaction.

Unidimensional or structural models, on the other hand, simulate the lining by continuous beam elements: the ground support is accounted for by using compression-only springs, while ground pressure is applied via distributed loads. The second approach allows defining ground loads acting on the lining without the need for a dedicated geotechnical model, as loads can be either obtained by closed-form solutions (Terzaghi, Beniaowski, etc.) or by the convergence-

*Corresponding author: amenozzi@systra.com

confinement method. This “beam-spring” model is thus very practical when dealing with multiple load cases (i.e. shrinkage, temperature, traffic, etc.).

Both structural and geotechnical approaches must account for the 3D coupling of consecutive rings and the associated bending moment migration between segments joints, which is a typical behavior of reciprocal structures. This effect is generally addressed in the analysis through an equivalent reduction of lining bending stiffness, according to Muir Wood theory (Wood, 1975):

$$M_0 = M + \zeta M = (1 + \zeta) M$$

$$M_1 = M - \zeta M = (1 - \zeta) M$$

$M = (M_0 + M_1)/2$: is the moment calculated with uniform reduced flexural rigidity

$M_2 = \zeta M$: is the design moment transferred to adjacent rings

$M_0 = M + M_2$: is the design moment for segments

$M_1 = M - M_2$: is the design moment for joints.

The design bending moments for segments (M_0) and joints (M_1) are thus obtained applying the amplification $(1+\zeta)$ and reduction $(1-\zeta)$ factors to the calculated stress resultants. The main limitation of this approach is related to the correct definition of the redistribution coefficient ζ , which is still too subjective (Pescara and Osgoui, 2014).

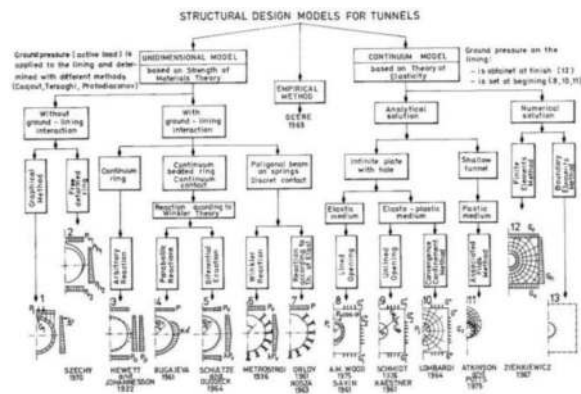

Figure 1. Literature overview of the most accredited traditional analytical models (Ifime, 1994).

1.2 A new design approach

Nowadays, the new horizon in civil engineering is represented by the effective implementation of digital technologies, with the aim of developing the so called “Digital Twin” of the infrastructure. This novel design process is strongly characterized by interoperability and collaboration, requiring BIM modeling, implementation of a dynamic and flexible database (conceived to acquire, organize and manipulate data coming from models and processes, in order to perform closed-form analyses and implement automated simulations) and systematic use of nonlinear FE models.

The next sections present in more details the integrated approach implemented and experienced by the authors during their daily engineering practice, and some successful applications within large infrastructure projects.

2 DIGITAL PROJECT - INTEGRATED DESIGN APPROACH

“Digital Project” is the patented name of the innovative approach developed by the authors’ Company, which involves a collaborative workflow leveraging BIM technologies, computer programming skills, database potentialities and nonlinear FE simulations. The conceived procedure is summarized in Figure 2.

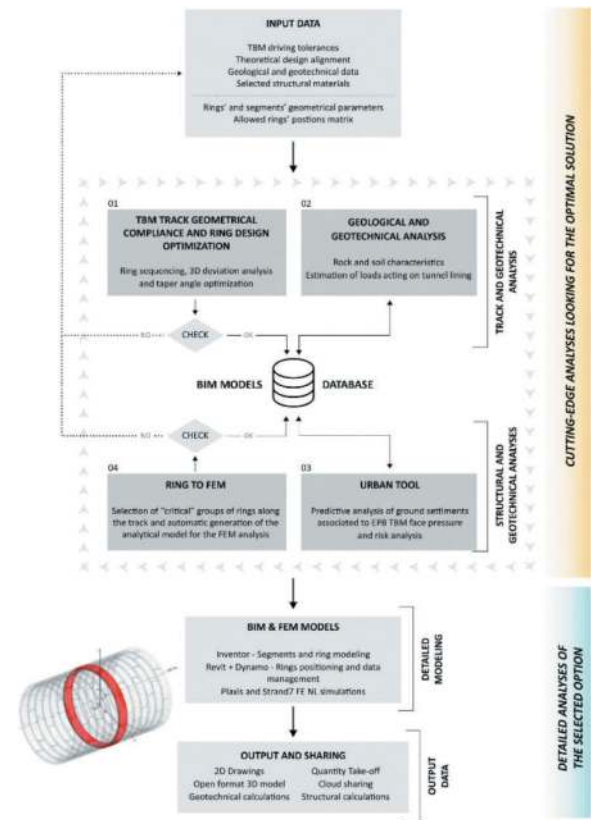

Figure 2. Flowchart illustrating the main steps required for the implementation of “Digital Project”.

2.1 Input data

A rich set of input data represents the starting point of the described process. In more detail, information can be subdivided between fixed and mutable data.

Fixed (or design) parameters are:

- TBM driving tolerances;
- Theoretical design alignment;
- Geological and geotechnical data;
- Selected structural materials.

Mutable inputs (susceptible to optimization as a consequence of the implemented analysis) are represented by:

- Geometrical parameters of rings and segments;
- Matrix of rings' allowed positions.

2.2 Cutting-edge analysis looking for the optimal solution

In order to take advantage of the powerful software packages currently available on the market, in the past years a big effort has been made in developing an integrated tool capable of optimizing the final design solution. This strategy allows engineers to access and manage every piece of information related to the project, thanks to a flexible and dynamic database.

The first step consists in developing the geometrical and informative model, available to the entire working team. The model takes advantage of BIM technologies to perform 3D geometrical evaluations, elaborate design input data, share all relevant information for geotechnical and structural calculations with the database, and visualize in a rational way the obtained results.

As the “engine” of the procedure is represented by the database, considering its importance within the integrated design process, NoSQL technology is used for the core structure, due to its flexibility and dynamism. In more detail, the database is designed to perform specific tasks aimed at supporting the project team in the iterative process of evaluating, validating and designing different solutions, allowing for an interoperable approach to infrastructure design.

The most relevant tools developed and implemented within the Digital Project strategy are briefly described as follows:

01A. Segmental lining geometrical optimization

This tool, conceived with reference to a universal type ring (Guglielmetti et al., 2007), optimizes the ring geometry in terms of taper angle and average length. Thanks to an efficient computational strategy, different options can be quickly analyzed according to the associated taper angle. The obtained results are then post-processed adopting multiple design criteria based on buildability and geometrical compliance.

01B. Evaluation of ring sequencing

The spatial deviation between the theoretical alignment - curvilinear geometry designed by road or rail engineers - and the “real” TBM path - polyline whose elementary unit is represented by ring width - can be analyzed as a function of the size and taper angle adopted for the ring.

By properly varying the input data, a series of analyses should be run using this tool, generating different results that - after a multi-criteria evaluation - allow for the definition of the best choice in terms of minimal deviation and optimized ring positioning. In more detail, the process simulates TBM advancement

during tunnel construction, determining the spatial deviation of each ring from the theoretical alignment (calculated considering also the main design constraints, as the allowable ring positions matrix).

Figure 3 Illustrates the implemented strategy and the results obtained for the specific case study described in the following.

02A. Geological and geotechnical data

Geological data are traditionally available in the form of 2D drawings. Starting from geological and geotechnical profiles or from survey information (like boreholes, MASW, etc.), all the meaningful design data are imported into the digital model using specifically developed automatized procedures. Project data typically stored in the database include: georeferenced geological stratigraphy, water table level, rock and soil characteristics, etc.

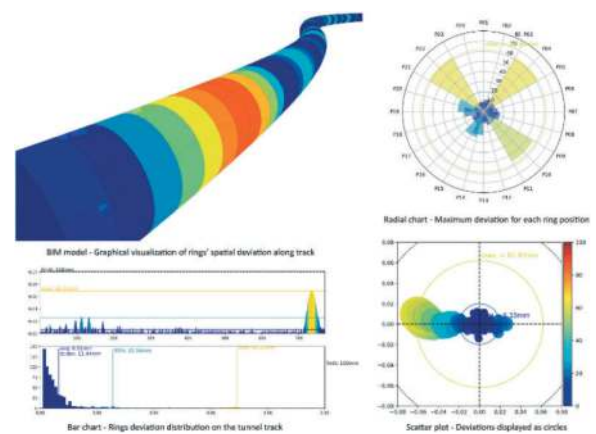

Figure 3. Schematic of the main features of the tool developed for the evaluation of ring sequencing.

03. Predictive analysis of ground settlements and risk analysis

In the context of induced surface settlements due to tunnel excavation in urban areas, the heuristic analysis of the system can be run through the massive implementation of closed-form formulations inferred from the most accredited references in the specific technical literature (Ghensi et al., 2019). SWS Digital Project has been successfully applied in many design cases to perform this challenging task, providing a reliable estimation of the expected ground settlements and a rigorous definition of the optimal TBM EPB face pressure (with the aim of minimizing risk of damage for existing buildings).

On the other hand, a different Digital Project application has been conceived to analyse deep rock tunnels, simulating TBM progress via an iterative analysis of rock mass response to excavation, based on the implementation of Monte Carlo analysis techniques. This application accurately investigates the system sensitivity to the typical uncertainties associated to the choice of design geotechnical parameters.

04. BIM and FE models

Geotechnical and structural engineers finally access the Digital Project database in order to make on-demand FEM models aimed at analysing the most “critical” sections of the alignment.

In particular, the analytical model generation is an automated process developed via the available API of the FE simulation software (in the specific case: Plaxis or Strand7). This approach guarantees reliability and precision, assuring a massive reduction of modelling efforts and allowing to focus mainly on decision-making processes and on accurate result analysis.

Furthermore, another advantage of this integrated approach is the automated coupling of geotechnical and structural models. Soil-lining interface stresses calculated by Plaxis are in fact exported in Strand7, completely defining the load case reproducing the ground pressure effect. The next Section illustrates the strategy implemented for the structural analysis of the concrete lining, together with additional details on FE models.

2.3 Detailed analysis of the selected option

The iterative process for defining the optimal design solution terminates with a detailed analysis of the selected option. This task requires the geometrical model of the ring (Inventor), the definition of tunnel coordination model (Dynamo + Revit), the nonlinear geotechnical and structural modeling of the system (Plaxis + Strand7) and the finalization of output files and documents.

One of the most challenging steps of the process is the modeling strategy selected for the automated generation of Strand7 structural models. First, the staggered layout of the ring-set to be included in the analysis is automatically imported in the FEM software from the Revit model.

Figure 4. Schematic illustrating the generation of the FE model for a typical ring-set.

“Beam” and “Link” elements are used to reproduce the geometrical configuration of the concrete lining, implementing compression-only supports to model soil-structure interaction. The applied stiffness is calculated using the Vesic (1961) formula:

$$K_R = \frac{E}{(1 + \nu) \cdot R}$$

Where: E ground Young’s modulus; ν Poisson Modulus of the ground; R outer ring radius.

This approach requires little computational effort, while guaranteeing easily understandable results; in addition, it introduces an innovation simulation of longitudinal and transverse joints. The following sections present this method and compare it with traditional approaches.

2.3.1 Nonlinear (NL) longitudinal joint model

The longitudinal joint (i.e., the joint between adjacent segments) is conceived to effectively simulate the nonlinear rotational spring behaviour suggested by JSCE, 2006. This Standard provides iterative analytical formulations in order to simulate the joint behaviour, accounting for the significant correlation between rotational spring stiffness and loading condition.

Joints mainly subjected to compression behave as standard rectangular sections in bending, while joints subjected to tension provide negligible rotational stiffness. These two extreme scenarios highlight the strong dependency of joints rotational stiffness on applied load eccentricity.

The main formulations for rotational spring stiffness are as follows:

Rotational stiffness of longitudinal joints:

$$k_{\theta} = \frac{b \cdot a^2 \cdot E}{12} \text{ Closed joint: low eccentricity (} e < a/6 \text{);}$$

$$k_{\theta} = \frac{9 \cdot b \cdot a \cdot E \cdot M \cdot \left(\frac{2M}{N \cdot a} - 1\right)^2}{8 \cdot N} \text{ Partially open joint (} a/2 < e < a/6 \text{);}$$

$$k_{\theta} = 0 \text{ Fully open joint (} e > a/2 \text{).}$$

Where, b width of the contact area; a height of the contact area; E concrete Young’s modulus; M joint bending moment; N joint axial force.

Joint rotation:

$$\alpha = \frac{8 \cdot N}{9 \cdot (1 - 2)^2 \cdot a \cdot E}$$

Where, $m = M/(N \cdot a)$ represents the eccentricity rate.

As joint stiffness varies with eccentricity, implementing these analytical formulations for each load combination is a time-consuming iterative process (SPRING METHOD):

- STEP1 – FE model solved assuming a rigid joint stiffness (closed joints);
- STEP2 – local evaluation of eccentricity (m) for each joint;
- STEP3 – local evaluation of joint stiffness and manual assignment to the model;
- STEP4 – new run of the FE solver (then back to STEP2).

In order to avoid the above iterations, a nonlinear joint model (Figure 5) is developed, where the

interface between consecutive segments is modeled via a series of rigid links and truss elements accounting for the actual segment thickness. The truss elements, spanning between the rigid links in the contact area, are characterized by a nonlinear stress-strain behavior (the parable-rectangle constitutive law typical of concrete - Figure 6).

A fast convergence of the analysis is ensured by the following modeling choices:

- Consider concrete crushing for $\epsilon_c > 3.5\%$;
- Assign a negative stress gradient at the compressive boundary of the table;
- Use negligible resistance for concrete in tension;
- Consider both the correct concrete initial stiffness E_{cm} and design resistance f_{cd} .

Figure 5. Modeling strategy adopted to simulate the NL behaviour of longitudinal joints.

The analysis convergence automatically implies the joint structural check as well. Thanks to the negative stress gradient at the constitutive law end, in fact, the solver stops in case of concrete crushing at the most compressed fiber or in case of a joint completely under tensile stresses.

This modeling approach has been validated by comparing the FEM output with the analytical results according to the previously listed formulations. In particular, given the joint geometry, concrete class and external axial compression, by progressively increasing the bending moment one can obtain the joint moment-rotation curve, as shown in Figure 6.

Figure 6. Stress-strain constitutive law (left) and validation results of the proposed modeling approach (right).

2.3.2 Nonlinear (NL) transverse joint model

The transverse joint (i.e., the joint between consecutive rings) is conceived to automatically simulate the redistribution of bending moments in multiple rings, without any processing of lining bending stiffness, typical of Muir Wood approach.

A set of tunnel rings is made of multiple components modeled in their actual staggered configuration and connected together via a proper arrangement of finite elements, simulating the bilinear behaviour exhibited by transverse dowels (Figure 7).

Figure 7. Modeling strategy adopted to simulate the NL behaviour of transversal joints.

At the end of the analysis, the maximum shear force in the dowels must be checked to guarantee compliance with their maximum capacity.

The adopted simulation strategy shows an excellent reliability, as the comparison between FE results and the iterative implementation of the traditional Muir Wood approach yields a bending moment difference less than 2%.

Figure 8. Force-displacement dowel behavior implemented in Strand7 (left) and typical dowel detail for Gran Paris M14 (right).

2.3.3 Main advantages of the proposed FEM approach

The proposed FE modeling approach, compared with the traditional Muir Wood approach, offers the following relevant advantages:

- Effective integration with BIM tools, supporting the interaction between different members of the project team and facilitating the implementation of geometry changes during the design phase;
- Precise estimation of the stress field acting in the longitudinal joints, providing valuable information for evaluating gasket water tightness and the overall tunnel sealing performance;
- Automatic redistribution of external forces between adjacent rings, avoiding bending stiffness calibration and manual processing of final results (as required in Muir Wood approach);
- Ability to study non-cylindrical load distribution (typically experienced immediately behind TBM tail shield, where a partial gap filling is extremely probable);

- Ability to perform structural checks for fasteners, guiding rods and concrete compressive stresses directly using the FE model, with significant time save and considerable accuracy improvement; these aspects are essential when multiple stakeholders play a role in the design process, considering that changes can occur even in the final phases of the project;
- In case of large deformations caused by longitudinal joints rotations, ability to consider the beneficial support offered by the contrast of the surrounding ground. This allows significant optimization for tunnels having a small cover (meaning small axial forces and, consequently, large eccentricity values).

3 THE GRAND PARIS M14 LOT 4: A RELEVANT CASE STUDY

The GP M14 Lot 4, about 4km long, is the last section of Paris Metro Line 14, connecting Pont de la Rungis Station with Morangis Maintenance Center. In more detail, this project required to design a single double-track tunnel, excavated through a relatively uniform and predominantly clayey soil strata using a 9.0m diameter EPB TBM (also named Koumba).

In this Design & Build contract with a total value of about 200 million EUR, SWS was responsible for the multidisciplinary design of the whole tunnel, providing site support for both temporary and permanent structures.

The application of the integrated design approach allowed for the proper definition of precast lining, suggesting the implementation of a 7+0 universal ring having a mean length of 1800mm and a thickness of 350mm. C40/50 concrete (EN 206-1) and B500C rebars (EN 10080) are the structural material for this project, providing high-performance anchored gaskets, equipped with hydrophilic bars, at all joints between segments. Figure 9 shows the geometry of the adopted segments.

Figure 9. GP M14 Lot 4 precast lining: segments delivered on site (left) and Koumba TBM ready for launching (right).

The limited value of overburden (variable from a minimum of 1.0 to a maximum of 2.0 diameters) and the alignment crossing with very sensitive areas of the city (including Orly airport, roads, bridges, buildings and strategic utilities), more than 400 tunnel sections have been analyzed by the integrated tool. 20 “singular” design sections, identified as the most critical along the alignment, were then automatically generated, and the database populated with a complete set of information regarding: overburden, geological and geotechnical data, water table, presence of buildings/structures and their relative distance from tunnel axis, foundations depth and precast lining characteristics.

This rational and reliable design approach was facilitated by a fruitful collaboration between all stakeholders involved in the project. On the other hand, automation and digital technologies ensured a sensitive improvement in terms of both design quality and efficiency, compared to traditional design approaches.

4 CONCLUSIONS

The integrated design workflow, together with the case study of Grand Paris M14 Lot 4 where this innovative approach was applied, lead to the following conclusions:

- Traditional design approaches of the past cannot compete with innovative procedures in order to reach an optimal design of precast concrete linings;
- Digital technologies, nowadays, can be considered mature enough to be systematically applied for the effective design of infrastructures;
- Interoperable BIM models, if properly developed and managed, can represent one of the most rational options to collect and organize all meaningful project data;
- A flexible database is an essential ingredient for expanding the current limitations identified in all off-the-shelf software that is currently available on the market, making possible a “real” integration between BIM and FEM for both structural and geotechnical problems;
- The massive implementation of closed-form analyses and the automated generation of specific FE models for the most “critical” sections of the infrastructure reduces computational time and increasing the quality and reliability of the project.

Data-driven underground construction management: a case study of the Big Circle Metro Line in Moscow

Michail D. Nadot, Valery V. Vyazovoy, Maria A. Lvovskaya & Aleksandr G. Polyankin*
LLC Mosinzhproekt, Moscow, Russia

ABSTRACT: Underground construction projects are complex and challenging, with the success of such endeavors heavily reliant on efficient management practices. The Big Circle Metro Line (BCML) in Moscow serves as an exemplary case study for the implementation of data-driven techniques in underground construction management. This paper presents an in-depth examination of the BCML project, highlighting the application of advanced automation, Building Information Modeling (BIM), information management, and data-driven technologies to optimize construction processes.

This paper elucidates the integration of data-driven methodologies at each stage of the BCML project, from initial design to operational handover. The strategic application of data-centric decision-making facilitated enhanced collaboration among stakeholders, optimal resource allocation, improved risk management, and increased overall project efficiency.

Key to the project's success was the utilization of BIM for 3D visualization, clash detection, and real-time updates, which ensured a cohesive and adaptive construction approach. Automation played a pivotal role in streamlining repetitive tasks, enabling precision and consistency. Furthermore, robust information management systems were employed to maintain data integrity and accessibility throughout the project lifecycle.

The paper concludes with insights on the transformative impact of data-driven practices in underground construction management. Lessons learned from the BCML project indicate that the judicious use of technology and data can lead to significant advancements in the field, ultimately enhancing the safety, sustainability, and success of underground construction endeavors.

Keywords: Data-driven management, underground construction, Building Information Modelling, automation, information management, project efficiency

1 INTRODUCTION

The construction of subterranean transportation infrastructure is a complex orchestration of engineering, logistics, and stakeholder management. Each phase of development presents unique challenges, amplified by the constraints of working beneath the urban landscape. In recent years, information modeling technologies have emerged as a cornerstone for enhancing efficiency and reducing the inherent risks associated with underground construction projects. This study focuses on the innovative application of these technologies during the construction of seven pivotal metro stations along Moscow's Big Circle Line (BCL).

The BCL project represents a monumental effort to expand Moscow's metro system, serving as a critical case study in the deployment of Building Information Modeling (BIM) and related information modeling tools. The integration of these models facilitated a more collaborative, accurate, and efficient

construction process, shifting the industry paradigm toward a data-centric approach. This paper details the key areas where information modeling technologies were harnessed to optimize construction workflows, improve decision-making, and deliver the project with a high degree of precision and efficiency.

2 LEVERAGING INFORMATION MODELLING TECHNOLOGIES AND 3D MODELS IN THE DESIGN AND CONSTRUCTION

The advent of advanced information modeling technologies has significantly transformed the landscape of underground construction projects. In the case of Moscow's Big Circle Line (BCL), these innovations have played a pivotal role in both design and construction phases, ensuring a streamlined, efficient, and cost-effective process. The application of Building Information Modeling (BIM) and 3D models has

*Corresponding author: Polyankin_alex@mail.ru

been central to this transformation, enabling a high degree of precision and collaboration among the diverse teams involved in the BCL project.

Information modeling technologies facilitated a multi-dimensional approach to the BCL's design, allowing engineers, architects, and construction managers to visualize the entire subway line within a virtual environment. This approach provided an intuitive understanding of complex structures and systems before physical construction commenced, thereby reducing the likelihood of costly errors and rework. BIM's capabilities for clash detection were particularly valuable in identifying and resolving potential conflicts between structural, mechanical, electrical, and plumbing systems, which are common in the confined spaces of underground construction.

The use of 3D models extended beyond the design phase, assisting construction teams with planning and sequencing of work. This ensured that construction activities progressed smoothly, with minimal disruption to the urban fabric of Moscow. Additionally, the 3D models were constantly updated to reflect as-built conditions, thereby maintaining an accurate record of the project's evolution over time.

Risk management were also enhanced through the use of BIM and 3D models. Simulations of construction processes and the behavior of structures under various stress scenarios enabled the proactive identification of risky concerns. This allowed for the development and implementation of risk mitigation strategies before the manifestation of any real-world issues.

Moreover, BIM facilitated improved communication and information sharing among stakeholders. With access to a shared model, all parties, including designers, constructors, city officials, and future maintenance personnel, could work from a single source of truth. This level of integration was paramount in managing the complexity inherent in the BCL project and is a testament to the capabilities of information modeling technologies in the realm of large-scale underground construction.

The adoption of BIM and the active use of 3D models in the BCL project not only improved operational efficiencies but also served as a beacon for future projects in the underground construction industry. The case of the Big Circle Line stands as a resounding endorsement of the potential that lies in embracing digital technologies and data-driven methodologies for the enhancement of construction management practices

3 INTEGRATING INFORMATION MODELS FOR ENHANCED CONSTRUCTION EFFICIENCY: A STUDY OF SEVEN METRO STATIONS IN MOSCOW'S BIG CIRCLE LINE

The following sections will dissect the specific applications of information models within the BCL project, beginning with the critical task of collision detection and prevention—a foundational aspect that

set the stage for the subsequent successes in construction management and operational execution. Through this exploration, we aim to illustrate the profound benefits that BIM and information modeling can bring to the field of underground construction, potentially serving as a blueprint for future projects around the globe.

3.1 *Collision detection and prevention*

The construction of seven key metro stations within western and eastern sections Moscow's Big Circle Line (BCL) utilized information models to preemptively identify and resolve design conflicts. By integrating BIM technologies, potential clashes between different design elements were detected during the pre-construction stage. This proactive approach effectively minimized delays and reduced the need for on-site rework, ensuring a seamless transition from design to construction.

3.2 *Workfront prioritization and focusing*

Through the strategic employment of information models, project managers were able to predict and prioritize critical work fronts, focusing resources and efforts where they were most needed. The models provided detailed insights into the construction sequence, allowing the team to anticipate and prepare for the next stages of development, bolstering productivity and maintaining project momentum.

3.3 *BIM-Database utilization for author supervision*

On-site author supervision was greatly enhanced by the use of a BIM-database. This centralized repository of project information offered supervisors instant access to detailed, up-to-date data, ensuring that construction adhered strictly to the design specifications. The integration of BIM within the supervision process facilitated informed decision-making and timely interventions, upholding design integrity throughout the construction phase.

3.4 *4D Planning and plan-fact analysis*

The implementation of 4D planning, which integrates the 3D model with the construction schedule, enabled a dynamic analysis of the planned versus actual progress. By visualizing the construction sequence over time, project managers could effectively monitor milestones and manage deviations from the plan, making adjustments as necessary to keep the project on track.

3.5 *Front-of-work and room management*

Information models played a crucial role in the management of construction fronts and spatial coordination within the constrained environments of metro station construction. The ability to visualize and

manage space utilization in real-time helped to avoid conflicts, optimize the use of available room, and ensure that different teams could work concurrently without impeding each other's activities.

4 CONCLUSIONS

The adoption of information modelling technologies across these seven metro stations of the BCL project exemplifies the transformative impact of BIM on underground construction management. These technologies brought about improvements in collision detection, work prioritization, author supervision, planning accuracy, cost control, and spatial management—culminating in a construction process that is more efficient, predictable, and cost-effective. This case study reinforces the value of integrating BIM and information models as standard practice in the complex field of underground construction.

Research on construction collaborative control method based on drilling and blasting tunnel equipment

Qin Nianwen*, Zeng Miaojun & Jiang Weiliang

China Railway Construction Heavy Industry Corporation Limited, Changsha, China

ABSTRACT: Shield method, TBM method and drilling-and-blasting method are the main construction methods of tunnel construction, among which drilling-and-blasting method has outstanding advantages such as wide geological adaptability, low construction cost and flexible construction organization, accounting for some 80% in tunnel engineering. As the drilling-and-blasting method is a step-by-step operation in different processes, various construction method, complex processes, various types of equipment and large personnel needs, it has urgent requirements on construction efficiency, safety and quality, and the complexity and difficulty of construction control are particularly prominent. How to further improve the modern construction capacity of tunnel engineering through mechanical, digital and informational means, and promote the information exchange and transmission among the project participating units has become an urgent problem to be solved. Aiming at the conventional equipment in the construction process of drilling-and-blasting method, this paper systematically carried out the research on the construction collaborative control method based on tunneling equipment, and put forward relevant suggestions on the improvement of equipment data supply capacity, the standardized construction of tunnel network, the interactive sharing of data standardization, and the deepening application of equipment data. And form an intelligent equipment cluster collaborative management and control platform with risk management, construction management, equipment management and quality management as its core functions. The platform has been demonstrated and applied in a number of key projects, with remarkable economic and social benefits, realizing safe, efficient, and high-quality construction of drilling-and-blasting tunnels.

Keywords: underground engineering equipment, intelligent tunnel construction, engineering management, tunnel network, risk warning

1 INTRODUCTION

Main tunnel construction methods include the shield method, TBM method and drilling-and-blasting method. Each method has the working mechanism and application scenarios different from one another. Among them, the shield method is usually used for underwater and soft soil tunneling, and the TBM method is usually used for hard rock tunnel excavation. The drilling-and-blasting method is especially suitable for the geological conditions with uneven hardness by virtue of its wider adaptability. The drilling-and-blasting method is a tunnel construction method based on multi-process cyclic operations such as drilling, blasting, mucking, primary support and secondary lining. By virtue of its significant advantages such as wide geological adaptability, flexible construction organization and high economical efficiency, it has been the main method for

mountain tunnel construction, accounting for 80% in tunnel construction. In the worldwide tunnel construction, the number and total length of completed and under-construction tunnels in China rank high. The tunnels under construction and under planning of China show an “ultra-long, ultra-large and ultra-deep” development trend, facing increasing risk geology and extreme construction environment, frequent information exchange and transmission needs among participating organizations as well as increasingly prominent complexity of construction management. In order to achieve the goal of “safe, efficient and high-quality” tunnel construction, it is urgent to improve the construction control capacity of the tunnel equipment in the drilling-and-blasting method and promote the digital and intelligent transformation and upgrading of tunnel construction.

The supporting mechanical equipment of the traditional drilling-and-blasting method has a low degree

*Corresponding author: qinnianwen@crchi.com

of informatization, and cannot meet the requirements of high-quality, high-standard and rapid construction under complex geological environment conditions for tunnel construction, which is mainly reflected in the following aspects. (1) Equipment supply data is insufficient. The control data of the tunnel construction process involves many aspects such as surrounding rock, construction, devices and quality. Traditional construction methods mainly rely on manual paper-based data filling, which is poor in timeliness and lacks intelligent equipment that can sense interactive data in a timely manner, and thus cannot provide quick and accurate data support for comprehensive control of tunnel construction. (2) Network construction is not standardized. As there are many processes in drilling-and-blasting tunnel construction, it is required to frequently relocate various terminals on the tunnel wall based on the construction progress. The multifarious devices, repeated link construction and low modularity of the traditional network deployment method result in difficult network maintenance and low availability, which brings great inconvenience to tunnel data transmission and construction management. (3) There is a lack of uniform requirements for data. The data generated during drilling-and-blasting tunnel construction have multiple sources and great structural differences. Unified interaction standards and application specifications have not been formed according to different data types, and the real-time interaction channel of underlying information is missing between equipment, resulting in information silos. (4) The data processing degree is low. At present, the application of construction control in various countries mainly focuses on tunnel boring machines. Information systems for data monitoring, visualization and analysis of shield tunneling machines, TBMs and large-scale engineering equipment have been established, such as the risk information management system for underground engineering construction that is developed by Italy GeoDATA and the TBM construction plan management and monitoring system developed by Germany ITC Engineering GmbH & Co. However, there is a little study on realizing comprehensive collaborative control of tunnel construction by the drilling-and-blasting method with intelligent equipment as the link.

Therefore, based on the above problems, this paper puts forward targeted suggestions in terms of improvement of the equipment data supply capacity, standardized tunnel network construction, standardized data interaction and sharing as well as deepened application of equipment data. It is suggested to carry out application research around intelligent risk warning, process organization and management, equipment monitoring management, intelligent quality control and other aspects, and to establish a collaborative control platform for intelligent equipment clusters to improve the informatization and intelligent control level of drilling-and-blasting tunnel construction, putting effort into the promotion of intelligent tunnel construction.

2 IMPROVEMENT OF EQUIPMENT DATA SUPPLY CAPACITY

2.1 Classification of data about tunnel construction control

The control of drilling-and-blasting tunnel construction involves many aspects such as risk management, construction management, device management and quality management. As shown in Figure 1, risk management focuses on environmental risks, progress risks, geological risks and equipment failures. Construction management mainly focuses on the construction organization level. Device management focuses on equipment state and equipment efficiency data. Quality management focuses on data that can directly reflect tunnel construction quality.

In order to effectively support the core contents of construction control such as risk management, construction management, device management and quality management, the source of data generation must be controlled. Specifically, data needs to be automatically collected, truly recorded and automatically transmitted. Therefore, as an important basis for each construction link, it is the best choice to supply data by equipment. On the whole, the above data can be divided into two types, i.e., real-time data and log data. By carrying various intelligent sensing elements on drilling-and-blasting tunnel equipment, the data perceptibility of equipment is improved.

Figure 1. Classification of data about tunnel construction control.

2.2 Real-time data

Real-time data includes environmental monitoring data, equipment failure data, process organization data and equipment state data. Their sources are detailed below.

The environmental monitoring data comes from the real-time monitoring of ambient air quality in tunnel construction by each process equipment, including the concentrations of CO, H₂S, CH₄ and other toxic and harmful gases as well as O₂ and dust, to support the application in environmental risk warning scenarios;

Equipment failure data comes from real-time monitoring of device operation state, which is used to improve the equipment failure diagnosis capacity. Different types of equipment have different types of operation failures;

The process organization data comes from the operation mileage, operation tasks, continuous working hours of each operation task and other aspects fed back by each process equipment in real time, so as to realize the automatic recording of the construction process in the tunnel and support the application in construction organization management scenarios by further utilizing the analysis results of geological identification data and configuration information in process plans;

Equipment state data comes from the real-time monitoring of equipment working state, and supports the application of equipment state monitoring scenarios.

2.3 Log data

Log data includes environmental monitoring data, progress deduction data, geological identification data, equipment efficiency data and quality control data. Their sources are detailed below.

The environmental monitoring data contained in the log data mainly refers to the monitoring data about tunnel surrounding rock deformation, specifically the multi-scan logs of the tunnel profile in the same mileage range by construction equipment in each process;

The progress deduction data comes from the actual working footage recorded by each process equipment, and supports the application in progress risk warning scenarios based on the project construction plan;

Geological identification data comes from the monitoring records of surrounding rock conditions in front of the tunnel face, including advancing speed, impact pressure, advancing pressure, slewing pressure, slewing speed, water pressure, water flow and other drilling parameters in the borehole log as well as images of the tunnel face, to support intelligent identification of surrounding rock;

The equipment efficiency data comes from the equipment efficiency data recorded in each process, such as the cycle times, cycle footage, cycle time, number of rock drilling holes, concrete spraying volume, number of arch assembly trusses, and number of anchor rod construction, so as to finally realize the efficiency evaluation of all equipment;

The quality control data comes from the detailed operation data of forepoling, drilling, shotcreting, anchor bolts and steel frames recorded by each process equipment. The tunnel construction quality control capacity is improved based on tunnel design data and construction inspection lot standards.

3 STANDARDIZED TUNNEL NETWORK CONSTRUCTION

3.1 Standardized network device

In view of the problems of disorder and difficult maintenance in existing tunnel network construction, based on the needs of tunnel informatization construction and application business in the drilling-and-blasting method, standardized and modular network devices are provided, including the base station devices for wireless networking and coverage, vehicle-mounted base station devices for access to wireless networks as well as the intercom, positioning and monitoring devices for various application scenarios. Standardization of network construction is realized through modularization of network devices, as shown in the network master station and slave station modules in Figures 2 and 3, so as to realize standardization of the network bearer, network extension and network management and to reduce personnel maintenance costs.

Figure 2. Introduction to functions of master station.

Figure 3. Introduction to functions of slave station.

3.2 Standardized tunnel network construction

3.2.1 Coverage of key construction areas

The lining jumbo and waterproof board jumbo that are configured in the secondary lining area of the tunnel in the drilling-blasting method are bench equipment. The excavation construction bench is also arranged in the tunnel excavation area. The position of the bench moves forward continuously with the excavation of the

tunnel face. According to the characteristics of the construction process in the drilling-blasting method, it is recommended to select the network building mode of combining optical fiber wired and wireless devices for mesh networking coverage, as shown in Figure 4.

Figure 4. Network coverage of key construction areas in tunnel.

The wired LAN of the optical fiber plus Ethernet is deployed at the construction site, and the master station LAN outside the tunnel is introduced into the tunnel through the optical fiber. Slave stations are arranged on the tunnel wall of the completed lining section to realize tunnel networking. Slave stations for network coverage are arranged on the waterproof board jumbo, and are used for the wireless mesh networking with the slave stations in the completed lining section, so as to realize wireless network coverage of key construction areas of tunnel excavation and support. The tunnel construction equipment ahead can access the wireless LAN through the vehicle-mounted wireless base station to support the two-way communication between underground tunnel equipment and the cloud collaborative control platform, realizing real-time data transmission.

3.2.2 Full coverage of construction area

When the tunnel network needs to cover the secondary lining construction area, such as automatic driving application scenarios and man-machine positioning application scenarios, the networking method shown in Figure 5 can be adopted.

Figure 5. Full coverage of tunnel construction area network.

Compared with the method of fulfilling network coverage of key construction areas only, in this method, slave stations are added at certain intervals

in the tunnel lining area, and are wired through optical fibers, so as to achieve full network coverage in the target area.

4 STANDARDIZED DATA INTERACTION AND SHARING

The data about drilling-and-blasting tunnel construction control that are collected by the equipment in each process need to be standardized on the edge side to form various standard data formats. The data is transmitted to the collaborative control platform of intelligent equipment clusters via the above network links in a standardized data interaction mode to support subsequent deepened data application.

4.1 Standardization of data formats

For the part of real-time data, a standard representation mode of data is refined and formed according to the common attributes of data, i.e. data message parsing rules, including the data field name, data type, data field index, data field description, data graduation value, data unit and subsystem. After receiving the real-time data message, rapid analysis, efficient storage and flexible use of real-time data are realized according to the data message analysis rules.

The log data part is finally concretized into the construction log, scan log and tunnel face image data of each process. The construction log includes the borehole log, anchor bolt log, vertical arch log, wet shotcreting log and lining log.

In order to facilitate rapid identification and classification of log files, the standard log file name shall include the work section name, operation mileage, operation time and process classification code. In order to quickly index the scan log corresponding to a construction section, it is necessary to add the information about scanning start and end mileages and the code of the scanning section type in the scan log name. For example, a scan log shall be named as: work section name_operation mileage_operation time_scanning start mileage_scanning end mileage_-process classification code_section type code.

In order to quickly analyze, store and apply log files, the text header of a log file shall include the working section name, operation time, operation direction, construction contractor, operation mileage, device information and operation positioning information.

The body of the log file can record and store core data in different dimensions, such as time series, spatial series and operation object series, according to specific construction forms. For example, the text of the lining log records the temperature, liquid level, pressure and other data at different detection positions by time; the text of the scan log records the over-excavation and under-excavation information, absolute coordinate information of sections at different mileage

positions as well as other information by space; the text of logs, such as those of boreholes, anchor bolts and arches, records the construction details of each borehole, anchor bolt and arch in the dimension of the operation object.

4.2 Standardization of data interaction

According to the different data types, application scenarios and generation methods, three data transmission modes and acquisition periods of the MQTT protocol, TCP protocol and HTTP protocol are determined.

Among them, the process organization data is connected to the collaborative control platform of the intelligent equipment cluster through the MQTT protocol, and the data is actively uploaded at a rate of 10 seconds/frame;

According to the data message parsing rules, the real-time equipment data can be converted, transmitted, parsed and stored at a rate of 1 second/frame through the TCP protocol;

Log data is actively uploaded to the collaborative management and control platform of intelligent equipment clusters through the HTTP protocol interface after log generation.

5 DEEPENED APPLICATION OF EQUIPMENT DATA

After the reception of the above data, according to the control requirements of drilling-and-blasting tunnel construction, deepened data application is carried out around risk management, construction management, device management and quality management, and four functional modules, i.e., intelligent risk warning, process organization and management, equipment monitoring management and intelligent quality control, are built, providing platform-based services.

5.1 Intelligent risk warning

5.1.1 Environmental risk warning

(1) Ambient gas monitoring

Based on environmental monitoring data, environmental risk thresholds, such as the concentrations of O₂, CO, H₂S, CH₄ and dust, are set for the collaborative control platform of intelligent equipment clusters. When abnormal environment is monitored, the platform gives an abnormality alarm and pushes the alarm information to on-site operators and construction management personnel in a targeted manner, ensuring the safety of construction personnel.

(2) Surrounding rock monitoring and measurement

Based on the 3D tunnel point cloud scan log obtained by the machine-mounted surrounding rock deformation measurement system, the basis

for surrounding rock monitoring and measurement data is formed through preprocessing operations such as slicing and compression of the point cloud. The point cloud data within the specified range around the five key points at the arch crown, spandrels on both sides and hances on both sides is taken. By comparing the changes in over-excavation and under-excavation of multi-scan point cloud data at different time points, the settlement, convergence and other deformation conditions of surrounding rock around the tunnel are analyzed; the deformation rate, deformation amount and other data information of surrounding rock are calculated as the basis for surrounding rock deformation risk; the risk alert threshold is set, realizing the control of surrounding rock deformation risk around the tunnel.

Figure 6. Technical route of surrounding rock monitoring and measurement.

5.1.2 Progress risk warning

Risk warning is provided for the construction progress in two dimensions, i.e., excavation and lining, based on the construction log of the whole process.

For excavation dimension, the difference between the construction mileage of the latest borehole log of the drill jumbo and the tunnel portal mileage is calculated as the actual excavation progress. The platform compares the calculation results with the construction plan and progress filled in by the user, analyzes these results, visually displays the results of comparison between the planned and actual progress in the form of Gantt chart, and generates daily, weekly and monthly reports on the construction progress. Additionally, the platform fulfills progress risk warning by setting the risk warning and alert thresholds for excavation progress lag.

For the lining dimension, the difference between the construction mileage of the latest lining log and the tunnel portal mileage is taken as the actual lining progress. By further calculating the spacing distance from different lining construction processes to excavation processes, based on the safety step requirements of different surrounding rock grades and different processes as well as the comparison results of plan and progress, a progress risk alert is provided for the advance or lag of lining processes to assist in construction management decision-making.

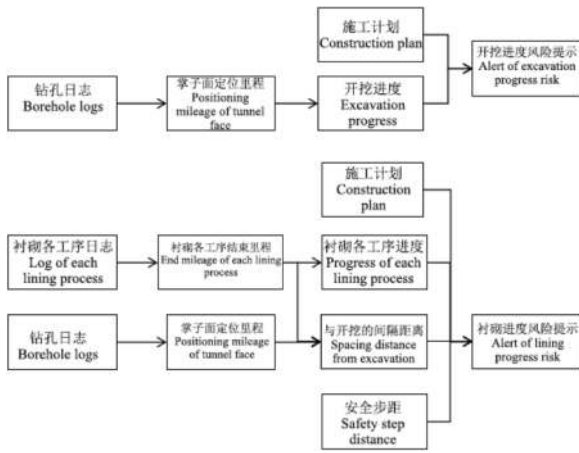

Figure 7. Technical route of progress risk warning.

5.1.3 Geological risk warning

Based on the drilling parameters and tunnel face image data collected by the borehole log of the intelligent drill jumbo, the surrounding rock conditions in front of the tunnel face are analyzed and evaluated. First, a sample and tag library of data and images while drilling is established. Threshold filtering, feature dimension ascending, data balance, isolated random forest, image preprocessing and other methods are applied to ensure the high quality of data samples during model training. The intelligent identification method of multi-model fusion surrounding rock based on multivariate features while drilling is adopted to realize the preliminary identification of the surrounding rock grade in front of the tunnel face. On this basis, based on the tunnel face image after adaptive processing, the Canny operator and morphological method are applied to extract the boundary information of the tunnel face. Neighborhood search and boundary aggregation methods are used to automatically connect discontinuous features on the same structural plane, so as to quickly, reliably and objectively obtain the geometrical geological information of the tunnel excavation face and further correct the identification results of surrounding rock based on parameters while drilling. When the identification result of surrounding rock is inconsistent with the design grade of surrounding rock, the platform will automatically give geological risk warning for the front of the tunnel face.

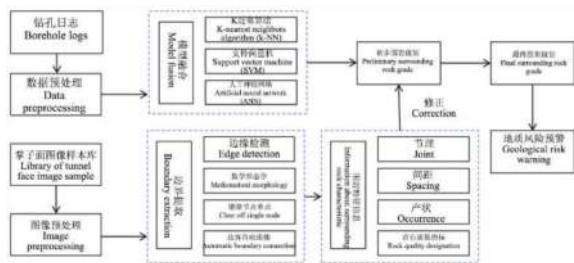

Figure 8. Intelligent identification technology route of surrounding rock.

5.1.4 Early warning of equipment failure

Based on the real-time data of equipment and according to the working characteristics of various intelligent equipment, the failure alarm data and failure types collected by intelligent equipment in real time are classified and matched to form failure analysis algorithms for different equipment and failures. The platform pushes the early-warning information about failures to relevant personnel directionally to ensure timely failure disposal, reduce equipment downtime and improve construction efficiency. Additionally, the platform will store and statistically analyze all failure alarm information for users to query and trace back.

5.2 Process organization and management

In view of the problems such as poor process connection and long cycle time caused by inadequate process management arrangement on the construction site and operators' failure to respond to process arrangement in time, corresponding algorithms are prepared to identify the current process and process operation results in real time based on the process organization data and the integration of previous processes, so as to realize real-time feedback of processes in the tunnel. Further utilizing geological data and process plan configuration information, the construction scheme setting of the next cycle is adjusted in time, and the subsequent on-site construction equipment and mobilization operation time of various construction personnel are scheduled, ensuring that the construction equipment and construction personnel can enter the site for construction in a timely manner.

Figure 9. Technical route of process organization and management.

Through the above construction process scheduling, it is possible to optimize the connection time between construction processes, mobilization of construction equipment and mobilization of various construction personnel, so as to improve the efficiency and progress of on-site construction.

5.3 Equipment monitoring management

5.3.1 Equipment state monitoring

All-round real-time dynamic monitoring of the working state information and position information of various equipment is fulfilled based on basic equipment information, equipment working state data, vehicle-mounted video images and other information, which is conducive to equipment safety control and data tracing.

5.3.2 Equipment efficiency accounting

Based on the construction logs and equipment state data dynamically uploaded by the equipment, equipment efficiency evaluation rules are formulated, and equipment efficiency accounting indicators are extracted, including working hours, construction footage, number of logs and failure conditions. Additionally, daily, weekly and monthly equipment construction efficiency analysis reports are generated, so that users can intuitively understand the use and efficiency of equipment construction.

5.4 Intelligent quality control

At present, the quality control and inspection during drilling-and-blasting tunnel construction are still mainly based on traditional manual methods. There is a lack of “independent, accurate and efficient” quality control means for tunnel construction. It is difficult to standardize the quality acceptance of “concealed works”. This paper aims to fulfill the intelligent control of tunnel support structure quality by analyzing equipment construction data. Based on autonomously-perceived information such as scan logs and whole-process construction logs, the tunnel solid model containing accurate time records is established; by formulating quality data processing rules and extracting intelligent quality control parameters, the quality control parameter database covering forepoling, drilling-and-blasting excavation, primary support and secondary lining of the tunnel is formed to integrate all elements of tunnel construction quality. Further utilizing the tunnel construction design data of the Design Institute and based on various tunnel construction inspection standards, a digital model for quality evaluation of the time-associated tunnel support structure is established to realize all-round, full-process, real-time and effective feedback based on intelligent operation quality information of equipment.

Figure 10. Technical route of intelligent quality control.

6 CONCLUSION AND PROSPECT

The collaborative construction control method based on drilling-and-blasting tunnel equipment focuses on the perception, analysis, decision-making, collaboration, interaction and other key technologies of intelligent equipment, so as to support the intelligent transformation and upgrading of the working modes of key links, such as risk warning, process organization, device management and quality control, during intelligent tunnel construction, which is of great significance for improving the intelligent tunnel construction level.

ABSTRACT: The application of Building Information Modelling (BIM) in Tunnelling involves the generation, co-evolution, and maintenance of digital models. This often requires the collaboration of multiple stakeholders on the same digital model over multiple project phases, which, in turn, necessitates the sharing of responsibility for the same model element among those stakeholders. For example, a niche in the tunnel inner lining may be designed simultaneously by a structural engineer, by a fire safety expert who needs to install a fire hydrant in it, and by a HVAC engineer who needs a ventilation control panel in it. Shared responsibility requires trust. Lack of trust often leads to the duplication of models so that each stakeholder can work on a separate model, free from the influence of the work of others. The consequence is a break-down of model continuity and unsustainable usage of personnel and resources. In this work, we present a method for introducing trusted elements into the digital model of the tunnel. This can be accomplished by anchoring those elements to contractually relevant documents, such as the Employer Information Requirement (EIR) according to the ISO 19650 series. Trusted elements can guarantee formally that a certain contractual or technical requirement has been fulfilled, e.g., that the measurement of carbon monoxide for the emergency ventilation system is designed in accordance with ISO 23431. In addition, formal requirements within a trusted element can be tested automatically by the common data environment (CDE) of the project. In case that one stakeholder changes the trusted element so that a requirement is no longer fulfilled, an automatic alert can be issued. We present a standardized workflow for the creation and maintenance of such trusted elements in a digital model on the use case of the design of a ventilation system in a road tunnel.

Keywords: Tunnelling, BIM, Digital model, Trust, Technical guidelines

1 INTRODUCTION

Over the past decades, the Architecture, Engineering, and Construction (AEC) industry, including the tunnelling sector, has been adapting the digital methods originating in automation (Barbosa et al., 2017). These include handling of both geometry and non-geometric, typically highly domain-specific, information (Hegemann et al., 2019). One of the most widely used such methods is Building Information Modeling (BIM) (Laakso and Kiviniemi, 2012; Borrmann et al., 2015). In spite of all these efforts, data integration remains a challenge not only when experts from multiple domains are involved (Haymaker et al., 2000; Lai and Deng, 2018; Rasmussen et al., 2019; Steel et al., 2012), but even within the same domain (Scheider and Kuhn, 2015; Millán et al., 2016).

One of the main goals of BIM is the generation and maintenance of a digital twin (Kaewunruen et al., 2018), a digital counterpart of a built structure that

both supplies and receives information from it, thereby regulating its function and reacting to changes in the state of its systems (Lai and Deng, 2018), respectively. Ideally, this digital twin should be a digital model with meaningful interconnections between model elements that carry unambiguous domain-specific semantics (ITA Working Group 22, 2022).

Often however, the digital twin corresponds to the ISO 11354-1 definition of a federated model (ITA Working Group 22, 2022). The federated model is simply a set of separate (partial) digital models with possible mappings between them (Leng et al., 2021), i.e., a landscape of heterogeneous syntax and semantics that cannot be easily managed or navigated. For example, querying the relevant information for a particular task, or tracking the direct and indirect effects of a model element update throughout the entire digital twin both necessitate the implementation of specialized views and workflows (Eastman et al., 2011; Hegemann et al., 2019), often embedded in a Common Data Environment (CDE).

1.1 Motivating example

This complexity and lack of transparency affects the level of BIM acceptance in the AEC industry in general and in tunnelling in specific (Lehoczky et al., 2022). For example, if during the operational phase of a road tunnel project we need to assess the air quality, different experts may use different technical guidelines, e.g., the ISO 23431:2021 “Measurement of road tunnel air quality”, or ISO 4224:2000 “Ambient air — Determination of carbon monoxide — non-dispersive infrared spectrometry method”. Those guidelines offer slightly different methods for the evaluation of carbon monoxide presence in air.

On the one hand, ISO 23431:2021, Section 5.5.2 describes the following method for the calculation of gas concentration over a measurement path in *ppm*:

$$c = \frac{c_r L_c}{L} + \frac{c_b(L - L_c)}{L} \quad (\text{ISO23431.3})$$

where c_r is the reference test atmosphere concentration in *ppm volume fraction*, c_b is the background pollutant concentration in *ppm*, L_c is the calibration cell length in *m* and L is the measurement path length in *m*. The conversion to mg/m^3 is described in Section 5.7:

$$C_m = \frac{C_v m}{V_m} \quad (\text{ISO23431.7})$$

where c_m is the gas concentration in mg/m^3 under the conditions of *standard temperature* and *standard gas pressure* of 101.3 kPa, c_v is the gas concentration in *ppm volume fraction*, m is the molecular weight of the gas, and V_m is the molar volume at 0 °C and at *standard gas pressure* of 101.3 kPa.

On the other hand, ISO 4224:2020, Section 11 defines the conversion from *ppm* to mg/m^3 for gases in the following equation:

$$\rho_1 = \frac{\rho_2 m_r 298 p}{24.45 T 101.3} \quad (\text{ISO4224.11})$$

where ρ_1 is the gas concentration in mg/m^3 , ρ_2 is the measured gas concentration in *ppm volume fraction*, m_r is the molar mass of the gas (e.g., 28 *g/mol* for CO), 298 is the standard absolute temperature in *K*, p is the measured gas pressure in *kPa*, 24.45 is the molecular volume of 1 mole in *l*, T is the measured absolute gas temperature in *K*, and 101.3 - the standard gas pressure in *kPa*.

The question is, how is an expert to know which guideline has been used and whether it has been applied consistently for all assessments in the federated model? In fact, instead of creating confusion and uncertainty, both of these technical guidelines can be used to create *trusted elements* in a digital model, regardless of its complexity. Our task is to utilise the equations and their parameters as *semantic anchoring points* for the relevant elements of the *digital twin*.

2 APPROACH

Our approach involves the formalisation of guidelines written in a natural language into a graph representation and the subsequent annotation of digital data models with elements of this graph.

2.1 Semantic anchoring

Let us have a look at one possible formalisation of both technical guidelines. Figure 1 shows on the right-hand side the graph representation of equation

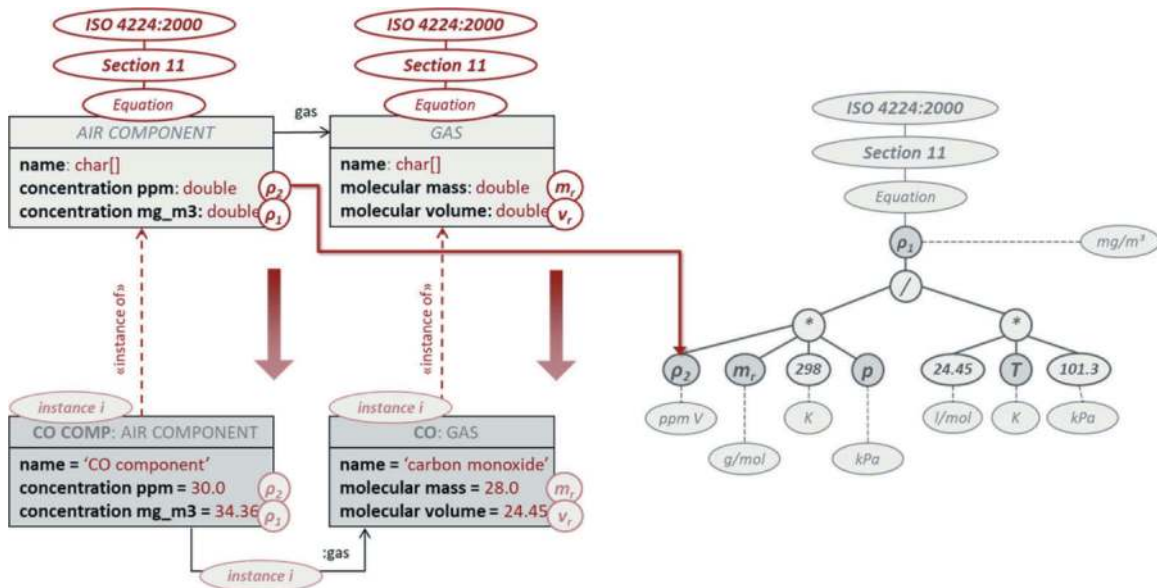

Figure 1. Mapping of a domain model to the ISO 4224:2000 guideline.

ISO4224.11 with both parameters and mathematical operations as nodes. The root of the graph indicates the identity of the guideline, followed by the section and equation (which in this case has no number). Since ρ_1 is a result of division, the only child node of ρ_1 is the corresponding operation, which has two children, both multiplication operations that produce the dividend and divisor, respectively. Each node that contains a parameter or a value has the corresponding unit attached to it, e.g., for ρ_1 it is mg/m^3 . These units are by no means just informative. They can be used to describe the *type* of the node they are attached to.

On the left-hand side of Figure 1 is an excerpt of a domain-specific digital model that uses this guideline as a *semantic anchoring point*. In the top row we see the type definitions, for example *AIR COMPONENT* and *GAS*. They tell us that the digital model can save air component objects described by attributes “name”, “concentration ppm” and “concentration mg_m3 ” and referencing objects of type *GAS*, i.e., gases, which in turn are described by attributes “name”, “molecular mass” and “molecular volume”. This is by no means a prescription of how such information should be structured, it is just an arbitrary example to illustrate the point that *any* object-oriented data model can be used in the exact same way.

In the bottom row on the left-hand side of Figure 1 we see the instances produced by the type definitions. *CO COMP* is an instance of *AIR COMPONENT* and, consequently, has slots that correspond to the type definition’s attributes. For example, attribute “concentration ppm” produces a slot by the same name that carries a specific value (the double 30.0). In the same way *CO* is an instance of type definition *GAS*. The relationship between the type definitions and their instances is represented by the red dashed arrows annotated with *instance of*.

Another type of relationship, between type definitions, is the one between *AIR COMPONENT* and

GAS, named “gas”. It indicates that each air component references a specific gas, i.e., that the air component makes sense only if its definition includes a specific gas, such as carbon monoxide. This relationship can be instantiated as well, as can be observed in Figure 1. There, the instance *CO COMP* references the instance *CO* via the instance of “gas”.

Now that we have a digital model capable of holding the information we need in order to comply with ISO 4224, Section 11, we can proceed with making the model elements we just described *trusted*.

The graph representation of the guideline has several features that enable *semantic anchoring* to any of its elements. First, its graph structure makes it easily serializable, e.g., in a common digital format, such as XML. This makes distribution of the formalised guideline or its hosting on a CDE platform quite trivial. Second, the graph structure is efficiently traversable, which presents an advantage in querying both the guideline and any digital model elements attached to it. Third, this structure is well suited for anchoring, since each graph node can play the role of an anchor. This is demonstrated in Figure 1, where both the type definitions and their attributes have been annotated with elements of the graph (see the red labels on the left corresponding to graph nodes on the right). For example, attribute “concentration ppm” of *AIR COMPONENT* has been annotated as “ ρ_2 ” and effectively anchored to the corresponding equation parameter, as indicated by the continuous red arrow pointing to the graph node.

We can observe that the structure of the *domain model on the left does not have to correspond in any way to the structure of the guideline or the equation on the right*, since annotations make the anchoring independent of structure.

Additionally, the anchoring in the type definitions is automatically transferred to their respective instances by the *class – object* relationship characteristic of most object-oriented programming languages.

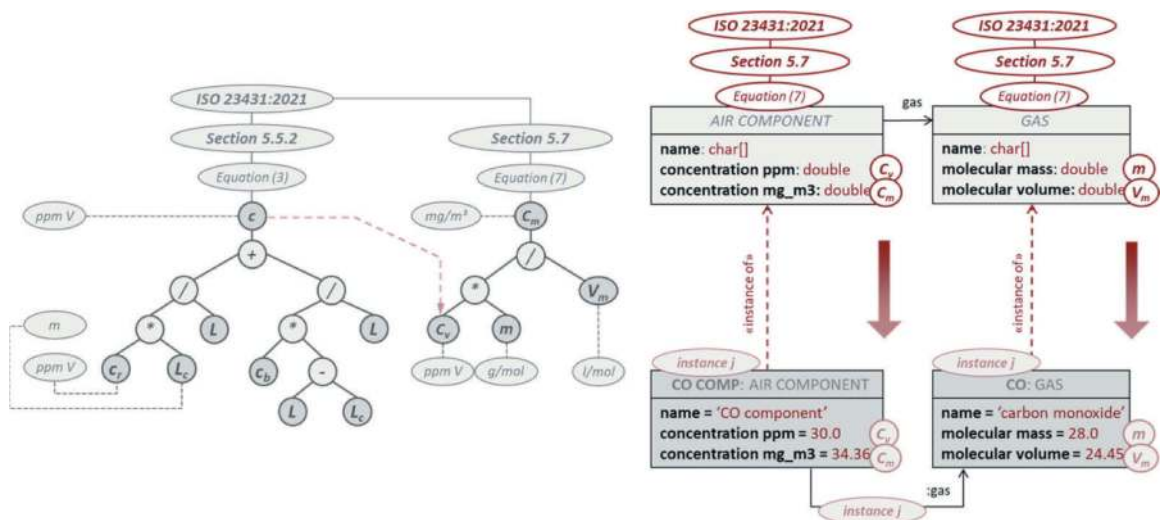

Figure 2. Mapping of the same domain model as in Figure 1 to the ISO 23431:2021 guideline.

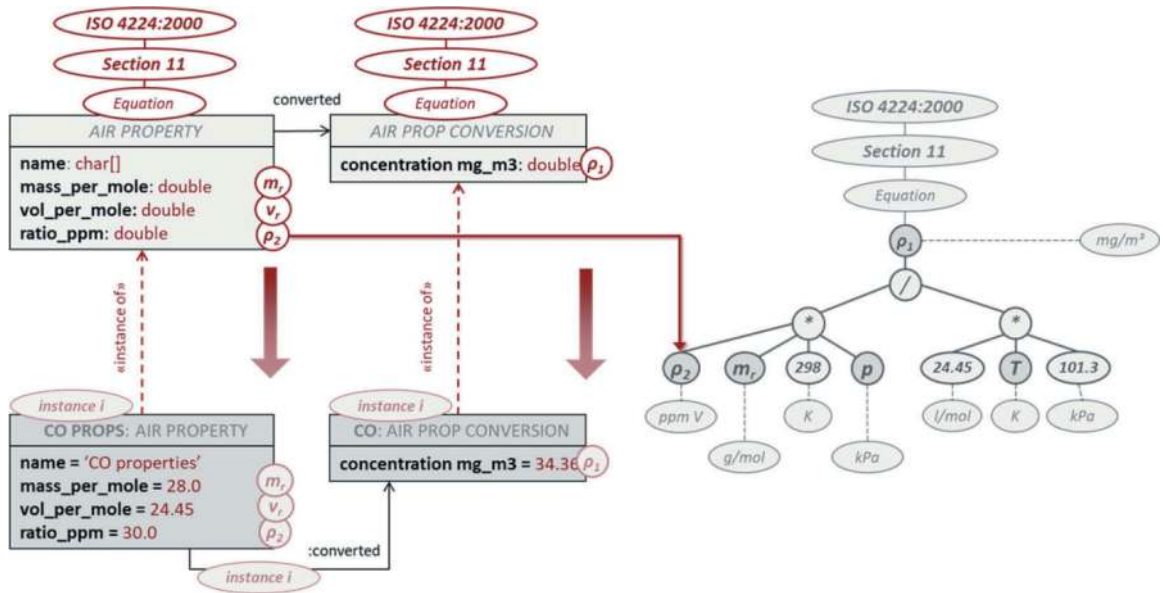

Figure 3. Mapping of a second domain model to ISO 4224:2000 (compare to Figure 1).

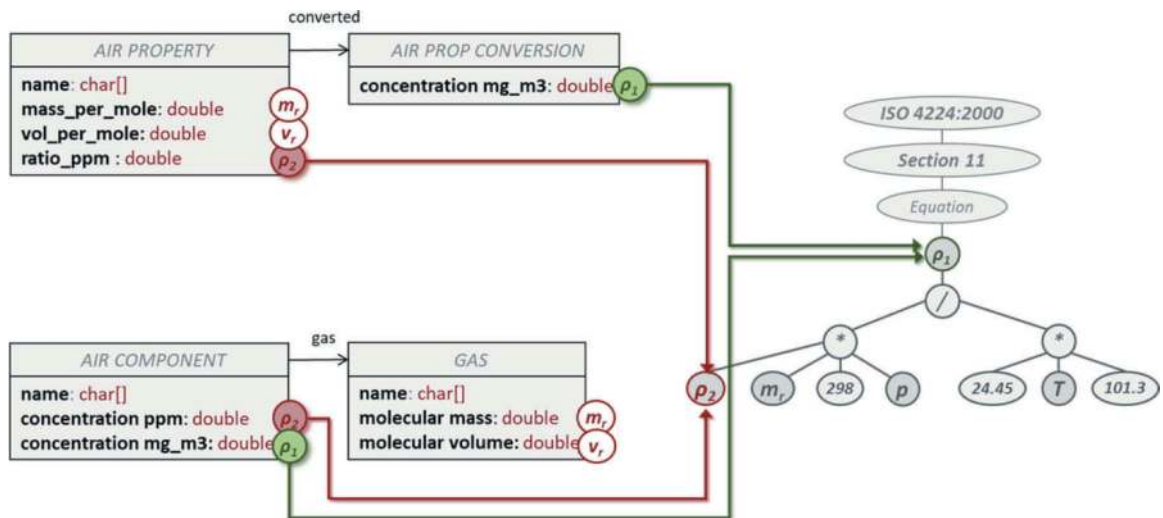

Figure 4. Data integration between two different domain models based on their anchoring to the same guideline equation.

Thus, annotations in the type definitions are sufficient for the annotation of all of their instances, regardless if there are ten or ten thousand of them. Furthermore, grouping of instances that build the same semantic unit are possible via instantiable relationships, such as the one between *AIR COMPONENT* and *GAS* (see the “instance i” labels in Figure 1).

A further example of the semantic anchoring of the same domain model, but this time to the ISO 23431:2021 guideline is shown in Figure 2. Here, we have two formalised equations, equation (ISO23431.3) on the left and equation (ISO23431.7) on the right. This gives us the opportunity to indicate that the result c of equation (ISO23431.3) is input C_v to equation (ISO23431.7). Otherwise, the domain model now has different annotations that indicate its anchoring to ISO 23431:2021.

It is of note, that these annotations are not mutually exclusive. On the contrary, they exist in parallel. In other words, *the same domain model can be anchored to multiple guidelines* to indicate its compliance to all of them, if necessary.

2.2 Data integration based on semantic anchoring

Apart from demonstrating compliance with technical guidelines and providing an automated path towards compliance checking (Jiang and Wang, 2021), this type of annotation allows for automated data integration.

Figure 3 shows a second domain model anchored to the same equation of the ISO 4224:2000 guideline as in Figure 1. Its type definitions differ not only in name, but also in structure from the one we discussed in

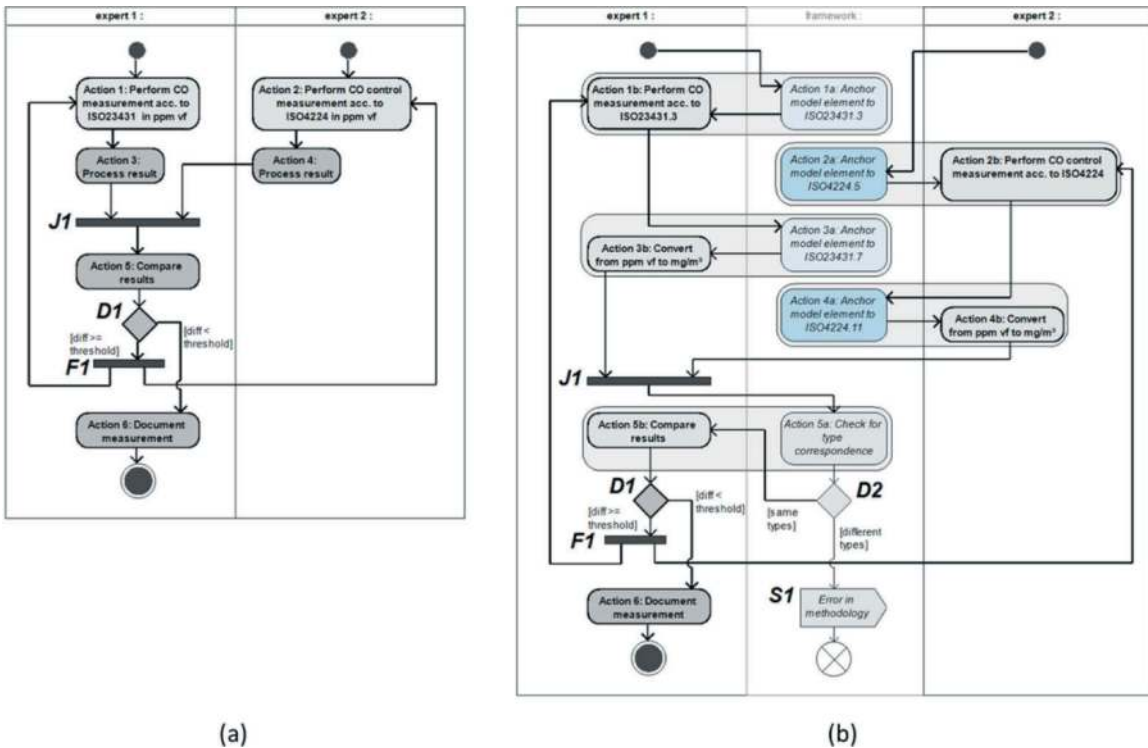

Figure 5. Practical application of semantic anchoring: (a) standard workflow, (b) adapted workflow including anchoring and automated compliance checking.

detail in the previous subsection. However, since the anchoring to the guideline depends only on the guideline’s own structure, and not at all on the domain model’s structure, the result are the same annotations, but attached to different elements of this second domain model. This is exactly what allows us to find a reliable mapping between the domain models in Figure 1 and Figure 3.

This mapping is shown in Figure 4. Since both the type definitions and their attributes have different names, a mapping based on those cannot be relied upon. A mapping based on their respective *semantic anchor points* on the other hand is both reliable, i.e., *trustworthy*, and can be performed automatically.

Let us look at anchor point ρ_1 first (shown in green in Figure 4), which corresponds to the gas concentration measured in mg/m^3 . This is the result node of the equation in Section 11 of ISO 4224:2000. In the domain model at the top of Figure 4, this anchor point is placed on attribute “concentration mg_m3” of type definition *AIR PROP CONVERSION*. In the domain model on the bottom, the same anchor point is placed on the attribute of the same name in type definition *AIR COMPONENT*.

Analogously, anchor point ρ_2 (shown in red in Figure 4), which corresponds to the gas concentration measured in *ppm volume fraction*, is placed on attribute “ratio_ppm” of type definition *AIR PROPERTY* in the top domain model and on attribute “concentration ppm” of type definition

AIR COMPONENT in the bottom domain model. We can see that neither name differences, nor attribute grouping within type definitions are of any relevance here. We can transfer or consolidate information along the green or red lines regardless.

2.3 Guideline-based type safety

So far, we were concerned with the semantics of the data models. Correct semantics, however, include correct units and unit conversion. In our case, we regard the unit associated with a graph node, e.g. mg/m^3 for node ρ_1 in Figure 3, as that node’s *type*. We use the fact that SI units can be subjected to automatic conversion, e.g., mg/m^3 multiplied with m^3 results in mg , to provide us with *type safety*. This is based on the formal mathematical methods for calculation with types, or *type reduction*, which proves type correspondence (Bertot and Castéran, 2004). This means that we cannot perform a mapping between, e.g., attributes of type g/m^3 and of type mg/m^3 since g/m^3 cannot be reduced to mg/m^3 . However, mapping between Pa and $kg/(m*s^2)$ is possible. This gives us an additional layer of *trustworthiness*.

2.4 The workflow

The methods we outlined in the previous sections can be applied in the following general workflow:

- **Guideline formalisation:** a standardisation body performs a partial or complete formalisation of a guideline;
- **Semantic anchoring:** the domain experts perform a *one-time* annotation of the domain model they utilise for a specific task, which anchors this model to the formalised digital form of the guideline;
- **Creation of trusted model elements:** the domain experts using the above-mentioned domain model instantiate it in the course of their regular work. This causes the anchors attached to the domain model's type definitions to be transferred to each and every instance automatically. All such instances can be regarded as *trusted*.
- **Automatic compliance checking:** Every trusted instance can be subjected to automatic compliance checking against the formalised guideline. This can be particularly useful in a scenario where multiple experts work on the same model and share responsibility for the same model elements. Trusted model elements can be checked for compliance after each significant update, which maintains their role as a *source of trust* in the digital twin.

This workflow can be applied both to a federated as well as to a monolithic digital model. It can run on a single machine or as a part of a CDE.

3 USE CASE MEASUREMENT OF CO CONCENTRATION

Here we give a brief (and simplified) example of the practical application of our approach on the use case of obtaining and recording measurements of CO concentration in a tunnel.

Figure 5(a) shows the standard workflow as a UML activity diagram. It involves two experts who perform measurements independently, according to ISO23431 and ISO4224, respectively. In *Action 1* expert 1 takes one measurement, while in *Action 2* expert 2 takes a control measurement. Following that, each processes the obtained results in *Action 3* and *Action 4*, respectively. The *Join Node J1* synchronises the information flows and transitions into *Action 5: Compare results*. The result of the comparison is fed to *Decision Node D1*. If the difference between the measurements is less than a predefined threshold, then the result can be regarded as valid and is recorded in *Action 6: Document measurement*, after which the workflow terminates. If, on the other hand, the difference exceeds that threshold, we transition to *Fork Node F1*, which transitions back to *Action 1* and *Action 2*, effectively forcing a repeat of both measurements and, subsequently, of the entire workflow we described this far.

If the difference in the two measurements results not from equipment calibration, or environmental conditions, but from an incorrect application of any of the referenced guidelines, there is a real possibility of this workflow causing an infinite loop, if run

in an automated fashion in a CDE. Alternatively, there will be a need for an in-depth manual check for the error to be detected. This problem should be mitigated by the adapted workflow we propose in Figure 5(b).

Here we introduce an additional actor, a framework that applies our *semantic anchoring* approach (see the swim lane between expert 1 and expert 2 in Figure 5(b)). One immediate consequence of this is the splitting of *Action 1* to *Action 5* from the standard workflow we discussed above into two new actions each. For example, before expert 1 can even take a measurement in *Action 1b*, the correct model element for the task is instantiated and anchored to the appropriate equation in ISO23431 by the framework in *Action 1a*. The same applies to *Action 2* from the standard workflow, which is split into *Action 2a* and *Action 2b* in the adapted workflow.

Action 3 and *Action 4* are also split. This time the processing of the results becomes an explicit conversion from *ppm volume fraction* into mg/m^3 (see *Action 3b* and *Action 4b*). But before the experts can perform the conversion, the appropriate model elements are again instantiated and anchored to the relevant equations by the framework in *Action 3a* and *Action 4a*, respectively. This allows us to pass through the *Join Node J1* with *trusted elements* in our model, which lend themselves to formal checks, e.g., type checking. This is exactly what happens in *Action 5a*. Here, the framework performs a type check. Since anchoring to nodes in an equation allows us to obtain a specific unit, which, as we discussed in Section 2.3, can assume the role of the *type* for the anchored model element, in *Action 5a* we check if the type of the measurement by expert 1 is reducible to the type of the measurement by expert 2. For example, if something went wrong during conversion for one of the experts, we might be comparing *ppm volume fraction* with mg/m^3 . This will immediately produce an error message (see node *S1* in Figure 5(b)) and will terminate the workflow, giving the experts involved the opportunity to address the issue without delay. Another possibility is the mishandling of units during calculation, which should also become apparent here, e.g., if we were comparing g/m^3 with mg/m^3 .

All of the above makes the comparison in *Action 5b* more reliable. Due to the utilization of *trusted model elements*, we can claim with some confidence, that if the results differ too much, the likeliest reason is not a data modelling error, but rather a problem with the actual measurement. In addition, the adapted workflow doesn't require the experts themselves to adapt (compare the expert swim lanes in Figure 5(a) and 5(b)). *The only adaptation that takes place is in the technology itself*. This makes the framework we present a good candidate to foster user acceptance and trust in the digital technology in tunnelling (Lehoczky et al., 2022).

4 RELATED WORK

The approach to increasing trust in the digital model of the tunnel we presented in the previous two sections builds on several well-researched concepts.

While there have been many proposals for the utilization of the blockchain technology in communication in the AEC industry (Elghaish et al., 2023; Raslan et al., 2020; Wonjiga et al., 2019), its application in interoperability has been limited to recognising the *presence*, but not the *semantics* of model updates (Xue and Lu, 2020).

On the other hand, graph representations of semantic concepts and the linking between such representations, even when stemming from different domains, shows promise (Witherell et al., 2013; Borrmann et al., 2014; Wang et al., 2023).

In the area of Automated Compliance Checking (ACC) there has been great emphasis on building codes and corporate guidelines as a trust-generating basis for digital models (Häubler et al., 2020; Jiang et al., 2022; Lehoczky et al., 2022).

These are all *a posteriori* approaches, i.e., based on checks of already existing models. However, the most robust approaches, those that provide an *a priori* guarantee of correctness, come from computer science. For example, a formal mathematical proof can guarantee the correctness of a digital model before even one element of it has been instantiated (Bidmeshki and Makris, 2015). This is also where the idea of type safety as a means of providing trust originates (Bertot and Castéran, 2004). It is of note that these approaches come at a very high performance (Bajczi et al., 2022) and maintenance (Sanchez-Stern et al., 2023) cost and are rarely applicable in the large digital models typical of the AEC industry and tunnelling. Nevertheless, in small but critical parts of the model, they can play a significant role.

5 CONCLUSION AND FUTURE WORK

In this paper we discussed a method for ensuring that no matter how complex the *digital twin* of a tunnel may become, it is always possible to ensure that those parts of it that are of critical importance for a certain domain can be designed as *trusted elements*. This trust is based on formalised technical guidelines from the domain itself that provide both *semantic anchoring* and *type safety*. The advantages of this approach include the ability to structure the domain model as required by the expert while at the same time maintaining compliance to a guideline with possibly entirely different structure. In addition, data integration of different domain models can be robust and reliable when built around *trusted elements*. The same method can be utilized to ensure compliance with an Employers Information Requirement (EIR), making parts of the digital twin an *implementation of a formalised contract*. All of this

should contribute to increased acceptance of the BIM method in the AEC industry and in the tunnelling sector.

Finally, the approach we presented here handles anchoring to information; in our future work we intend to extend this idea to the geometry of the tunnel, in order to produce *trusted geometry*.

Why is it worth using BIM in tunnelling?

Florent Robert*

CETU, Bron, France

Nataliya Dias

Andra, Châtenay-Malabry, France

ABSTRACT: Digital transformation is underway in the tunnelling sector. BIM (Building Information Modelling) is gradually taking root in our practices in major underground infrastructure projects. Following the impetus given by the French national research project MINⁿD for BIM in infrastructures, AFTES (the French association for underground space and works) decided to set up a working group dedicated to new digital technologies for underground works, with BIM at the forefront. The decision has been made to publish a first recommendation to present BIM in an accessible way and familiarise the various players in underground construction with the concept. The recommendation will also set out to meet the expectations of stakeholders: tunnel owners, project managers, construction companies, tunnel operators or maintainers of the structure built using the BIM framework. The recommendation will show the links between the various players and the various phases in the lifecycle of the project, from design through to construction and operation. For this type of approach to be successful, it must be supported by the main player in the construction process: the owner. This recommendation is therefore specifically aimed at project owners, to raise their awareness of the challenges of BIM.

Keywords: BIM, tunnelling, owner, designer, contractor, maintainer

1 INTRODUCTION

A number of countries have made, or are in the process of making, the use of BIM in infrastructure more or less compulsory. This is particularly the case in Italy, the United Kingdom and certain Nordic countries. Some major contracting authorities, such as Luxembourg's rail company, are going even further by requiring the use of libraries of proprietary objects supplied by them and the use of specific software tools. For its part, the German tunnelling association, DAUB, has already put forward several recommendations describing how to use BIM in underground structures [1] [2] [3]. The ITA has also published two guidelines on the use of the ISO 19650 standard [4] [5] and on Bored tunnels [6] in 2022.

In France, there is currently no regulatory obligation to use BIM. There have been incentives in the building sector with the Building Digital Transition Plan (PTNB) in 2015, which has been extended with the BIM 2022 plan, but limited to the building sector. In the infrastructure sector, the French national research project MINⁿD [7] for BIM in infrastructures has been working since 2014 to promote the use of BIM in infrastructure. At Andra's initiative, MINⁿD has been

looking at specific use cases for underground works since 2017 ([8] [9]). Work was carried out on the development of taxonomies and neutral formats, which were then taken to the international level within building SMART International [10].

In 2019, the French Tunnelling Association (AFTES), aware of the challenges and expected benefits of BIM, set up a working group dedicated to new digital technologies, GT 45, to explore the subject. It quickly became clear that we needed to answer the question "why" use BIM for underground infrastructures.

In an attempt to answer this not-so-trivial question, which goes beyond the strictly French framework, the AFTES has drafted a recommendation ([11] currently being published) on the expectations of the main players in the construction industry, be they the project owner, the project manager, the construction company or the operator-maintainer.

2 THE POTENTIAL BENEFITS OF BIM

One of the recurring questions on the subject of BIM relates to the benefits that such an approach can

*Corresponding author: florent.robert@developpement-durable.gouv.fr

bring in relation to the investment made. On this subject, the European Commission has produced a methodological document for calculating the costs and benefits of using BIM in public procurement procedures [12]. This document analyses several types of projects (including infrastructures). Overall, the higher the level of BIM maturity, the greater the benefits in both financial and environmental terms.

Above all, BIM means access to structured information for everyone, at any time, according to pre-established rules. But access to information is not an end in itself; the benefits come from using it to improve project control and limit a whole range of non-quality issues. The models, the digital mock-ups, the information and the data they contain are made available to all those involved in the project, guaranteeing that financial, timescale and/or technical objectives are met.

One of the ways in which BIM can be put to good use is by improving collaboration between teams, by sharing project information in a structured way, and by tracing the decisions made throughout the life of the project, thereby optimising its design, construction and operation. By centralising data (one single source of truth), BIM ensures that up-to-date information is stored and made available. The benefits of BIM are discussed in more detail in paragraph “BIM-related issues for the owner”.

Through a more integrated design process, the use of BIM is expected to reduce the number of late design modifications thanks to cross-referenced information updated in real time: correcting a project at the design stage is less costly than a modification during the construction phase. By way of example, BIM makes it possible to detect layout and/or geometry conflicts between different elements from different trades, and to optimise collaboration between the different trades. This is illustrated by the Mac Leamy curves (Figure 1), which show the benefits of early integrated design:

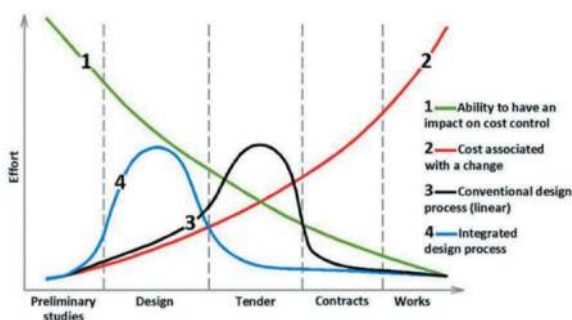

Figure 1. Mac Leamy curves.

Thanks to the integrated design process, it is possible to make some decision changes at an early stage when ability to have an impact on cost control is high and when the cost associated with this change is still low.

BIM also helps to optimise the project because, as a process (with human and technological resources), it enables:

- **Improved performance for everyone involved**, because the use of BIM in their work is a source of efficiency and continuous improvement. Although the benefits for the owner are not necessarily direct and immediate, they are at least indirect, over the long term. Another benefit derived from BIM is that it limits errors, inconsistencies and non-quality, therefore reducing the differences between the initial forecasts in terms of costs and deadlines, the actual timescales and the final cost.
- **Improved overall efficiency** of the project’s production system, made up of all the project stakeholders:
 - The implementation of BIM at the overall project level enables easier exchanges of controlled, produced and used data by the stakeholders, each for their own requirements. Not only is this a performance factor for the stakeholders, it also helps the project owner to meet obligations to provide relevant and valid data, providing better visibility and greater confidence in the said owner’s control of the project.
 - The collaborative nature of BIM is also demonstrated by the fact that it provides a powerful framework for collaboration and interface management, and guarantees the consistency of the models developed by all the participants, both within and between phases of the project. In this respect, BIM is a way for the owner to reduce the risk of inconsistencies and errors between its various co-contractors and partners, by anticipating and limiting the need to rework the design or construction.

Figure 2. Simulation of the integration of the infrastructure into the landscape (source CETU).

- **Better consideration of the structure’s environment** (Figure 2), particularly the physical environment, guarantees greater relevance of the structure, and is also a factor in risk reduction. This is where BIM’s power of spatial integration comes into its own. The power of BIM also lies in the ease with which it can be understood. A digital

mock-up is less open to misinterpretation than 2D plans, sections or sketches, forcing everyone to create their own spatial representation.

The benefits can also be seen in terms of **sustainability**, by limiting environmental impact, enabling eco-design at an early stage in the design process, better control of calculations and management of carbon footprints, and optimisation and reduction in the waste of materials used. The health and safety benefits can also be highlighted during the construction and operation phases, through the potential reduction in the number of accidents as a result of better anticipation of design, even though we still lack hindsight on this subject. Finally, the persistence of the data is a tremendous advantage over the lifetime of the project, enabling it to be more durable, reliable, safe and available.

3 SPECIFIC FEATURES OF UNDERGROUND STRUCTURES

Underground structures have specific characteristics that must be taken into account as part of a BIM approach implemented on a project. These include, but are not limited to:

- **The importance of geology, geotechnics and hydrogeology**, and the need to separate factual information from interpretation. In other words, Book A (factual data) and Book B (interpreted data) (cf. recommendations of AFTES WG32 [13] [14]). It should be noted, however, that it is possible to deploy a BIM approach on a project without incorporating these key areas.
- **Georeferencing** is particularly important for underground structures. The structure must be perfectly positioned both on the surface and at depth in order to assess its impact and optimise its location, particularly in relation to its environment (starting with the geology) and the positioning of emerging structures (tunnel portals, ventilation shafts, etc.). In addition, on long structures, the rotundity of the Earth must be taken into account. Some major projects even have their own georeferencing system (for example, the “LTF2004” coordinate system was created in 2004 with the IGN (for France) and the IGM (for Italy) for the Lyon-Turin Euralpine Tunnel).
- **Underground structures can have a complex geometry** and, in addition to the fact that they can be linear, they can interface with volumetric structures (underground stations, etc.) and have variations in geometry (section enlargement, cross-over, connections with shafts, etc.) that are difficult to apprehend in space, making the BIM approach all the more beneficial and effective.
- **Uncertainty**: whatever investigation campaign is carried out, there is still residual uncertainty as to the ground conditions that will actually be encountered, and consequently as to the suitability of the excavation and temporary support methods, and as to the stresses to which the structure will be subjected. The question is how to use digital models of the structure and its environment to better manage this uncertainty, bearing in mind that BIM is not intended to eliminate all risks, but rather to help manage them.
- **Neighbouring structures**: this is a problem that can exist for any structure, and in particular any structure foundation, but which is particularly acute in underground works (urban ones in particular). A virtual 3D model of the planned structure and the existing structures, in which the digital model of the project should play a key role, should make it easier to perceive interferences (primarily geometric but also geotechnical), and facilitate their management. BIM may not be absolutely necessary in this respect, but it does make it effectively possible and on an ongoing basis as the project evolves. Beyond the geometric contact or parametric conflict, there is the question of the wider impact that the structure may have on the surrounding area, and using the BIM model to better assess these impacts.
- **Excavating the ground**: one of the specific features of underground work is that the ground is excavated in order to build the final structure. The features encountered (geology of the face, water ingress, faults, etc.) disappear as the excavation progresses and the support and final lining are put in place. Hence the importance of collecting this information, storing it and using it over time: firstly, during the construction phase, to ensure that the support is appropriate for the geology encountered, and to have reliable information on the conditions actually encountered, particularly in the event of a dispute, then secondly, during the operation/maintenance phase, because in the event of pathologies observed several years after commissioning, archived data related to the ground encountered during excavation can be very useful for diagnosis and the repairs to be implemented.
- **Auscultation**: the structure under construction and the finished structure, including the surrounding area where appropriate, can be instrumented and auscultated. The resulting data must be able to be stored and used at any time during the life of the structure.
- **Temporary structures**: temporary support structures that remain behind the final lining once it has been put in place and that have been determined using the observational method, or technical or reconnaissance galleries or shafts that are subsequently “abandoned”. It is important to keep a record of these structures in the event of subsequent intervention, in order to avoid incidents or unnecessary complications.

4 BIM-RELATED ISSUES FOR THE OWNER

Deploying BIM on a project makes it easier for the owner to achieve the objectives it has set for the project, or to aim for higher objectives. This applies to the programming phase of the project, the design phase, the construction phase, and then to the operation of the completed project, and the performance of this operation in terms of cost, quality, deadlines and compliance with expected functionalities.

It is important to note that BIM is not just a matter for each individual; the greater the number of stakeholders involved, the greater the benefit. The project owner will also derive even greater benefits. The owner is in fact the one who has the final say in setting up a BIM approach for the project, and in involving its service providers. It is therefore the quality of the BIM organisation that the owner puts in place for its project that will determine the level of benefits it derives from it. There is no tunnel management or operation company that does not itself have an information system. The data and data structures of this information system are defined during the definition, design and construction phases and are fed into the BIM process. It is therefore essential for the project owner to specify its BIM requirements in order to feed the future information system of those involved in operation and maintenance.

The expectations of the owner with regard to BIM as a **support for project management** are to achieve at least the objectives defined in its BIM policy. The owner establishes contracts with its partners for the development of initiatives that contribute to or even extend these objectives, in accordance with 5 strategic areas of project management for the project owner and with regard to:

- Technical control, quality, performance, safety and environment requirements;
- Cost and deadline control;
- BIM Management and the efficient use of digital mock-ups;
- Consultation, communication and decision-making tool;
- Technical management of assets and configuration management by future operators-maintainers.

With regard to BIM as a **model of data relating to the structure**, describing its physical characteristics, and a digital mock-up of the project representing it, project owner expectations are related to:

- **Quality**: the digital project mock-ups should effectively constitute, at all times, a quality reference database of project management and asset data, i.e. the information contained therein is exhaustive, verified and easily accessible. Digital project models should provide privileged access to such information and the place where it is stored. This will ensure that everyone involved, including the owner, has accurate knowledge of the project, whatever the stage it is at. This

implies rigorous management of the model and its successive reference versions;

- **Durability**: the digital mock-ups of the project need to be durable. This implies having them in non-proprietary formats, whose continuity and availability are guaranteed over time, including after completion. In practical terms, this means providing digital mock-ups in a neutral, interoperable format. Today, it is clearly recommended to use IFC formats as they result from the ISO 16739 standard. Note that the data and associated documents (EDM) must also be durable;
- **Interoperability**: that the digital mock-ups of the project are interoperable with other tools or information systems useful to the operation, for the various participants and in particular for the owner, and that they are integrated into the overall information system that the owner uses to manage and operate the project. This means that all those involved in the project, who will be producing data and contributing to BIM, must comply with common requirements in terms of what they produce.

With regard to BIM as a **collaborative tool**, expectations are related to:

- **Sharing**: the expectation is that BIM, digital mock-ups and databases will be effectively shared by all those involved in the same phase of the project, and will be effectively used as a support for collaborative working. By facilitating coordination and collaboration between the players involved, the aim is to improve the overall performance of the project, so that everyone benefits, directly or indirectly;
- **Consistency**: the expectation is that those involved in the project, who are the producers of the information and data making up the BIM, will comply with common standards, which will enable the above-mentioned exchanges on the one hand, and the creation of a consistent database on the other. This is a prerequisite for successful sharing. These include file formats such as IFC (Industry Foundation Classes), which is recommended for digital mock-ups, and BCF (BIM Collaboration Format) for managing BIM subjects;
- **Opposability**: the expectation is that the BIM model thus created can be used as evidence in exchanges between the various players, in terms of its representativeness of the structure. In fact, for a structure that is still in the planning stage, and even once it has been completed, the BIM model contains and enables the manipulation of a much greater quantity of data than is possible with other models. This expectation is therefore driven by a concern for efficiency and consistency. It corresponds to the question of the contractual value of BIM;
- **Transversality or Digital Continuity**: the expectation is that the BIM model created during

one phase of the project's life cycle as deliverables, through the collaborative work of all the players in that phase, can actually be a working basis that is directly integrated by the players in the next phase, as input data.

5 BIM-RELATED ISSUES FOR THE PROJECT MANAGER

From the outset, the project manager needs to be fully aware of the owner's objectives, needs and requirements, which are expressed in part in its Employer Information Requirements or BIM specifications and thus anticipate the following points as far upstream as possible:

- Processes, methods, workflows, exchanges and collaboration, production, verification and validation circuits for digital mock-ups and data;
- Recommendation of the resources needed to successfully complete the project (players, skills, profiles);
- Data coding and structuring, level of information need;
- Tools, softwares, platforms (in particular BIM collaboration platform - BCP or Common Data Environment - CDE) and formats.

Where possible, the project owner must also be aware of the BIM requirements of the future infrastructure manager and maintainer, and where applicable the transport operator, which may differ from those of the project owner, in order to anticipate the best way to return the data. These specifications may, if necessary, be specified later in the life of the project, but in any case, before the specifications for the works that will use them are drawn up. This return of data constitutes the completion of the project and takes the form of the final implementation file (as built), which will be submitted to the operator.

It would be normal for the BIM approach to a project to be set out at the latest when the project management contract(s) is (are) signed, as far as the project owner is concerned, and at the latest during the phase of the award of the works contracts, as far as the future companies holding the works contracts are concerned.

This means that the project owner must be able to provide a framework for this process before launching the call for tenders for the project management team. It can call on the services of an Assistant to the Contracting Authority (ACA) for this purpose.

At the very least, the initial framework should include:

- The designation of the person in charge of the process, who could be called the BIM Project Manager: the project owner or an ACA delegated by the project owner;

- The initial CDE holder: ideally the BIM approach leader;
- Mandatory or priority use cases for the design phase;
- A minimum structure or a principle for structuring the project;
- Specification of interoperable exchange formats at least for the design phase, ideally for the entire project lifecycle;
- The contractual status of the mock-ups for the design phase with regard to the validation of deliverables by the project owner.

However, given the duration of underground works projects and the BIM practices that still need to be refined for this profession, this framework must be able to evolve. In particular, the framework for the works supervision of the project manager could be postponed until the contracting with the construction companies occurs, which would require a modification to the project management contract during the construction phase.

6 BIM-RELATED ISSUES FOR THE CONSTRUCTION COMPANY

In order to achieve the objectives set and to enable the expected uses, all stakeholders involved in a project developed using BIM must have clear and achievable requirements in terms of the information to be provided during the construction phase. The teams in charge of BIM management must define the EIR (exchange information requirements) as defined in NF EN ISO 19650 parts 1 (5.3) and 2, so that the construction company can create and fill in the project information model (PIM) for the construction phase (see Figure 3).

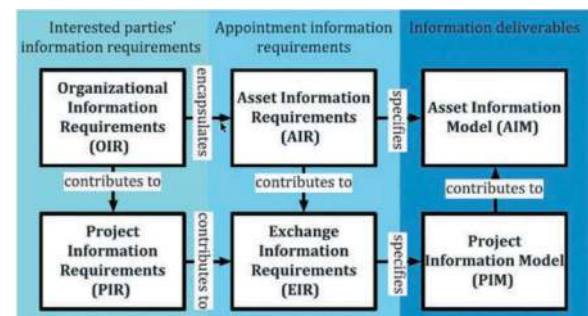

Figure 3. NF EN ISO 19650-1: Hierarchy of information requirements.

The construction company, intervening in the middle of a chain of actions, must have reliable design data, in particular usable 3D models, correctly codified and checked in order to carry out its task.

6.1 Existing environment data

The existing environment can be described by 3D models of structures already built, geological and geotechnical models, buried networks (classified and in 3D), and other data sources (GIS, City Information Modelling, databases) in the possession of the owner or the project manager.

For subsurface data, it is important to clearly define the contractual value of the data present in a model (reference must be made to the compendium of factual data (book A) and to the interpreted model (book B)).

For existing structures related to the project, whether or not they have been reworked, it is always useful to have as-built surveys and 3D scans that have been coloured and, if necessary, classified.

6.2 Model of the structure to be built

Models of the structures to be built are an essential part of any project. Provided that they are well organised, codified, etc. and where the owner has required the contractor to produce them from the digital design models, they can be used, among other things, to manage quantities in conjunction with the quantity take-off.

It is important to know the degree of reliability or maturity of the data supplied.

The construction company can either develop its own model based on the elements provided in the contract, or retrieve and appropriate the model provided by the owner and produced by the project manager during the design phase. In the latter case, a non-recourse clause should be included in the contract.

7 BIM-RELATED ISSUES FOR THE OWNER-MAINTAINER

7.1 Owner-maintainer's expectations

Once the work has been completed, while it is in the operational phase, the “as built” BIM model, also represents a valuable asset for the owner/operator/maintainer from which it can derive multiple benefits:

- Alongside the physical structure, the owner/operator/maintainer will be able to use the “as-built” BIM model to access the verified data that it or its contractors will need for the future management, operation and maintenance of the structure, and ultimately for its dismantling.
- In addition to the data describing the physical structure being built, which is sometimes referred to as legacy data, the BIM can be linked by the owner/operator/maintainer to other tools in its information system, and the model, as a virtual model, can become a particularly ergonomic and powerful access point for data relating to the operation, maintenance and management of the assets that make up its structure. This interoperability enables the development of high-performance

applications based on BIM, for the management of these activities, or the control of systems or equipment. This is the digital twin.

The desired interoperability of BIM means that the owner/operator/maintainer must clearly express its requirements for the data model, and the information it expects to find in it, in good time. It can be even more difficult for the owner-builder to do this if the operator or maintainer is only known at a late stage.

It should also be noted that many of the data concerning the as built structure, included in the corresponding BIM model, are not commonly used in the operational phase. For reasons of database size, this leads us to consider that the owner/operator/maintainer can request an additional version of the “as-built” mock-up, purged of data that is not useful for day-to-day operational use.

It should also be emphasised that the foreseeable life of the infrastructure in operation represents the longest period in the life cycle of the structure. In fact, this period is much longer than the initial phase leading from the first sketches to the tender and then to the works.

It should be noted that in certain situations, such as when regulatory compliance work or major renovation operations are being carried out, maintenance operations become a project in their own right, leading to the partial or complete delivery of a new structure. This means that the data needs to be kept up to date as part of the management of an existing asset, and this will undoubtedly require a new organisation to be put in place.

7.2 Involving the owner/operator/maintainer in the BIM process

The infrastructure manager must define the data required for the proper management of the infrastructure. By means of a set of specifications, it must specify the organisation of the data it needs to meet its objectives. All this corresponds to the AIM (Asset Information Model) defined by standard NF EN ISO 19650-1 [4]. The AIM is fed by the PIM (Project Information Model) supplied by the works company. Depending on whether or not the infrastructure manager is mature in its BIM approach, the AIM will be integrated very early in the process, or if this is not the case, the manager must be involved upstream in the BIM approach to develop its AIM in order to formalise its requirements and structure the data and models so that they are adapted to its activity.

7.3 Issues at stake for the owner/operator/maintainer

Traceability of the various construction phases

One of the special features of underground work is that some of the structures are no longer visible once the work has been completed: the excavated soil, the support and the waterproofing system are no

longer accessible, and only the lining can be inspected. As a result, the BIM model provides access to the information and elements behind or forming part of the tunnel lining.

Points of attention that seem important for the operator and maintainer are as follows (non-exhaustive list):

- The digital model must provide easy access to information, in particular everything behind the concrete lining;
- The digital model should make it possible to trace specific events during the construction phase in terms of geology or difficulties encountered, as these may have an impact on the structure years later;
- The digital model should make it possible to highlight localised particularities (type of lining, dimensions of the structure, geology encountered, etc.) and keep track of the origin of these constructional particularities (design phase, works phase, etc.).

This will be of interest to

- The owner, who wants to know about and monitor the condition of the infrastructure for which it is responsible;
- The operator, who needs to know the information required to operate the infrastructure safely (headroom, gauge, condition of equipment, minimum operating conditions, etc.);
- The maintainer, who needs all this information to carry out its work.

System interoperability

For operators and maintainers, the interoperability of BIM is crucial to making it possible to track assets and maintenance operations on structures and equipment in computerized maintenance management system (CMMS) software. Interoperability will ensure the link between the BIM model and the operating management software. In this respect, it should be borne in mind that the as built model(s) may need to be updated to meet the needs of operations and maintenance, both in terms of the information contained and the level of geometric detail or operations management software. In addition, interoperability must enable information to be transmitted according to the players involved: exchanges between players specify the data to be exchanged.

Operational safety

The use of virtual reality, which is based on the BIM model, may be of interest to external players such as the emergency services. Virtual reality makes it possible to carry out visits to the infrastructure and training staff without having to interrupt traffic (or activity), while guaranteeing that safety personnel have a good knowledge of the structure (see Figure 4). Obviously, the need for real exercises remains. This approach could be taken into account right from the project design phase.

Figure 4. Realistic representation of a safety exercise (source Andra).

Maintenance safety

Virtual reality used as a training medium is an interesting use case, useful for both the operator and the maintainer. In fact, this form of visualisation enables them to familiarise themselves with the infrastructure without having to physically visit the site.

Furthermore, in the case of dedicated modules, it is possible to simulate situations that are considered dangerous without actually being exposed to the risks.

Preparing works to be carried out on the structure BIM model visualisation tools can be used to:

- Prepare works to be carried out on the structure (safety, security, time saving, better training and efficiency);
- Prepare the phasing of works;
- Check available templates and define works methods;
- Identify storage areas prior to works;
- Define routes;
- Simulate the works before carrying it out in the field.

This is of real benefit to maintainers, who can prepare their work as effectively as possible.

Figure 5. Realistic representation of a tunnel fire (source Andra).

In the case of an intervention during the operational phase (fire drill, for example, see Figure 5), the operator will also be interested in all these aspects, as it will be able to simulate and visualise

the impact of the intervention on the infrastructure for which it is responsible.

Feedback integrated into the design

By including the operator in the design phase, on subjects such as evacuation strategies, smoke extraction, or flooding, the operator will be able to share its experience and provide guidelines for adapting the infrastructure to the use that will be made of it once it is in service.

In addition, by including the maintainer in the design phase, it will be possible to design and build structures and systems that can be easily maintained. For example, the design will avoid cladding structures that prevents inspection of the structure behind them.

The Project Information Model (PIM)

The Project Information Model (PIM) submitted by the construction company, can be sent to the operator and maintainer as soon as the works have been handed over.

BIM should make it possible to improve the operation and maintenance of structures. To make this improvement possible, we need a digital as built model that is adapted to future needs. Involving operators and maintainers early on in the BIM process will ensure that the completeness and quality of the information delivered meet their requirements. Similarly, operators and maintainers will have to indicate their requirements in terms of level of information need. At the same time, the structure of the data will also have to be provided. This requires upstream work to be taken into account right from the start of the project's BIM process.

As far as the completeness of the data is concerned, it is a question of striking the right balance between an abundance of information, some of which will never be used, and a lack of information which would hamper the ability of the operator and/or maintainer to achieve their objectives. This is particularly true of the use of point clouds, the relevance of which for simple structures can be questioned, given the size of the files to be stored.

Traceability of subsequent modifications

For the maintainer and owner, it is important to:

- Be able to modify the model following interventions/modifications made throughout the life of the infrastructure, the aim being to have a digital twin that reflects reality.
- Trace changes in equipment and structures over time and make it possible to specify the date of changes/modifications.

Digital twins

Operation and maintenance require the management of information flows modelling all the states of a structure over time. It is this concept that needs to be integrated very early on in the life of a project.

To date, there are different ways of looking at digital twins, depending on their level of connection (IoT or other), the technological building blocks

applied (SCADA, GIS, BIM, CMMS, etc.) and the vision expected of them (web portal, 2D, 3D, cartographic, etc.). Unlike static data models, digital twins are dynamic, "living" entities that evolve over a defined timeframe, or even in real time. This is because the virtual representation of the structure can be connected to the various sensors installed throughout the infrastructure, via a processing system that enables the descriptive, relational or analytical data from the virtual twin and the real structure to be displayed and synchronised.

Once informed of this data, it is possible to use the digital twin to run simulations of interventions, study performance problems and generate possible improvements, all with the aim of generating valuable information that can then be reapplied to the original real physical object.

In this way, the definition of a digital twin specific to the infrastructure to be operated or maintained must be guided by its use, depending on the interoperability of the technological systems in place or to be built. By integrating the digital model into the digital twin, and therefore a geometric and information reality, the latter will have to keep pace with changes in the actual structure by updating the data in the virtual structure.

8 CONCLUSION

Digital transformation is having an impact on our businesses and the way we work, starting with the use of BIM. A BIM approach cannot be improvised, and must be understood and prepared for by all those involved in underground construction, starting with the owner. It is the owner who initiates the BIM approach, who decides whether or not to include it in the contractual requirements, who defines its BIM policy and strategy and who transposes it into its contracts (BIM specifications) with the project manager and the works companies. If the "constructor" project owner does not operate the infrastructure, the infrastructure operator/maintainer must be involved in this process as early as possible. In order to benefit from the advantages of BIM, the project owner (including the infrastructure operator/maintainer) must establish the digital continuity of its operation, define the roles of each party, the nature of the deliverables, what they are expected to achieve and the objectives and uses to which they are to be put.

To this end, the owner must be clear about its strategic objectives, which it has defined and described in its BIM specifications. It must also be clear about who it is entrusting with BIM management and what its responsibilities are. In addition, the owner must be able to require the BIM project manager and the BIM management team to clearly detail the level of information need required, according to the notion of the right level of information (neither too much nor too little), depending on the phase, discipline

and profession of the various people involved in the BIM model.

It is also important not to underestimate the resistance to change that this entails within the structures of the various players, as well as the investment required. A BIM approach, just like a Quality approach or a project to reorganise an entity, whose principles it resembles, must be supported at the highest management level of the players involved, starting with the management for deployment within a legal entity or by the project owner in the case of a project.

Digital automation in the structural modelling process for tunnel linings – A digital tool-based case study

Arjun Shivasami* & Grant Heath
Mott MacDonald, Sydney, Australia

ABSTRACT: Automated design processes are often relied upon for efficacy and innovation in engineering, particularly for complex problem-solving needs in tunnel projects. This paper will present a case study within a project in Australia where SpeedBot's modern digital techniques, including Computational Design (CD) streamlined the modelling process, allowing for various iterations of loading sequences and lining thicknesses to determine the effects of increased loading on a large span cavern. The case study presented in this paper required the structural modelling of a cavern subjected to surcharge loading from aboveground building development, with varying potential loading conditions due to the unknown load path due to the surrounding geology. Multiple structural models were required to analyse best and worst-case scenarios, however, various amendments such as tunnel lining thickness and assumed load dispersion width would need to take place within each model. The time estimated to undertake all required models was significant, however the project did not have the luxury of time. SpeedBot was adopted as a feasible approach to undertake all the required models not only in significantly less time than conventional modelling techniques, but providing a singular modelling approach, improving accuracy. Tunnel designers implemented SpeedBot for the modelling of tunnel concrete linings, through digital collaboration using commonly used commercially available software. This enabled the integration of computational processes, producing output files that can be recognised by Autodesk ROBOT for designers to undertake the required structural analysis. SpeedBot's scripted automation arrangement allowed the first step in the structural engineering process to be automated, significantly reducing modelling time, allowing more time for tunnel designers to analyse output results and focus on first principles for better outcome. The digital tool enabled the designers to compare the potential use of unreinforced vs reinforced concrete linings and promoted optimal solutions in the early stages of design.

Keywords: Tunnel Concrete Linings, Digital Tool, Computation Design, Automation, SpeedBot, Sustainability

1 INTRODUCTION

Designing tunnel support systems is both a complex and extensive process, with structural checks needing to be undertaken for both temporary and permanent support systems. These forms of analysis are resource-intensive and can take weeks for multiple models to be developed and run, consuming large percentages of allocated budgets for the design process. As a minimum, permanent concrete tunnel linings require greater analysis in the form of a bedded beam model using industry-standard structural software and are more time-consuming in terms of structural design than primary support systems, such as shotcrete linings and rockbolts arrangement. Time is also heavily invested during this process for multiple engineers to review the analysis undertaken, requiring collaboration between engineers to determine the approach taken for the analysis and understand the complexity of the model.

This situation was outlined as a potential area for the use of an automation tool during the concept design for one of Mott MacDonald's transportation projects. Additional surcharge loading from a new building to be situated directly above a large span cavern was identified to be a possible risk for the design, giving concerns over the structural adequacy of the permanent lining. To raise concerns further, the additional development loading was in a region of low ground cover above the cavern crown and the load path through the surrounding medium could not be easily determined, requiring multiple analysis options to be conducted. To address these challenges, Mott MacDonald saw opportunities in digital tool implementation into major projects and drew on the capabilities of digital tools in the form of a tool codenamed 'SpeedBot'. The tool leverages the capability of various commercial structural

*Corresponding author: arjun.shivasami@mottmac.com

analysis software's to synchronously automate building multiple bedded beam models representing a 2D tunnel concrete lining, along with the spring stiffness that accounts for the interaction with the surrounding medium. The scripted automation arrangement of 'SpeedBot' proved pivotal in the turnaround of the required modelling, which included multiple models detailing different potential load dispersion sequences due to unknown load paths through the surrounding geology. By implementing scripted automation, significant time was saved by the engineers involved, enabling the analysis undertaken to feed efficiently into further steps like structural design and detailing.

2 SPEEDBOT OVERVIEW

During any structural analysis of tunnel lining, the designers will be required to run a multitude of numerical simulations to understand the performance of the concrete lining and its interaction with local ground conditions, loadings, and their combinations. This becomes critical especially when the properties and behaviour of a given ground are not known, resulting in varying possibilities acting on a tunnel lining. This section of the paper will introduce the concept of automation for structural modelling using SpeedBot and the breakdown of its advantages. A task like this for a single cross section can generally take up to 32 manhours for a designer to complete from start to finish, consuming the focus of the engineer and limiting the time for engineering innovation to be considered during the overall process.

The overall concept of SpeedBot, is to remove significant portions of manual labour from the structural modelling process, highly reducing human errors and allowing tunnel designers to focus their time on research of viable inputs to best change the overall outcome. SpeedBot facilitates Finite Element Analysis (FEA), which is quite complex during model building, to be completed in significantly less time than standard modelling techniques, approximately 12 times faster for a single model to be produced. The approach allows the team to share standardised practice content globally across the organisation, lifting the standard and capacity of other projects and teams.

The benefits of SpeedBot are utilised during the modelling stages when inputs and parameters are to be defined. Through the scripted automation demonstrated in Figure 1, manual inputs for tunnel models, such as tunnel geometry, load patterns and magnitudes, load combinations, materials properties, and spring stiffness, are streamlined and scripted into the physical modelling process producing a completed model within few minutes rather than several hours when conventional modelling techniques are applied. Tunnel modelling for structural analysis is not a one-cycle process, inputs will need to be changed and altered several times before a model is reviewed and

finalised for design. This requires multiple designers to use a significant portion of project budget to develop these models. SpeedBot provides an alternative to applying these changes to the model, providing substantial savings with reduced modelling time.

The most immediate benefit of SpeedBot is the time and cost saving in structural model building and overall design process but in the long-term, it sets a pathway to sustainable outcomes. Building complex geometries into a 2D tunnel model can be difficult and introduces a large potential for human error. By implementing automation tools, the complexity is simplified completing the model building in few minutes and without any potential for human error within structural software during plotting, defining of geometry, loading, combinations, and support stiffnesses. Not only is time saved in the creation of a model, but also in any subsequent model iterations. In the manual development of tunnel models, even the smallest adjustment to geometry requires an almost entire rebuild of the model, but with automation, these changes are incorporated and updated almost instantly and without error. This exponential reduction in design manhours facilitates the designers to focus more on engineering fundamentals rather than spending time on labour-intensive computations and modelling.

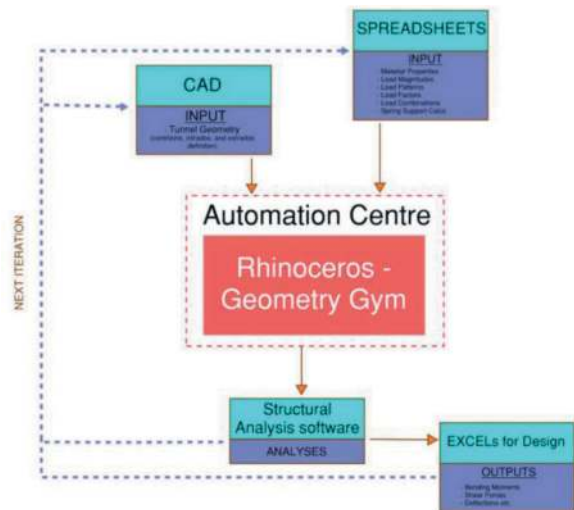

Figure 1. Automation scheme of SpeedBot.

A simplified digital approach provides the designers with more opportunity to do additional sensitivity checks, and trial and error exercises to avoid generalisation and conservatism in the tunnel design, so to a larger extent aiming for optimised and hence the more sustainable solutions. The SpeedBot tool combines the various functionalities of Excel, VBA, Rhino, Grasshopper, and Geometry Gym plugin library to offer an innovative approach to generate 2D tunnel profiles subsequently ready for analysis by structural software. By leveraging the specific capabilities of each application and then linking

them together into a digital workflow, SpeedBot enables efficient tunnel modelling and prepares for quick analysis, reducing human errors and manual effort but ensuring accuracy. A complete breakdown of the various functionalities SpeedBot utilises was documented by Shivasami et.al. (2023) in the paper SpeedBot – A digital tool for automating the structural modelling process for tunnel linings.

3 SPEEDBOT IMPLEMENTATION FOR TUNNEL LINING UTILISATION CHECKS

This section of the paper demonstrates the advantages of implementing SpeedBot into a major transportation project where the structural adequacy of a tunnel permanent lining was investigated for various possible loading conditions that were not originally envisaged in the reference design.

The automated approach to the tunnel modelling offered by SpeedBot and the eventual analysis was implemented during the concept design of one of the major rail transportation projects currently under construction in Sydney. The structural adequacy of a station's permanent lining was under investigation due to an unforeseen addition to the concentrated surcharge loading from a newly proposed overhead building development in proximity to the tunnel in question is shown in Figure 2. Due to this additional loading, and the uncertain distribution path the loading may take through the surrounding rock, the potential increase in the lining utilisation needed to be checked. However, multiple beam-spring models for each loading circumstance would be time-consuming and expensive. Due to the sudden change, a quick turnaround was needed since the luxury of time was not available, but the prompt technical advice must also be reliable and accurate as it could have potential impact on major contractual decisions. The assembly of one model, due to the complexity and unknown loading conditions can take up to a week to model for a single possible loading condition. For multiple loading conditions, this process can be quite lengthy, requiring multiple tunnel designers to produce multiple models, and introducing different modelling approaches which can lead to a validation process to avoid errors in modelling and misinterpretation of parameters by other tunnel engineers.

The undrained cavern under investigation had a span greater than 25m, a constant 800mm thick concrete lining above the spring line, with very little clearance from the crown of the tunnel to the load point in the ground, of only 3.5m. The loading conditions and magnitudes from the building was known, however the load path possibilities from the structural toe of the foundations onto the cavern were uncertain, resulting in designers assuming the load path through various inclination angles. The load dispersion inclination angles proposed under

the footings were 30, 45, and 60 degrees from the underside of the four proposed structural element's foundation, two walls of varying thickness with strip footing and two pad footings supporting column loads. This approach provided more realistic loading possibilities for the surrounding geology while providing crucial information on the lining's behaviour under various loading conditions. In addition, a standalone 20 kPa traffic surcharge was considered as an alternative load case to the new building development to determine which loading case would increase the stress within the tunnel lining.

Figure 2. Plan of identified loading conditions on station cavern.

To accurately simulate the conditions in the cavern, the lining was modelled as a series of 500mm straight beam elements 1000mm in depth in the out-of-plane direction, analysed as a beam spring model accounting for appropriate load factors and combinations for Ultimate Limit State (ULS) and Serviceability Limit State (SLS). The geology surrounding the lining was represented as compression-only radial and bi-directional tangential spring support stiffnesses, at increments of 500mm, acting at the supports of the straight beam members. The thickness of the lining members below the spring line were incrementally increased towards the invert of the tunnel at 500mm increments, representing the transition to the invert region of the tunnel.

A specific challenge that designers identified during their preliminary review of the cavern focussed on the concentrated regions of high loading, potentially altering the standard compression/tension zones, and bending moment patterns the lining was originally designed for. Figure 3 illustrates the possible inclination angles of the loading dispersion through the surrounding rock. The identified loading regions on the tunnel lining above the widest span of the tunnel profile showed some regions had very high loading concentration at different locations along the crown of the cavern.

Since the loading inclination angle was not certain, analysing the lining for various potential angles was the only option, otherwise, the design would be incomplete and a high risk if not accurately investigated. The idea of implementing SpeedBot during this phase of the design had positive feedback from the designers, with specific problems and issues being identified as a result, which conventional modelling practices may not have revealed.

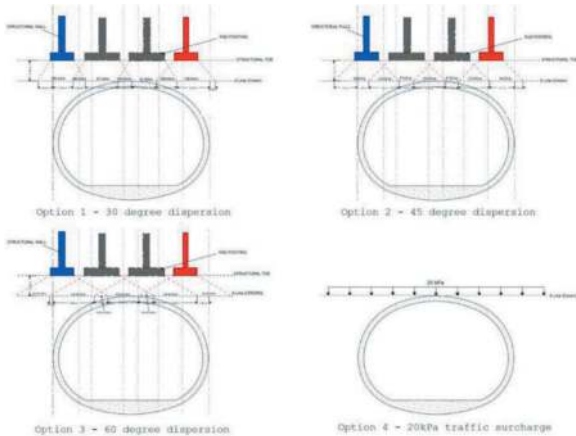

Figure 3. Load dispersion comparison between various options.

The modelling process for this sort of optioneering structural investigation using conventional modelling methods would take a few weeks, including various checks being time-consuming. These requirements include geometry development through AutoCAD, the application of load patterns, manual input of various load factors and combinations, and assigning support stiffnesses within the designated structural software once the tunnel profile has been imported into the structural software. In some instances, the designers chose to build the tunnel profile manually within the structural software which is even more time-consuming. Figures 4 – 7 demonstrate the interface of SpeedBot at different phases of the overall design process, including load combination definition, to results interrogation.

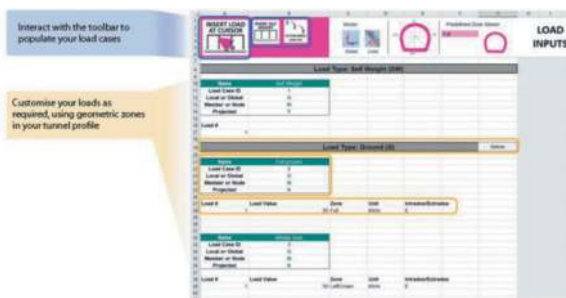

Figure 4. Principal load cases and its pattern definition in SpeedBot through MS Excel interface.

In this case study, the output from SpeedBot was analysed using Autodesk Robot 2022 (ROBOT), that was utilised to investigate the change in forces to the tunnel lining. Loading diagrams, such as bending moment and shear diagrams indicated the regions where significant force increases were situated along the crown and side walls of the lining, while producing result output spreadsheets, documenting the magnitude of loads at each node. These loads are inputted into a pre-determined spreadsheet template, which was created with various structural checks in accordance with BS-EN1992-1-1-2004 for unreinforced concrete and AS5100 for reinforced concrete, including stress/strain, flexural, and shear checks, determining the adequacy of unreinforced concrete. Both unreinforced and reinforced lining solutions were analysed as options and investigated to provide feasible construction options, as designers settled that both options had advantages and disadvantages given the identified loading and design life requirements.

SpeedBot enabled various iterations of loading models to be produced in significantly less time than traditional modelling techniques, allowing varying lining thickness and loading configuration for a proposed unreinforced tunnel lining. Table 1 shows the options tested for each loading configuration, determining the required lining thickness for each loading type, to withstand the additional forces imposed on the lining. As expected, the designers observed that the various loading cases predominantly had tension as a critical force type on the lining, resulting in unreinforced lining suggestions to be of increased thicknesses. Note that Table 1 only shows a small section of the results for the options executed in SpeedBot since documenting the results of all optioneering exercises is out of this technical paper's scope.

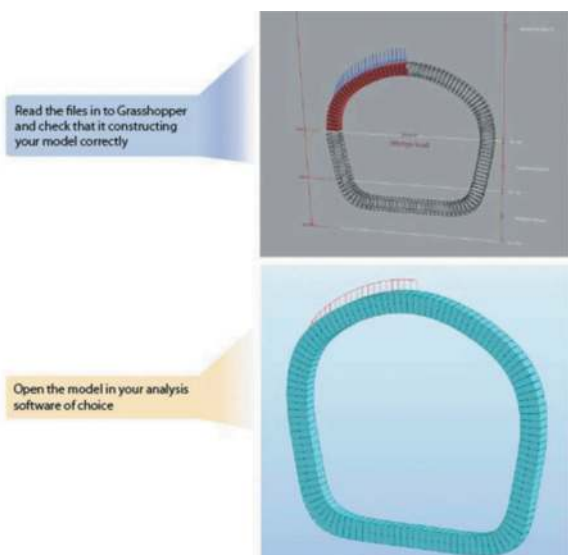

Figure 5. Example of executed automation and transition into Autodesk Robot.

Table 1. Unreinforced concrete lining utilisation at varying thicknesses and loading cases.

Loading Action	30 Degrees		45 Degrees	
	Thickness (mm)	Utilisation (%)	Thickness (mm)	Utilisation (%)
Compression	500	80	500	78
Tension	800	93	850	99
Shear	400	95	400	91
Loading Action	60 Degrees		Traffic Surcharge	
	Thickness (mm)	Utilisation (%)	Thickness (mm)	Utilisation (%)
Compression	500	78	500	97
Tension	800	94	900	97
Shear	400	93	400	93

Table 2. Maximum crown deflection for all loading cases at 800mm thick lining.

Loading Action	30 Degrees		45 Degrees	
	Thickness (mm)	Max Deflection (mm)	Thickness (mm)	Max Deflection (mm)
Max. Crown Deflection	800	7.12	800	6.73
Loading Action	60 Degrees		Traffic Surcharge	
	Thickness (mm)	Max Deflection (mm)	Thickness (mm)	Max Deflection (mm)
Max. Crown Deflection	800	6.86	800	6.63

The aim of this paper is to demonstrate the capability and the benefits of implementing SpeedBot for tunnel lining optioneering analyses through a case study. Significant time was saved compared to traditional modelling techniques which would take tunnel designers many weeks to complete all the models tested and verified.

To determine serviceability checks for both unreinforced and reinforced concrete linings, the maximum crown deflection was determined for all loading actions at a lining thickness of 800 mm. The maximum deflection identified in Table 2 was identified at the crown of the tunnel profile as anticipated.

Similar to the unreinforced concrete checks, SpeedBot enabled accelerated design checks for reinforced concrete linings using RAPT, determining the required lining thickness and reinforcement to withstand the above load cases. RAPT was used to examine the outputs produced from SpeedBot, in the form of a predetermined template, producing M-N interaction diagrams against AS 5100 to determine the adequacy of the proposed lining thickness and its reinforcement arrangement.

Despite the problem at hand being very specific and the models developed only addressing specific concerns, further optioneering prospects for this case study were identified by designers during the above process. Identified areas for optioneering studies of the developed models included modelling various ground conditions, such as higher/lower groundwater levels or soft ground conditions. The designers opted to use the

available data from the identified boreholes within the region of the cavern, recognising the quality of the ground in which the cavern would be encased. This caused alterations to the structural models for various scenarios through the radial and tangential spring stiffness, representing the behaviour of the surrounding geology to the lining. Additionally, different load combinations also impacted the results produced from all models. The various possible load combinations for the analysis were identified and used for the completeness of the study. The ground conditions and load combinations could be altered quickly and tested seamlessly with the implementation of SpeedBot.

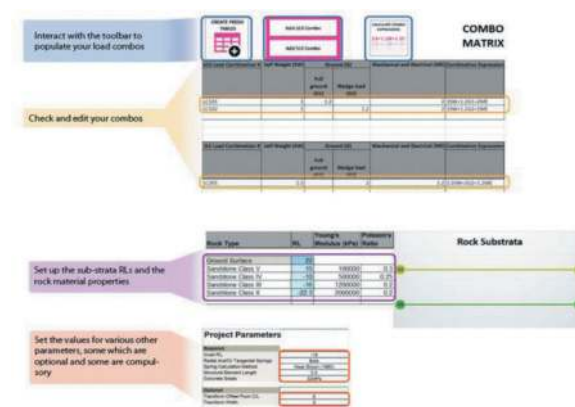

Figure 6. Load factors and its combination definition in SpeedBot through MS Excel interface.

Overall, the lining for the cavern was concluded to be a minimum of 900mm for unreinforced concrete option, and 750mm for reinforced concrete option. The final recommendation was that the lining was to be completely reinforced, citing sustainability interest over increased excavation volume, muck removal and, production of concrete for a significantly thicker tunnel lining, including potential safety considerations for future developments around this location, and increasing surcharge loading during the life cycle of the asset. Concerns were also raised as designers noticed that tensile utilisation was the critical case for all loading cases and the location of the over-utilised beam segments all being located above the spring line i.e., predominantly in the crown and side walls. The lining thickness would be significantly increased in this region if unreinforced, by altering the geometry of the tunnel profile and resulting in a significant increase in excavation and concrete use resulting in higher carbon embodiment.

Figure 7. Example of results interrogation in Autodesk Robot.

4 REFLECTION OF DIGITAL TOOL IMPLEMENTATION

This section of the paper will provide a reflection of how SpeedBot not only streamlined the analysis discussed in this paper but how automation tools are advancing the tunnel design space. Outside of SpeedBot's time-saving solutions through advanced automation, reducing lengthy modelling processes, it offers various benefits which further promote the direction the tunnel engineering field could ultimately follow moving forward.

4.1 *Designing resilient and sustainable infrastructure*

The advanced simulations that SpeedBot offers through the automation process for computational engineering greatly impact various conditions of tunnel design, allowing designers to integrate sustainability and resilience conditions into tunnel projects. These considerations include environmental impacts, various design choices, optimisation of resources, and energy efficiency. SpeedBot enabled multiple tunnel lining models to be run much quicker

than standard modelling practices, which for the case study presented in this paper, enabled the design of more sustainable linings. This was achieved through various iterations of each model within reasonable timing, varying lining thickness to reduce potential carbon emissions from concrete and steel construction. Tunnel designers also had the ability to spend time on innovation during the early design process without concerns over budget constraints due to the streamlined modelling process of SpeedBot. The streamlined modelling approach allowed designers to focus on engineering basics to attain a highly machine optimised lining section design at specific areas, rather than focussing on generalised lining design, hence supporting good sustainable practices.

4.2 *Efficient and cost-effective solutions*

The most obvious cost-effective solution noticed by designers was the significant reduction in overall modelling and analysis time for multiple loading sequences. Computational digital tools such as SpeedBot utilise algorithms and design tools to optimise the design process, which provides financial and technical benefits. Financial benefits which were observed by designers during the above case study included considerable time savings for multiple model iterations, reduction in software use which can minimise licencing fees for software's that charge on per day of use, and resource optimisation allowing resources to be spread across other projects which benefit the client and consultant. Technical benefits observed by the designers were highlighted by the singular modelling approach in which SpeedBot was developed. The streamlined knowledge transfer allowed multiple designers to follow the modelling and analysis of each load case, allowing collaborative input for result analysis and report writing. This became pivotal during troubleshooting sessions where initial results during the early stages of the design process did not look correct to designers. Implementing a singular modelling approach through SpeedBot enabled peer review sessions regarding the design to be streamlined, as all designers followed the same design and modelling approach, eliminating the need for initial review time and eventual discussions regarding the models produced. All loading cases were addressed using the same approach, providing confidence in the quality of output produced by the designers.

4.3 *Creative and innovative designs*

Conventional engineering practices and technical tools to some extent deter innovation and creativity due to the complexity and time-consuming requirements currently in practice. Enhancing Digital tools such as SpeedBot and harnessing the power of Artificial Intelligence (AI) can allow engineers to push the conventional practice boundaries to develop creative

designs. Conventional designs for tunnel linings for these situations around aboveground developments and high-ground surcharges would dictate an assumption of reinforced concrete linings from the start of the design process. SpeedBot allowed designers the time and resources to swiftly consider other lining options, such as unreinforced or SFRC or bar reinforced linings. Further implementation of digital tools in the form of AI can promote the streamlined design process offered by SpeedBot. Deep Machine Learning (DML) utilises data sets from previous projects to form assumptions and potentially run computational designs without the need for human inputs, allowing designers to encourage innovation through reduced time consumption for initial modelling stages.

5 CONCLUSIONS

Owing to the continuous advancement of technology, engineering consultancies have realised the transformative advantages of incorporating digitalisation in computational design. This approach provides a framework for informed decision-making, promoting collaboration and innovation that leads to superior and sustainable outcomes for the planet. Among the design processes that have benefited from digitalisation, the tunnel design process stands out, with the SpeedBot tool proving valuable in reducing the time spent on modelling. This allows designers to focus on analysing multiple alternative options, leading to more intricate thinking and a broader range of optimisation possibilities.

This paper presented a case study detailing the benefits of SpeedBot in running optioneering assessments for 2D bedded beam models at a high level. Immediate advantages include reduced man-hours and design schedule expeditiousness, while long-term benefits include the elimination of human-instigated errors in structural models and highly refined sustainable results. In this example, the decision to recommend reinforced lining may seem to have a higher carbon footprint, but careful consideration of the required over-excavation, increased muck disposal, and higher concrete volume for unreinforced concrete thickness predicts a more onerous outcome. Additionally, the need to future-proof the lining design for new developments in this location

above the cavern has governed the decision for the lining to be reinforced and more flexible.

Moreover, SpeedBot enables the analysis of a greater number of locations along the tunnel alignment, resulting in a more accurate and practical solution that avoids surplus generalisations in the design. This tool is particularly useful for designers who are embracing the digital revolution of tunnel design through automation and Artificial Intelligence (AI). It provides sustainable solutions to tunnel problems and proves invaluable to the field. As engineering continues to leverage advanced technologies and methodologies, the future promises to exceed client expectations and shape a better, more sustainable planet.

Demonstration of parametric analyses in ground models by applying programming logics using a digital tool named ParaRanger

Arjun Shivasami*, Roshan Nair & Lachlan Dunbar
Mott MacDonald, Sydney, Australia

ABSTRACT: The use of numerical analysis routines in tunnel designs has increased with the availability of ample computing power. This has led to development of highly optimal and sustainable solutions that require minimal human effort. This paper discusses the development of a digital tool that streamlines and automates the numerical analysis process for tunnel problems. A digital tool is developed using programming language and third-party packages. It has two components that work together as an interface between the logic and software. The first component is a front-end graphical interface that provides a user-friendly interface for input and output options. The second component interacts with a commercial software to modify the model parameters as specified by the user to perform the calculations and organise the results for subsequent processes. The tool allows for multiple analyses of a single base model without creating multiple models from scratch.

The paper demonstrates use of this tool in an underground tunnel support analysis for a pumped hydropower project. The user-developed geotechnical model for headrace tunnel in RS2 (Rocscience) is used as seed file. The concept stage geotechnical investigation provided large variance in ground parameters, namely strength and stiffness, which was captured as a statistical input. An automated setup created batch files for processing the varying input parameters and tunnel support system. Once the analyses were completed, the displacement and stability factor output matrix template were utilised by the designer to devise tunnel support strategy. This tool is a significant advancement in parametric analyses as it helps to run several sensitivity models with limited human intervention. The tool's ability to organize results in a user-defined and well-formatted manner makes it ideal for informing subsequent numerical analysis. The tool saves time and reduces the cost of running parametric analyses. It suggests innovative solutions with opportunities to manage risks, especially during the early stages of design.

1 INTRODUCTION

Analysis of geotechnical problems requires to simulation of existing ground conditions and envisioned changes in the factors like incidental loads, presence of water and ground properties. Many of these factors are progressively updated and linked to the maturity of the elements in various design phases. Probabilistic analysis approach like Monte Carlo method and Latin hypercube is usually used to deal with such variability and still require development of behavioural models to train the outcomes (Cheng et al., 2019; Mitelman et al., 2023). Many resources are usually spent to develop the process and thereby impacting the meaningful interpretation of output. The variability in parameters leads to complex, time consuming and repetitive process to arrive at design

solutions (Yang et al., 2022). During initial concept stages, simpler analysis methods are generally employed aiding interpretation of highly variable geotechnical data and to understand the behavioural pattern resulting in optioneering. Further, in the detailed design stages, the options are evaluated based on more reliable data and refinement of design models occur. During construction, monitoring of the response of ground assist in real-time decision making and risk assessment, allowing for adjustment and improvements as needed (Wiles, 2005). In these design stages, numerical modelling has become an indispensable tool to develop interpretative ground models and carry out the analysis enhancing the precision and reliability while minimizing potential risk (Oreste, 2002). However, more often large amount of information available from

*Corresponding author: arjun.shivasami@mottmac.com

numerical analysis output bias the outcome (Phoon et al., 2022).

In the current form, a common commercial numerical analysis software lacks an in-built ability to generate batch process catering large input variability. Additionally, the post processing outputs are filtered and collated for each parametric analysis. Both tasks require careful handling of large amount of data and potentially prone to human-made errors. These limitations can be addressed by employing additional programming logics that can collaborate with the commercial software to obtain the needed outcomes. Various programming languages can help in generating subroutines which may either directly be incorporated into a software or communicated using third-party digital tools. The digital tools can be programmed to gain access to the numerical analysis software core to automate the process, modify design elements and its properties, filter outputs, present the outputs in desired form. Numerical modelling procedures by using custom-made digital tools can provide superior solutions in comparison to machine learning (Chen et al., 2020).

This paper demonstrates a successful implementation of a digital tool in numerical analysis of underground tunnel. Mott MacDonald's in-house developed

tool, ParaRanger, was used to input the variable parameters to a commercial numerical analysis software (RS2 Rocscience) consecutively and perform numerous analyses. The tool was developed with the intention of feeding the parametric input into a developed baseline model, modifying the selected elements in the model, automating the generation of batch files and presenting the desired outputs for post processing.

2 COMPOSITION OF THE STUDY

In a project, numerical analyses of a design element are developed through a systematic process. The process can be summarised into three stages, i.e., pre-processing, numerical simulations, and post-processing. This process is performed iteratively for the variables to optimise the solution and guide the design outcome of the problem. The resource requirements can vary significantly for various components. These requirements can be generalised as shown in Table 1. Nearly 80% of the resources are utilised to carry out pre-processing and numerical simulations, whereas critical task of data visualisation, analysis and interpretation often ends with least resource allotment. There is a need to reduce the manual interventions in

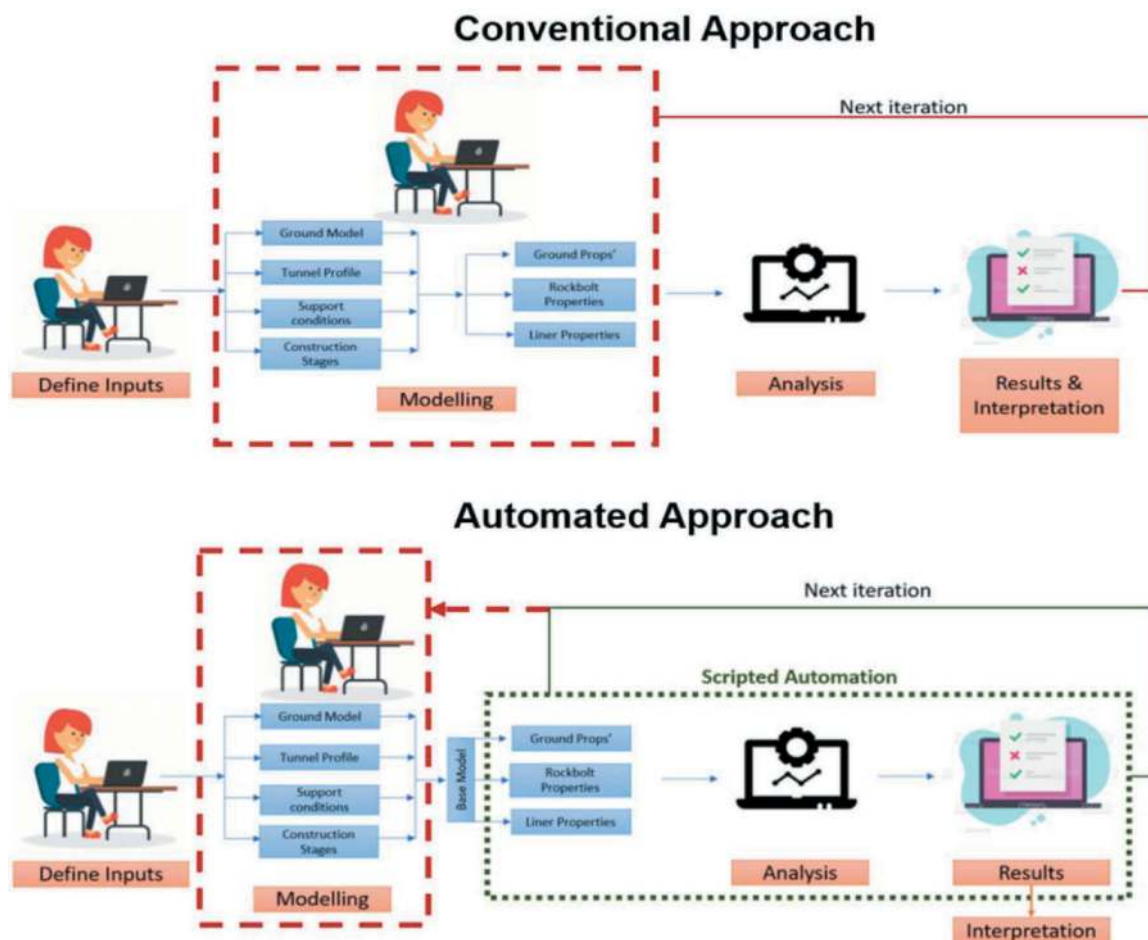

Figure 1. Comparison of automated approach of ParaRanger (Shivasami et al., 2023).

Table 1. Resource requirement for problem analysis.

Stage	Component	Resource requirement
Pre-processing	Problem formulation	50%
	Ground model development	
	Discretisation	
	Error management	
Numerical simulations	Data input	30%
	Convergence analysis	
Post processing	Parametric analysis	20%
	Visualisation of results	
	Optimisation	
	Validation and verification	
	Documentation and reporting	

the first two stages and direct the effort to drive post-processing. Digital tools can contribute to modify this skewed allotment by automation of initial stages and present numerical output in comprehensive format. Shivasami et al. (2023) presented a digital tool, ParaRanger, to aid the numerical analyses through programming language Python. The tools help to reorganise the conventional parametric analyses process through scripted automation (Figure 1).

The digital tool was developed through Mott MacDonald's in-house efforts by integrating an automation scheme to RS2 (Rocscience) software and augmenting the design decisions with well formatted analysis output. ParaRanger was adopted for analysis and design of an underground headrace

tunnel in a Pumped Hydroelectric Energy Storage (PHES) project. The analysis and the outcomes are presented in following sections.

The ParaRanger tool provides a user interface to define the inputs to the numerical software, RS2. A baseline model is initially created by the user which defines the ground conditions, tunnel excavation geometry, boundary conditions, adopted constitutive model and construction stages. This base file is used as a canvas by programming logics in ParaRanger to carry out series of parametric analysis. These parametric analyses represent the combination of design variables such as geotechnical properties of the modelled stratigraphy and ground support (rockbolt and shotcrete) properties. The ParaRanger tabulates the numerical simulation outputs and presents the critical information in both visual and report format. During post-processing, these outputs are then used by the designer to formulate the design. In this study, ParaRanger is targeted to automate data input, generation of batch files (for parametric study), instruct RS2 to process these files and provide a formatted output for swift optimisation and documentation.

3 DEMONSTRATION OF THE PROCESS

It is proposed to excavate a 6m diameter headrace tunnel to connect the water intake structure of upper reservoir to the powerhouse through pressurised penstocks. The underground part of the penstock houses a steel liner to cater for internal water pressure during the operational stage and is not intended to support the loads transferred from the excavated rock mass. The headrace tunnel was required to be designed to fulfil both initial support and long-term support of the excavated ground and to limit ground deformation to the steel liner. The waterway alignment had an invert gradient of about 10-12% towards powerhouse. It was intended to support the excavated ground with combination of shotcrete with steel fibres and fully grouted rock bolts. The annulus between the rock and steel liner was proposed to be back-filled. The tunnel supports are designed to accommodate 100% of the ground loads and considered as a permanent support throughout the design life of headrace tunnel. The geotechnical investigation within the site was limited due to the early stages of the design. The information relied on very limited boreholes drilled around the proposed tunnel and imposed low confidence on the geotechnical parameters along the alignment.

The site featured a complex suite of granites, volcanics and conglomerates which had been transformed by a large-scale geological activity. The true extent of the rockmass affected by the shear zones and other low strength deformed structures was not able to be determined due to lack of available investigative data. The interpreted geological information indicated the natural material on the ground level comprises of residual soil and extremely weathered rock. The overburden above the tunnel was around 12m at the portal and maximum of 40m at the deepest location. The headrace tunnel was intended to be excavated in rockmass (volcanics, greywacke, slate) of varying weathering grade. The ground stratigraphy was interpreted to be 1.5m of soil material, overlying slightly weathered to fresh metasediment for the remaining depth with three distinct structural discontinuities. The stratigraphy was classified into three specific rockmass units as indicated in the Table 2.

It was expected that the tunnel will be under prolonged groundwater head of 30m due to the frequent recharge of upper reservoir. It was anticipated that the block failure will be the predominant failure mechanism and the ground supports in the form of rock bolts and shotcrete may be required to arrest the ground movement. Due to limitation of insitu stress data at the early design stage, a parametric analysis was carried out for KH/Kv values of 0.8, 1 and 1.5. The other loads considered in the analysis included seismic loads, construction loads, excavation sequence loads, long-term permanent loads from the equipment. The design methodology adopted for the

Table 2. Summary of geotechnical parameters.

Parameter	Symbol	Unit	Value					
Classification parameter

Tensile strength	Sigma(t)	kPa	30	40	170	240	540	600
Deformation modulus	Erm	GPa	3	3	10	18	27	32

analysis is shown in Figure 2. This paper discusses the numerical analysis carried out in phase 3.

The ParaRanger digital tool was used to develop the ground support system for the headrace tunnel. The assessment involved determination of the required type and quantity of support to construct the headrace tunnel for the uncertain ground conditions. Typical rock support considered included steel fibre reinforced shotcrete and fully grouted Double Corrosion Protection (DCP) rock bolts to resist any imposed deformation on the structure and have an acceptable factor of safety for ultimate limit state design. Considering these design criteria but with a focus on displacement, the project team undertook an assessment to assess the influence of key parameters on deformation.

The rockmass information in Table 2 provided a low confidence data along the tunnel alignment. In order to provide a more definitive design recommendation and evaluate all the risk with variability in data, parametric analysis was carried out to design robust support systems. The parametric analysis included variation to the input parameters as given in Table 3. In each of the listed parameters the support system details were varied which included the bolt length and spacing and shotcrete (liner) thickness.

Table 3. Details of parametric analysis.

First variable (parameters)	Range	Second variable (support system)
Youngs modulus	3-32 GPa	Rock bolt spacing and shotcrete thickness
Cohesion	350-2200 kPa	Rock bolt spacing and shotcrete thickness
Tensile strength	30-600 kPa	Rock bolt spacing and shotcrete thickness

The usual procedure of conducting such parametric assessments is to manually set up a number of finite element models with singular variations between first and second variables. This time consuming and

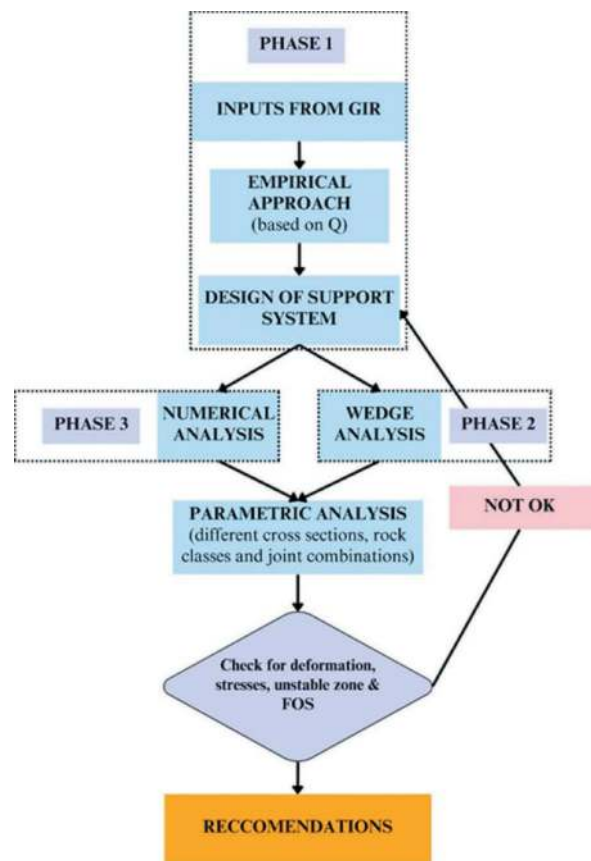

Figure 2. Design methodology for the headrace tunnel.

repetitive process has the potential to introduce error into the analysis as the user must carefully set up the models, change the required parameter, run the model, log, and interpret the data. The use of ParaRanger tool facilitates the above process with significantly lesser user interventions. The user first starts by setting up a ‘base case’ in RS2 as shown in Figure 3.

In the project, the base case model adopted characteristic strength and stiffness parameters defined by geotechnical interpretive report (GIR). The model was prepared based on the two-dimensional geological model which had two layers namely ‘Rock 1’

Figure 3. Base case model setup by the user.

and 'Rock 2' of varying thickness and the geotechnical properties as presented in Table 2. The model was discretised with six-noded triangular elements and mesh gradation within 3 times the tunnel diameter has been set at 1.5m and beyond which graded uniformly up to the boundaries. The horizontal to vertical in-situ stress ratio was conservatively assumed to be unity due to lack of site-specific information. The side boundaries of the model were considered roller in vertical direction, whereas the bottom of model was fixed. The parametric study envisaged to vary the geotechnical properties (i.e., first variable) and support system (i.e., second variable) ensuring all other input to be constant. Further, the ParaRanger input window was used to manipulate the information in the RS2 base model. The Pararanger simulated the geotechnical parameters at pre-set intervals along with pre-defined support system as per the details provided in the input window. A typical input window depicting the iteration for Young's modulus and rock bolt spacing is shown in Figure 4.

The tool triggers the batch analysis of each combination of the parameters. This process fully automates the process that would usually be required to generate individual models. The tool also provides an output selection window which provides a portal for choosing specific output plots along desired path or location (Figure 5).

There are multiple options provided in this form to setup display information on displacements and stresses in the ground, as well as bolt and liner forces and moments. For the study, crown and wall displacements along with structural forces in the bolt and shotcrete was obtained for various parametric analysis as shown typically in Figure 6.

The parametric analysis indicated that the variation of Young's modulus (stiffness parameter) of the immediate rock stratum influences the displacements around the tunnel than cohesion as expected. The failure mechanism was predominantly structurally controlled as identified from the analysis. Maximum crown displacements are about 9mm for high cover section, whereas wall displacements are negligible. There was localised displacement associated with simulated shear zones in the model. The settlement on the ground surface was observed to be maximum of 2mm to 3mm for low stiffness top layer. Based on the analysis, the support system comprised of 3m long grouted rock bolts at varying spacing of 1.5m and 2.1m for anticipated rockmass of Rock 1 and Rock 2, respectively, whereas for headrace tunnel in Rock 1, spot bolting was recommended. By systematically simulating a wide range of possible ground conditions, it was possible to establish the most critical parameter influencing the design and find an optimised solution. This expedited the user intensive task of running sensitivity analyses and provided more time to carry out post-processing activities.

4 PROJECTED UTILISATION OF THE DIGITAL TOOL AND BENEFITS

Generally, the engineering standards mandates rigorous sensitivity analyses to capture the variation of ground parameters. The on-project demonstration captured that the ParaRanger tool can potentially reduce the user time to undertake model generation (batch process) for sensitivity analyses by 70%. The input-output form provides a good platform for error

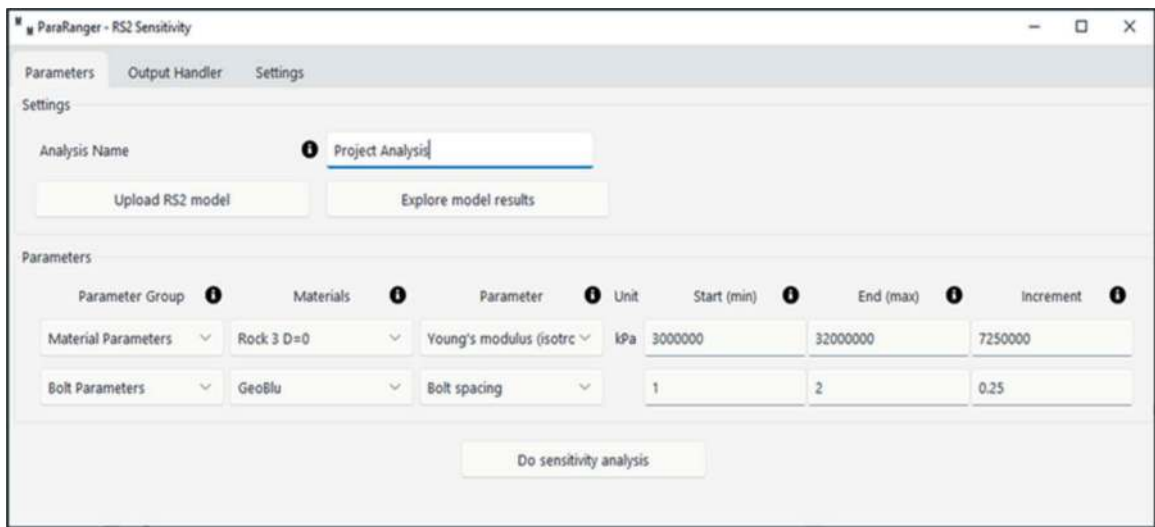

Figure 4. ParaRanger input window defining the variables.

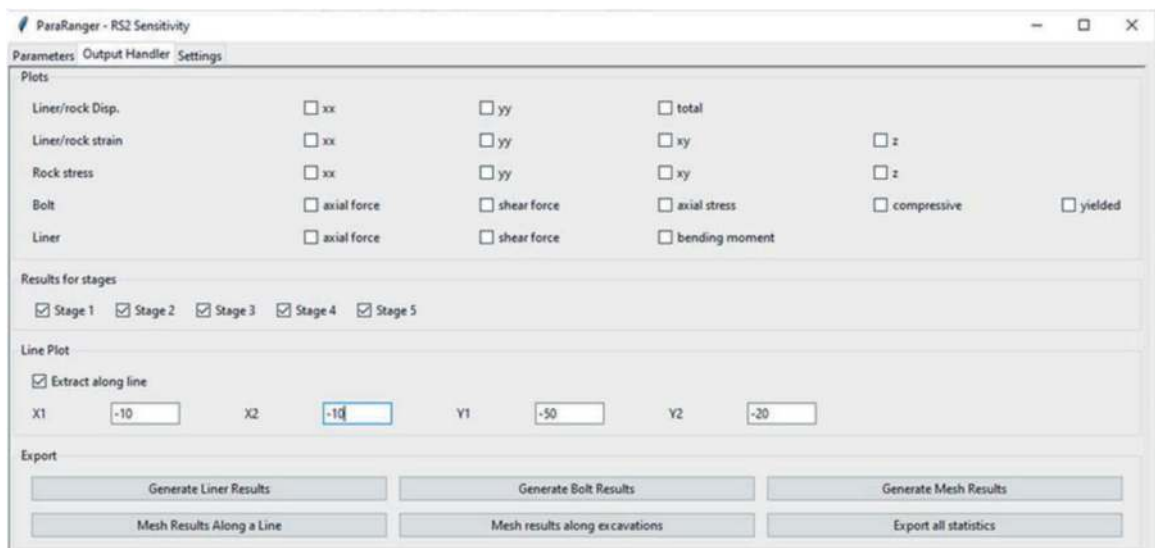

Figure 5. ParaRanger output selection window for post-processing.

elimination. The matrix of desired results aids decision making process and evaluating critical parameters in design. In tight project timelines, these benefits improve efficiency and has financial benefits. In the study, the ParaRanger tool enabled the project team to develop a design solution based on a sound and numerically guided assessment of the ground variability from limited site investigations. The ParaRanger tool is still in development and future development works may include additional functionality to make changes to the geometry of the base case as well as to be able to test strength parameters of soil models other than Mohr coulomb and Hoek brown.

The ParaRanger tool was initially developed to speed up parametric analyses in soil-structure interaction numerical models during a project's early design phases. This is a stage where the inputs

required for the numerical models are uncertain, leading to a need for running multiple scenarios with varying ground conditions and associated design necessities. However, with the right knowledge and experience, the same tool can also be used for detailed engineering, resulting in better outcomes. During the detailed design of a project, the level of information available on the ground conditions and parameters is generally rich compared to its early design stages. This gives an opportunity for the designer to refine the tunnel support design further using ParaRanger for a defined ground condition, resulting in a more optimal and sustainable solution.

The process of running repeated analyses is automated through scripted programming, which leads to a huge reduction in time and cost savings. Additionally, ParaRanger directly addresses the most onerous

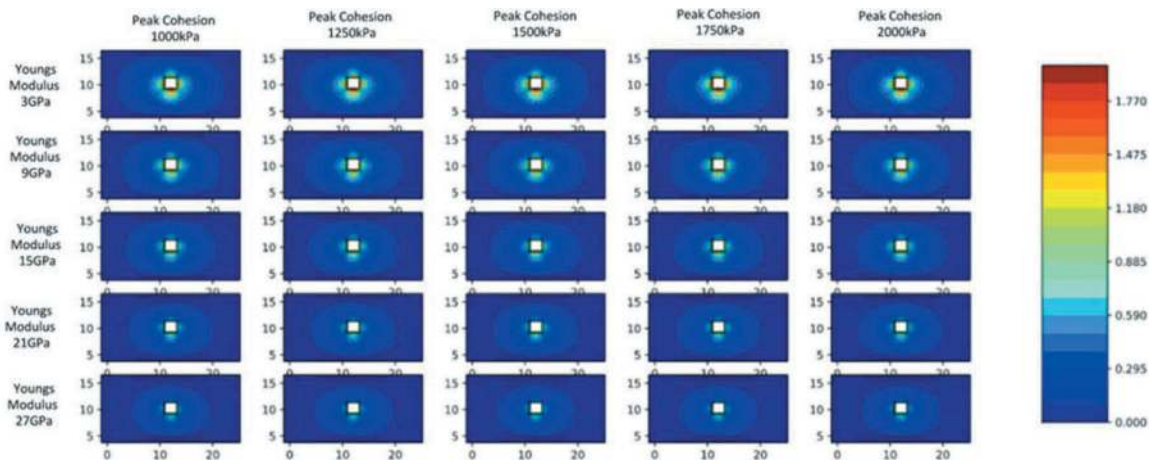

Figure 6. Typical output matrix generated by ParaRanger for post-processing.

task in any parametric analysis, which is carefully documenting the outputs from various numerical models in a unique scale and comparing them to interpret results efficiently. This tool automatically extracts results from various models and prints them into a common unit scale for easy evaluation, taking the designers from a data-rich information-poor state to a data and information-rich state. The tool also enables experienced designers to summarize outputs in an Excel template for advanced design determinations.

Moreover, the manual process of result extraction and interpretation has some degree of human error embodied due to the monotonous nature of the task involving many datasets, which is almost eliminated using this automated digital tool, providing higher confidence and reliability of the design outcomes despite the uncertainty in the input. The current version of ParaRanger focuses on parametric analyses using the commercial software RS2 developed by Rocscience. The next mission for Mott MacDonald's design team is to develop a framework and scheme that can be readily adopted by other ground-based numerical software to benefit from automation in parametric analyses. The ultimate vision for the team is to leverage the vast amount of existing ground data from boreholes and other investigations in an area and implement Artificial Intelligence (AI) in the process. The AI will run an autonomous parametric analysis only based on a possible range of ground parameters from existing ground data and potential support requirements learned from previous projects, with limited to no input from designers, to arrive at a highly optimized but pragmatic solution for a given ground problem.

5 CONCLUSION

Engineering consultancies have a responsibility to prioritize sustainable design solutions that benefit

the environment while remaining cost-effective. One promising way to achieve this is through embracing innovation, especially digitalization. Custom digital applications that automate traditional engineering processes have become increasingly popular. Mott MacDonald's ParaRanger digital tool is a prime example of such an application. Its success lies in its ability to reduce ambiguity and increase design reliability. Additionally, it captures valuable data on how the design reacts to various uncertainties in ground conditions and supports requirements during early project stages, which enables appropriate investigations in site and lab procedures to better understand ground uncertainty.

This paper highlighted the effectiveness of the digital tool ParaRanger by presenting a case study that used the tool to test different ground conditions with varying input values, including Young's Modulus, cohesion, and tensile strength. Several parametric analyses were conducted to increase confidence in uncertain ground conditions. Furthermore, different support systems were examined to ensure that the chosen design was reliable and could be implemented with confidence. Overall, the case study demonstrates the potential of ParaRanger as a valuable digital tool for designing and analysing structures in diverse ground conditions. As a result, a well-refined design range for the best to worst ground conditions were developed.

By promoting a digital culture in tunnel engineering, this tool significantly reduces human error and allows for highly optimized solutions. The digitalization of design is an inevitable trend, and tools like ParaRanger are exciting additions to the tunnelling industry and other fields. They are also critical tools for ushering in Artificial Intelligence (AI) into the engineering computation space. Overall, ParaRanger and other digital tools are essential for engineering consultancies seeking to prioritize sustainable design solutions while remaining cost-effective.

ABSTRACT: In recent years, the need to improve productivity including labor savings through mechanization, automation and improvement of the construction method itself, has become an urgent demand of the times, and it is necessary to actively address this issue and establish such technology as soon as possible. In particular, it is necessary to respond to the demand for improved productivity and quality at tunnel mountain sites through management methods that do not rely on conventional experience and sensory perception. Therefore, we have conducted a trial project to improve the productivity of workers and staff at mountain tunnel sites and to reduce the amount of excess concrete during shotcrete installation by using AI-based video judgment technology. This report provides an overview of the trial technology and its results.

Keywords: AI, cycle time, increased productivity, reduced waiting time, carbon neutral

1 INTRODUCTION

Until now, the construction of mountain tunnels has relied on the experience and senses of skilled technicians under the special construction conditions of excavating uncertain ground. However, a shortage of skilled workers is predicted in the near future due to a decrease in the number of workers resulting from a shrinking population and the aging of skilled engineers. Therefore, a management method that does not rely on conventional experience and sense is needed. Under such background, many reports have been accumulated through the application of i-construction and DX promoted by the Ministry of Land, Infrastructure, Transport and Tourism. In this report, we focus on two issues in the construction cycle at mountain tunnel sites: (1) improving the efficiency of construction management work performed by main contractors (hereinafter referred to as “staff”) and (2) reducing the amount of shotcrete wasted of during shotcreting.

In particular, the second issue sometimes results in insufficient or excess concrete, depending on the skill level of the nozzleman, which leads to the waste of excess concrete. If the amount of concrete required can be quantitatively determined, construction can be performed without relying on experience and sense. Furthermore, the reduction of concrete waste will reduce CO2 emissions and contribute to decarbonization. This report describes the results of this trial project, which was funded by MLIT.

2 OVERVIEW OF TECHNOLOGY

In this paper, three technologies were tested with the aim of improving labor productivity. The trial site was the “Kumamoto 57 Takimurozaka Tunnel West New Construction (2nd phase)” and the Project Client is Kyushu Regional Development Bureau of MLIT. A summary of the site is shown in Table 1.

Table 2. Work with waiting time.

Target person	Work contents
Worker	Delivery of materials
Worker	Mucking
Staff	Observation of face
Staff	Quality control

2.1 Technology to reduce waiting time by AI judgment

This technology reduces waiting time by installing webcams at 40 m behind the tunnel face and near the parking area, using AI to automatically identify the work status based on the images, and then notifying the relevant workers in real time. Judgment is based on the detection of construction machinery working on the face, the combination of construction machinery that appears in each cycle, and the expected order of cycles. The results are notified to staff and workers through the company’s SNS. In this trial, the effect of reducing waiting time was verified for the works shown in Table 2.

2.2 Material loss reduction system

This system aims to reduce material loss of shotcrete by calculating the discharge volume of shotcrete using AI video judgment, calculating the amount of waste based on the difference from the mixing quantity, and learning the optimum re-bounce rate for the next construction. Figure 1 shows an overview of the system. A vehicle-mounted 3D scanner (Figure 2) is used to measure the shape of the face, calculate the difference from the design surface of the shotcrete, and calculate

the required mix volume, which takes into account the rate of concrete bounce during the shotcreting. This mixing rate is automatically notified to the batcher plant via the company’s SNS for mixing. The AI camera installed on the shotcreting machine is then used to determine the time required to spray the concrete, which is then multiplied by the hourly discharge capacity of the sprayer to calculate the actual volume of concrete to be sprayed. After the shotcreting, the amount of waste is calculated by calculating the difference between the quantity of mix and the actual quantity calculated by the AI judgment. The amount of waste is re-calculated as a modified bounce rate by learning through a series of repeated cycles. The cycle shown in Figure 1 was repeated to verify the effect of reducing the amount of shotcrete waste.

2.3 Improving work efficiency by using cloud services

Figure 3 Shows an overview of this initiative. The information necessary for on-site management is uploaded from existing tunnel construction management software to a cloud server, and measurement results, face photographs, and other data are automatically compiled into reports by using a report generation service. The latest information on measurements and other data is automatically updated, making it possible to immediately check the latest information if it is available on the Internet. In addition, by linking tunnel design and support patterns information necessary for control of management to a data management service on the cloud and inputting the results of formwork inspection, it is possible to process the data from the inspection results and generate forms for control of actual measurements documents. In this trial, the application and effects of the reporting system were examined.

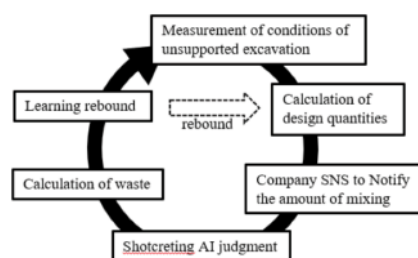

Figure 1. System overview.

Figure 2. Vehicle-mounted 3D scanner.

Figure 3. System overview.

3 AI-BASED VIDEO JUDGMENT TECHNOLOGY

The system configuration is shown in Figure 4. Video images from cameras installed in the tunnel are transferred to a PC for AI judgment and analysis, and judgment is performed. After the judgment is made, the results are notified to the company's SNS, and the video data and judgment data are automatically transferred to a cloud server for storage.

3.1 AI cycle automatic judgment

Since the combination of construction equipment used in each cycle of tunnel construction is almost similar, AI automatically determines the work to be done by detecting the appropriate construction equipment from the images captured by cameras installed in the tunnel. Figure 5 shows the judgment accuracy of the automatic cycle time judgment system by AI. The figure shows the percentage of actual work that was determined by the AI. For most of the works, the appropriate work content could be determined with a probability of 80% or more. However, the accuracy of the judgment was poor in some cases, such as work F which is support erection and work G which is secondary shotcreting. This is presumably due to the fact that the evaluation accuracy was affected by the tunnels environment (illumination, dust, etc.), since camera images were used for the evaluation. In addition, incorrect judgments were sometimes made when the construction cycle differed from the normal cycle, such as when there was problem occurred.

3.2 AI judgment of time to shotcreting

The system detects the arm part from the images captured by two cameras installed on the shotcreting machine and determines its movement to count the time when the machine is actually shotcreting. In the construction of this system, we created an arm detection segmentation model for discharge to detect the arm and determine whether the arm is moving, and created an algorithm that uses the output of the model to make AI judgments. Figure 6 shows the situation of AI detection during shotcrete. Figure 7 shows the accuracy of the judgment of shotcreting time. The time when concrete is being sprayed from the nozzle of the shotcreting machine is defined as the shotcreting time, and the time when concrete is not being sprayed is defined as the time when the shotcreting machine is stopped. The figure shows that the time when shotcrete is actually being sprayed can be correctly determined. The correct answer rate was approximately 80% for each hour of shotcreting, and approximately 90% for the entire work, including the time when the machine was stopped. These results indicate that the AI can determine the time of shotcreting during the work period.

3.3 Parking area AI judgment

Judging whether the tunnels are passable or not by image classification based on the images captured by cameras installed in the tunnels' parking areas. The results of the judgment will be notified to the

company's SNS. To create this system, an image classification model was created to determine whether the parking area is passable, and an algorithm was created to use the output of the model. Figure 8 shows the accuracy of the AI judgment. The figure shows that the AI was able to determine almost accurately that the tunnel was impassable by detecting the construction equipment. The AI's accuracy rate for determining whether or not the tunnel is passable is approximately 90%.

4 TRIAL RESULTS

4.1 Reduction of waiting time using AI judgment

Figure 9 shows an example of the screen shot of the company's SNS notification screen, in which the result of the AI's judgment can be seen. Table 3 shows the waiting time reduced by the trial. The waiting time before the trial was used as the target time for comparison of the trial results after interviewing the subjects.

The trial reduced the waiting time for each work by 40% to 60%. In addition, the AI judgment of the parking area reduced the waiting time for material loading and unloading to zero. This technology was found to be effective in reducing the waiting time sufficiently.

4.2 Reduction of material loss

A total of 13 trials were conducted in the shotcreting at the trial site. The first to fifth trials were test trials for adjusting the trial environment, etc., and the verification of the trials was conducted from the sixth trial. Figure 10 shows a comparison of the required mix volume obtained by the 3D scanner and the plant mix volume. The variation of the deviation decreased as the trials were repeated, and at the 10th trial, the deviation was 0.01 m³. Figure 11 shows a comparison of the shotcrete quantity determined by the AI and the quantity calculated from the plant's mixing results. The average error was about 1.2 m³. The AI judgment of the quantity of shotcrete

Figure 12. Amount of shotcrete waste.

could be performed within the range that would not cause any problems in construction. Finally, Figure 12 shows the results of the amount of waste. The figure shows that the amount of shotcrete waste decreased after the sixth trial. A comparison of the average amount of shotcrete waste before and after the trial shows that the amount of shotcrete waste was reduced by about 70%. The technology was found to be effective in reducing the amount of shotcrete waste.

4.3 Improved efficiency of construction management

This trial focused on the monitoring management, face management, and control of actual management, which are the most frequently performed by the staff, in order to improve efficiency. Figure 13 shows an example of the automatically processed results of tunnel settlement and convergence. The figure shows a graph of tunnel displacements transferred to the cloud using a reporting system. Information such as settlement trends and distance from face is automatically processed and can be accurately graphed. These results can be checked under the Internet environment. This makes it possible to understand the behavior of the ground in a more timely manner. Figure 14 shows an example of a list of photographs of a face. The figure shows a list of face photographs automatically generated by selecting any cross section based on the photo data in the cloud. The photographs of the

face are used as materials for selecting appropriate support patterns. Therefore, the amount of time spent by the staff in compiling the photographs of the face could be reduced. To improve the efficiency of control of actual measurements, the cloud-based tunnel design data, support patterns, and other data are linked to automatically create a reporting system for the actual measurements. Figure 15 shows the form selection screen. The measurement result input screen (Figure 16) is created by selecting the construction type and support patterns to be created. By inputting the measurement results, a report converted into a prescribed format (Figure 17) is created. This graphically displays necessary information such as measured values, differences from control criterion, and control criterion. This technology enables direct input of measurement results on site using a tablet terminal or similar device. This reduces the amount of time

Figure 17. Example of a created report.

spent by staff on control of actual measurements. Although the working time for each staff varies, they spend approximately 15 to 150 minutes/day on construction management. By utilizing cloud services, these works can be automated, and a reduction of up to 150 minutes/day can be achieved.

5 CONCLUSION

Regarding the efficiency of the staff's construction management, the trial technology reduced worker waiting time by up to 22 minutes and staff waiting time by up to 32 minutes. In addition, the use of cloud services can save up to 150 minutes of construction management for staff. Considering these effects, this technology is expected to increase worker productivity by up to 5% and staff productivity by up to 40%. In addition, the use of cloud services can be expected to improve the efficiency of information sharing and the enhancement of construction support through the accumulation of construction data. Meanwhile regarding the reduction in the amount of shotcrete, AI judgment technology reduced the amount of shotcrete waste by 70%. In general, about 270 kg of carbon dioxide is emitted per m3 of concrete during its production process. In

other words, the reduction in the amount of shotcrete waste can be achieved to reduce carbon dioxide emissions by approximately 432 kg per construction, contributing to the realization of a carbon-neutral society. Even though it is proven that this technology is expected to improve labor productivity, the trial period was too short to obtain sufficient data. Therefore, we would like to confirm the certainty of labor productivity improvement by continuing the trial over a longer period of time since construction management are not limited to those described in this report. We would like to continue to develop the construction management in order to further improve its efficiency as a whole.

ACKNOWLEDGMENTS

This report is based on consortium formed by Shimizu Corporation, Lightblue Technology, and Enzan Koubou co, ltd, using PRISM budget promoted by the Ministry of Land, Infrastructure, Transport and Tourism (MLIT). We would like to express our deepest gratitude to the people at the Kumamoto River and National Highway Office, Kyushu Regional Development Bureau, MLIT and the consortium members for their guidance and cooperation in this trial.

ABSTRACT: To effectively address issues in process of shield tunneling for subway construction, including insufficient real-time monitoring, delayed risk response, and limited visualization. This study proposed an integrated management platform of shield construction based on digital twin, analysed remote communication based on cloud service, real-time risk early warning mechanism in TBM operation, as well as integration approach for multi-source information using BIM and GIS technologies. Finally, taking a subway project as an example in case study, the functionalities of platform is demonstrated, such as virtual tunnel and construction simulation, real-time visualization of operating parameters of shield machine, integrated monitoring of shield machine group, visual display of surrounding stratum information, and risk monitoring and early warning in shield construction. The implementation of this platform can improve efficiency, quality and safety of subway shield construction, and also provide valuable insights for the process control of other shield construction projects.

Keywords: Subway shield construction, TBM (Tunnel Boring Machine), Digital twin, Real-time monitoring, Building Information Modeling (BIM), Geographic Information System (GIS)

1 INTRODUCTION

The shield tunneling method has become a primary construction technique for urban subway tunnels and some railway tunnels in China. In actual subway construction environment, due to complex and varied hydrology and engineering geology of the surrounding strata, and different mechanical properties of soil layer, accidents such as stratum collapse and underground water seepage may occur during the excavation of shield tunnelling, which may cause hidden dangers. However, the current safety and risk control practices for shield tunneling primarily depend on manual surveying on environmental conditions, timely analysis and processing of measurement data to provide information feedback place high demands on workers. Therefore, in terms of construction monitoring, Ye et al. (2013) applied FBG sensing technology to monitor temperature and strain in adverse environments, ensuring the safety of railway shield. Shen et al. (2014) investigated an integrated approach for machine guidance and operation monitoring in tunnel construction. Huang et al. (2018) and Xie et al. (2018), have demonstrated

utilization of real-time monitoring systems and platforms in shield tunnelling, specifically in relation to TBM (Tunnel Boring Machine) and surrounding rock or settlement control.

Although the guiding system of TBM can provide a certain degree of guidance and positioning function during operation, it lacks the capability for real-time remote monitoring of shield machine equipment. Other innovative methods were developed by Zhang et al. (2021), Zeng et al. (2022) and Huang et al. (2022) respectively, and were applied to real-time monitoring of shield machine operation and tunnel construction to determine operating status of tunnel boring machines. To ensure safety of tunnel construction, hazards of shield tunnelling were analysed and evaluated (Hyun et al. 2015). Multi-source information fusion technology used by Zhou et al. (2020) for risk assessment and management. Ding et al. (2013) developed a real-time safety early warning system for cross-channel tunnel construction based on IoTs (Internet of Things) technology. The warning of abnormal working status provided by Gong et al. (2021) was utilized to monitor and control the TBM excavation process.

Moreover, with development of IoT technology, the application of digital twin technology in construction management (e.g. Boje et al. 2020, Al-Ali AR et al. 2020, Pan and Zhang. 2021, Ye et al. 2022) with great success, including real-time sensing and monitoring, data integration and analysis, simulation and optimization, as well as visualization and collaboration. These can provide more comprehensive and precise construction data and information in real-time, as well as rich management tools and new possibilities for integrated monitoring and control of shield construction.

In this paper, the integrated management platform of shield construction was designed and developed based on digital twin technology, with the application of key technologies and methods of IoT, Building Information Modeling (BIM) and Geographic Information System (GIS), which enables real-time and all-around integrated management and control to improve efficiency, quality and safety of shield construction in subway engineering.

The structure of this paper is as follows: Section 2 describes digital twin based platform architecture of shield construction. Section 3 discusses the key technologies and methods to realize integrated management of shield construction process. In Section 4, the specific implementation and application of platform functionality is shown in a case study. Finally, the conclusion is given in Section 5.

2 DIGITAL TWIN-BASED PLATFORM ARCHITECTURE OF SHIELD CONSTRUCTION

2.1 Overall framework design

To improve efficiency, quality and safety of shield tunnel construction in subway project, an integrated management platform using digital twin technology is proposed in this study, overall framework is designed as shown in Figure 1, mainly consists of four levels: physical perception layer, network transmission layer, digital service layer, and management application layer. By adopting a hierarchical design approach, the functional modules of platform are organized to facilitate seamless data exchange and interoperability between layers.

2.2 Physical perception layer

During the process of tunnel excavation with TBM, the physical perception layer is mainly responsible for real-time collection of various data and information related to equipment operation and construction environment. In tunnel construction, the shield machine, as a critical mechanical component, is equipped with sensor devices to monitor its operating status parameters such as cutterhead torque, excavation volume, grouting volume, propulsion speed, slurry properties, inclination angle, and

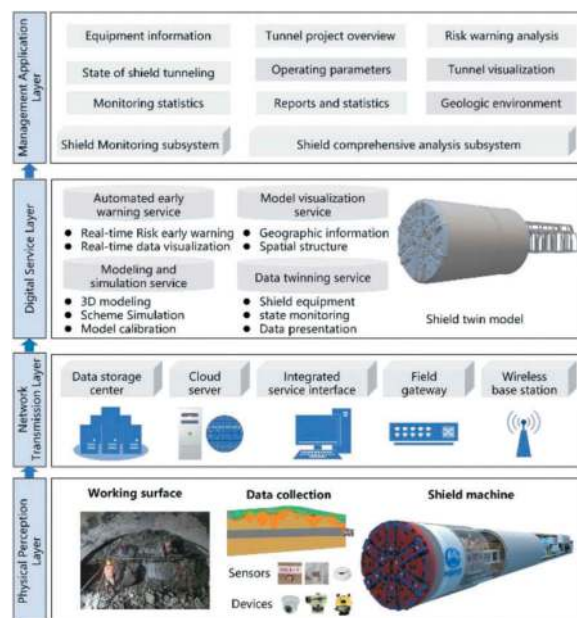

Figure 1. Overall framework of integrated management platform of shield construction based on digital twin.

supervising equipment faults, wear degree in real-time. Combined with tunnel construction working face, various environmental monitoring sensors are required in shield tunnelling process to real-time monitor factors such as temperature, humidity, dust concentration, hazardous gases within the tunnel, as well as data regarding tunnel displacement, deformation, groundwater levels, and soil pressure. sensor sampling frequencies can be set for different monitoring indicators to ensure data accuracy and timeliness. In addition, laser scanners are arranged to scan and capture shape and structure of tunnel cross-section, meanwhile total stations are used for precise positioning and measurement of tunnel size. Cameras installed at site record construction details and changes. These devices and sensors work together to achieve full monitoring during shield construction.

2.3 Network transmission layer

Network infrastructures are established to collect various data from perception layer in tunnel construction sites, enabling real-time transmission, storage, and analytics. The 5G, base stations, and onsite gateways are utilized to build wireless communication links both inside and outside the tunnel, facilitating data transfer to remote monitoring servers. Based on system functions and data requirements, a combination of local storage and cloud services is adopted. Large databases such as MySQL and MongoDB are used to manage real-time monitoring data, spatial data, etc. Integrated service interface including Web API (Application Programming Interface), database connections, file transfer protocols, RESTful, and RPC (Remote Procedure Call), which serve

as intermediaries for data transfer and information upload. They are responsible for coordinating and managing communications between different data sources and system modules.

2.4 Digital service layer

The digital service layer adopts service-oriented design with different microservices collaborating, including shield tunnel digital twinning, visually modeling and simulation, as well as automated warning and dynamic risk analysis. The visually modeling and simulation service builds digital replicas to simulate actual construction status and predict scenarios, and also adopts BIM and GIS technologies to achieve visualization of construction environment model. The data twin service monitors real-time operational status of TBM equipment. The automated early warning service conducts real-time risk monitoring and alert throughout the entire process. This layer integrates, processes and analyses multi-source data on shield tunnel construction, providing effective support for construction decision-making.

2.5 Management application layer

The management application layer is responsible for real-time online interaction between users and the system with the B/S (Browser/Server) mode, which includes the shield monitoring subsystem and shield comprehensive analysis subsystem, integrating multiple functions and configuring virtual environments and data displays based on user needs. The application layer provides specific applications such as report statistical analysis, monitoring and early warning management, risk management and equipment management to support decision-making. Through visual online display, users can intuitively understand the real-time working status of shield machine, tunnel geological condition, environmental indicators, and overall situation at construction site.

3 KEY TECHNOLOGIES AND METHODS

3.1 Remote communication based on cloud service

At shield tunnel construction site, some base stations with different functionalities are connected to the gateway to communicate and control various terminal devices and sensors. To ensure secure transmission of data, collected information is sent to monitoring center via a VPN (Virtual Private Network) wireless transmission link. In data storage process, the hyper-converged server technology is utilized to integrate computing, storage and network in physical server. These are then virtualized into logical resources using virtualization technology, and SaaS cloud services are provided in an integrated environment for flexible allocation and management. Based on this, according to monitoring requirements and system design,

remote monitoring functionality of shield machine is deployed using containerization and integrated with other business systems. The server deal with data from sensors and monitoring devices through remote desktop services, authorized engineers and administrators can access to monitoring center using IP address and port, connecting to control room interface of TBM to monitor key data in real-time at construction site, as shown in Figure 2. Notification services are used to send real-time alert messages to relevant staff with SMS, email, or mobile applications, ensuring that issues are addressed promptly.

Figure 2. Remote monitoring interface.

3.2 Risk management and early warning response

3.2.1 Risk classification and control

By identifying and sorting out various potential risks, including TBM failures, changes in geological conditions, and tunnel collapse risks, etc. each potential risk source is analyzed and evaluated to determine its possibility and severity. Based on risk assessment results, the identified risks are categorized and ranked to establish a risk register. Typically, different risk levels indicate the severity of risks, including major, high and low degrees. The identified risks are ranked and divided into high, medium and low risk levels. Based on the risk levels, corresponding emergency plans and preventive measures are formulated for the confirmed risk sources, including risk control measures in construction methods, safety equipment, safety training, contingency plans, special monitoring, etc. For high-risk events, priority is given and more stringent control measures should be implemented.

3.2.2 Real-time warning and response

Regarding to key monitoring data such as tunnel geological subsidence, TBM operational parameters, and attitude, a real-time monitoring and warning mechanism has been established, as shown in Figure 3. During this stage, the warning rules including the setting of critical state and threshold values for warning indicators such as rate and cumulative

values, as well as the definition of warning levels. The monitoring system automatically and timely detects collected monitoring data according to warning rules. Once a specific indicator reaches or exceeds the threshold, different warning signals and warning information, including specific response measures and designated responsible personnel, are generated based on different warning levels. These information are communicated to relevant personnel, including manager, engineer, and safety officer, through communication channels such as SMS and application notifications. After receiving the warning information, immediate action needs to be taken at construction site following the established response procedures and measures, which include adjusting direction and attitude of TBM, controlling excavation speed. For high-risk early warnings, stricter control measures such as immediate shutdown and emergency plans will be taken to prevent accidents and ensure project safety.

Figure 3. Real-time dynamic early warning mechanism.

3.3 Information integration with BIM and GIS

The BIM and GIS technologies play a significant role in integration of multiple source information. By integrating them, more comprehensive and accurate representation of scenes can be achieved. The technical process of BIM and GIS data fusion for visualization as illustrated in Figure 4, involves following steps: In data preparation phase, 3D models of tunnel infrastructure are constructed using BIM tools according to design drawings and engineering demands, various geospatial data, including maps, satellite imagery, and terrain models, will be integrated into a unified geographic coordinate system. In data conversion phase, conversion tools such as FME (Feature Manipulate Engine) or formats like IFC or CityGML are utilized to align GIS data and BIM models within the same geographic coordinate system such as WGS84, CGCS2000. In data association phase, data relevant to specific BIM projects or scenes is selected and extracted. The association between GIS data and BIM models is established based on spatial location, geometric topology relation, and shared attributes or unique identifiers, resulting in formation of an integrated information model. Finally, in process of visualization, the integrated data is utilized for comprehensive analysis and display in a GIS environment, which includes static models such as tunnelling equipment and tunnel structure models, as well as real-

time dynamic information from IoT data, such as equipment working status, risk resources at tunnel construction site, enabling construction teams to quickly grasp the site conditions and make timely decisions.

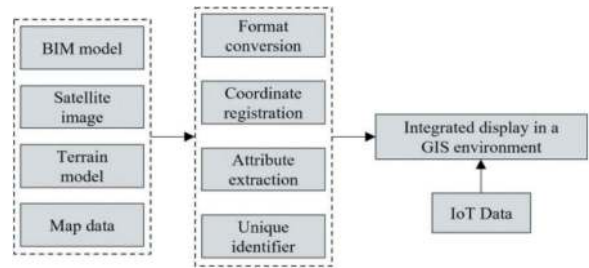

Figure 4. BIM and GIS data fusion for visualization.

3.4 Digital twin modelling for TBM and tunnel

The construction of a digital twin model is a critical step to simulate and monitor various aspects of subway tunnel construction. BIM technology has a vital role in efficiently constructing detailed 3D scenes and facility models to enable visualization. The typical workflow involves following steps: First, digital models are usually created using BIM software such as Autodesk Revit, including the mechanical equipment model of TBM, as shown in Figure 5, to simulate the shield construction process.

Figure 5. 3D model of TBM equipment.

Next, for completed tunnel structures, the laser scanner can be used to perform scene scanning and obtain detailed point cloud data, including information about the shape, dimensions, structure, and surface features of tunnel. The point cloud data is then imported into dedicated laser scanning software, such as Faro Scene, to generate an accurate digital 3D model corresponding to physical entity, as shown in Figure 6, and store it in a usable format. This 3D model can be used for assessment of accuracy and inspection of quality defects in tunnel structure. These models can be integrated into BIM platforms as part of digital twin model, and be further enriched with additional information as needed, such as surface texture details, to reflect the actual scene.

Figure 6. Tunnel 3D model from point cloud.

Additionally, it is necessary to map parameters and state variables from actual scene to model. Through establishing a correlation between characteristics of engineering physical entities and their real-time behavioural processes, including parameter mapping and state variable mapping. By associating real-time data with corresponding elements in the BIM model, this integration enables feedback and synchronization between the physical construction site and the model, realizing a dynamic digital twin for status monitoring in subway tunnel construction.

4 CASE STUDY AND PLATFORM APPLICATION

In major tunnel project of Shenzhen Metro 14, the development and implementation of the proposed integrated management platform for shield construction have achieved comprehensive data collection, processing, analysis and decision support as follows.

4.1 Virtual tunnel and construction simulation

In virtual tunnel scene roaming, users can interactively explore the 3D structure of tunnel through a web browser, as shown in Figure 7. The immersive experience enables users to navigate and overview the tunnel layout in detail. Moreover, the assembly of shield segments can be thoroughly checked in virtual environment to verify the accuracy of design. Additionally, the virtual tunnel scene can serve for training new employees, helping them better understand the construction process and tunnel structure, and facilitating effective learning of knowledge.

Figure 7. Virtual tunnel scene.

Simulation technology for shield tunnelling is used to analyse the process of shield operation and muck discharge as shown in Figure 8. Based on geological information and exploration data, this technology can simulate potential changes in underground lithology and geological conditions, and predict geological hazards such as geological water inrush, geological faults, and landslides that may occur during construction. The use of construction simulation can empower managers to identify potential risk factors and proactively formulate corresponding safety precautions.

Figure 8. Construction simulation.

4.2 Real-time visualization of multi parameters

In construction of earth pressure balance shield, the monitoring parameter provided by platform can show pressure of soil bin in different parts to ensure stability of excavation face and maintain the balance state within safe range. Simultaneously, it can also track and record changes in shield operation and driving parameters, including shield advancing speed, cutter head torque, thrust, cutter head speed and penetration degree, as shown in Figure 9.

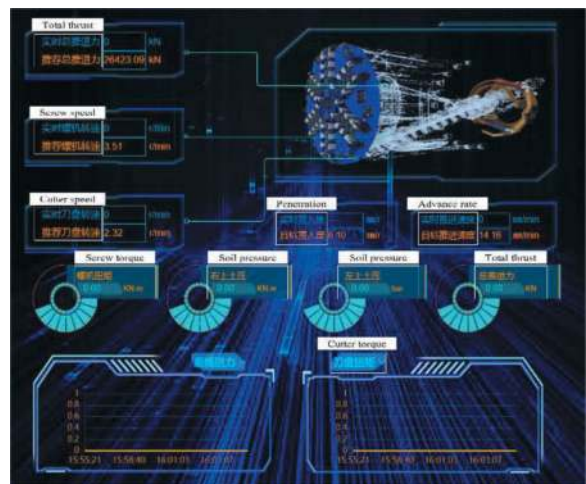

Figure 9. Real-time visualization of operating parameters.

These data allow engineers and operators to tightly control tunnelling speed of shield machine, and adapt to variations in geological conditions. In addition, timely analysis and feedback of monitoring data can facilitate the control of attitude of shield such as tilt and offset, to maintain stability of shield machine throughout construction process.

4.3 Integrated visualization and monitoring

4.3.1 Shield machine group monitoring

The monitoring system for shield machine group can be integrated with geographic information to provide a spatial representation of each shield machine on a map. Each machine is labelled on the map, and users can click on the label to enter the real-time monitoring interface of each shield machine and view its operational status. When an alarm or fault occurs in the shield machine, corresponding marker on the map will flash, attracting operator's attention to the issue, as shown in Figure 10. A comprehensive overview of all the shield machines in group enables the operator to quickly identify and check the number, location, operating status of shield machines, and resolve any problems that may arise to ensure the safety of shield construction.

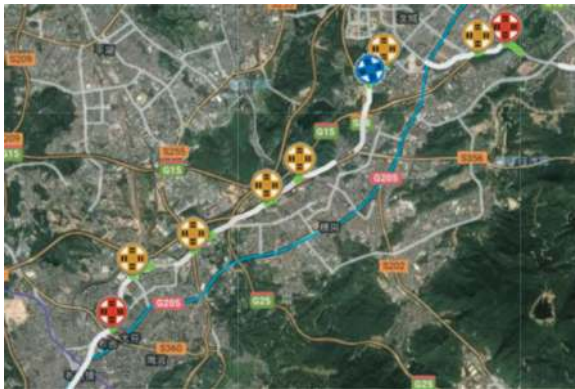

Figure 10. Working plane location of shield machines.

4.3.2 Surrounding stratum information display

The position tracking of shield machine and updating of its tunnelling status, as well as information display on stratum cross section and geological environment change along the line are shown in Figure 11. By using different colours to mark and highlight the stratigraphic and geotechnical features of current tunnel section, the management personnel can intuitively access this information and assess any environmental risks that may arise during shield construction, and guide shield excavation and driving accordingly.

4.4 Risk monitoring and early warning

During operation of shield machine, potential risk events are predicted through risk identification and

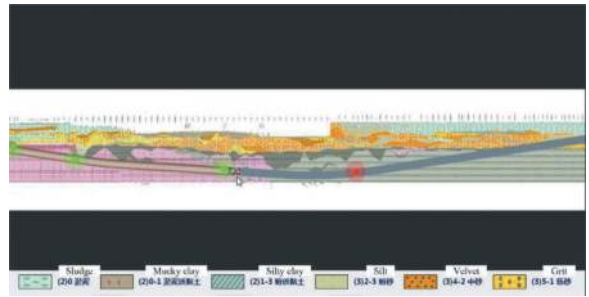

Figure 11. The working plane of shield machine group.

assessment, as shown in Figure 12. One such potential risk is the accumulation of muck in chamber, and corresponding preventive measures are formulated to address this issue. Meanwhile, to mitigate this risk, real-time monitoring of shield machine's working parameters, such as thrust and propulsion speed. Once the potential risk event or parameter abnormality is detected, the platform will timely issue warning signals. In such cases, notifications are promptly sent to engineer and safety personnel at site. By taking proactive measures to timely address potential risks, the construction team can effectively manage operation of shield machine and maintain a safe working environment.

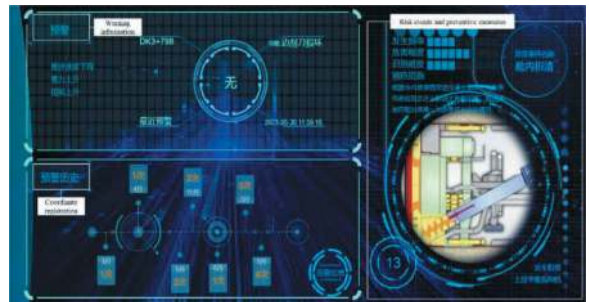

Figure 12. Real-time visualization of operating parameters.

5 CONCLUSIONS

According to current situation and technical requirements of subway shield construction management, the framework for integrated management platform of shield construction based on digital twin was proposed in this study. Firstly, the platform utilized remote monitoring and cloud service for real-time transmission of monitoring data. Then, a whole-process risk monitoring and early warning mechanism was established to enable early detection and response to risks arising from geological conditions and shield machine status. Furthermore, through the integration of BIM and GIS technology, real-time analysis and visualization of information on geological conditions, surrounding environment, and shield machine working process were discussed. Finally, through a case study, the application of this platform has been verified in informatization, visual management of shield

construction. However, despite digital twin technology facilitates comprehensive management practice of platform in subway engineering, further considerations for integrating more advanced monitoring and intelligent technologies, such as data-driven decision-making analysis based on big data, are required to enhance safety and efficiency of tunnel construction.

A study of digital quantitative evaluation system for the safety risk management in the construction activities of transportation hubs

Renxue Wen

Sino-Railway South Constructing Group Co Ltd, Shenzhen, China

Dongjian Gao*, Wenwu Yang & Wingfei Mou

AECOM, Hong Kong, China

ABSTRACT: This article systematically quantifies the main characteristic indicators of production factors ‘5M1E’ in the construction of large and complex urban transportation hubs through the classification and rating management of construction safety risks and the information management of on-site hazard investigation mechanisms. Preliminary assessment is firstly carried out, focusing on the general conditions of the construction site, to identify the items of high-risk category. Based on the overall risk assessment, conduct comprehensive fuzzy hierarchical calculation and analysis of the multi-level influence degree (weight) on the hazards derived from the high-risk factors that might lead to major safety accidents. The analytical outcome will be further used for detailed quantitative assessment and hierarchical management of high-risk work breakdown structure (WBS) elements, which ultimately ensure the mitigation and control of major construction safety accidents.

Keywords: Construction safety, Factor quantification, Digital risk assessment, Refined management

1 INTRODUCTION

The utilization and development of urban underground space (UUS) are essential to address the increasingly severe situation of the scarcity of urban land in China. Underground space is usually used for underground transportation, underground service facilities, underground complex, and underground municipal infrastructure (Cheng et al., 2019). For underground transportation, such as subway, rapid transit etc., transportation hubs are usually constructed below the ground surface in urban area as well. However, underground engineering projects usually bear high risk and extreme complexity due to large-scale investment, long construction period, complicated construction technologies and massive social and environmental impact, etc. (Qian & Rong, 2008). Therefore, competent and adequate strategies should be developed and implemented to address the risks in the construction of underground transportation hubs. Categorization of risks on a project should be applied in order to acquire a more sophisticated and comprehensive understanding to benefit and raise efficiency for the development of measures to cope with potential negative consequences. Usually, risks can be divided into “market-related”, “technical”, and “institutional”, etc. and previous research shows that the majority of risks could be tackled by the means of management instead of

technology, which is usually more widely reckoned as the foremost attribution of risk response (Roger & Donald, 2001). For mega engineering projects especially of which the construction is subject to substantial uncertainties, a well-rounded systematic evaluation of risks accounting for sufficient factors and variables is the foremost step in the process of risk management. An appropriate methodology for risk evaluation should be carefully considered and selected by decision-makers of projects. According to relevant studies, the main evaluation methodologies that have been developed include: Hazard Examination, Analytical Method of Hazard and Operation, Expert Investigation, FMEA Method, Fault Tree Analysis (FTA), PRA method, Analytical Hierarchical Process (AHP) and MODM method, Influence Diagram (ID), Bayes Network (BN) etc. (Cao & Xu, 2005).

Each method for evaluation has its own advantages and weaknesses and particular attention has to be given with regard to the development of risk management methodology for a specific project. Analytical Hierarchical Process (AHP) was created in 1970s by T. L. Saaty, who was a prominent operations research analyst. It used pair comparison to determine judgement matrix and the weights of different variables based on the eigenvalues of the matrix (Saaty, 1980). This method is featured by combining both quantitative and qualitative principles and is widely adopted for

*Corresponding author: Jason.gao@aecom.com

cost-performance analysis, resource allocation, conflict analysis in a whole variety of industries (Saaty, 1993). This study focuses on improving the efficiency of risk management in construction projects, which contain a multitude of uncertain variables and multi-level decision making and management mechanism. Therefore, Analytical Hierarchical Process (AHP) is adopted as the core technique in the development of the assessment methodology in this study to cope with the challenges. Fuzzy Comprehension Evaluation (FCE) is used to revise AHP so that the evaluation results could be represented mathematically. Also, Fault Tree Analysis (FTA) is implemented for deducing the root causes of risks and hidden dangers based on the analytical results.

At present, engineering risk level assessment is mainly based on the risk probability level and risk loss level matrix for risk level assessment. However, engineering risk assessment is mainly based on qualitative and empirical methods in practice. Due to the fact that the risk probability level is difficult to quantify. This method usually depends on Engineering Judgement, which requires experts in relative fields with extensive experience and knowledge to provide the input for the assessment. Furthermore, qualitative and empirical assessment cannot cater for the accuracy and practicality in the ever-changing construction industry, which generates an urgent need to convert the traditional methodology to a dynamic one with the means of quantification. Combining the rapidly developing technologies of digital engineering and Building Information Modelling (BIM), the characteristics of various elements of construction projects (i.e. safety risk causing factors) are able to be quantified and evaluated in a standardized procedure.

With accurate risk assessment approaches, an overall managerial framework should be established to connect “evaluation” and “response”. Mature management systems for safety and risk have been established with the development of major infrastructure projects, such as Hong Kong-Zhuhai-Macau Bridge, over the course of decades (Yang & Hu, 2016). The philosophy of whole-process risk management has been proposed by Yang et al. (2018), which has been examined and improved in the subsea tunnel construction projects. Similar to underground projects, subsea tunnelling is also featured by high-intensity of risk and a well-schemed whole-process management workflow which is embedded in planning, feasibility study, design, tendering, construction, handover and operation stages, and ensures corresponding actions can be taken effectively and timely.

This study is aiming at using mathematical means combining the application of digital technology to facilitate the workflow and outcome of risk management in mega construction projects such as underground transportation hubs. It investigates the risk impact on the Casual Chain of individual work units, which are described using Risk Breakdown Structure (RBS) and WBS respectively under various working conditions

and environmental conditions and analyse and calculate the safety risk values based on the multi-level classification of the construction work and quantitative assessment. Lastly, the mechanism of hierarchical management of construction safety risks is established on the assessment results. A software program is developed and elaborated in this study to substantiate the theoretical proposition of dynamic risk management.

2 LOGICAL RELATION OF CONSTRUCTION SAFETY RISK FACTORS

Systematic risk management is essential for managing risks effectively and the initial step is to identify valid risk factors for future analysis (Park et al., 2017). The two major sources of safety risks of engineering construction are: unsafe behaviours of people and unsafe states of things, which are in logical conjunction (‘AND’). People’s behaviour (Man) could be further divided into individuals and organizations, which are in logical disjunction (‘OR’). The unsafe state of things includes factors of Machinery, Method (construction methods), Environment, Materials, and Management (construction/project management), which are in logical disjunction (‘OR’). In a construction unit, the risk values of factors of Man, Machinery, Environment, Method, Material and Management (so called ‘5M1E’) will affect the high and low safety risks of the construction unit. As shown in Figure 1, assuming that R_M , R_{MC} , R_{ML} , R_{MD} , R_E , and R_{MG} are risk functions for Man factor, Machine factor, Material factor, Method factor, Environment factor, and Management factor, respectively, the system risk function $R_{WBS}(x)$ for a certain Work Breakdown Structure (WBS) is a combination of ‘AND’ and ‘OR’, denoted as:

$$R_{WBS}(x) = (R_M(x) \cup R_{MG}(x)) \cap (R_{MC}(x) \cup R_E(x) \cup R_{ML}(x) \cup R_{MD}(x)) \quad (1)$$

3 TECHNICAL ROADMAP FOR SAFETY RISK QUANTITATIVE EVALUATION

Based on the workflow of typical risk management in project management, the Technical Roadmap for safety risk evaluation is developed by including the quantitative methodology. The procedure mainly consists of five steps:

1. Risk identification: to identify general risks in the holistic perspective;
2. Digital quantification of risk factors: to calculate the weights of risk elements classified into six risk factors (“5M1E”);
3. Quantitative risk assessment: to calculate the risk values for high-risk items based on the results of step 1 and step 2;

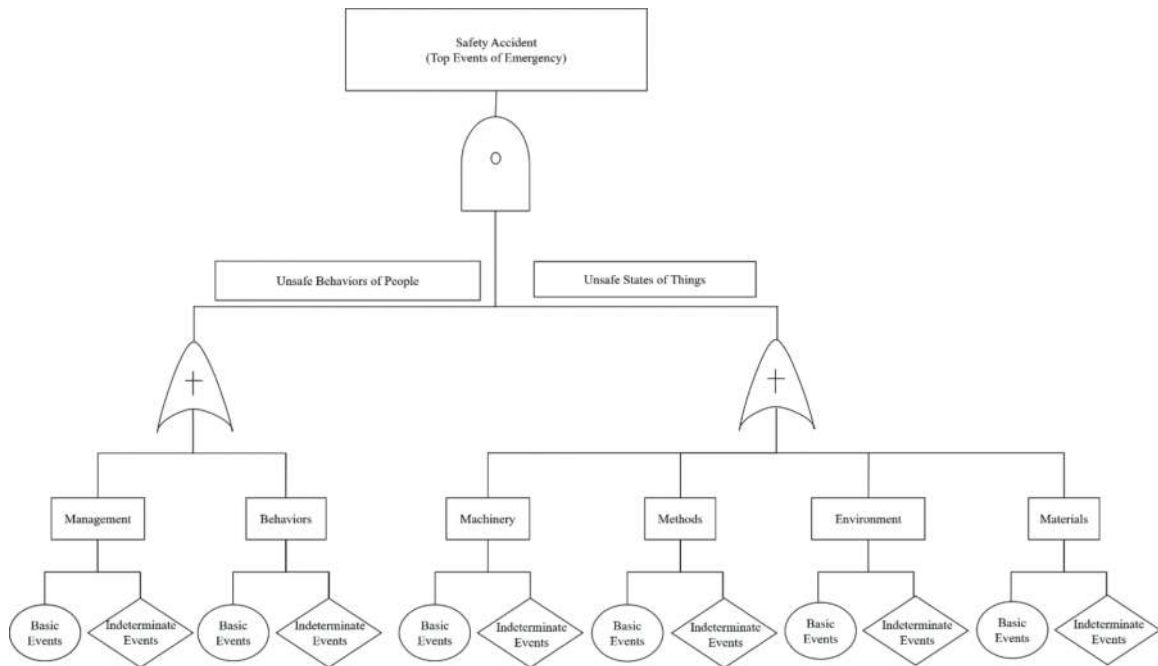

Figure 1. Typical fault tree analysis of construction risk accident.

4. Risk classification management: to continuously manage risks and prioritize high-risk elements;
5. Dynamic management and risk elimination: to develop plans and take measures to mitigate, eliminate and monitor risks.

4 SAFETY RISK FACTOR QUANTIFICATION STANDARD

Risk identification investigates in both internal and external risks of projects. Following the process of “risk identification → risk analysis → risk assessment → risk disposal”, the ‘5M1E’ elements of potential risk accidents in construction projects are quantified and evaluated sequentially. Application of Fuzzy Interpretative Structural Modelling (FISM) analysis method to identify potential sources of risk that may lead to accidents, as shown in Figure 3.

Based on existing relevant codes, regulations and standards, as well as analysis of historical accidents in the industry, a multi-dimensional and multi-indicator quantitative evaluation is conducted for each element. For example, the safety ability of construction workers is divided into four dimensions: skill quality, physiological quality, psychological quality, and construction environment. Each dimension is further divided into multiple indicative elements. At present, the content and indicators of digital quantitative assessment for safety risk management include: man factor (R man): 32 elements for individuals and 28 elements for teams; Machinery factor (R machinery): 28 elements; Environmental factors (R environment): 27 elements; Method factor (R method): such as

11 elements for foundation pits; Material factor (R material): 6 elements; Management factor (R management): 45 elements.

5 RISK FACTOR QUANTIFICATION

The quantitative evaluation of each risk factor will adopt the fuzzy mathematics theory, establish a three-level fuzzy comprehensive judgment model and carry out risk evaluation level by level. The multi-level Analytic Hierarchy Process (AHP) will be used to determine the weight of factors at all levels and finally determine the risk level. Using the feature root method to obtain the relative weights of each level, the calculation process is as follows:

The equation of R_i is:

$$R_i = \sum_{j=1}^n \sum_{k=1}^m C_{ij} \cdot r_{ij} \quad (2)$$

For major risk source (items), for specific construction work units, according to WBS-RBS risk matrix structure analysis and dynamic iterative quantitative assessment of “5M1E” elements:

$$R_{WBS(i)} = \sum_{i=1}^6 K_{RBS(i)} \cdot R_i \quad (3)$$

where R_i is the risk value of a “5M1E” element, and $K_{RBS(i)}$ is the impact weight coefficient of each risk factor.

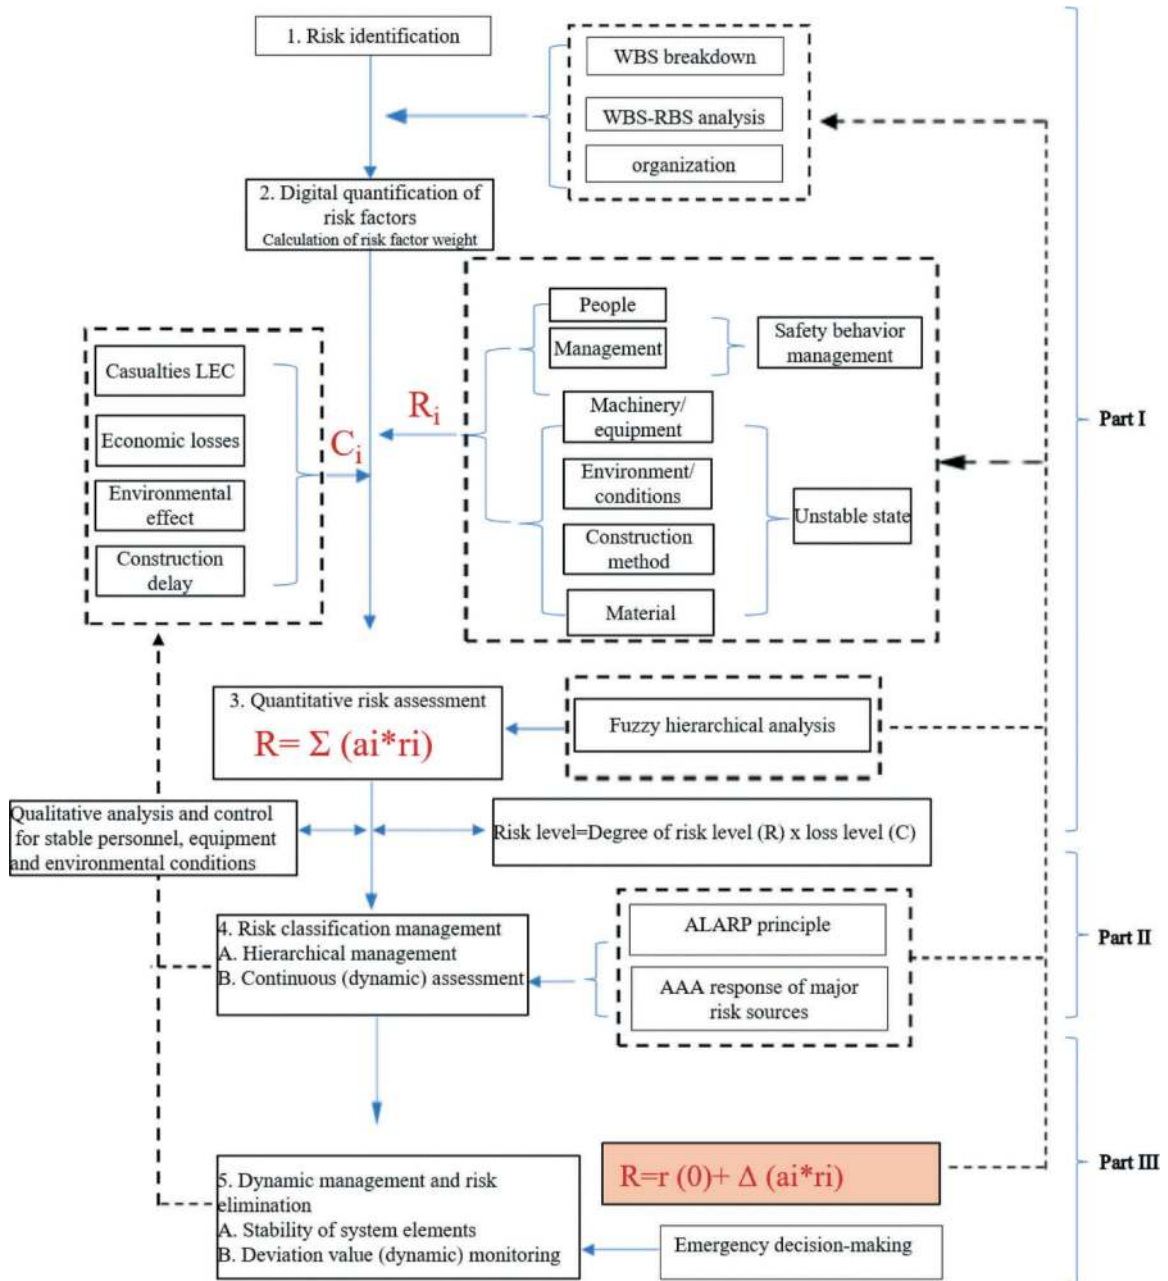

Figure 2. Typical safety risk quantitative evaluation management Framework.

6 DEVELOPMENT OF SAFETY RISK INFORMATION MANAGEMENT SYSTEM

We have developed a safety risk information management system software program using Python 3.9 programming language and SQLite 3 database for construction process. The architecture of the system consists of four levels: 1) Information Display; 2) Application Support; 3) Capability Support; 4) Interface and Transmission, as shown in Figure 5. The system is featured for extension functions of Data-driven analytics, GIS/BIM and IoT for smart construction (Yang & Xia, 2018). The data and

information during construction are stored in the system's database on demand. Users will use the interface to input, exchange and display information. The quantitative assessment of risk is based on data in the database, and is analysed through risk analysis algorithms in various application modules. The quantitative evaluation results are displayed in the system interface through values, charts, visualization methods, etc., as shown in Figures 6 and 7. Construction managers or other responsible staff for safety management can refer to the evaluation results of the system to properly manage construction safety risks and develop corresponding emergency response strategies.

7 APPLICATION OF THE SYSTEM IN A MEGA TRANSPORTATION HUB PROJECT

Figure 3. Risk Factor – Fuzzy Interpretative Structural Model – Analytical Network Process (FISM-ANP).

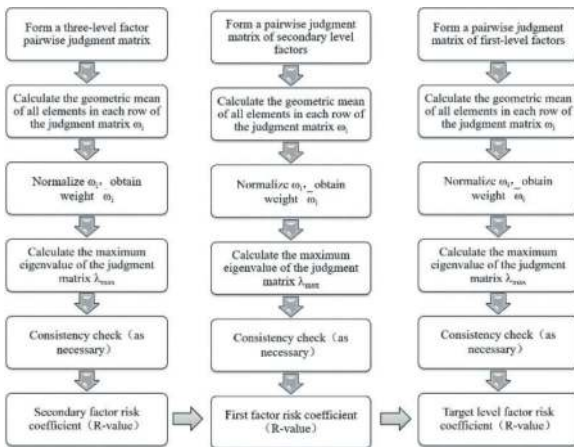

Figure 4. Flowchart for the analytical hierarchical process.

The Shenzhen Huangmugang (HMG) Hub Project is the reconstruction and expansion of a mega comprehensive transportation hub located at one of the most active areas in Shenzhen, China. It is an interchange station for metro Line 7, Line 14 and Line 24 and integrates Bus & Taxi Services, Pedestrian & Bike Transportation, and underground commercial space. Due to the complicated construction process of underground structural system transfers, interface with existing structures and utilities as well as ground stability during construction of a 40m deep excavation below ground, effective risk control measures are crucial to be implemented throughout the whole construction phases in order to address the enormous potential engineering risks especially those related to safety. Therefore, the Safety Risk Information Management System is applied in this project to improve the safety management for the whole construction activities.

The framework of the system consists of two major stages: 1. overall qualitative risk assessment (at the global level) of the project prior to the construction commencement; 2. quantitative evaluation for Level I (extremely high risk level) and Level II (high risk level) based on the overall risk assessment results. Figure 8 illustrates a typical quantitative evaluation for various factors and overall risk level.

The two stages are further broken down into several steps. Step 1 is to evaluate the project at the holistic level, where the construction type is defined and high-risk items (Levels I and II) are identified by applying relevant codes. Step 2 is to divide high risk items using Work Breakdown Structure (WBS) and Risk Breakdown Structure (RBS). With the developed algorithm, quantification analysis can then be performed, and the risk values are quantified at Step 3. The situation in a construction project would usually be varying constantly, and step 4 implements the

Table 1. The influential weights of construction quality of workers.

Level 1 Indices	Level 2 Indices	Influence Weights	Level 3 Indices	Influence Weights
Man factor	B1 Skill Quality	0.365	C1 Years of experience	0.058
			C2 Expertise level	0.387
	B2 Physiological Quality	0.125	C3 Safety knowledge	0.355

Figure 8. Illustrative evaluation result of safety factors (man, machine, material, method, environment and management).

dynamic evaluation process to cope with the updated site situation where new risks could emerge and level of severity could change. Elimination of hidden hazard exists throughout the whole process of a construction project, which includes tracing back to the root causes with Fault Tree Analysis (FTA) and the timely response according to contingency plans developed based on relative standards. The procedural steps are shown in Figure 9.

In the construction of HMG project, three construction sites are divided and safety risk management is performed based on the work fronts and phasing conditions. At the early stage of the project, safety risks are identified on the scale of the holistic construction area and phases, where 480 items are

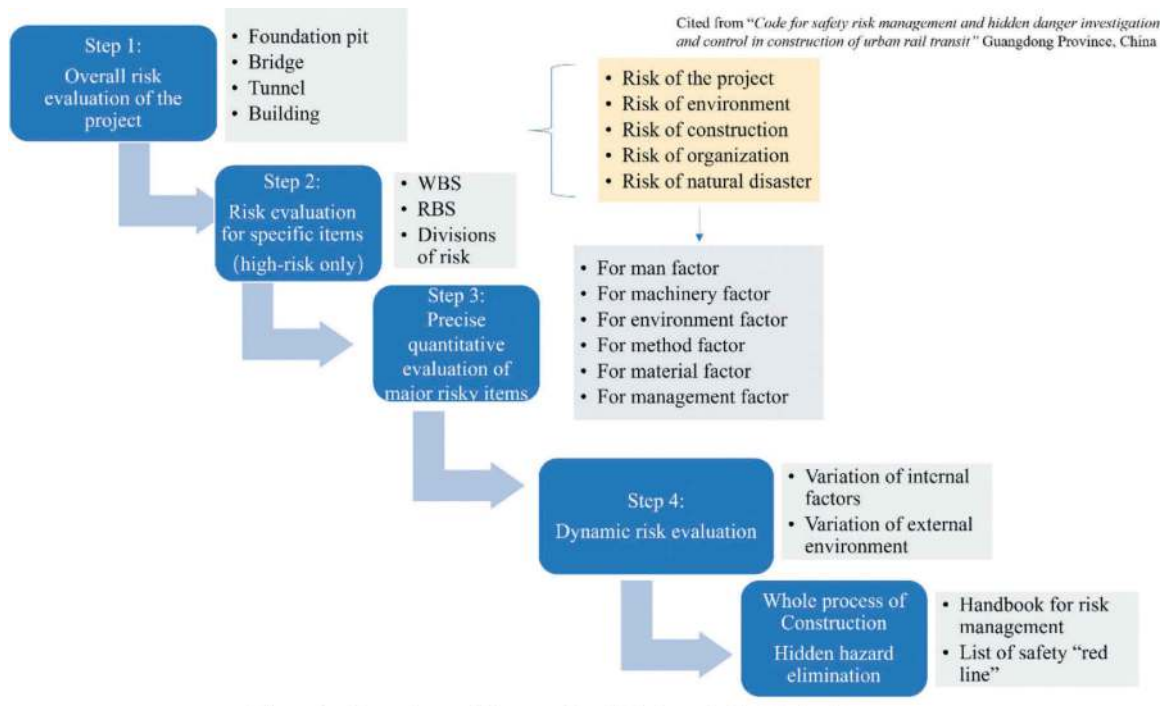

Figure 9. Procedures of construction risk quantitative evaluation.

from site I, 173 items are from site II, and 198 items are from site III. The program was used to analyse the risk items that have been identified and the preliminary assessment results show that there are four high-risk items: 1. geological fault risk; 2. V-shape columns risk; 3. Line 7 existing structure risk; 4. deep excavation risk. Further quantitative assessment and FTA are conducted, the analytical results are provided to the contractor, and several special measures are then developed and implemented accordingly, including removal of existed structure walls, top-down excavation, application of V-shape columns, and application of advanced tunnel reinforcement, etc. Despite the well-rounded risk management considerations, a few incidents still occur due to the lag of the implementation of the construction measures/contingency plans by the contractor. For example, 6 months after starting to apply the system a sudden seepage of ground water occurred at the fault zone identified by the system with the assistance of a 3D geological model. This incident is a proof that our risk identification methodology is valid. However, the lesson learned is that risk response time is also an essential factor in terms of the efficiency of the risk control. Additional features could be added to the system so that required response time window could also be suggested in conjunction with identified hidden hazards. The overall construction work of HMG has been successfully completed without major safety accidents in October, 2022.

8 CONCLUDING REMARKS

With increasing complexity and scale of construction projects in this modern era, conventional risk management means, which mainly relies on empirical analysis, will need to be geared up. The study proposes to use quantitative methodology to address the challenges in that regard. The algorithms of Safety Risk Quantitative Evaluation Management are derived considering the logical relationship of construction safety factors. Through the systematic and quantitative analysis of six 'risk factors' in construction projects, a quantitative risk assessment procedure with multiple steps are developed. Dynamic risk management is also realized based on assessment results with the corresponding risk-elimination and response mechanism. The authors integrate all the aforementioned concepts and developed a software program named Safety Risk Information Management System to facilitate the management workflow. The application of this system in the HMG Transportation Hub project in Shenzhen has shown that it could effectively quantify and evaluate major safety risks in such large-scale and complex construction projects, and predict the Causal Chain of construction safety risks, and achieve effective prevention and control of safety risks, significantly improving the quality and effectiveness of safety risk management.

Further development of the system's extension functions of Data-driven analytics, GIS/BIM and IoT, would be meaningful for smart construction.

Research on data management and analysis of BIM technology

Yang zhaofeng*

Department of Geotechnical Engineering, Wuhan China Geo University, Wuhan, Hubei, China

ABSTRACT: BIM technology is the soul of information and digital. Accompanied by the development of big data, cloud computing, Internet of Things, artificial intelligence and other cutting-edge technologies, the digitisation and informatisation of BIM technology is also in constant depth. BIM technology, as an important supportive technology for digital construction, plays an active guiding role in infrastructure projects. This paper provides new thinking and solutions for the construction of tunnels and underground projects through the data management and analysis of BIM technology in the construction of tunnels and underground projects. It is not only the key to the future field of urban underground space, but also an important trend in the development of global digitalisation and information technology.

Keywords: BIM technology, digitalisation, information technology

1 INTRODUCTION

BIM is leading the way in a technological revolution that the engineering and construction industry is currently undergoing a technological revolution, and BIM is constantly changing the way the construction industry builds and collaborates. The core value of BIM technology lies in the ability to extract the information of the building model and use it in the process of project management such as cost, schedule, quality, and safety, breaking the information island barriers of all parties involved in the construction and realizing the data sharing of the whole process of the construction project.

2 BIM TECHNOLOGY IN BRIEF

2.1 Definitions

The full English name of BIM is Building Information Modeling, which is more consistently translated as Building Information Modelling in China. BIM technology is a data-based tool applied in the construction industry, which integrates all kinds of project-related information through parametric models, and shares and transmits them during the whole process of the construction project, and plays an important role in improving productivity, saving costs and shortening the construction period. It plays an important role in improving productivity, saving cost and shortening construction period, etc.

The U.S. National BIM Standard defines BIM in three parts: 1) BIM is a digital representation of the physical and functional characteristics of a facility (construction project); 2) BIM is a shared knowledge resource, a process for sharing information about this facility and providing a reliable basis for all decisions made during the full life cycle of the facility from conception to demolition; 3) during different phases of the facility, different stakeholders collaborate by inserting, extracting, updating and modifying information in the BIM to support and reflect their respective responsibilities.

2.2 Characteristics

2.2.1 Completeness of model information

Distinguished from traditional CAD 2D plan drawings, it contains complete building information such as equipment name, structure type, construction process, cost, manpower and machinery.

2.2.2 Relevance of model information

The objects in the model recognise each other and when one of them changes, all the objects associated with it are automatically updated.

2.2.3 Consistency of model information

Consistent model information at different stages eliminates the need to repeat inputs and avoids errors caused by inconsistent information.

*Corresponding author: 954689932@qq.com

2.3 BIM-based project data and information management

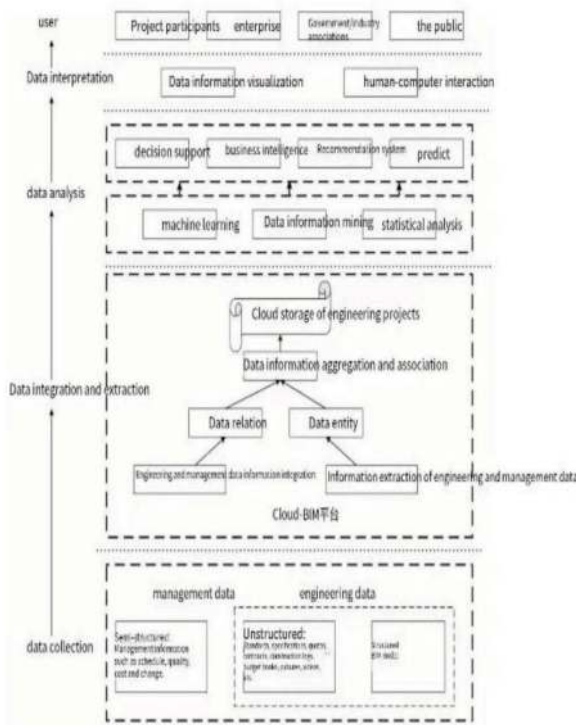

Figure 1. BIM-based project data and information management.

BIM-based project data and information management collects, extracts and integrates heterogeneous data sources at different stages of a project in real time, while also storing the data in logically centralised but physically heterogeneous cloud storage, and analyses the stored data using appropriate data analysis techniques to generate rich reports and analysis data, from which it extracts useful knowledge and presents the results to end-users in an appropriate way as a basis for decision-making in engineering project management, as shown in the figure below. As shown in illustration, it is divided into the following steps: data collection, data extraction and integration, data analysis, and data interpretation.

3 DATA MANAGEMENT AND APPLICATION OF BIM TECHNOLOGY IN THE SPECIALISED FIELD OF TUNNELLING AND UNDERGROUND ENGINEERING

BIM technology is the soul of information and numbers. The information management for the tunnelling and underground engineering profession is geared towards the consideration of the whole life cycle, with data flowing within the respective phases on the one hand, and between the phases on the other. Through

the systematic management of the whole life cycle surface information and monitoring and measuring data, it can provide the basis of accurate decision-making for project decision-making. Adopting computer AI, VR and BIM information technology to build a 3D tunnel and surrounding rock environment information model, and developing a cloud BIM platform that can realise information storage and query, 3D visualisation, engineering hydrogeological information reproduction, real-time feedback of design and construction monitoring data, and real-time sensing of safety risks, It provides a new idea and solution for the construction of tunnel and underground engineering.

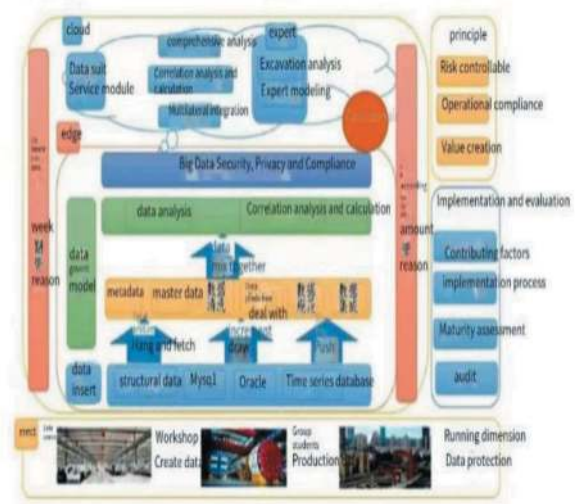

Figure 2. Architecture for managing data and information through the life cycle.

3.1 Application of information technology in tunnel and underground construction based on BIM technology

3.1.1 Digital design methods are a continual improvement in the planning process for tunnel construction. Such developments include rule-based system implementations, concepts for integrating data across documents and models, and new evaluation methods that utilise digital design capabilities. For planning purposes along the tunnel construction route, the integration of hardware and software products such as touch tables and virtual reality devices enables decision makers to be directly involved in the planning process. In the tunnel construction practice and planning phase, the process is simplified through the adoption of the Building Information Modelling BIM concept and the use of geometric BIM sub-models as a basis for structural analysis. As the construction industry transitions to digitalisation, information technology IT plays a huge role in large-scale projects for tunnel construction. Different IT applications are used at different stages of the project and stored in multiple formats. In addition, computer-aided design CAD,

for example, has had a clear impact on the way project data is presented. However, using IT tools that are standalone applications with limited interoperability with other platforms, data cannot be exchanged between applications and information sources in a project, and due to the lack of compatibility, information can be exchanged with errors and also lost. The emergence of Building Information Modelling BIM solves the problems associated with decentralised data management. BIM provides an innovative and collaborative solution that enables organised and efficient workflows throughout the entire project life-cycle: planning, design, construction, operations, maintenance and possibly later demolition phases. BIM technology can connect information databases with parametric 3D models to better visualisation, coordination and management of construction projects, thus reducing construction costs and errors. For this purpose, the Tunnel Information Model TIM was developed and integrated to improve the usability and compatibility of the structural tunnel simulation with the BIM methodology.

3.1.2 In BIM-based approaches, information is used as a basis for decision-making and project management. Certain information can only be processed by exploring constraints and dependencies. Relevant information can be decomposed and structured through so-called interaction chains. An interaction chain can be defined as a series of interrelated processes that can depend on each other and whose results can be directly used to evaluate relevant project constraints. The execution of an interaction chain requires the provision of relevant information. This includes available product data as well as interim simulation results. In order to manage this information, a 4D information model has been developed. In tunnelling projects, information is often time-dependent and distributed across different systems and various data formats. Based on the BIM concept in the field of tunnel construction, the Tunnel Information Model TIM creates a comprehensive container for tunneling projects and allows the integration of interaction chains for project evaluation.

3.2 *Digital research application based on BIM technology in the construction of tunnels and underground projects*

The study of digital design of tunnel routes is one of the most important studies in tunnel construction. Comparison of different route options allows cost-effective planning and reduces project risks. Often, variations in route options are effective because the criteria allow for alternative methods and need to be evaluated by experts. The weighted decision matrix method is used to evaluate the variables of such options, and a certain number of route options are studied before the best route option is selected. The most important element of the variables in tunnel design is the impact on the environment, such as critical settlements in protected areas or collisions with

underground structures. Traditionally, a route consists of a route and a gradient. The route describes the alignment of the line in a two-dimensional plane, while the gradient adds elevations based on the current curve section. The combination of these two design perspectives creates a three-dimensional line that can subsequently be used for element placement in a BIM-based process. Below are some of the methods used in the digital design of BIM tunnel lines.

3.2.1 *Integrated platform*

The Tunnel Information Modelling TIM framework has been adapted and further developed into an integrated platform. The platform advances the TIM framework by including route planning methods, integrating BIM and GIS data, and creating an interactive planning environment. The framework has been designed to utilise roomware products, primarily touch table devices, to enable collaborative, interactive and continuous exploration of planning variables. A key feature of the integrated platform is therefore the multi-touch interaction with the planning environment, which allows for real-time updating of planning variables in a collaborative environment.

3.2.2 *Lines in parametric tunnel design*

In BIM-based projects, lines are used to position elements relative to the path and inclination of the line axis. In road and railway projects, for example, they are used to generate street and railway systems semi-automatically, including technical equipment and information about ground stripping on the construction site. However in projects in the field of tunnels lines are used to generate tunnel models with cross sections and design parameters as a reference for the modelling process. By using line and cross-section information to generate tunnel models in mechanised tunnelling, the process of aligning elements to lines relies on a series of transformations applied by the system. These models are exported as industrial base class IFC models and can be used for infrastructure information delivery and visualisation of tunnel excavation. A prototype example of the IFC Tunnel Extension is used here to create semantically correct tunnel models and line alignments for data exchange.

3.2.3 *Collaborative exploration with roomware products*

The process of planning indoor equipment routes relies on the feedback and knowledge of experts. In a synergistic environment, the results of planning, design and evaluation can be directly justified. The benefits of a synergistic approach here can lead to significant improvements in the decision-making process for line selection. For example it can reduce the number of planning variables and shorten development times by directly implementing changes. In order to realise the application of the synergetic approach to route planning, interactive exploration on a touch-table device is required. Such an indoor device can be surrounded

and interacted with by a group of people. In order to handle user interactions, planning applications running on such devices need to integrate multi-touch strategies and simplify the planning process to enable semi-automatic re-evaluation of modified routes. With this aim a set of multi-touch strategies is investigated and implemented into the integrated platform. These touch strategies are mainly designed to handle simultaneous multi-touch interactions of the user on groups of areas and locking on touch interactions with elements that are far from the user's viewpoint. Thus with each interaction, the line can be modified and planned using touch and the updated line will be re-evaluated in real time and the results visualised for validation of the interactive planning tool.

3.2.4 *Integration of BIM and GIS*

The platform mainly considers the integration of documents and models used in the BIM and GIS domains, which are often considered as integrated approaches. This is because their information complements each other in the context of the spatial environment. However the concept of integration of BIM and GIS is usually used as an umbrella term to differentiate the integration approaches in terms of the scope and purpose of the information considered, and is categorised according to the integration effort and the terminology used. Considering this approach, the integrated platform belongs to the classification of the integration based on instance level information, and the differences in this classification perspective and links are based on the use of queries with spatial reasoning. The considered documents and models include map data such as cadastral data, built environment, terrain and ground models. However, the integration of the BIM and GIS domains proves to be challenging due to the differences in the format, level of detail and scope of the considered data, and the fact that the documents and models may differ in the level of development including various geometric representations.

3.2.5 *Rule-based line evaluation and data acquisition*

When exploring the integrated environment, rule-based exploration can add value to the information acquisition process and be used to check constraints and requirements. Considering the overlay nature of documents and models in the BIM and GIS domains, spatial reasoning methods can be applied. The context of the route plan is also incorporated into the reasoning approach, thus creating range-rich relationships between elements. These relationships were then used to query information between documents and models, enabling a semi-automated assessment of relevant requirements and constraints. Further research examined the application of the decision-making model to the selection of a single vs dual tunnel system and the selection of a tunnel boring machine. A query

highlights a set of elements which can then be evaluated in more detail. For direct visual feedback, these results can be selected and coloured, allowing for visual validation and subsequent integrated investigation.

3.2.6 *Constraints and requirements*

Examine these range-specific requirements and develop a valid set of variables. These variables are evaluated using assessment criteria, such as risk assessment and cost estimation. Interactive results from settlement analyses and building damage risk assessments can be integrated in the evaluation process. The decision-making process in the field of tunnelling can be significantly improved by using decision models, which consist of rules for reasoning in a decision-making system. In the field of tunnelling, this study shows that decision models can enhance the decision-making process and that the weighting of individual criteria affects the evaluation results, which also applies to route analysis and selection.

3.2.7 *Utilising semantic web methods*

The use of semantic web technologies and methods allows the integration of data from the BIM and GIS domains. Since it is considered that data from BIM and GIS domains will lead to a mixture of 2D and 3D representations, these representations can also be defined in different coordinate reference systems CRS. Geometries in the Semantic Web are usually represented using the WKT representation, which is a concise and streamlined version of the most important geometric representations. By utilising WKT-CRS, i.e. the WKT representation extended to handle geometries defined in different CRSs, the geolocation of these elements can be handled naturally. This approach of using the Semantic Web for correlating data and obtaining relevant information has been validated by many studies. Incorporating this spatial reasoning approach into an integrated platform enables semi-automated query execution on documents and models for data acquisition and evaluation. This concept in been elaborated and implemented to establish context-rich relationships between documents and models by including constraints and requirements in the query process.

3.2.8 *Applications for decision-making and review*

In the decision-making process for the selection of a route, it is common to use different route variants to be compared based on assessment criteria, for example using a weighted decision matrix approach. The method considers the assessment and comparison of a range of constraints and requirements to select the preferred variant, e.g. based on a cost-effectiveness examination. Such an assessment method is based on the characteristics of the planning environment and the relevant data. In order to identify the relevant data for carrying out the expedition, the spatial environment must be examined. By using Semantic Web technology, several semi-automated data acquisition cases can

be executed. These filtered subsets can be highlighted to provide visual feedback on the results. As these queries take into account the constraints and requirements of the route planning process, they can be incorporated into the decision-making process by integrating the results as relevant information for the expedition criteria in the methodology.

4 CONCLUSIONS AND TRENDS, OUTLOOK

At present, with the gradual improvement and application of BIM technology in the construction industry, BIM data will be widely used in the whole life cycle of buildings, and even radiate to the

management of the entire digital twin city. From a technical point of view, it is predicted that if BIM semantics and knowledge are widely understood and applied in the future, and continue to accumulate and refine, BIM is likely to be closely integrated with artificial intelligence technology, injecting new vitality and impetus into the sustainable development of the construction industry, and also bringing greater transformative innovation to our work and life. In summary, BIM technology not only promotes the progress and upgrading of existing technologies, but also affects the change of production organization mode and management mode, and promotes the change of people's thinking mode. Through this paper, it is understood that BIM technology is not only the key to the field of urban underground space in the future, but also an important trend in the development of global digitalization and information technology.

ABSTRACT: The subway tunnel is a crucial component of urban rail transportation systems. With the rapid development of urbanization, the focus on tunnels has shifted from construction to operation, making effective and convenient tunnel inspection vital for ensuring safety. This paper introduces a novel method called Neural Radiance Fields (NeRF) for achieving efficient and accurate 3D tunnel reconstruction. The method offers a new solution direction for visualizing the tunnel interior and enables remote inspection, enhancing tunnel safety analysis and evaluation capabilities. This study determines device parameters and data acquisition methods through indoor pre-experimental investigations, employing three computer vision evaluation metrics: PSNR, SSIM, and LPIPS. An image dataset of a subway tunnel was acquired within Shanghai Metro Line 18, spanning from Guoquan Road Station to Fushun Road Station. Subsequently, gamma correction was applied to address uneven brightness in the tunnel image set. Then, by utilizing the Colmap software, the camera pose trajectory within the tunnel interiors was computed, which served as a crucial component of the NeRF algorithm. Finally, a high-quality 3D tunnel model was constructed based on NeRF algorithm, enabling immersive exploration and inspection of the tunnel. Compared to traditional Structure-from-Motion (SfM) reconstruction methods, the speed and quality of tunnel 3D reconstruction based on NeRF have been significantly improved. This work provides a possibility for efficient tunnel surveillance and maintenance.

Keywords: Shield tunnel structure, 3D reconstruction, Image acquisition, Visualization

1 INTRODUCTION

The development and use of urban underground space has brought new vitality into the development of tracks and underground buildings, among which, the metro is the focus of underground space construction in major cities because it can solve the huge pressure brought by daily heavy traffic, improve the city's land use rate and save land resources. However, with the increase of metro service time, the tunnel lining structure due to geological environment changes, vehicle load impact,

their own material properties, etc., will inevitably produce a variety of diseases, mainly manifested as: water seepage, lining cracks, joints, joints open, tube sheet misalignment, longitudinal uneven settlement, tube diameter convergence deformation, and so on (Fang et al., 2022). These diseases will not only reduce the service life of the tunnel, but also bring great safety hazards. It can be seen that the use of efficient and reliable testing equipment and technology to detect tunnel defects in a timely manner is the only way to rule out potential safety hazards in tunnel structures in advance,

*Corresponding author: 937742775@qq.com

so as to safeguard the safety of the public in their daily travel (Cui et al., 2022).

As one of the most popular research directions in the field of computer vision, 3D reconstruction technology provides a new solution direction for the visualisation of shield tunnel disease detection and identification. The first stage of 3D reconstruction is about the application of stereo vision technology: Stentoumis et al. (2015) invented a tunnel inspection device based on binocular stereo vision technology, which is able to realise 3D reconstruction of tunnel surface lining. However, this device can only realise the reconstruction of the tunnel within a local area, and the reconstruction speed is slow, so there is still much room for improvement. The second stage of 3D reconstruction is about the application of 3D laser scanning technology: Xie & Lu (2017) took the lead in using terrestrial laser scanning technology (TLS) to develop a new set of 3D modelling algorithms, which can pre-process the raw point cloud data acquired by TLS, extract the tunnel axes, carry out the coordinate conversion, and ultimately generate a 3D model of the tunnel. The third stage of 3D laser scanning is about the application of Structure from Motion (SfM):Xue et al. (2021)proposed a new method for 3D reconstruction based on the SfM method and Direct linear transformation (DLT) method. This method gives the point cloud data scale information, which lays the foundation for future disease quantification and tunnel service performance evaluation based on point cloud data. However, when using this method to reconstruct the shield tunnel as a whole, the constructed model contains a large number of holes, the modelling quality is poor, there is a problem of missing information, and the detection and quantification of disease information is not achieved.

However, with the rapid development of deep learning technology, voxel-based 3D reconstruction technology has gradually become the mainstream of 3D reconstruction technology with its advantages of high efficiency and high accuracy, and Neural Radiance Fields (NeRF) is one of them. Therefore, this paper is based on the NeRF technology for the left shield tunnel of Shanghai Metro Line 18 to carry out visual three-dimensional modeling experiments, to help the visual display of shield tunnel disease detection research which lay the foundation for the realization of the future remote inspection of shield tunnels.

2 METHODOLOGY

The core idea of the NeRF algorithm is to represent a static 3D scene as a deep fully-connected neural network without any convolutional layers, with the aim of achieving new view synthesis for complex scenes(Barron et al., 2021). For a particular static scene, images containing camera positions and camera parameters are provided as a training set to

motivate the neural network to predict a scene model with good continuity. Finally, by inputting any camera position and orientation, the neural network can synthesise a new view by volume rendering.

2.1 NeRF neural network structure

The NeRF algorithm constructs a Multi-Layer Perception (MLP) neural network. The input of the neural network is a 5-dimensional vector $(x, y, z, \theta, \varphi)$ including the position of the observation point in the absolute coordinate system $x = (x, y, z)$ and the viewing angle of the camera $d = (\theta, \varphi)$; the output is the RGB colour $c = (r, g, b)$ and density σ of the corresponding position (voxel).

In practice, the position vector \mathbf{x} is first fed into the MLP network, which outputs the voxel density σ and a 256-dimensional intermediate variable, and then the intermediate variable and the viewpoint vector \mathbf{d} are fed into an additional 128-dimensional fully connected layer to predict the RGB colour vector. Figure 1 shows the specific structure of the NeRF algorithm.

Figure 1. Specific structure of the NeRF algorithm.

2.2 Volume rendering with radiance fields

NeRF represents a 3D static scene as an MLP neural network, so that a new view can be synthesised for 3D reconstruction by simply asking for the density σ and RGB colour c of any point (voxel) in space (Pumarola et al., 2021). When the static scene is imaged by a camera with a known position and viewpoint orientation, each pixel on the resulting 2D image actually corresponds spatially to the projection of all consecutive spatial points on a ray emanating from the camera as the origin, and therefore all points on this ray need to be integrated using the voxel rendering algorithm, as shown in Figure 2.

Voxel density $\sigma(x)$ is the differential probability that a ray terminates at an infinitesimal particle at location x , which can also be interpreted as the opacity of a point at that location(Mildenhall et al., 2020). And when a virtual camera observes along a particular direction, the points on its observation ray are continuous, so the colours of the pixel points on its corresponding imaging plane can be obtained by integrating the colours of the points on the observation ray. Marking the camera location as the origin o and the camera's observation direction vector as \mathbf{d} , the observation ray can be expressed as $r(t) = o + t\mathbf{d}$, and the near boundary of the

observation is t_n , and the far boundary is t_f . The colour of the pixel $C(r)$ corresponding to this observation ray is shown in equation (1) and equation (2).

$$C(r) = \int_{t_n}^{t_f} T(t) d(r(t)) c(r(t), d) dt \quad (1)$$

$$T(t) = \exp\left(-\int_{t_n}^t \sigma(r(s)) ds\right) \quad (2)$$

The function $T(t)$ represents the cumulative transmittance along a ray from t_n to t_f , which is the probability that the ray will travel from t_n to t_f without hitting any other particle.

Figure 2. Voxel rendering process.

In practice, the number of consecutive points on each ray is infinite, so numerical approximations are needed to select the sampling points. A common method for rendering discrete voxel meshes is the deterministic product method, thus, N points are uniformly sampled in the region of integration for continuous integration. However, this method is not applicable to the MLP neural network in NeRF, because a fixed sampling habit will cause the MLP network to learn only at definite discrete points, which is not conducive to improving the resolution of the NeRF algorithm. For this reason, NeRF uses a stratified sampling approach, where the region on the ray to be integrated is first divided uniformly into N parts, and then uniformly randomly sampled from the N small regions as shown in equation (3).

$$t_i \sim u\left[t_n + \frac{i-1}{N}(t_f - t_n), t_n + \frac{i}{N}(t_f + t_n)\right] \quad (3)$$

Hierarchical sampling ensures that the MLP learns in a continuous manner even when only discrete points are captured, thus guaranteeing the continuity of the NeRF representation of the scene. The classical body rendering algorithm can therefore be reduced to a summation form as shown in equation (4) (5) (6).

$$\widehat{C}(r) = \sum_{i=1}^N T_i (1 - \exp(-\sigma_i \delta_i)) \quad (4)$$

$$T_i = \exp\left(-\sum_{j=1}^{i-1} \sigma_j \delta_j\right) \quad (5)$$

$$\delta_i = t_{i+1} - t_i \quad (6)$$

2.3 Sampling methods from coarse to fine

The Neural Radiation Field represents a 3D static scene as an MLP neural network and is able to synthesise new views by a classical voxel rendering algorithm that can obtain the density and RGB colour of any voxel in space. However, in order to achieve high-resolution modelling of complex scenes, two further improvements need to be introduced: i) positional coding to help the MLP network represent high-frequency functions, and ii) a multi-layer voxel sampling procedure to ensure continuity of the NeRF algorithm's representation of the scene.

2.3.1 Positional encoding

Rahaman et al. (2019) have shown that deep learning networks prefer to learn low frequency functions, so introducing position vector \mathbf{x} and viewpoint vector \mathbf{d} directly into the MLP network leads to poor performance in synthesising colours and geometries for high-resolution new views. Instead, mapping the inputs to a higher dimensional space first before they are passed to the network using position coding can effectively fit the high frequency changing data.

Reformulation function F_θ as a composition of two functions $F_\theta = F'_\theta \gamma_j$, in this case γ_j is a mapping from the real number field R to a higher dimensional space R^{2L} , F'_θ is still the same simple MLP network mentioned.

2.3.2 Hierarchical volume sampling

The classical voxel rendering algorithm operates on the principle of sampling uniformly on the rays emitted by the camera and performing a summation computation on the N sampled points. This rendering strategy is inefficient in the first place, as there is a large amount of space and occluded regions that do not contribute to the rendering that are also subjected to the sampling computation; and the fixed sampling convention causes the MLP network to learn only at definite discrete points, which is not conducive to improving the resolution of the NeRF algorithm.

Therefore, the NeRF algorithm adopts the sampling principle of stratified volume sampling, thus, a multilayer voxel sampling method from rough to fine according to the proportion of the samples contributing to the final rendering effect, as shown in Figure 3. The specific implementation steps are as follows: firstly, sparsely collect N_c sample points by stratified sampling method, and perform rough mesh rendering on these sample points.

The normalised probability density function can be regarded as the probability density function along the ray direction, which reflects the distribution of the static scene in the ray direction, that is, the degree of contribution of the sampling points to the final rendering effect. Based on this probability density function, the inverse transformation sampling method is used to sample another N_f sampling point, so as to realise the weight sampling.

Figure 3. Multilayer voxel sampling method from coarse to fine.

3 PRE-EXPERIMENTAL VALIDATION

3.1 Equipment selection

The main factors affecting the imaging of the lens are the focal length and aperture size, which together determine the depth of field of the captured image, which refers to the clear scope of the image can be determined by the lens. Near the focal point of the lens, the image points show a conical convergence and then spread to form a dispersion circle. The size of the dispersion circle determines the degree of clarity of the image. The radius of the dispersion circle gradually increases as the distance of the centre of the dispersion circle from the focal point increases, and when the clarity of the image can no longer be ensured at a certain critical position, the dispersion circle is called the permissible dispersion circle. The distance between the centres of the front and back dispersion circles is called the depth of focus, while the corresponding field of view distance on the other side is called the depth of field.

Equation (7) represents the formula for the depth of field.

$$DOF = \frac{2f^2 \cdot F \cdot \delta \cdot D^2}{f^4 + (F \cdot \delta \cdot D)^2} \quad (7)$$

The specific requirement of equipment selection is to ensure that the camera's nearest shooting point falls within the depth of field range area. By analysing the imaging factors, it can be known that the nearest shooting distance of the shooting system is determined by the focal length of the lens. When the focal length is smaller, the range of view of the lens will be larger. Therefore, a wide-angle lens should be used during the process of picture acquisition of the shield tunnel.

Through comprehensive consideration of multiple brands and models of camera lenses on the market, this paper finally chose the Sony FE 14mm f1.8 GM 14GM lens, as shown in Figure 4. The lens is a compact and lightweight ultra-wide-angle, large-aperture, fixed-focus lens with two built-in XA (Super Aspherical) lenses and two XD linear motors. It offers excellent image resolution while maintaining constant focusing accuracy.

Figure 4. Sony FE 14mm f1.8 GM 14GM Lens.

Take the shield tunnel from Shanghai Line 18 Guoquan Road Station to Fushun Road Station as an example to verify the feasibility of the Sony FE 14mm f1.8 GM 14GM lens as a shield tunnel image acquisition lens:

Sony FE 14mm f1.8 GM 14GM lens with a built-in image sensor of 43mm * 36mm and a focal length of 14mm.

From this, the field of view of the lens can be calculated as shown in equation (8).

$$\alpha = 2 \arctan \left(\frac{21.5}{14} \right) = 113.86^\circ \quad (8)$$

The inner diameter R of the shield tunnel is 5.5m, so the closest distance in the picture is 1.8m.

$$d_{\min} = \frac{\frac{R}{2}}{\tan\left(\frac{\alpha}{2}\right)} = \frac{2.75}{\tan(56.93^\circ)} = 1.79m \approx 1.8m \quad (9)$$

The focusing distance is taken as 3m, the aperture is selected as f1.8 maximum aperture, and the foreground depth is calculated as 3m by equation (10).

$$DOF_1 = \frac{F \cdot \delta \cdot D^2}{f^2 + F \cdot \delta \cdot D} = \frac{1.8 \times 43 \times 3000^2}{14^2 + 1.8 \times 43 \times 3000} \approx 3m \quad (10)$$

The above calculations show that the depth of field of the Sony FE 14mm f1.8 GM 14GM lens can cover the entire area within the field of view of the filming equipment, which can be applied to the 3D

reconstruction data acquisition requirements of shield tunnels, which are one-dimensional linear structures with narrow space and long depth.

Another requirement to ensure the reconstruction accuracy of the Neural Radiation Field (NeRF) algorithm is to obtain high-resolution image data, and the clarity of the image is determined by the performance of the camera, so another important task in the selection of filming equipment is to choose a camera with high sensitivity performance that is compatible with the lens. Sony FE 14mm f1.8 GM 14GM lens is E-mount, so Sony A7R4 α7R IV A7RM4 camera is chosen to go with it.

3.2 Test programme determination

After selecting the model of the filming equipment, it is necessary to further determine the image acquisition method. Considering that the structure of the corridor is similar to that of the tunnel, which is a linear structure with long depth and small lateral dimensions and the lighting conditions are similar at night. So the corridor is selected as the object of this pre-test for 3D reconstruction, and the quality of the reconstructed model is compared with that of the different schemes, so as to guide the image acquisition scheme of the field test.

The modelling object of the pre-experiment is the indoor corridor on the fourth floor of the Southwest Eight dormitory building of Tongji University and the longitudinal cross-section of the corridor is approximately rectangular, as shown in Figure 5.

Figure 5. Dormitory corridor.

3.2.1 Image acquisition method

The first acquisition method records video along the corridor in the longitudinal direction and then extracts the images through the frame extraction algorithm, screening and deleting jittery and blurred images. This scheme has the highest acquisition

efficiency and the frame extraction algorithm can set the interval between images by itself, with the highest degree of superposition between images. The limitation of this scheme is that it is impossible to set the exposure time so when the lighting conditions are poor, the acquired images will be polluted by lots of interference points and the image quality is not high.

The second acquisition method is to take an image every 1m along the longitudinal direction of the corridor. The advantage of this scheme is that the clarity of the image set can be ensured during the image shooting process and the brightness of the image under poor lighting conditions can be compensated by extending the exposure time. But the limitation is that the shooting angle is fixed and it is not possible to obtain the observation image of the target scene at multiple angles.

The third method is to take multi-angle shots along the corridor longitudinally, one shot at each shooting point at 45° intervals from left to right and the interval between adjacent shooting points is taken to be 2 m. The advantage of this scheme is that it can obtain the observed images of the target scene at different observation angles, which improves the accuracy of the MLP network in the neural radiation field algorithm in the representation of the target scene. The limitation is that the angle needs to be adjusted when shooting, which is less efficient.

3.2.2 Comparison of different acquisition methods

The model obtained after 3D reconstruction of the acquired corridor images using the NeRF algorithm is shown in Figure 6.

Figure 6. NeRF reconstruction results.

In this paper, three classical image evaluation metrics in the field of computer vision, namely PSNR, SSIM and LPIPS, are cited to evaluate the 3D models obtained from the above three image acquisition methods. Among them, the peak signal-to-noise ratio PSNR is in dB, and the larger its value is, the lower the distortion of the image is, and the image is about close to the original. The interval range of structural similarity SSIM is [0,1] and the closer its value is to 1, the more similar the two images are. And the smaller the value of Learning Perception Image Block Similarity LPIPS, the more similar the two images are.

Table 1. Comparison of reconstruction results.

Method	PSNR/(dB)	SSIM	LPIPS
First method	12.54	0.376	0.577
Second method	12.72	0.365	0.558
Third method	15.83	0.403	0.621

As can be seen from Table 1, the multi-angle photo-taking method (third method) has the best evaluation effect among the above four evaluation indexes. In addition to this and combined with the reconstruction model visualisation evaluation, although the basic structure of the corridor can be reconstructed by using different acquisition methods, the model texture generated by using the third method is smoother with the least number of collapses or depressions of the plane, the least number of transition zones and the portrayal of model details is closer to the real state, so the final image acquisition test of the shield tunnel lining structure will adopt the image acquisition method of taking pictures from multiple angles (third method).

4 CASE STUDY OF SHANGHAI METRO LINE 18 TUNNEL

4.1 Image acquisition process

The test object of this paper for data collection of shield tunnel is the left shield tunnel of the section from Guoquan Road Station to Fushun Road Station of Shanghai Metro Line 18. The line map of Shanghai Metro Line 18 and its internal lining structure are shown in Figure 7.

Figure 7. Interior lining of the metro.

According to the analysis of the results of the pre-experiment, it can be seen that the use of multi-angle photography can obtain the observation results of the target scene in multiple angles, which can help the NeRF algorithm to better reason and restore the reconstructed target's three-dimensional model. In

addition, the acquisition method is simple and easy to promote, compared with the previous use of 3D laser scanning, which does not require a complex operation process or high test costs. And the acquisition method is very efficient and can cover a long distance of the shield tunnel, which can meet the real-time requirements of the tunnel inspection. Therefore, the image acquisition test for the tunnel lining structure also adopts the method of multi-angle shooting.

Due to the long exposure time, a tripod is needed to fix the camera in order to eliminate the blurring of the effects caused by shaking during the shooting process. As the selected tunnel section is a turning section, the track has a certain slope. So after setting up the tripod, it is also necessary to level the tripod according to the bubble.

After completing the debugging of the camera and the erection of the tripod, the debugged camera parameters are used to take preliminary shots of the tunnel and view the image effect in real time. When the camera's parameters are set to ISO value 640, shutter time 2.5s, aperture size f5.6, the resulting image is basically no noise, full-frame clarity to meet the test requirements, so the shield tunnel image acquisition test throughout the whole to maintain the above parameter settings. The field test finally captured 184 clear and effective images, each with a resolution of up to 9504×6336 pixels.

4.2 Image enhancement pre-processing

In order to save energy and reduce emissions, only one side of the tunnel is equipped with lighting sources, resulting in uneven brightness and darkness in the captured raw images and the lining information in the dark areas can not be revealed. Therefore, it is necessary to pre-process the original image with image enhancement to recover the hidden lining details in the dark part, so as to improve the reconstruction model effect. In this paper, the gamma transform method is used to perform image grey scale transformation. The principle is to perform an exponential transformation on the grey values of the image and restore the lining information in the dark part by adjusting the value γ . As shown in the Figure 8, the best image enhancement effect is achieved when $\gamma = 0.6$.

4.3 Camera trajectory solving

From 2.2, we know that the input to the NeRF algorithm is a 5-dimensional vector that includes the coordinate position of the observation point in the absolute coordinate system and the observation angle of the camera, so the camera's position and trajectory need to be measured before carrying out the NeRF reconstruction.

When the camera shoots the target scene at different positions, it obtains the image A, image B and image

Figure 8. Image enhancement results.

C of the same feature point of the target scene under different observation angles. And each change of camera position can be regarded as the superposition of the effect of camera's translation of a certain distance and the rotation of a certain angle, so the essence of the camera trajectory solving is to request solving the transformation matrix of the change of the camera's position when shooting each image.

In this paper, we use colmap to solve the camera trajectory, and the result is shown in Figure 9, in which the red four-pronged cone represents the position of the camera where the image is taken, and the direction of the bottom of the four-pronged cone represents the camera's orientation. Finally, the information containing the camera internal reference and trajectory is converted into a json file.

Figure 9. Camera trajectory solving results.

4.4 NeRF 3D reconstruction

After the above json file containing the camera internal reference, trajectory information and the pictures of the shield tunnel structure processed using gamma transform are obtained, a 3D model of the

shield tunnel in various 3D forms can be produced, as shown in Figure 10.

Figure 10. NeRF modelling of shield tunnels.

The NeRF model of the shield tunnel was compared with the 3D reconstruction model obtained from the conventional SfM method and the results are shown in Table 2.

Table 2. Comparison of NeRF and SfM methods.

Method	NeRF	SfM
Reconstruction Efficiency	High	Time-consuming
Memory footprint	Moderate	More
Point cloud density	Moderate	Intensive
Point cloud quality	Higher	Average
Reconstruction scope	Large	Smaller
Texture details	Approximate reproduction of details	Rich texture, high reproduction
Remaining functions	Ability to composite new views	None

Table 2 shows that the two different 3D reconstruction methods, NeRF and SfM, have their own advantages and disadvantages in the 3D reconstruction of shield tunnels. Compared with SfM, the reconstruction speed of NeRF technology has been improved a lot and NeRF reconstruction adopts a hierarchical sampling volume rendering method, which greatly reduces the memory occupancy rate of computing devices. In addition, the NeRF model has a higher point cloud quality, a larger reconstruction range, and more importantly, it is able to achieve the synthesis of new views, which has a broader research prospect in the future.

5 CONCLUSION

Based on the basic principle of NeRF, this paper summarises and puts forward a new method applicable to the 3D reconstruction of shield tunnel structure by exploring the image acquisition scheme of tunnel lining structure through equipment selection

and conducting corridor pre-tests. The feasibility of the above method is verified by carrying out NeRF 3D reconstruction experiments on the left shield tunnel of the section from Guoquan Road Station to Fushun Road Station of Shanghai Metro Line 18. Finally, the NeRF reconstruction method is compared with the traditional SfM method, which highlights the superiority of the NeRF reconstruction method more intuitively.

ABSTRACT: Despite the widespread use of TBMs in tunneling projects, accurate estimation of TBM performance, especially in various geological conditions, can still be challenging. Comparing the most common rock mass classification systems, the RMR classification system shows a better correlation with the TBM penetration rate, due to using uniaxial compressive strength (UCS) as an input parameter in this classification system. RMR parameters are available in most tunneling projects, but it should be noted that the RMR system, was developed to classify the rock mass conditions in terms of tunnel stability and support design, and the effective parameters were selected accordingly. So, when the target is to use the RMR input parameters to predict the TBM performance, modifications should be made in the parameters. This study is offered a new TBM performance prediction model based on the input parameters of the Basic RMR in different rock types, through machine learning-based regression analysis. The proposed model has been developed based on the analysis of a comprehensive database of TBM performance in various rock types. Because different rock types have different fabrics and respond differently to shear forces, incorporating the effects of rock type into performance prediction models can improve the accuracy of estimates, for this reason, the lithology parameter is also included in the model. The model can be practical, especially in the design phase of a tunneling project.

Keywords: Machine learning, Performance prediction, Regression analysis, RMR classification system, TBM performance

1 INTRODUCTION

Since the use of tunnel boring machines (TBMs) requires major investments and high levels of geological risk, therefore, after determining the geological characteristics of the tunnel route and selecting the appropriate machine, the TBM performance should be estimated in the existing geological conditions. TBM performance prediction models consist of two main groups of theoretical and experimental models. The theoretical models have been developed based on the laboratory cutting tests; however, considering the restrictions in the generalization of these stages in the

laboratory due to the complexity of the interaction between the rock mass and the machine, these models have not been able to implement all the factors affecting the machine performance. The experimental models have been developed using field data from the machine's performance in different geological conditions, and they have the advantage of naturally taking into account all the effects caused by the ground and the machine. On the other hand, with the development of different machines with different capabilities, the application of these models comes with limitations. In addition, given the fact that the presented models have been developed for specific ground conditions, they

*Corresponding author: am.dardashti@gmail.com

cannot be generalized to all geological conditions. In recent years, some researchers have used computer modeling and machine learning (ML) techniques in order to develop experimental models for prediction of the machine performance, including Grima et al. (2000), Yagiz and Karahan (2011), Jahed Armaghani et al. (2017), Koopialipour et al. (2019), Salimi et al. (2019), and Zhou et al. (2020). AI techniques is considered as a good idea for estimation and modeling due to no need for formulation, their dynamicity, as well as the possibility of including the more effective parameters. According to recent studies, there is a high correlation between predicted and actual values of machine performance in ML-based methods (He et al., 2022).

In addition, some research has been done to predict TBM performance based on existing rock mass classification systems. Due to their simplicity, universal acceptance, and availability of effective parameters, these classifications are considered as suitable methods for estimating the TBM performance. Compared to the most common rock mass classification systems, RMR shows a better correlation with the TBM penetration rate, which is due to the use of uniaxial compressive strength (UCS) of intact rock as an input parameter in this classification system (Salimi, 2021). It has been also mentioned in previous studies, including Hassanpour et al. (2009, 2011) and Salimi et al. (2016). According to Rostami (2016), the most important geological characteristics that affect the TBM penetration rate are rock strength (UCS or BTS), joint frequency, direction, and condition, as well as rock abrasiveness. Exception of rock abrasiveness, which controls the disc cutter wear and thus the utilization, the other parameters are the same as those used in the RMR classification system. Thus, it is reasonable to be able to use the existing RMR rock mass classification system with some modifications in order to predict the TBM performance. It should be noted that the RMR system, like other rock mass classification systems, was developed to classify the rock mass conditions in terms of tunnel stability and support design, and the effective parameters were selected accordingly. So, if the target is to use the input parameters of the RMR system to predict the TBM performance, there is a need to modify the parameters and their weightings (Salimi, 2021). The main goal of this study is to investigate the possibility of using input parameters of the RMR rock mass classification system for estimating the TBM performance using ML algorithms.

Previous studies show that an increase in rock mass quality usually leads to a decrease in the TBM penetration rate. However, the weak condition of rock mass does not help to increase the penetration rate, as it causes instability. Thus, it is clear that the TBM penetration rate indicates a large dispersion compared to the rock mass classification systems. Sapigni et al. (2002) achieved a quadratic relationship between penetration rate (m/hr) and RMR system, which has also been confirmed in Hassanpour et al. (2011).

Sapigni stated that the correlation of the machine penetration rate with the RMR is significant, but it cannot be used for numerical prediction because the RMR does not consider the rock-machine interaction parameters. He pointed out that the rock type affects the TBM performance so that with the same TBM in different rocks with identical RMR, lower penetration rates are obtained in stronger rocks, indicating that factors related to rock type, e.g., texture, schistosity, and tensile strength can significantly influence the chip formation mechanism. Therefore, the conventional RMR system is not enough to predict TBM performance.

Today, with the development of ML algorithms and new data analysis methods, new studies have been conducted with the help of these methods to use the parameters of rock mass classification systems in predicting TBM performance e.g. Salimi et al. (2019) and Gholami et al. (2012). This study attempts to provide relationships for the prediction of TBM performance in different geological conditions with the help of ML algorithms, using the input parameters of the RMR system, which were measured in all the studied tunneling projects.

2 STUDIED PROJECTS AND DATA COLLECTION

To develop empirical equations for the estimation of TBM performance in different geological conditions using input parameters of the RMR system, the boring data from different tunneling projects were collected and compiled into a database. Operational data and the actual machine performance, as well as the engineering geological characteristics of related rock mass in different geological conditions, have been collected in this database. Tables 1 and 2 itemize the main characteristics of 10 TBM tunneling projects in the database. The database contains 523 tunnel sections, which are typically between 5 and 20 meters long, consisting of several excavation cycles, and reliable operational data of the machine and engineering geological characteristics of rock mass are available in these sections. The recorded data of these sections have not had many fluctuations, and the machine's performance has not faced a specific and unknown problem. The studied tunneling projects include Yinsong water supply tunnel, lot 4 and Yinhan water conveyance tunnel in China (Gong et al., 2021), MINAS water conveyance tunnel in Ecuador (Gong et al., 2021), Manapouri second tailrace tunnel in New Zealand (URS Company, 2003; Hassanpour et al., 2011), Maroshi - Ruparel water supply tunnel in Mumbai, India (Jain et al., 2014) and Zagros water conveyance tunnel, lot 2 (Hassanpour et al., 2009; 2016), Karaj-Tehran water conveyance tunnel, Lot 1 (Hassanpour et al., 2010; SCE company, 2006), Ghomrood water conveyance tunnel, Lots 3 & 4 (Hassanpour et al., 2009; 2011; SCE company, 2004), Kerman water conveyance tunnel, Southern Lot (Pourhashemi et al.,

Table 1. Lithology and geological characteristics of the studied tunneling projects in the database.

No	Projects	Geological zone	Formation	Lithology	Tunnel Length (km)	Available data (km)	Max. overburden (m)
1	Yinsong water supply tunnel, Lot 4 (China)	-	-	Granite (4423 m), Diorite (1547 m), Limestone (3161 m), Tuffs (890 m), Sandstone (356 m), Slate (546 m), Tuff sandstone (884 m)	20.2	11.807	< 300
2	Yinhan water conveyance tunnel (China)	-	-	Phyllite (1200 m), Carbonaceous phyllite (509 m), Phyllite and meta-sandstone (3554 m), Amphibole-quartz schist (1067m)	19.98	6.33	1500
3	MINAS water conveyance tunnel (Ecuador)	-	-	Tuffs (1736 m), Diorite (3148 m), Tuffs and adamellite (402m)	11.392	5.286	600
4	Manapouri second tailrace tunnel (New Zealand)	-	Paleozoic metamorphic and igneous rocks of the Fiordland Complex	Gneiss, Calc-silicate and quartzite and the intrusive rocks (Gabbro and Diorite)	10	9.7	1200
5	Maroshi-Ruparel water supply tunnel (India)	Deccan traps (Lava flows of Basaltic rocks)	Upper traps (Upper Cretaceous to Lower Eocene)	Fine compact basalt, Porphyritic basalt, Amygdaloidal basalt, Pyroclastic rocks (Tuff, Tuff breccia) and Intertrappeans (Shale)	12.24	5.83	82
6	Zagros water conveyance tunnel, Lot 2 (Iran)	Zagros Simply folded zone	Carbonate-Argillaceous rocks of Pabdeh, Gurpi and Ilam Formations	Limestone, Shale and Limy Shales	26	15	650
7	Karaj-Tehran water conveyance tunnel, Lot 1 (Iran)	Central Alborz	Pyroclastic rocks of Karaj formation	Tuffs, Shaly and Sandy Tuffs, Agglomerate	15.9	8.7	600
8	Ghomrood water conveyance tunnel, Lots 3 & 4 (Iran)	Sanandaj-Sirjan metamorphic belt	Jurassic metamorphic rocks (low to medium grade) and Cretaceous Limestone	Limestone, Shale and Sandstone, Slate, Phyllite, Schist with Quartzitic veins	21.5	15	700
9	Kerman water conveyance tunnel, Southern Lot (Iran)	Sahand-Bazman magmatic belt (Urumieh-Dokhtar zone)	Tertiary volcanic, pyroclastic and plutonic rocks	Andesite, Andesitic Basalts, Tuff, Rhyolite, Granodiorite, Agglomerate	19.2	5.5	940
10	Golab water conveyance tunnel (Iran)	Sanandaj-Sirjan metamorphic belt	Sedimentary and Igneous rocks of Eucen to Jurassic	Periodic series of argillite shale and metamorphic sandstone, schist and amphibolite	10	8	-

2021) and Golab water conveyance tunnel (Fatemi, 2016; ICE, 2009) are in Iran.

The lithology and geological characteristics of the studied tunnels are summarized in Table 1. As seen in this table, these projects account for a wide range of geological conditions, and in terms of lithology, they contain all types of igneous, sedimentary, and metamorphic, as well as pyroclastic rocks. A wide range of engineering geological characteristics can also be identified in the rock mass along the tunnels. It has been identified from weak and crushed to massive and integrated rock masses, and from rocks with little abrasion to highly abrasive rocks. Due to the

extensive geotechnical characteristic of rock mass in the compiled database, it is possible to develop a comprehensive model for predicting the TBM performance in various geological conditions.

Table 2 shows the characteristics of the TBMs used in the studied projects. The TBMs in the tunneling projects, including Karaj (lot 1), Zagros (lot 2), Ghomrood (lot 3 & 4), Kerman (Southern lot), Golab tunnel in Iran, and MINAS in Ecuador are similar to each other to a large extent, and all of them are double-shields (Telescopic). Two machines used in the Yinsong and Yinhan projects in China are open machines. The machine used in the Manapouri is different from other

projects, an open TBM with a diameter of about 10 *m*, which is two times greater than the diameter of the machines used in other projects. In the studied tunnels, the machines have flat cutter heads, cutter head diameters ranging from 3.6 to about 10 *m*, disc cutter diameters of 432 *mm* (17 *inches*) and 483 *mm* (19 *inches*), and average cutter spacing of 62 to 90 *mm*.

3 THE DATABASE

Researchers have introduced various indicators to evaluate TBM performance. The field penetration index (FPI), introduced by Nelson et al. (1983), has been successfully used to establish the correlation between rock mass characteristics and TBM performance (Salimi et al., 2019). FPI is calculated by dividing the disc cutter load (F_n in *kN*) by the penetration rate (P in *mm/rev*). This index integrates the effects of penetration rate, disc cutter load, and revolutions per minute (RPM) into one factor. FPI is a machine-independent parameter that can be calculated and integrated from the boring data of machines of different sizes, types, and cutter loads, making it a suitable choice to evaluate TBM performance in this study due to its simplicity, measurability, and scalability across different machine sizes.

While rock mass classifications are generally designed to estimate rock mass behavior, load distribution, and design tunnel support, they are not specifically tailored for predicting machine performance in mechanized tunneling. Therefore, classification systems often include some parameters that may not be necessary for estimating the boreability properties of the rock mass, such as groundwater conditions, joint orientation, and stress-related parameters. In light of this, Hoek and Brown recommended using only the first four parameters of the RMR classification system to determine the rock mass boreability properties, comparable to what is done in GSI (Geological Strength Index) to estimate rock mass characteristics (Hoek et al., 1995; Hoek and Brown, 1997). This approach allows for a more focused evaluation of TBM performance.

The RMR classification system utilizes six parameters, including the uniaxial compressive strength (UCS), the rock quality designation (RQD), joint spacing (J_s), joint surface conditions (J_c), groundwater situation, and adjustment concerning joint orientation versus the tunnel axis, to determine the geomechanical condition of the rock mass. Each parameter is given a specific rating based on the relevant tables, and the sum of the ratings of the six parameters is known as adj-RMR. The Basic RMR is obtained from the sum of the ratings of the first five parameters, where the direction of the joints is not adjusted. Also, RMR'_{89} is calculated the same way as the Basic RMR, just the groundwater situation is always considered dry, and its rating is counted 15.

Based on previous studies, Basic RMR and RMR'_{89} have shown a stronger correlation with TBM

performance compared to adj-RMR, indicating that adjusted parameter of joint orientation does not significantly improve the correlation (Sapigni et al., 2002; Hassanpour et al., 2011; Salimi et al., 2019). The joint orientation parameter primarily relates to the stability conditions of the rock mass and does not directly indicate the ease or difficulty of tunnel boring. Although joints depending on their orientation with tunnel axis, play an important role in the propagation of cracks during excavation, previous studies indicate that establishing a clear relationship between joint orientation and machine performance is challenging (Salimi, 2021; Hassanpour et al., 2011). In fact, in blocky and layered rock masses with two or three similar joint sets (Isotropic rock mass), the joint orientation effect can be assumed to be very insignificant. The orientation of discontinuities can only affect the machine performance in cases where a main and dominant joint set, such as heavily layered and schistose rocks (Anisotropic rock mass). In this case, when the machine advances parallel to the dominant joint set, the cracks are propagated vertically to the joint surfaces and reduce the penetration rate. When the machine advances perpendicular to the dominant joint set, the rock fracture is created in line with these joint surfaces. This mode usually has the most suitable penetration conditions, as discontinuities help to create and expand cracks between two adjacent disc cutters.

In the compiled database, the majority of tunnel sections are situated in isotropic or relatively high isotropic rock masses, and the effect of joint orientation on machine performance is deemed insignificant. While recognizing the important role of joint orientation in the propagation of cracks during excavation, due to the challenges in finding the relationship between joint orientation and performance, and considering the isotropic rock masses in the database that were not appropriate to assess this parameter, the adjustment parameter of joint orientation was excluded in development of empirical equations for TBM performance prediction using RMR input parameters in this study.

To determine the parameters J_s and J_c in the RMR system, the critical joint set, which has the most significant impact on tunnel stability, must be considered. In this study, since the data were collected from mechanized tunneling projects, the critical joint set that influences machine penetration rate was identified. The α angle, representing the orientation between the critical joint set and the tunnel axis, was calculated based on the orientation of layering or schistosity surfaces, if present, or the joint set with the most significant impact on penetration rate ($\alpha = 45^\circ - 70^\circ$) in some cases in the studied projects.

According to Hassanpour et al. (2009), groundwater condition is not a directly influential parameter on the machine penetration rate. However, the mere presence of water, regardless of its quantity, can weaken the strength of the rock mass. Moreover, a high flow of water can wash away the filling materials within joints, further reducing the strength of the

rock mass. Interestingly, groundwater indirectly plays a positive role in increasing the machine penetration rate by altering the rock mass and reducing the strength of both the rock mass and the joint filling materials. Laughton (1998) and Nelson (1983) have also studied the effect of groundwater conditions on TBM performance and found that it often affects the advance rate (AR) rather than the penetration rate (P) through machine utilization. The instability of the tunnel walls is often associated with groundwater flow into the tunnel, and this is the reason for the inclusion of Gw in the RMR system. Accordingly, the groundwater condition parameter was omitted in the modeling process for developing experimental equations in this study. Ribacchi and Lembo-Fazio (2005) argued that given that the RMR classification is usually performed during the excavation of a tunnel, a more simple procedure would be to adopt a slightly modified RMR indicated as RMRP, for which a fixed value of 15 (dry condition) is given to the partial rating of groundwater condition and no correction factors related to joint orientation are applied. Eventually, two parameters of groundwater condition and joint orientation were eliminated in developing empirical equations for TBM performance prediction using RMR input parameters in this study.

It should be noted that in the weighting scheme of the RMR system, the groundwater conditions and the uniaxial compressive strength (UCS) carry equal weights. However, Salimi et al. (2019) demonstrated that the effects of these two parameters on the penetration rate and TBM performance are significantly different. By utilizing the principal component analysis (PCA) method and conducting multiple analyses with various input parameters to obtain the most influential parameters, it was found that UCS, RQD, joint spacing (Js), and joint surface conditions (Jc) have the most significant impact on TBM performance (Salimi et al., 2019).

Moreover, Farrokh et al. (2012) and Salimi et al. (2019) proposed the rock types in the form of Rock Type Code (RTC) as an input parameter in the model for prediction of the TBM performance, because the rock texture, including the cement type, the cementation degree, the shape and size of the grains, affects the machine penetration rate significantly. According to the results of sensitivity analysis and parametric study of the model proposed by Fatemi et al. (2016), the RTC parameter has a great impact on estimating the rock mass boreability. Thus, considering the previous studies, RTC was added to the model input parameters for the prediction of the TBM performance. Seven categories of Rock Type Code (RTC) classified by Hoek and Brown (1980) and Stevenson (1999) were used in this study (Table 3).

In this table, the first four categories are sedimentary rocks, the fifth is metamorphic, the sixth is igneous, and the seventh is volcanic and pyroclastic rocks. It is worth mentioning that although gneiss is a metamorphic rock, it behaves similarly to granite,

Table 3. Classification of rock types (RTC) in the database (modified from Hoek and Brown, 1980).

Rock Type	Code
Claystone, mudstone, marl, slate, phyllite, argillite	C
Sandstone, siltstone, conglomerate, quartzite	S
Limestone, chalk, dolomite, marble	L
Karstic Limestone	K
Metamorphic rocks such as gneiss and schist	M
Coarse igneous such as granite and diorite	G
Fine volcanic such as basalt, tuff, and andesite	V

especially when it has weak foliation, and accordingly, it is included in the G category in this study. Due to the absence of karstic limestone in the database, the K category has been removed.

As mentioned, four parameters of Basic RMR, i.e., UCS, RQD, Js, and Jc, as well as, RTC were used as initial input parameters to develop the experimental relationships for TBM performance prediction through the ML-based regression analysis. The frequency percentage of tunnel sections of different RTCs in the studied database is shown in Figure 1. Since the joint condition parameter (Jc) is qualitative and descriptive, it's defined based on the partial rating in RMR classification system (0 - 30) in this study. The statistical analysis of the machine performance parameters (FPI and P) and the input parameters used in the modeling (UCS, RQD, Js, and Jc) are summarized in Table 4. In the studied database, there is a wide range of FPI from 2.14 to 150 (*kN/cutter/mm/rev*) and penetration rates from 1.5 to 41.4 (*mm/rev*).

Figure 1. The frequency percentage of different RTCs in the studied database.

Since the rock texture, both grains and matrix directly affect the physical and mechanical properties of the rock, it is expected that in rocks with the same lithology, the machine performance be similar, which is why more focus is on the lithology in this study. Based on the lithology category (RTC), six lithology categories (RTC) are defined based on the available tunneling project data, including:

Table 4. Statistical analysis of TBM performance parameters and four input parameters of BRMR.

	N	1st Min.	1st Qu.	Median	Mean	3rd Qu.	Max.	Variance	Std. Deviation	Skewness	Kurtosis
FPI (<i>kN/cutter/mm/rev</i>)	523	2.14	10.49	16.68	26.37	31.50	150.0	689.11	26.25	2.31	5.89
P (<i>mm/rev</i>)	523	1.50	4.50	7.80	8.78	11.10	41.39	36.86	6.07	1.96	5.32
UCS (<i>MPa</i>)	523	4.25	38.50	65.0	80.93	120.0	300.0	3357.05	57.94	0.86	0.29
RQD (%)	523	10	45	75	67.15	90	100	708.02	26.60	-0.53	-1.03
Js (<i>m</i>)	523	0.03	0.13	0.28	0.37	0.43	2.00	0.11	0.33	1.92	3.84
Jc (Partial rating in RMR)	523	4	10	16	16.05	20	30	30.17	5.49	0.21	-0.62

- 81 tunnel sections in Class C (claystone, mudstone, marl, shale, slate, phyllite, argillite) with $FPI_{max} = 24$ (*kN/cutter/mm/rev*)
- 158 tunnel sections in Class G (coarse igneous such as granite, diorite, pegmatite, gneiss) with $FPI_{max} = 150$
- 54 tunnel sections in Class L (limestone, chalk, dolomite, marble) with $FPI_{max} = 58.26$
- 74 tunnel sections in Class M (metamorphic rocks such as amphibolite, schist, calc-silicate) with $FPI_{max} = 77.2$
- 34 tunnel sections in Class S (sandstone, siltstone, conglomerate, quartzite) with $FPI_{max} = 73.82$
- 122 tunnel sections in Class V (Fine volcanic such as basalt, rhyolite, andesite, tuff, pyroclastic) with $FPI_{max} = 141.33$

As expected, the highest FPI values were observed in igneous rocks (G), while the lowest values were measured in weak sedimentary rocks such as argillite (C).

4 METHODS

In this study, to develop empirical relationships based on input parameters of the RMR classification system, machine learning methods including regression algorithms, were implemented. The currently used AI-based models for TBM performance prediction have been based on supervised learning techniques. In these approaches, input and output parameters are trained to the algorithm, the structure of predictive models is constructed, and then the best model is selected to analyze the relationship between independent and dependent variables. In ML, mathematical algorithms try to optimize a function which is a combination of independent variables, so that the value predicted by the function becomes close to the actual value of the dependent variable. In this research, the dependent variable of machine performance (FPI) is predicted by the use of the independent variables, including the four input parameters of Basic RMR, i.e., UCS, RQD, Js, and Jc, as well as, RTC. Since the dependent variable of FPI is continuous, regression algorithms are suitable for modelling. First, the classic regression algorithm

and then more recent algorithms, including Stepwise Regression and Regularization algorithms, i.e., Lasso and Ridge Regression algorithms, are implemented on the dataset. For this purpose, the data is divided into two parts, Train and Test/Validation, and different models are applied to the Train dataset. Different generations of ML algorithms have been implemented to approach the best model so that the model generalizability is satisfied and the model works well on the data outside the range of input data and predicts correctly. If two linear regression hypotheses have been established, generalization is provided (Hastie et al., 2009).

Correlation analysis provides a general overview of the relationship between the independent variables and the dependent variable (FPI). The scatterplot and correlation matrix between variables are presented in Figure 2. As expected, the highest correlation was observed between UCS and FPI (0.74) and joint spacing (Js) and FPI (0.78), which had the greatest impact on the machine performance, followed by RQD with 0.62 and then Jc with 0.38. Previous studies including Robbins 1992, Laughton

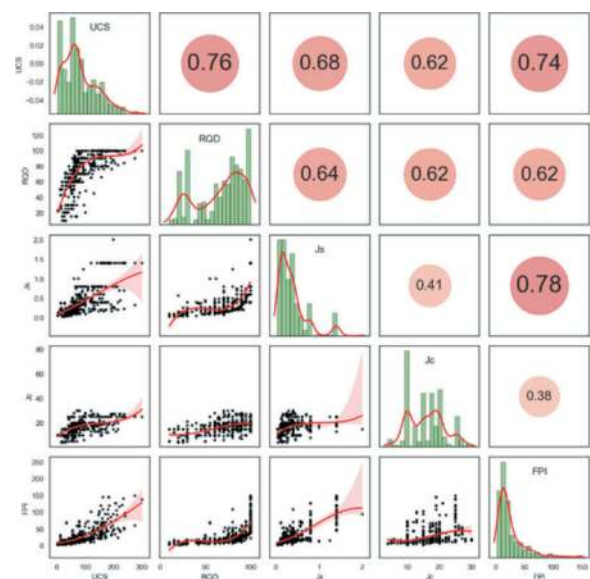

Figure 2. The scatterplot and correlation matrix between independent and dependent (FPI) variables.

1998, and Hassanpour et al. 2011, 2016, also show that UCS is a very important factor in rock boring by TBM. The correlation between independent variables themselves should also be considered because it may cause multicollinearity between variables and affect the regression coefficients, for example RQD has a correlation of 0.64 with Js, which is due to the effect of the discontinuity spacing in defining the RQD. It is important to note that the relationship between all independent input variables and FPI is positive, and with the increase of each independent variable, FPI increases.

5 DEVELOPMENT OF EMPIRICAL RELATIONSHIP FOR TBM PERFORMANCE PREDICTION

Data-based empirical relationships are widely used to predict target variables based on independent variables. In recent years experimental relationships have been valuable in rock engineering projects, because they are more practical compare to complex theoretical analyses. To develop the empirical equations of machine performance prediction, the regression algorithms were implemented on the Train dataset, which includes the FPI as the parameter for evaluating TBM performance, and the Basic RMR parameters (UCS, RQD, Js, and Jc) as well as lithology category (RTC). In this way, the input parameters of the Basic RMR system, which are often available in various tunneling projects, will be used to estimate the FPI. Since ML-based regression analysis enabled the modeling of categorical parameters in regression algorithms, the lithology category (RTC), a qualitative and categorical parameter, was included in the modeling. According to Rostami (1997), by calculating logarithmic regression, instead of linear regression, power functions are developed, and this makes the equations in boundary conditions be estimated with less error. Equation (1) is the best model obtained from training regression algorithms on the Train dataset with R^2 about 0.82. The equation was obtained to predict FPI in different lithologies, and the RTC coefficient was determined for each lithology.

$$FPI = 6.066 (UCS)^{0.25} (RQD)^{0.22} (J_s)^{0.4} (J_c)^{-0.15} (RTC) \quad (1)$$

$$(R^2 = 0.82)$$

where FPI is Field Penetration Index ($kN/cutter/mm/rev$), UCS is uniaxial compressive strength (MPa), RQD is Rock Quality Designation in percentage (0 - 100 %), Js is joint spacing (m), and Jc is joint condition in Basic RMR system and defined based on the partial rating in RMR classification system (0 - 30). As mentioned, the joint set which has the greatest impact on the TBM penetration rate, was used to determine the Js and Jc.

The T-test results of Equation (1) indicate that the P-value of Jc is greater than 0.05, and this parameter

is not signified, and it is better to be removed from the model. This decision is justified as Jc correlation with FPI was inferior to that of the other parameters. Upon removing Jc, the model was optimized, resulting in Equation (2) with the same performance ($R^2 = 0.81$). In Equation (2), FPI is estimated accurately by utilizing the three input parameters of Basic RMR and the RTC coefficient proportional to the lithology, as outlined in Table 5. The specific values of RTC in Equation (2) are detailed in Table 5. It is worth noting that in the G and V categories, which encompass a wide range of rock strengths, the tunnel sections were analyzed separately based on strength (below 150 MPa and above 150 MPa). The corresponding RTC coefficients were obtained for each strength range. Therefore, when using Equation (2) for the G and V categories, attention should be given to the UCS value, and the appropriate RTC coefficient should be used to predict FPI.

$$FPI = 5.173 (UCS)^{0.22} (RQD)^{0.19} (J_s)^{0.41} (RTC) \quad (2)$$

$$(R^2 = 0.81)$$

Another critical point is that the multicollinearity of the parameters could cause the T-test results to be unreliable because the regression coefficients may not be correctly estimated. Multicollinearity of variables in statistical analysis and machine learning is detected using the Variation Inflation Factor (VIF), and $VIF > 10$ indicates strong multicollinearity in regression (Hastie et al., 2009). The VIF of all independent variables in Equations (1) and (2) were smaller than 10. Then, the model is exposed to the Test dataset. Figure 3 illustrates the measured FPI versus the predicted FPI using Equation (2) for both Train and Test datasets, providing a visual representation of the model's performance.

Table 5. The values of RTC in Equation (2) (RTC table is modified from Hoek and Brown, 1980).

Rock Type	Code	RTC
Claystone, mudstone, marl, slate, phyllite, argillite	C	1
Sandstone, siltstone, conglomerate, quartzite	S	1.598
Limestone, chalk, dolomite, marble	L	1.325
Karstic Limestone	K	-
Metamorphic rocks such as schist	M	1.202
Coarse igneous such as granite, diorite, and gneiss	G ₁ (UCS < 150 MPa)	1.177
	G ₂ (UCS \geq 150 MPa)	1.848
Fine volcanic such as basalt, tuff, andesite, and pyroclastic	V ₁ (UCS < 150 MPa)	0.8
	V ₂ (UCS \geq 150 MPa)	1.876

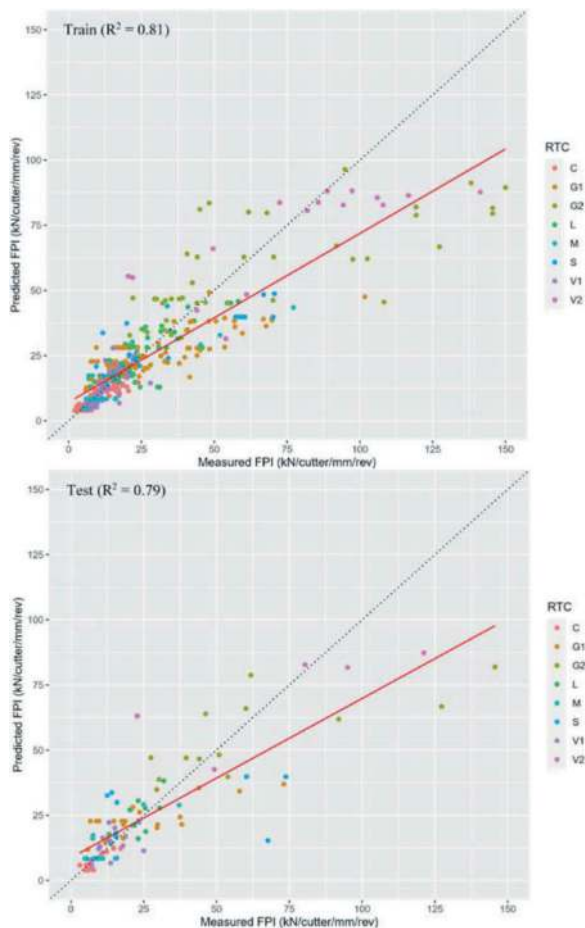

Figure 3. The measured FPI versus the predicted FPI via Equation (2) for Train and Test datasets.

6 CONCLUSION

Various experimental models have been introduced to predict the TBM performance, and many efforts have been made by various researchers to predict the TBM performance based on rock mass classification systems. The RMR classification system shows better correlation with the penetration rate of TBM, which is due to the use of UCS as the input parameter of this system. The RMR like other classification systems, has been developed to analyze the tunnel stability and support design, and the selection of effective parameters has also been accordingly. So, if the goal is to estimate the TBM performance, changes should certainly be made to the parameters. In this study, the input parameters of the Basic RMR (UCS, RQD, J_s , and J_c) and lithology category (RTC) were utilized to estimate the Field Penetration Index (FPI) through machine learning-based regression analysis. This equation can be easily used to predict FPI in all rock types accurately.

ABSTRACT: Rapid urbanisation and global callout for sustainable and resilient underground infrastructures, especially transportation and railway tunnels, are possible through digitalization approaches. Machine learning is one approach that has been used to classify and predict the solutions to a given set of problems through supervised and unsupervised algorithms. This paper proposes analysing the supervised algorithms' performance to classify the Tunnel strains and checking the strength of agreement (SOA) for the assessment metrics. These algorithms are Tree based (Decision Tree and Random Forest), Functional based (Logistic Regression and Linear Discriminant Analysis), and Margin based (Support Vector Machines: One vs One). To improve the feature dimension in the input data the encoded feature inputs are used: Rock Type, Location, and Tunnel names along with considering conventional feature inputs: Diameter, Cover Depth, Q-value, and Support Stiffness. The functional based algorithms have shown the best efficacy with improved feature space in these experiments. The improvement in accuracy for predicting training class labels with max. SOA: 0.81 observed as 14-26% whereas for testing class labels with max SOA: 0.52 observed as 8-12%. This study would contribute towards improving the performance of supervised algorithms with better feature space and reduce errors in classification of tunnel strains by these digital methods.

Keywords: Tunnel, Digital Methods, Prediction Feature Space, Tunnel Strain Classification, Strength of Agreement (SOA)

1 INTRODUCTION

The global demand of sustainable and resilient underground infrastructure eyeing for rapid urbanisation is being lead from the front by transportation and railway tunnels. The digital engineering has the calibre to cater this global call out very smoothly and rapidly. And Machine Learning is one the digital engineering aspect which strong arms the decision-making process based on the prior experience and training. This approach has shown very promising and trustworthy results in its other areas of its applications such as medical, material, management, economical, technological and communications (Ali et al. 2020; Mienye and Sun 2021). The machine learning is found to be trained and tested in tunnel and rock engineering in many literatures.

In the current trends of development of machine learning predictions for Tunnel hazards, the tunnel squeezing has caught the special focus by Chen et al. 2020; Fathipour-Azar 2022; Feng and Jimenez 2015. The tunnel squeezing is a phenomenon dependent on time involving the creep of the soft and weak rock mass especially in a highly structurally stressed environment. In this condition the tunnel walls tend to move inwards due to redistribution of stress after excavation and finally contracting the excavated cross-section. The extent and scale of squeezing depends lithological conditions, rock mass in-situ mechanics and strength.(Sheil et al. 2020; Zhang, Li, and Wang 2020). Unplanned or excessive reduction in the tunnel cross-section affects the equilibrium and stability of the tunnels. This imposes a serious safety and economical risks to the tunnel construction. Therefore,

strength of agreement and accuracy in the prediction of tunnel strain will be having an important contribution towards tunnel construction.(Sheil et al. 2020).

Monitoring the tunnel squeezing through convergence is an important aspect in the conventionally and mechanically excavated tunnels. The envelopes of wall convergence could be recorded by monitoring equipment system. This data would be then utilised to assess and select the appropriate design and supporting structures of tunnel. (Huang et al. 2017). Although the monitoring approach is one of the very effective approaches, but it was found to be very difficult to predict the actual convergence. (Zhou et al. 2023). The relationship between convergence, lithological properties, rock mechanics and strength are nonlinear which were being tried to correlate by numerous literatures using empirical relationships, numerical expressions, statistical methods, and inference systems. (Fathipour-Azar 2022). Although, each system has their own constraints and limitations if the application is generalised for the real-world problems. In contrast ML has been applied to many Tunnel engineering problems to predict the strain or the convergence of the tunnel walls such as Sun et al. 2018 applied the M-SVM approach using the H, D, Q, and K predictors and Chen et al. 2020 using the decision tree approach utilising the H, D, K, SSR, and GC predictors. The other approaches followed by several leading researchers could found in the Table 1 below for predicting the strain or convergence of the tunnel walls using different classifiers.

Following the similar trend, in this study it is aimed to classify the strain in to 3 classes non-squeezing, squeezing and severely to extremely squeezing strain ranging from class 1 to class 3. The novelty in this approach is the utilisation of the data boosting methods by introducing the bias due to tunnel name, location, and lithology of the ground. This approach is found to be contributing towards improving the precision of prediction and strength of agreement with the classification made using different algorithms. Especially in the functional based algorithms with good measure. The algorithms tested in this study are Tree based (Decision Tree and Random Forest), Functional based (Logistic Regression and

Linear Discriminant Analysis), and Margin based (Support Vector Machines: One vs One). These algorithms are described in detail in section 3 of this paper. In these algorithms the tree based, and margin-based methods are most used approaches found in the literature (Fathipour-Azar 2022; Feng and Jimenez 2015; Lu, Cheng, and Chen 2020; Sun et al. 2018). The functional based algorithms are only tested by Fathipour-Azar 2022 where the accuracy of the methods are found to be very low and unsuitable for such predictions of Tunnel strain classifications. Thus, the requirement of improving such methods and checking their final strength of agreement from training to predictions is being aimed in this study.

2 DATASET DESCRIPTION & PREDICTING FEATURES

In this study a dataset from Sun et al. 2018 with 117 datapoints are used to train and test the proposed approach for supervised algorithms. These datapoints were curated from different worldwide case studies and literatures where tunnel squeezing is the prime criteria. Based on the (Hoek and Marinos 2000) criteria where the tunnel squeezing is partitioned into total five groups from non-squeezing strain to extremely squeezing strain, here in this case that has been considered from non-squeezing strain to severe (up to extremely) squeezing strain and considered as three groups. These groups are defined as three cases from 1 to 3 and varying from $\epsilon < 1\%$, $1\% < \epsilon < 2.5\%$, and $\epsilon > 2.5\%$ respectively as shown in the Figure 1 which are the output classes as well. To verify this segregation the datapoints are conventionally trained with the decision tree based on (Fathipour-Azar 2022) approach where strain is considered as one of the inputs. The verified segregation plot could be observed from the decision tree plot where the segregation points are 2.48%, and 1% tunnel strains.

The primary input features used in this study are diameter of tunnel (D), cover depth of tunnel (H), stiffness of tunnel supports (K), and rock quality

3 SUPERVISED ALGORITHMS

Figure 1. Tunnel Squeezing classification adapted from Hoek and Marinos 2000; Sun et al. 2018.

index for excavated tunnel (Q). These are considered based prior study by Chen et al. 2020; Fathipour-Azar 2022; Sun et al. 2018. The additional features which are introduced in this study to improve the predicting capabilities of the conventional machine learning supervised algorithms are Rock Type, Location, and Tunnel names as the bias in the system. As it is observed in the data set it covers the large range of rock types and tunnels worldwide. In the dataset the case-1 to 3 datapoints are 28,16, and 49 respectively with total of 93 as training datapoints and 24 testing data points in the similar ratio after randomising and splitting. The partitioning of training and testing dataset for this study is done in 80% & 20% respectively. Also, in this study the K-fold cross validation is performed to evaluate the optimum hyperparameters of the supervised algorithms. This evaluation has been carried out after performing the fold sensitivity study. This fold sensitivity study allows to check the optimum fold at which the highest accuracy could be achieved. This provides the freedom to analyse the dataset as per its own baseline instead of following other literature. The 5-fold cross validation is found to be the optimised fold for finding the optimised hyperparameters of the supervised algorithms in this study for the dataset chosen.

This section provides the overview and brief description of the supervised algorithms used in this study. As discussed the Sun et al. 2018 dataset in this study is tested on the 4 sets of experiment. With the experience from Chen et al. 2020, Sun et al. 2018 and Zhou et al. 2022 studies the high efficacy algorithms such as decision tree and support vector machines are chosen in this study to check their efficacy to predict the tunnel squeezing class. Based on these, the other tree-based algorithms such as random forest and XG boost are also being part of this experiments along with logistic regression and linear discriminant analysis which are functional based algorithms. Thus, there are total six algorithms which are being chosen to test in this study and assess their performance based on different performance assessment metrics. These algorithms are all available online and can be easily downloaded from python sklearn official network (<https://scikit-learn.org>). The combination of experiments followed in this study are given in the table-2 below. The algorithms used in this study are briefed as follows:

3.1 Tree based algorithms

It works on the principle of recursive partitioning of the dataset into subsets at nodes and creating tree like models where end node (i.e., leaf node) gives the label or class predicted from the hyperparameters used for training. The split at the node occurs based on the least error and maintaining homogeneity of the subset. The fully grown tree with fixed nodes would be able to predict and classify the datapoints into desired classes. These trees are prone to overfit the training dataset making the classification very complex, so the pruning techniques are employed by providing the constraints on tree depths, and number of leaf nodes. The ensemble methods like random forests and gradient boosting methods are also used. The random forest works on the principle of growing forest with many

Table 2. Test combinations and planned experiments for this study.

classification trees which classifies based on the input vectors and votes for a particular class. The result of the forest choice would be from most voted class. (Hastie, Friedman, and Tibshirani 2001).

In this study the decision tree, random forest, and gradient boosting (XG boost) methods are employed as Tree based supervised algorithms.

3.2 Functional based algorithms

It works on the principle of defining a hypothesis based on the input features and target variables or classes in the linear regression function. Here the decision boundary distinguishes between class k and l with the sets of input feature points for which $\hat{f}_k(x) = \hat{f}_l(x)$ where the dataset is divided into k classes, and it's fitted as a linear or nonlinear function. Here since the input feature space is divided into regions of constant classification and piecewise hyperplane decision boundaries. Here the regression approach is a member of a class of methods that model discriminant functions $\delta_k(x)$ for each class and then classify the x to the class of the largest value for its discriminant function. (Hastie et al. 2001) These functions could be linear discriminant, quadratic discriminant, regularised discriminant, and logistic regression. The classification in these methods is done based on maximum likelihood of any class with least error. The likelihood functions here are developed using the conditional likelihood which specifies the conditional distribution and appropriate for multinomial distribution for any N number of observations.

In this study the linear discriminant analysis and logistic regression analysis methods are utilised for tunnel strain classification. Since these methods are observed to be performing poorly in Fathipour-Azar 2022 study and could be further improved with data boosting feature space as done in this study.

3.3 Margin based algorithm

In margin-based algorithm, support vector machine in this case, the decision boundary is chosen to be the one for which the margin is maximised. In this method the optimal decision boundary also known as hyperplane in this case maximises the margin between datapoints of different classes. It works on the principle of finding the best hyperplane which distinguishes the data points into k classes by using the support vectors. Mathematically linearly separable datasets described by $w^T x + b = 0$ where w : weight vector perpendicular to hyperplane, x : input data and b : bias term. The distance between the hyperplane and support vector is computed as the margin and inversely proportional to weight vector ($\|w\|$). Maximising the margin translates in to minimising the norm of the weight vector and satisfying the constraints. The SVM can also be extended to nonlinearly separable data using the kernels. It implicitly maps the inputs into

a higher dimensional space making it linearly separable. This approach allows the SVM to handle the nonlinear and complex classification very well. (Bishop 2006).

In this study the kernel tricks are used in the support vector machines with one vs one strategy for the tunnel strain classification. The results observed in the experiments are discussed in detail in the section 6 of this paper.

4 PERFORMANCE ASSESSMENT METRICS

In this study to evaluate the performance of different algorithms developed for this paper are assessed on these metrics: Accuracy, Precision, Recall, F1 score, and Cohen's kappa metric (strength of agreement: SOA). From the confusion matrix (CM) as shown below the true positive (TP), false positive (FP), true negative (TN) and false negative (FN) are used to evaluate the algorithms on these metrics. Where TP and TN are the cases when the predicted and actual class of the data point matches i.e., the right classification of a certain class, and FP and FN are the cases when the predicted class is misclassified. For e.g.: If a data point is of actually class-1 and it is classified or predicted as class-1 then it's the case of TP, or if it is classified as class-2/3 it is the case of FN. Also, if as per the actual classification it is class2/3 and it is classified as same then its TN or else FP with reference to class-1 classification. The representation of these metrics mathematically are as follows:

		<i>Class-1</i>	<i>TP</i>	<i>FN</i>
	<i>Actual</i>	<i>Class-2/3</i>	<i>FP</i>	<i>TN</i>
<i>CM</i>	=		<i>Class-1</i>	<i>Class-2/3</i>
<i>Confusion Matrix</i>			<i>Predicted</i>	

$$\text{Trace (CM)} = TP + TN$$

$$\text{Sum (CM)} = TP + FP + TN + FN$$

$$\text{Accuracy} = \text{Trace (CM)} / \text{Sum (CM)}$$

$$\text{Precision, } P = TP / (TP + FP)$$

$$\text{Recall, } R = TP / (TP + FN)$$

$$\text{F-measure} = 2P * R / (P + R)$$

Where:

Cohen's kappa

(Cohen 1960;

Tallón-Ballesteros and Riquelme

2014)

$$= \frac{N \sum_{i=1}^m CM_{ii} - \sum_{i=1}^m C_{i\text{corr}} C_{i\text{pred}}}{N^2 - \sum_{i=1}^m C_{i\text{corr}} C_{i\text{pred}}}$$

TP = True Positive; TN = True Negative

FP = False Positive; FN = False Negative

N = Total data points in confusion matrix (CM)

Also, $N = \text{Sum (CM)}$

CM_{ii} = i^{th} diagonal element of confusion matrix (CM)

$C_{i\text{corr}}$ = Sum of all elements in the i^{th} row of the correct or actual class

$C_{i\text{pred}}$ = Sum of all elements in the i^{th} column of the predicted class

The Cohen's kappa metric which is also called the strength of agreement for the predicted classes with respect to the actual classes is a statistical test, which was initially used for inter-rater reliability. Now a days it is utilised for comparing the accuracy of Machine learning algorithms to any random classifier. (Mienye and Sun 2021). The expression given above for the multiclass classification scheme is adapted from (Cohen 1960; Tallón-Ballesteros and Riquelme 2014) and its interpretation for multiclass for this study is referred to (Wardhani et al. 2019). In this interpretation different scales of strength of agreement are detailed as follows:

Table 3. Cohen's Kappa Analysis (Wardhani et al. 2019).

Kappa score range	Strength of Agreement
<0.00	Poor
(0.00, 0.20]	Slight
(0.20, 0.40]	Fair
(0.40, 0.60]	Moderate
(0.60, 0.80]	Substantial
(0.80, 1.00]	Almost Perfect

5 PROPOSED APPROACH

In this study as discussed earlier a total of six algorithms are chosen to test and assess their performance based on different assessment metrics. For these algorithms along with the data available as the conventional inputs such as depth (H), Diameter (D), Rock quality index (Q-value), and Support Stiffness (K), the text inputs such as the Tunnel name, lithology and location inputs are proposed to be used in this study. These informational and numeral inputs will improve the predicting capability of the machine learning models which is a hypothesis for performing this study. The flow chart of the process of performing the training and then predictions in this study is given in the Figure 2 below. In this flow chart the start to end process has been detailed. It is a generalised flow chart for this study. For the EX1 and EX3 the text inputs will not be utilised and hence those steps to be ignored in especially EX1 and EX3 tests. And sensitivity test for K-fold cross validation has also been proposed as

a part of this study. Since, it has been observed in other literature that K-fold cross validation is being performed based on prior experience and literatures referred. Whereas the K-fold cross validation could be limited to certain number of folds to have an optimum performance of the model because each dataset performs differently on each model and hence the sensitivity study could actually help in fixed K-folds for respective dataset. For this dataset the 5fold cross validation is found to be optimum and proposing the same for future use of this dataset.

6 RESULTS AND DISCUSSION

6.1 Assessment results

As discussed in the previous section there are 4 sets of experiments in this study where with each step the predicting capability is assumed to be improved.

6.1.1 EX1 results

Starting with the first set of experiments the training accuracy of the tree-based algorithms are found to be perfectly fitting all the data points in the training with accuracy of 100% and testing accuracy of 75%, 75%, and 83% for DT, RFDT, and XGBDT respectively. Whereas the accuracy for LOGRE, LDA and SVMOVO are found to be 71%, 63% and 71% for training dataset and 63%, 54%, and 54% for testing dataset respectively. Similarly, looking at SOA metric for tree-based algorithms in both training and testing dataset it is varying from substantial SOA to almost perfect SOA except for XGBDT performance on testing dataset which is in moderate SOA range as observed from the Figure 4 to 7, whereas for both functional based and margin-based algorithm its varying from fair SOA to moderate SOA.

6.1.2 EX2 results

In this experiment the training accuracy of the tree-based algorithms are found to be perfectly fitting all the data points in the training with accuracy of 90.3%, 97.8%, and 97.8% and testing accuracy of 75%, 75%, and 70.8% for DT, RFDT, and XGBDT respectively. Whereas the accuracy for LOGRE, LDA and SVMOVO are found to be 84.9%, 89.2% and 88.2% for training dataset and 70.8%, 66.7%, and 62.5% for

testing dataset respectively. Similarly, looking at SOA metric for tree-based algorithms in both training and testing dataset it is varying from substantial SOA to almost perfect SOA as observed from the Figure 6 and 7, whereas for both functional based and margin-based algorithm its varying from moderate SOA to substantial SOA. Exceptionally for LDA the SOA for both training and testing is in fair SOA range only.

6.1.3 EX3 results

In this experiment the training accuracy of the tree-based algorithms are found to be perfectly fitting all the data points in the training with accuracy of 90.3%, 94.6%, and 97.8% and testing accuracy of 75%, 79.2%, and 70.8% for DT, RFDT, and XGBDT respectively. Whereas the accuracy for LOGRE, LDA and SVMOVO are found to be 88.2%, 89.2% and 88.2% for training dataset and 70.8%, 66.7%, and 70.8% for testing dataset respectively. Similarly, looking at SOA metric for tree-based

algorithms in both training and testing dataset it is varying from substantial SOA to almost perfect SOA as observed from the Figure 6 and 7, whereas for both functional based and margin-based algorithm its varying from moderate SOA to substantial SOA. Exceptionally for LDA the SOA for both training and testing is in fair SOA range only.

6.1.4 EX4 results

In this experiment the training accuracy of the tree-based algorithms are found to be perfectly fitting all the data points in the training with accuracy of 90.3%, 94.6%, and 97.8% and testing accuracy of 75%, 79.2%, and 70.8% for DT, RFDT, and XGBDT respectively. Whereas the accuracy for LOGRE, LDA and SVMOVO are found to be 88.2%, 89.2% and 88.2% for training dataset and 70.8%, 66.7%, and 70.8% for testing dataset respectively. 6.2 Discussion on patterns recognised

- The improvisation observed from the EX1 to EX2 performance of the algorithms are: for both functional and margin-based algorithms both train and testing accuracy along with kappa score are improved as observed from the Figure 6 and 7. These improvement in accuracy are 14% to 26% in training and 8% to 12% in the testing dataset as observed in section 6.1.1 and 6.1.2. Also, for the tree-based algorithm the accuracy and kappa score for both training and testing has been observed to be reduced a little because of introduction of new inputs as one hot encoding

which might not be performing well in the feature space of these algorithms.

- While comparing the EX1 to EX3 results it is observed that all algorithms have improved their accuracy and kappa score. Especially the DT accuracy on testing has been improved by 8% and kappa score by 13% and for the margin-based algorithms the testing accuracy has been improved by 11% and kappa score has been improved by 27%.
- In comparison between the EX2 and EX3 results the functional based and margin-based algorithms are performing better in EX2 along with XGBDT which is a tree-based algorithm and other tree-based algorithms are performing better in EX3 in both training and test phases.
- In the last phase EX4 the functional based algorithms LOGRE and LDA are improved greatly improved as compared to EX1 where their testing kappa score was very low in the range of random prediction only (<0.25), in the EX4 it came in the moderate SOA range by improving from 0.25 to 0.443 and 0.214 to 0.529 SOA along with improved testing accuracy from 62.5% to 70.8% and 54.2% to 66.7% respectively. While the testing accuracy for the SVMOVO improved from 54.2% to 70.8% with change in SOA from 0.214 to 0.529 SOA which are very good improvement both qualitatively and quantitatively. But, in the tree-based algorithms only RFDT has shown some improvement in testing accuracy from 75% to 79.2% and in terms of SOA from 0.593 to 0.669 SOA whereas both DT and XGBDT has shown slight decrease in their performance indicating towards unsuitable feature space for them. Here the precision signifies the TP predictions in the respective class whereas the recall signifies the TP in that overall class actually and F1 signifies the trade-off between these two. As observed from the Figure 8 for precision the class-2 strains are not well recognised in all the algorithms whereas in the recall and F1 score plot especially for SVMOVO and LDA it is behaving like binary class prediction only in EX1 results. In the EX4 results finally this class got some recognition and false predictions are decreased. As the misclassifications observed during the EX1 are as shown in the Figure 9 below compared to the EX4 results in the form of confusion matrix for better understanding.
- In the initial patterns observed in this study the 8 & 10-fold cross validation were adapted referring to previous studies by Chen et al. 2020; Fathipour-Azar 2022; Sun et al. 2018 but while performing the experiments it has been observed that choosing a fold for cross-validation might sometime reduce the overall accuracy of the algorithm and the requirement of optimum fold for cross validation was felt. So, a sensitivity study is performed as part of fold optimisation technique to have an optimum result and check the optimum performance of the algorithms as shown in Figure 10.

Figure 8. Precision, Recall, and F-measure plot for EX1 and EX4.

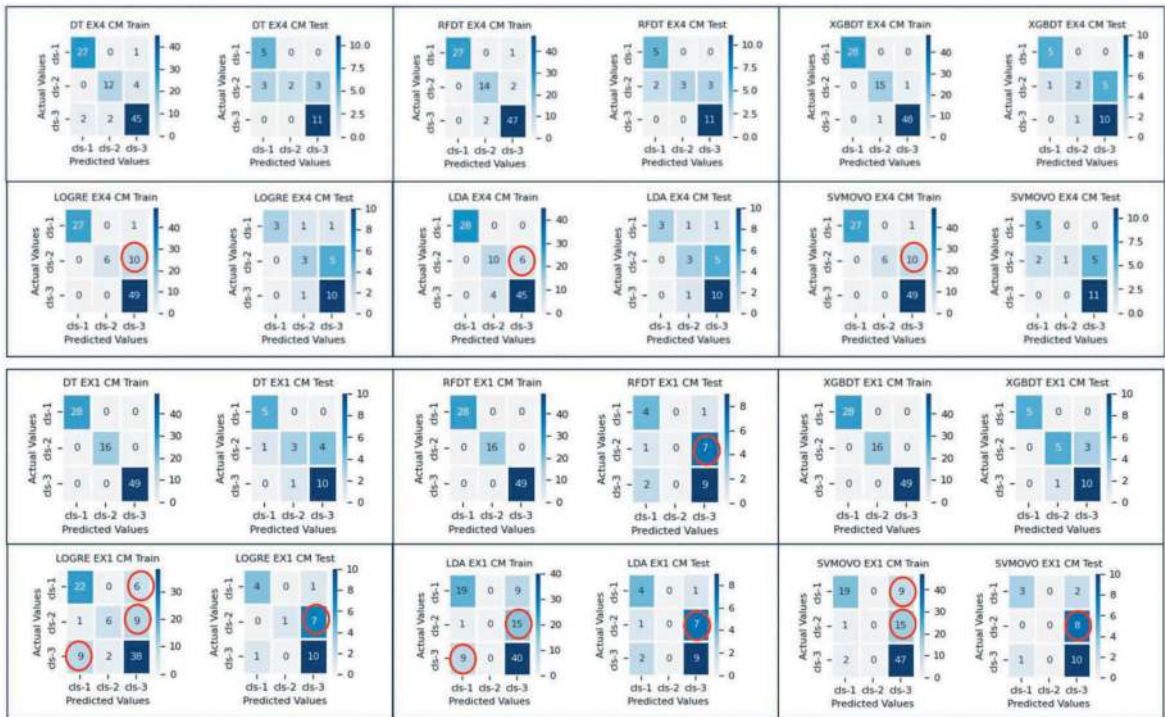

Figure 9. Confusion Matrix plot for EX1 and EX4 performance on training and testing dataset (Misclassifications >5 marked in red).

7 CONCLUSIONS

The major conclusions found in this study are:

- Hypothesis for data boosting encoded parameters is found to be true substantially for functional based algorithms and slightly for Random Forest (Tree based algorithm)
- The contribution of the new encoded parameters is evident from the EX2 tests in the initial phases.
- The overall improvement in accuracy for functional based algorithms for predicting training class labels with max. **SOA: 0.81** observed as **14-26%** whereas for testing class labels with max **SOA: 0.52** observed as **8-12%**.
- 5-fold CV found to be optimum in a **sensitivity study on K-fold cross-validation (CV)**

- Also, the precision, recall and F measure in predicting TP in class-2 & trade-off between the other classes in overall classification is greatly recognised in this study as observed from Figure 8.

Hence this study is contributing towards improved performance of supervised algorithms with better feature space in tunnel strain classification by digital methods.

ABSTRACT: Tunnel lining crack is a crucial indicator of tunnels' safety status. Aiming to classify and segment tunnel cracks with enhanced accuracy and efficiency, this study proposes a two-step deep learning-based method. An automatic tunnel image classification model is developed using the DenseNet-169 in the first step. The proposed crack segmentation model in the second step is based on the DeepLabV3+, whose internal logic is evaluated via a score-weighted visual explanation technique. Proposed method combines tunnel image classification and segmentation together, so that the selected images containing cracks from the first step are segmented in the second step to improve the detection accuracy and efficiency. The superior performances of the two-step method are validated by experiments. The results show that the accuracy and frames per second (FPS) of the tunnel crack classification model are 92.23% and 39.80, respectively, which are higher than other convolutional neural networks (CNN) based and Transformer based models. Also, the intersection over union (IoU) and F1 score of the tunnel crack segmentation model are 57.01% and 67.44%, respectively, outperforming other state-of-the-art models. Moreover, the provided visual explanations in this study are conducive to understanding the "black box" of deep learning-based models. The developed two-stage deep learning-based method integrating visual explanations provides a basis for fast and accurate quantitative assessment of tunnel health status.

Keywords: Tunnel crack, Deep learning, Image classification, Semantic segmentation, Visual explanation

1 INTRODUCTION

Due to the issues of traffic congestion and increased population, numerous transportation infrastructures have been constructed and operated during the past decades (Jiang et al., 2023; Feng et al., 2023). With advantages such as high construction efficiency, high flexibility, low resource consumption, and minor environmental disturbance, tunnels have been widely used and become the core infrastructures (Zhang et al., 2023). However, the tunnels in service, as geotechnical infrastructures, are inevitably subjected to the joint

action of adjacent excavation disturbance, untimely maintenance, deterioration of materials, temperature variation, improper construction, and groundwater (Feng et al., 2023). Various defects, such as crack, leakage, and spalling, often occur on the tunnel linings, necessitating timely inspection and management.

Numerous statistical results show that lining crack is one of the most severe defects in tunnel engineering (Huang et al., 2022). The occurrence of cracks on the lining surface will affect the reliability and integrity of the tunnel structure to an extent, thereby causing water leakage, concrete corrosion, and

*Corresponding author: fengyongtj@tongji.edu.cn

reduced lining-bearing capacity of tunnels. Without limiting their expansion, cracks may lead to serious safety accidents (Zhou et al., 2023). Hence, it is necessary to carry out regular crack inspections to ensure the long-term stability and safety of the tunnels. Traditionally, tunnel crack detection relied on manpower. However, the necessity of active use of intelligent recognition technology for tunnel lining cracks has been emphasized due to the low accuracy, low efficiency, high subjectivity, and high risk of manual visual inspections. Deep learning, especially convolutional neural network (CNN), which has made a paradigm shift recently, provides unprecedented opportunities to facilitate fast, accurate, and automatic recognition of tunnel lining cracks.

In the past, many researchers have delved into CNN-based approaches for tunnel lining crack identification. Huang et al. (2018) established a two-stream algorithm based on FCN, where one stream was employed to segment the cracks by sliding-window-assembling operation, and the other was used to segment leakages by resizing-interpolation operation. Yang et al. (2018) also adopted FCN to semantically identify and segment pixel-wise cracks at different scales, and then utilized traditional digital image processing techniques to quantitatively measure the morphological features of cracks. Miao et al. (2019) proposed a novel semantic segmentation by integrating the UNet with squeeze-and-excitation and residual learning blocks to segment crack and spalling defects. Following the same design paradigm, Hou et al. (2021) and Dang et al. (2022) also improved the UNet through adding residual learning units to complete the tunnel lining crack segmentation task. In the work of Gao et al. (2019), an optimal adaptive selection model (RetinaNet-AOS) based on RetinaNet was developed for semantic segmentation on tunnel lining crack images. Xu and Yang (2019) implemented crack identification by means of Mask R-CNN, which has been widely used in the field of tunnel lining defect detection. Similar to the tasks completed by the Mask R-CNN, Zhao et al. (2021) presented an improved PANet model to obtain refined crack segmentation results, achieving complete separation of cracks from the lining backgrounds. After that, Zhou et al. (2022) applied YOLOv4 enhanced by EfficientNet and depth-wise separable convolution to detect three types of tunnel lining defects, i.e., crack, water leakage, and rebar-exposed. Considering the excellent detection performance of the YOLO series models, Liu et al. (2022) coupled YOLOv5 with a transfer learning technique to localize the cracks in the road tunnel lining images.

Based on the above, it can be summarized that existing studies have achieved outstanding results in tunnel lining defect identification by investigating more perfect algorithms or improving existing ones. However, in real-world applications, it is common that image acquisition devices acquire a large amount of lining image data, including abundant normal (defect-free) images and anomalous (crack) ones. The existing engineering requirement is to efficiently,

accurately, and automatically identify cracks from massive amounts of tunnel image data, which has become a considerable and urgent challenge for previous research. Most of the available studies directly treat the crack recognition problem as a single-attribute classification or separately strive to find the locations or areas of the cracks as a localization or segmentation problem. To address these limitations, this study proposes a tunnel lining crack recognition framework in a two-stage manner, which combines image classification and segmentation. The purpose of tunnel lining image classification is to determine whether the image contains cracks, while the aim of tunnel lining crack segmentation is to extract cracks from backgrounds in crack images, which are different in definition. Image classification is much easier than crack segmentation. Specifically, the image classification task classifies the tunnel lining images as defect-free or crack ones, while the segmentation task getting the crack pixels from images is much more complex and time-consuming. Consequently, a tunnel lining image classification model named DenseNet-169 is adopted in the first stage to classify and save the images containing cracks. Another tunnel lining crack segmentation model called DeepLabV3+ is exploited in the second stage to process the crack images and isolate the cracks from backgrounds.

Nevertheless, deep learning models also have deficiencies and limitations, such as being considered as ‘black box’ models, which have trouble in explaining physically and rely heavily on hyperparameter settings. To account for mechanisms behind the ‘black box’ of the crack segmentation model and build trust in deep learning models, this study employs an advanced visual interpretation technology, i.e., score-weighted class activation mapping (Score CAM) (Wang et al., 2020). The motivation behind Score CAM is to generate heatmaps highlighting meaningful regions to intuitively explain the CNN-based models’ internal mechanism.

2 METHODOLOGY

2.1 *Framework for tunnel lining crack identification*

This study designs the tunnel lining crack recognition framework in a two-stage manner, which is shown in Figure 1. In the beginning, the tunnel lining images collected from practical tunnel engineering are fed into the automatic classification stage, where an image classification model is responsible for selecting and saving crack images from massive tunnel lining image data. Specifically, the DenseNet-169 model takes the lining image as an input and outputs two probabilities to determine whether the image belongs to a crack or defect-free image. Subsequently, the images containing cracks are further input into the second stage to isolate the cracks from the backgrounds. That is, the DeepLabV3+ model is dedicated to identifying the pixels belonging to cracks in the

images. Through these two stages, cracks' locations and geometric shapes are extracted with high precision and efficiency. The deep learning models employed in each stage are described in detail in the following subsections. Moreover, a CNN explanation step is also incorporated into the overall framework to understand the operational mechanism of the segmentation model and build trust in CNN.

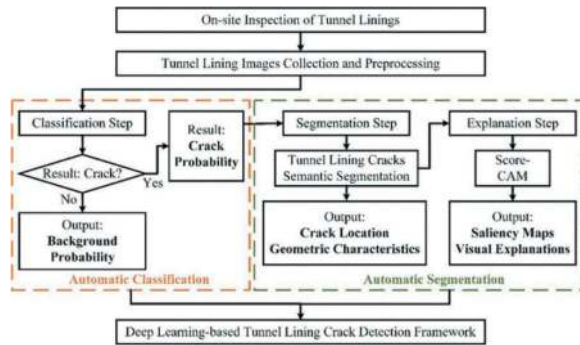

Figure 1. Pipeline of tunnel lining cracks identification.

2.2 Tunnel lining image classification model

Powered by the successful application of dense convolutional network (DenseNet) (Huang et al., 2018), this study employs DenseNet-169 as the automatic classification model for tunnel lining images in the first step. DenseNet is a type of convolutional neural network that directly connects all layers (with matching feature-map sizes) with each other for maximum information flow between layers in the network. In particular, each layer obtains additional inputs from all preceding layers and passes on its feature maps to all subsequent layers, as observed in Figures 2 and 3.

Figure 2. Architecture of DenseNet.

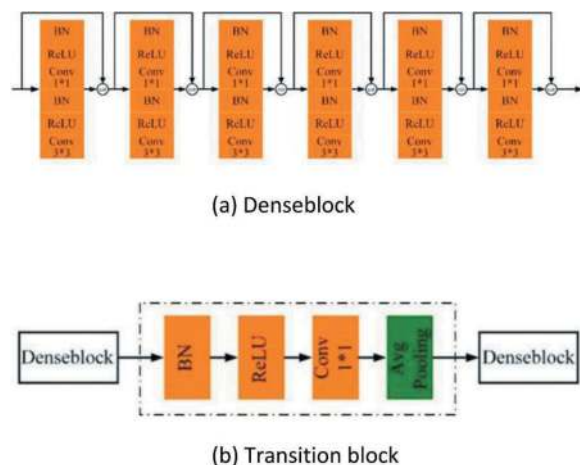

Figure 3. Details of modules in DenseNet.

DenseNet is a multi-stage architecture where the first stage consists of a standard 7×7 convolution, batch normalization, ReLU activation function, and maximum pooling, followed by four stages consisting of Denseblocks and three stages composed of Transition blocks, and finally, a global average pooling layer and a fully connected layer responsible for outputting the predictions. DenseNet-169 is one of the DenseNets, containing 6, 12, 32, and 32 Denseblocks in four stages, respectively. It is worth pointing out that the cross entropy function is chosen as the model's loss function.

2.3 Tunnel lining crack segmentation model

After selecting images containing cracks from a large number of tunnel lining images, a crucial task is to segment the cracks from the images in an end-to-end and pixel-to-pixel manner. To this end, DeepLabV3+ (Chen et al., 2018) serves as the crack segmentation model in the second step. Like most semantic segmentation models, the DeepLabV3+ model comprises an encoder and a decoder, with the overall architecture shown in Figure 4.

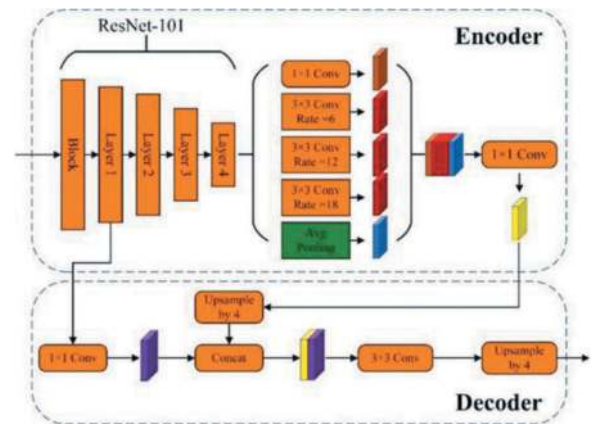

Figure 4. Overall architecture of the DeepLabV3+ model.

ResNet-101 (He et al., 2016) is used as the backbone structure to extract shallower features containing spatial information and deeper features containing semantic information for tunnel lining cracks. Concretely, the ResNet-101 includes a 'Block' for down-sampling operation with a factor of four, followed by 'Layer 1', 'Layer 2', 'Layer 3', and 'Layer 4' for feature extraction. The innovation of the DeepLabV3+ model is the atrous spatial pyramid pooling (ASPP) in the encoder. Discontinuity problem is prevalent in crack segmentation tasks. The reason for this phenomenon is the loss of multi-scale information about the cracks. To compensate for this deficiency, the ASPP structure is created with multiple dilated convolutions. For a dilated convolution with a dilation rate of d and kernel size of N , the receptive field reaches the same as that of a standard convolution with a kernel size of $(N-1) \times d + 1$. As a result, dilated

convolution is capable of increasing the receptive field while maintaining the size of the feature maps, thereby reducing the loss of crack feature information caused by consecutive convolution and pooling down-sampling operations. In ASPP, three dilated convolution operations with dilation rates of 6, 12, and 18 conduct multi-scale sampling on the feature maps output by ResNet-101. In addition, the ASPP integrates a 1×1 standard convolution operation and an average pooling operation, which together with the dilated convolutions, form feature maps containing multi-scale information about the cracks. A 1×1 convolution then processes the features to realize further feature extraction and dimensionality reduction. In the decoder, the shallow features generated by ‘Layer 1’ of ResNet-101 are collected and then concatenated with upsampled deep features obtained from ASPP. Skip connection enables the deep learning model to combine local spatial features of cracks with global context information, thus further relieving the discontinuity problem in crack segmentation. Fused features are then subjected to successive 3×3 convolution and $4 \times$ bilinearly upsampling operations to restore the size of the original input image and produce the final semantic segmentation result.

Last but not least, the loss function is also crucial in segmenting tunnel lining cracks. Tunnel lining cracks are slender and small targets in the image compared to the background. To put it differently, the crack pixels are much less than the background pixels in tunnel lining images. Therefore, the imbalanced data will make the segmentation model biased towards the background class rather than cracks. To address this issue, dice loss is selected as the loss function of the DeepLabV3+ model.

2.4 Visual explanation methods

As described before, this study aims to understand and explore the mechanisms behind the ‘black box’ of the crack segmentation model. An advanced visual interpretation technology, i.e., Score CAM, is leveraged, and its detailed processing steps are as follows.

Given the CNN model (i.e., DeepLabV3+ in this study) $Y = f(X)$ that takes X as an input and outputs a scalar result Y . We select a targeted convolutional layer l in f and the corresponding activations as A . Define the k -th channel of A_l as A_l^k . Given a known baseline input X_b , the contribution of A_l to Y is expressed as follows.

$$C(A_l^k) = f(X \circ H_l^k) - f(X_b) \quad (1)$$

$$H_l^k = s(Up(A_l^k)) \quad (2)$$

where $Up(\cdot)$ represents the up-sampling operation of A_l into the input size. $s(\cdot)$ denotes the normalization operation converting each element in the input matrix to the interval $[0, 1]$.

For a class of interest c (i.e., crack in this study), $Score-CAM_{Score-CAM}^c$ is defined as follows.

$$L_{Score-CAM}^c = ReLU\left(\sum_k C(A_l^k)A_l^k\right) \quad (3)$$

Define a weight coefficient $\alpha_k^c = C(A_l^k)$, then the equation (3) can be abbreviated to equation (4).

$$L_{(Score-CAM)}^c = ReLU\left(\sum_k \alpha_k^c A_l^k\right) \quad (4)$$

Based on the above steps, visual heatmaps can be acquired to understand the crack segmentation model’s internal structure and decision-making mechanism.

3 DATA

All experiments in this study were carried out based on an open-source dataset named NUAACrack-2000 (Qiu et al., 2022; Zhang et al., 2021), where the tunnel lining images were captured in China. On the basis of the NUAACrack-2000, two datasets were established: one was exploited for training and testing of the DenseNet-169 model, and the other for training and testing of the DeepLabV3+ model.

Figure 5 illustrates the typical crack and defect-free images in the image classification dataset, and Table 1 summarizes the number of different types of images. A total of 1942 images with a pixel size of 512×375 were divided into training set, validation set, and testing set according to a ratio of 7:2:1.

Figure 5. Examples of tunnel lining image classification dataset.

Table 1. Dataset for image classification experiment.

	Training	Validation	Testing	Total
Background	333	94	47	474
Crack	1029	293	146	1468
Total	1362	387	193	1942

After that, 1468 crack images and their ground truths made up the semantic segmentation dataset, as shown in Figure 6. Each crack image corresponds to a label, which was used to supervise the training of the segmentation model. These crack images were also partitioned based on the holdout approach in a ratio of 7:2:1. That is, 1028 images were used for training, 294 images for verification, and the remaining 146 images for testing.

Figure 6. Examples of crack segmentation dataset.

4 EXPERIMENT

The experiments in this study mainly involve two parts: image classification and crack segmentation. In the first part, the image classification dataset was utilized to train and test the DenseNet-169 model. In the second part, the crack segmentation dataset was used for the training and testing of the DeepLabV3+ model. Comparative experiments with other dominant models and visual explanations were also included in this section.

4.1 Experimental environment

Experiments were conducted under the computer configurations of the Windows 10 operating system, one NVIDIA GeForce RTX 3090 graphics processing unit (GPU), and one Intel Core i9-12900KF central processing unit (CPU). Python 3.8.12, Pytorch 1.12.0, CUDA 11.6, and CUDNN 8.3 constitute the computation software environment.

4.2 Tunnel lining image classification experiment

4.2.1 Evaluation criteria

This study adopted two commonly used measures, accuracy and frames per second (FPS), to evaluate the performance of the classification model.

4.2.2 Model training and testing

To accelerate training speed and save computational resources, all images in the classification dataset were resized to 224×224 before being input into the model. The batch size was set to four; that is, the model processed four images simultaneously in each iteration. To ensure the convergence of the model, the training epoch is determined to be 100. The learning rate is another important hyperparameter. For the purpose of finding the global minimum of the deep learning model, a dynamic learning rate schedule was adopted instead of a constant learning rate. Specifically, the initial learning rate of 0.005 was decreased every ten epochs with an attenuation factor of 0.1. After completing training, the performance evaluation of the model was performed on 193 testing images. Figure 7 intuitively displays the predicted results of the DenseNet-169 model on several images in the testing set. As seen in Figure 7, the deep learning model automatically outputs two probability values for each image and then determines the image's category. The first row in Figure 7 lists four images classified as background, and the second row shows the

examples identified as crack images. Through calculation, the accuracy of the DenseNet-169 model reaches 92.23%, and the FPS reaches 39.80.

Figure 7. Predictions of DenseNet-169 on several testing images.

4.2.3 Comparison with other models

For the sake of further evaluating the classification performance of the DenseNet-169 model for tunnel lining images, six state-of-the-art deep learning models were implemented for comparison. The models used for comparison include CNN-based models and visual Transformer-based models, namely DenseNet-201, EfficientNet-B0, ResNet-50, ResNet-101, Swin Transformer, and Vision Transformer. As reported in Table 2, the DenseNet-169 outperforms the other six deep learning models in terms of accuracy, as reflected in the 2.07%, 16.58%, 17.10%, 18.65%, 16.58%, and 16.58% improvement over DenseNet-201, EfficientNet-B0, ResNet-50, ResNet-101, Swin Transformer, and Vision Transformer.

Table 2. Results of image classification experiments.

Models	Accuracy (%)	FPS (f/s)
DenseNet-169	92.23	39.80
DenseNet-201	90.16	35.60
EfficientNet-B0	75.65	40.77
ResNet-50	75.13	60.22
ResNet-101	73.58	51.68
Swin Transformer	75.65	42.48
Vision Transformer	75.65	69.64

DenseNet-169 incorrectly classified 12 crack images as defect-free images. As for Swin Transformer and Vision Transformer, these two models wrongly classified all defect-free images as crack images, resulting in the lowest accuracy. The reason for this is inferred to be twofold: on the one hand, the small size of the classification dataset used in this

paper prevents the self-attention mechanism in the visual Transformer from realizing its potential, and on the other hand, the imbalance in the number of positive and negative samples leads to a bias in the recognition ability of the models towards the crack images.

From the perspective of the running speed of the models, the FPS of DenseNet-169 is higher than that of DenseNet-201 but lower than that of other models. Improving the running speed of the classification model deserves further research in the future.

4.3 Tunnel lining crack segmentation experiment

4.3.1 Evaluation criteria

This study exploited four metrics widely used in semantic segmentation tasks, i.e., precision, recall, F1 score, and Intersection over Union (IoU), to comprehensively assess the crack segmentation models.

IoU and threshold d were introduced to compare the similarity between two arbitrary cracks. For crack images, the IoU between the segmented crack and ground truth was calculated to judge whether the crack has been detected. Generally, the threshold d was set to 0.5 (Liu and Wang, 2022). In this study, when the IoU is greater than 0.5, it is considered that the model has detected out the crack; otherwise, it is not. IoU also served as the primary evaluation indicator for segmentation models in this paper.

4.3.2 Model training and testing

During the training process, the original images were first resized to 512×384 pixels, which would not cause a large amount of calculation and is easy to work with. Accordingly, the batch size was set as 8. The learning rate was also dynamically adjusted, with a value of 0.001 for the first 50 epochs and 0.0001 for the last 50 epochs. A total of 100 rounds of training ensured the convergence of the crack segmentation models. After each round of training, the model was evaluated on the validation set, and the training and validation loss curves were recorded in Figure 8. It can be seen from Figure 8 that the training loss declines rapidly over the first ten epochs, then slowly decreases in the next 40 epochs, and stabilizes around 0.2 over the last 50 epochs. Validation loss shows fluctuations in the first 50 epochs and stabilizes in the next 50. Based on the values of the loss function on the validation set, the optimal trained model was determined and saved accordingly.

The best-trained model was tested using crack images in the semantic segmentation dataset, and the results showed that the DeepLabV3+ model achieved 57.01% IoU, 67.44% F_1 score, 62.95% precision, and 82.12% recall. There is a significant gap between the precision and recall of the DeepLabV3+ model. It should be emphasized that deep learning models must detect all cracks as much as possible from the perspective of engineering applications. Hence, it is reasonable to improve the recall of tunnel lining crack segmentation during practical inspection tasks, even at the expense of precision (Ren et al., 2020).

Figure 8. Visualization diagram of loss curves of DeepLabV3+ model during training and validation process.

4.3.3 Comparison with other models

Extensive comparative tests were completed to further verify the applicability and superiority of the DeepLabV3+ model in tunnel lining crack segmentation. Four dominant semantic segmentation models, namely DeepLabV3 with backbone ResNet-101, PSPNet with backbone ResNet-50, UNet backbone by VGG-13, and UNet++ backbone by VGG-13 were trained with the crack segmentation dataset for more comprehensive comparisons.

As shown in Table 3, the DeepLabV3+ model obtains the best IoU of 57.01%, which is 1.77%, 5.77%, 0.17%, and 0.59% higher than DeepLabV3, PSPNet, UNet, and UNet++, respectively. Similarly, the precision of DeepLabV3+ is the highest, improved by 2.02%, 3.72%, 0.60%, and 2.64% compared to DeepLabV3, PSPNet, UNet, and UNet++, respectively. The F_1 score for DeepLabV3+ is only slightly lower than UNet but higher than the other three models. The recall of the DeepLabV3+ model is lower than that of UNet and UNet++ but 0.83% and 8.52% higher than that of DeepLabV3 and PSPNet, respectively.

Table 3. Results of semantic segmentation experiments.

Models	IoU (%)	F_1 score (%)	Precision (%)	Recall (%)
DeepLabV3+	57.01	67.44	62.95	82.12
DeepLabV3	55.24	66.33	60.93	81.29
PSPNet	51.24	62.18	59.23	73.60
UNet	56.84	67.68	62.35	83.91
UNet++	56.42	67.31	60.31	84.91

Representative testing results predicted by different deep learning models are depicted in Figure 9 to complement the quantitative comparison results above, with the orange dashed box and red dashed box denoting the incorrect and missed detections. From top to bottom of Figure 9, they are the raw images in the crack segmentation dataset, labels, and predicted results made by DeepLabV3+, DeepLabV3, PSPNet,

UNet++, and UNet. The DeepLabV3+ model performs best on the four testing samples, as seen by the comparison of segmentation results of different models. For case 1, the cracks can be accurately isolated by DeepLabV3+ and PSPNet. However, a small section of crack is omitted by DeepLabV3. There are some false detections in the identification results of UNet. UNet++ also has the situation of false detections. For case 2, all models successfully segment the cracks, except for PSPNet, ignoring large sections of the crack. As seen in the third and fourth columns of Figure 9, the features of the cracks do not differ significantly from the background features, posing a challenge for crack identification. In case 3, a small portion of cracks are not segmented by PSPNet and UNet, and a small background area is falsely identified as cracks by UNet++. In case 4, DeepLabV3, PSPNet, UNet++, and UNet have different degrees of missed detections. Additionally, a small portion of background pixels are mistakenly detected as crack pixels. The width of the crack segmented by the DeepLabV3+ model is larger than the actual crack width. Nevertheless, the predicted result retains more edge information relative to the other four models.

Figure 9. Comparison of prediction performance of different models on the test set.

These quantitative and qualitative comparative results above indicate that adopting the DeepLabV3+ model in the second step of our proposed framework for crack segmentation is effective and superior.

4.4 Visual explanations

The heatmaps of some key modules of the DeepLabV3+ model are generated based on the Score CAM technique to focus on the encoding and

decoding process of the model and understand the decision-making process. For a brief discussion, Figure 10 presents the heatmaps of the key modules of the DeepLabV3+ model when a single tunnel crack image is used as input. As depicted in Figure 10, the model focuses on the image globally during the encoding process. At the stage of Layer 2, the model pays attention to crack, lining surface, and lighting. Until the stage of Layer 4, the model emphasizes the crack, but the highlighted areas (dark-colored) do not precisely fit the crack. During

Figure 10. Visual explanations for several key modules of the DeepLabV3+ model based on Score CAM.

decoding, the DeepLabV3+ model gradually focuses on the crack itself. Another interesting finding is that the low-level and high-level feature maps used for the concatenation operation shown in Figure 4 present completely different heatmaps. The heatmaps demonstrate that high-level feature maps focus on the global features of the tunnel lining image due to the inclusion of strong semantic information, while low-level feature maps focus on local regions of the image, confirming that shallower feature maps contain rich spatial information.

5 CONCLUSION

This study proposes a two-step deep learning-based method for the automatic classification and segmentation of tunnel cracks. DenseNet-169 serves as the tunnel lining image classification model in the first step, through which the crack images can be separated and saved from massive image data. In the second step, the DeepLabV3+ model is employed to separate cracks from backgrounds in the crack images. An advanced visual explanation technique is integrated into the two-step method to understand the ‘black box’ of the crack segmentation model. The superiority and rationality of the two-step method are demonstrated through extensive comparative experiments. DenseNet-169 achieves 92.23% accuracy, which is improved by 2.07%, 16.58%, 17.10%, 18.65%, 16.58%, and 16.58% over DenseNet-201, EfficientNet-B0, ResNet-50, ResNet-101, Swin Transformer, and Vision Transformer. The FPS of DenseNet-169 reaches 39.80, exceeding that of DenseNet-201. For DeepLabV3+, an IoU of 57.01% is obtained, which is 1.77%, 5.77%, 0.17%, and 0.59% higher than DeepLabV3, PSPNet, UNet, and UNet++, respectively. Furthermore, the provided visual explanations show that the segmentation model focuses on the image globally during the encoding process and gradually focuses on the crack itself during the decoding process. Another interesting finding is high-level feature maps focus on the global features of the tunnel lining image due to the inclusion of strong semantic information. In contrast, low-level feature maps focus on local regions of the image, confirming that shallower feature maps contain rich spatial information.

There are still some flaws that need to be addressed in the future. Firstly, it is urgently required to introduce model light-weighting techniques to accelerate the image classification models. Secondly, essential image pre-processing or post-processing approaches need to be incorporated into the crack segmentation process to eliminate the complex environmental interference, thus obtaining refined segmentation results. Thirdly, expanding the tunnel lining image classification and crack segmentation datasets to guarantee higher generalization and robustness of the models. Besides, deep learning-based models

should be integrated into intelligent detection devices, such as unmanned aerial vehicles (UAVs), to realize automatic and real-time detection of tunnel lining cracks.

ACKNOWLEDGEMENTS

Much of the work described in this paper was supported by the National Key Research and Development Program of China under Grant No. 2020YFC1808105, Science and Technology Commission of Shanghai Municipality under Grant No. 21DZ1204400, and the National Natural Science Foundation of China under Grant No. 42372335. The writers would like to greatly acknowledge all these financial supports and express their most sincere gratitude.

ABSTRACT: The use of the TBMs (tunnel boring machine) is increased in the last decades because of the efficiency and safety during the excavation process. Moreover, the TBM solutions is widely preferred by Contractors to reduce the risks during the construction, have lesser economical deviation from the forecast costs and time. To ensure lower construction cost and higher project safety, it is necessary to adjust the operating parameters of the TBM depending on the geological conditions. The method for improving the adaptability of the TBM is to utilize real on-time monitoring data to predict the future operating values of the TBM. There have been several studies on the prediction of operating parameters. Among them, prediction of the thrust force and torque have been considered one of the important research projects. A study applying random forest (RF) was also conducted based on heterogeneous in situ data. Recently, some works using machine learning (ML) techniques have been reported to effectively analyse complex field data. Based on data collected from the field, some authors employed gene expression programming (GEP) to predict thrust-related parameters, while others used support vector regression (SVR) in hard rock conditions. The aforementioned works are, however, based on predictions based on experimental data (normally in one single tunnel) or on empirical dataset with the same geological parameters. The aim of this paper, so, is to provide a prediction of the TBM machine parameters to be used during design stage employing the so-called Unscented Kalman Filter (UKF) and be used by the average engineers. The approach employed will take as starting point the average formulations (semi-empirical and analytical) giving a guide to manage the ranges of values based on stochastic approach. The methodology will be applied to a practical example in four HSR (High-speed railway) tunnels in the northern Italy.

Keywords: Tunnelling, TBM, Performance prediction, Back-analysis, Kalman Filter

1 INTRODUCTION

Tunnel boring machines (TBMs) are widely used in areas with considerable urbanization for power supply, water supply, and subway construction. However, the adaptability of the TBM for the future environment is sometimes limited by geological conditions such as rock fracturing, faulting, spalling, squeezing, and high-water pressure (see for instance [1] and [2]). To ensure lower construction cost and higher project safety, it is necessary to adjust the operating parameters of the TBM depending on the geological conditions. The method for improving the adaptability of the TBM is to utilize TBM monitoring data in real time to predict the future operating values of the TBM. There have been several studies on the prediction of operating parameters. Among them, prediction

of the thrust and torque have been considered one of the important research issues (see for instance [3], [4], [5], [6], [7] [8] and [9]). Recently, some works using machine learning (ML) techniques have been reported to effectively analyse complex field data. Based on data collected from the field, Naghadehi et al. [10] employed gene expression programming (GEP) to predict thrust-related parameters. Salimi et al. [11] used support vector regression (SVR) in hard rock conditions. A study applying random forest (RF) was also conducted based on heterogeneous in situ data [12]. The aforementioned works are, however, based on predictions based on experimental data (normally in one single tunnel) or on empirical dataset with the same geological parameters. It is known that different machine parameters may be the sign of the different geological parameters and, indeed, of

*Corresponding author: cosmeiasiello@gmail.com

different type of rings, normally depending of the reinforcement placed. The aim of this article, so, is to provide a prediction of the TBM machine parameters to be used during design stage employing the so-called Unscented Kalman Filter (UKF) (see for instance [13] and [14]) approach taking as reference the torque force measured during the TBM tunnel execution.

2 CASE APPLICATION

The project consisted in the new HSR (High speed-railway) between Milan and Ventimiglia in northern Italy. The tunnels have been bored by a Herrenknecht TBM single shield. The machine had a total length of 150 meters including the back-up; an excavation diameter of 11.8 m, an external diameter of 11.54 m and a net inner diameter of 10.74 m; an installed power of 4,000 kW supplied by 10 engines to rotate the cutter-head; a maximum tunnelling speed of 100 mm per minute. The reinforced concrete lining is composed by 7 segments, 6 segments and one keystone. The ring length is 1.7 m and it has been designed to assume right and left positions within the tunnel (taped ring). The segments thickness is 0.4 m while the height of contact between joints is 0.17m. The segments were designed with conventional steel bars reinforcement concrete. The lining geometrical definitions are collected in Table 1:

Table 1. Lining geometrical definitions.

Parameter	Unit	Value
Outer Diameter	m	11.54
Segmental Thickness	m	0.40
Ratio thick/outer diameter	-	1/28.85

Figure 1 shows the cover, respect to tunnel crown, for the 4 tunnels depending on the GSI values. The dataset employed in this paper is around 4500 rings. The maximum cover is around 350 m while the minimum is around 20 m. GSI (geological strength index) varies from 15, for fault areas, till 55.

Figure 1. Ring Dataset in function of cover and GSI value.

During detailed design, 145-point load tests were carried out to better estimate the direct standard laboratorial uniaxial compressive tests and indirect tests such as the PLT. There have been different attempts to provide an empirical index-to-strength conversion factors between the UCS and $I_s(50)$, to reveal their correlations and demonstrate practical application (see for instance references from [15] to [18]). Figure 2 shows the distribution of $I_s(50)$.

Figure 2. Distribution of $I_s(50)$ values.

These correlations are very important to estimate the UCS and hence, the TBM machine parameters; in fact, in technical literature there are many examples how to correlate UCS with field penetration index (FPI), as collected in [19], with specific energy as shown in [20], or to calculate the cutting force exerted by the TBM as suggested by [21], or to estimate the penetration rate (PR) as demonstrated in [22] and finally, as suggested in [23] depending on the torque as shown in Figure 3.

Figure 3. Estimated penetration as function of Torque based on UCS values.

The methodology followed in the detailed design was:

1. Estimation of the UCS values for rock mass based on PLT tests or another specific test
2. Use the correlations between UCS and PR

3. Calculate the penetration (mm/min) as function of PR (mm/round) based on technical literature data (see for instance [24] and [25])
4. Correlate the penetration with Torque, specific energy, and Thrust force

This methodology allows to calibrate the ranges of values for TBM machine parameters and, so provide the designed countermeasures forecast; for example, depending on the geological conditions, it is possible to vary the quantity of reinforcement within the segments. However, the data extrapolated from the UCS, although very useful during the design stage, are related only to a small dataset and could not give a complete picture of the excavation of the tunnels. The approach followed in this paper was to use the partial information from the design to double check the design estimation and, at same time, forecast the possible deviations. The approach employed to analyse the data was through the Kalman filter.

3 KALMAN FILTER METHODOLOGY

The Kalman Filter is a mathematical tool for finding the best estimate for the state of a system in a discrete time process that is assumed as a linear stochastic differential equation ([11]). Following the approach of [15] we could consider the following discrete nonlinear time system:

$$x_{k+1} = f(x_k) + w_k \quad (1)$$

$$y_k = h(x_k) + v_k \quad (2)$$

where $x_k \in \mathbb{R}^{n_x}$ is the unknown state of the system and $y_k \in \mathbb{R}^{n_y}$ corresponds to the output data. In this paper x_k are:

- A: estimated penetration during design stage (mm/min)
- B: UCS data from design stage

Whereas y_k are the observed TBM machine parameters.

In order to provide an adequate initial model, all previous information on the input parameters x_k must be assessed. This previous information will come with an associated error of modelling w_k that can be represented probabilistically by means of a multivariable Gaussian probability density function with zero mean and covariance matrix Q_k . In this paper, the implicit error in the input parameters is represented by the initial standard deviation as shown below.

On the contrary, the error related to monitoring measures (v_k) is usually given by the manufacturer of the TBM, so it also turns out to be an independent and Gaussian random variable, with zero mean and covariance matrix R_k . The nonlinear functions

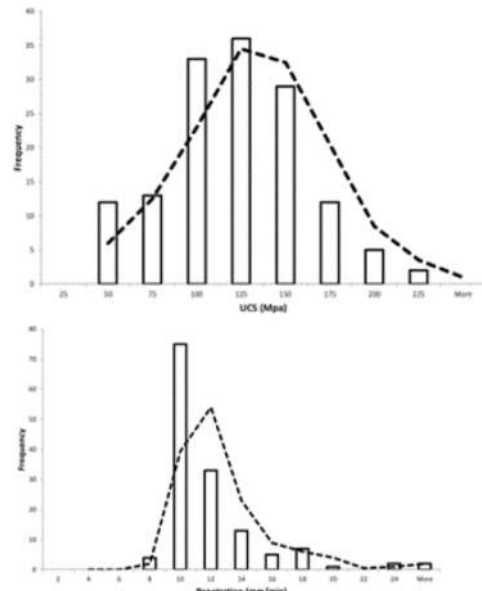

Figure 4. Distribution of designed values of UCS and penetration.

f and h represent the dynamic process and the measurement model, respectively. The estimation of the state consists in elaborating an outlook of x_k employing y_k for each time k . For this reason, the interest of the user should be focused on obtaining the probability distribution function (PDF) of x_k conditioned to y_k or, in other words, the probability of reproducing the observed measurements (TBM machine parameter) with a particular set of input parameters. The probability of a parameter set given the observations is:

$$p(x_k|Y_{k-1}) = \int p(x_k|x_{k-1})p(x_{k-1}|Y_{k-1})dx_{k-1} \quad (3)$$

The application of the Bayes Theorem to the observations leads to the updated equation of the parameters set, which is:

$$p(x_k|Y_k) = \frac{p(y_k|x_k)p(x_k|Y_{k-1})}{p(y_k|Y_{k-1})} \quad (4)$$

Where:

$p(x_k|Y_k)$ is the probability of a certain estimation for the set of geotechnical parameters given the observed measures. This term is also known as the a-posteriori PDF

$p(y_k|x_k)$ is the probability of computing the observed measures through the NLFEA given a certain set of geotechnical parameters.

$p(x_k|Y_{k-1})$ is the probability of a certain estimation for the set of geotechnical parameters given the previous observed measures. This term is also known as a-priori probability

$p(y_k|Y_{k-1})$ in equation (4) is the normalised probability or so-called scale factor so the $p(x_k|Y_k)$ could be between 0 and 1.

In this way expressions (3) and (4) represent the fundamental estimation of the Bayesian system of the equations (1) and (2) depending on time k. The approach is depicted schematically below:

Figure 5. Principles of Bayesian Filter.

However, equations (3) and (4) cannot be used in a simple way to find the PDF of a random vector belonging to a very nonlinear system, since a computationally demanding random sample simulation procedure must be adopted. This issue can be addressed by using the first two statistical moments (mean and covariance) of a Gaussian probability density function assumed for the parameter vector x_k . This procedure then aims for finding the PDF of the parameter's estimation. In this case, so, the search problem turns easier to solve by implementing the approach previously mentioned, with the unknown parameter standing for x_k at time k. The new equations (3) and (4) can be expressed in terms of the Kalman filter as the predictions:

$$\hat{x}(k|k-1) = E[f(x_{k-1}|Y_{k-1})] \quad (5)$$

$$P_{(k|k-1)}^x = Cov[f(x_{k-1}|Y_{k-1})] + Q \quad (6)$$

and the updated formulation can be expressed as:

$$\hat{y}(k|k-1) = E[h(x_k|Y_{k-1})] \quad (7)$$

$$P_{(k|k-1)}^y = Cov[x_k|Y_{k-1}] + R \quad (8)$$

$$P_{(k|k-1)}^{xy} = Cov[x_k, h(x_k)|(Y_{k-1})] \quad (9)$$

$$\hat{x}(k|k) = \hat{x}(k|k-1) + P_{(k|k-1)}^{xy} (P_{(k|k-1)}^y)^{-1} (y_k - \hat{y}(k|k-1)) \quad (10)$$

$$P_{(k|k)}^x = P_{(k|k-1)}^x - P_{(k|k-1)}^{xy} (P_{(k|k-1)}^y)^{-1} P_{(k|k-1)}^{xy} \quad (11)$$

As shown in Figure 6, the Kalman filter employs a repetitive prediction-update procedure to obtain the mean and covariance of x_k from measurements. Equations (8), (9), (10), (11) and (12) show how this

implementation depends on the determination of the mean and covariance of the random state vector through the nonlinear functions $f(\cdot)$ and $h(\cdot)$.

Figure 6. Principle of Kalman Filter technique.

However, in the case of nonlinear systems, as those commonly encountered in Geotechnical Engineering, the problem is more complicated, and has attracted a lot of research in recent years. Thus, different families of Kalman Filters have been developed for non-linear systems, with three clear outstanding algorithms: EKF (Extended Kalman Filter), UKF (Unscented Kalman Filter) and EnKF (Ensemble Kalman Filter). In this work, the so-called Unscented Kalman Filter (UKF) or, for a better understanding, the Kalman Filter with the application of the Uhlmann transform, has been used. This technique is based on the so-called Unscented transform (UT), which uses deterministic points to trace the mean and covariance of a random variable transformed to a nonlinear system (see for instance ref [26]). The basic idea of the method is to represent the probability distribution of each random variable by means of a set of points (sigma points) deterministically chosen in such a way that the mean and covariance are represented. Then, it is possible to propagate these sigma points through the nonlinear function, obtaining a new set of points that are then used to obtain the mean and covariance of the transformed variable utilizing a weighting procedure.

Figure 7. Uhlmann unscented transformation based on reference [12].

The procedure is to generate a first set of points considering the initial mean and covariance (red ellipse in Figure 7) and, subsequently this system is projected through a nonlinear function to generate a new set of sigma points which are used to calculate the new mean (the "star" point at the right of Figure 7) and its covariance (ellipse in Figure 7). In order to develop the UKF, it is necessary to apply the Uhlmann transform, both in the prediction and update processes,

which involves state transformations of the nonlinear functions f and h , respectively.

4 RESULTS

The relationship between the measured and estimated penetration is shown in Figure 8 with R^2 of 0.78. The main differences are related to the extreme values (low and high values) and these differences are not quite interesting because they are not attributable to the lack of reliability of the methodology but to specific issues highlighted on field.

Figure 8. Correlation between estimated and measured penetration (r.p.m.).

Figure 9. Correlation between estimated and measured Torque (MNm) and Correlation between estimated and measured Thrust Force (kN).

Figure 9 shows the same correlation for the Torque values. In this case the R^2 value is quite lower because the methodology employed was not able to forecast the on-field problems, which are clearly highlighted as the lower points in the figure.

5 CONCLUSIONS

From the above considerations, the following conclusions can be drawn:

- The estimation of the TBM machine parameters during the design stage is very important to efficiently forecast the geological conditions during the excavation tunnelling. The most employed methods are the so-called semi-empirical methods.
- From the back-analysis carried out through the application of probabilistic estimators (Unscented Kalman Filter, UKF) it is concluded that this technique constitutes a powerful and versatile calculation tool that, quickly and accurately, allows to obtain very satisfactory adjustments. During the iteration process of the UKF, it has been possible to observe the special relevance of the maximum and minimum limits of each parameter to be estimated and entered in the filter.

The proposed methodology, based on Kalman filter, due to its robustness and versatility can be employed by the designers to efficiently forecast the TBM machine parameters during design stage in absence of field data.

ABSTRACT: Under the current large-scale operational tunnels, tunnel structure maintenance is an important issue and requires complex decision making, especially involving rapid perception and analysis of structural defects. However, traditional manual inspection and experience driven maintenance decision methods are low efficiency, prone to subjectivity, and gradually unable to meet the engineering requirements. Thus, an intelligent decision support system (DSS) for tunnel structural defects maintenance is present in this paper to realize automatic decision making for tunnel structural defects maintenance. Firstly, a deep learning model for tunnel structural defects detection based on YOLOv8 is built to quickly identify the category and location of defect in an image via supervised learning. Then, a Knowledge Graph (KG) is constructed to store the related maintenance knowledge exist in unstructured format (i.e., standard) through ontological approaches. Besides, the structured data reflecting tunnel structural state (i.e., defect location) can also be added to KG. Finally, on account of the model recognition results, a semantic reasoning language is adopted to automatically inference the optimal maintenance decision from the KG. An evaluation of the DSS is additionally performed to validate rationality and effectiveness of the methodology, the results show that the DSS can achieve reasonable maintenance decision for tunnel structural defects.

Keywords: Tunnel maintenance, Defects detection, Decision making, Computer vision, Graph database

1 INTRODUCTION

With the increasing development of transport infrastructure, railway tunnels (e.g., subway tunnels) have become an important part of urban transit system. However, due to the complex underground surroundings, various structural defects (e.g., leakage, crack) may appear during tunnel operation. Regular inspection and timely maintenance are necessary to guarantee tunnel serviceability. Currently, this task is mainly implemented by manual based method, which is time consuming, subjective, and gradually unable to meet the engineering demands under current large-scale operational tunnels. Thus, it is required to

develop a more intelligent and efficient detection and maintenance decision method (Xue et al., 2018).

In recent years, deep learning techniques have been widely used in the field of civil engineering (Wang et al., 2023; Li et al., 2023; Fu et al., 2023; Xue et al., 2022; Yu et al., 2021). Owing to the powerful representative ability of deep learning model and strong hardware (graphics processing unit, GPU), given different data as input, the model can be trained iteratively to complete corresponding task. Xue et al. (2018) firstly developed a Moving Tunnel Inspection (MTI-100) equipment to achieve automatic tunnel defects images acquisition. Then the VGG (Simonyan et al., 2015) and Faster R-CNN

*Corresponding author: jiaruofeihan@163.com

(Ren et al., 2015) models were in turn utilized to perform defects classification and detection, demonstrating the feasibility of deep learning methods. Huang et al. (2018) adopted two fully convolutional network (FCN; Long et al., 2015) to separately segment crack and leakage contours in images collected by MTI-200a, and realized better performance than traditional digital image processing methods. Zhao et al. (2020) used Mask R-CNN (He et al., 2017) instance segmentation model to segment leakage and the number of pixels including in segmented area were employed to quantify defect. Xue et al. (2020) adopted Cascade R-CNN (Cai et al., 2021) to realize finer leakage segmentation, and designed a field experiment to construct a conversion formula between pixel number and defect area. Zhao et al. (2021) took the crack discontinuities into account, added a semantic branch to PANet (Liu et al., 2018) to refine the crack segmentation performance and designed an algorithm to compute crack length and width. Zhou et al. (2021) considered the depth of spalling defect and adopted a laser scanner to generate RGB-D format images, D³Net (Fan et al., 2021) was then used to segment spalling and calculate the defect volume. The above research mainly utilized different models for each defect, while there are multiple defects present meanwhile in the real context, and thus a model for recognizing two or more defects is necessary.

Based on various defect data, including leakage area, crack length etc., it is also important to evaluate the defect severity and decide maintenance measures. Li et al. (2017) selected six kinds of common defects and conducted 40 samples to regress a tunnel serviceability index (TSI) formula for tunnel condition evaluation through expert rate and partial least squares (PLS) method. Chen et al. (2019) further considered the influence of additional factors (e.g., buried depth, age), constructed a Multiple Indicators Multiple Causes (MIMIC) model to quantify the influence and optimize the original TSI. Zhu et al. (2021) took the subjective factors of expert annotation and insufficient samples in original TSI into account, proposed a cloud based random forests (CRFs) model to solve the two problems and reconstruct TSI through semi-supervised learning. Liu et al. (2023) considered the complex interactions among key performance indicators (KPIs), combined pair copula constructions (PCCs) and Bayesian networks (BN) to assess subway tunnel state. Though different tunnel structure evaluation methods have been studied and maintenance measures are decided for each evaluation level, it is mainly some advice about whether to maintain. However, it may be more applicable to directly determine how and what to maintain for serving the practical engineering by combining decision making with defect detection.

Accordingly, an intelligent decision support system (DSS) is constructed in this study to determine reasonable maintenance methods for

three common tunnel structural defects (leakage, crack, and block). This system mainly consists of two parts, one is a deep learning model to detect defect location and category in image and provide a coarse quantification information, the other is a knowledge graph storing detection results and maintenance standard to decide defect maintenance method automatically. The rest of this paper is formed as follows. Section 2 introduces the data acquisition method and deep learning model for defects detection in detail, followed by the construction of maintenance knowledge graph in Section 3. Then Section 4 displays the model training process and maintenance decision results, and finally Section 5 concludes the study.

2 RAILWAY TUNNEL STRUCTURAL DEFECTS DATASET AND DETECTION MODEL

With a defect image as input, the purpose of detection model is to predict defect location and category in the image. Generally, the model can be divided into two parts, backbone and head. The former is used to extract feature maps containing high-dimensional semantic information from images. And the latter predicts several bounding boxes and corresponding category probability vectors for each point on feature maps. Based on the difference between predictions and ground truths (GTs), model parameters are iteratively updated during the training process through gradient backpropagation, which is also called supervised learning. Thus, dataset has an important impact on the model performance, sufficient images are necessary to guarantee steady training process and powerful recognition capability.

2.1 Data acquisition

As shown in Figure 1, the cross sections of a single hole double track railway tunnel with different

Figure 1. The cross sections of a single hole double track railway tunnel with different design speeds (mm).

design speeds are quite distinct, and the section size is relatively large, requiring a general and efficient image collection measure. To this end, a comprehensive detection device is designed and developed to achieve rapid acquisition of railway tunnel structure images (Figure 2). Taking line scan camera as the main component, the basic acquisition module is established by combining with light source, memory card and other supporting facilities, and totally six modules are adopted to form the detection device. Finally, the main body is mounted on a track engineering equipment to realize movable inspection.

Figure 2. The comprehensive railway detection device.

Considering the large section size of railway tunnel, full section inspection in single operation may require larger device size, more detection modules, and higher resource consumption etc., a special device structure is designed considering the characteristics of round-trip inspection. As shown in Figure 3 (a), for an interval tunnel inspection, the detection device covers half of the structure in a single operation from the beginning to the end. Then on the way back, the device covers the other half by rotating the device horizontally as shown in Figure 3(b). Owing to the special design, the device cost can be significantly reduced, and this design may also be extended to the inspection of other large section projects.

Figure 3. Image acquisition process for a single hole double track railway tunnel. (a) Image acquisition range of single operation. (b) Detection device rotation for image acquisition of another half cross section.

To verify the above work process, an inspection operation is carried out in a railway tunnel in southern China (Figure 4) at a speed of 40 km/h. The sample images collected by each

module is shown in Figure 5, indicating that this inspection process is reasonable and the image quality is relatively superior. Besides, each image is named and stored as 'R_N_I', where R means the device operation direction (s or x), N represents the module number, and I is the number of images collected by a module. After locating defect in an image, the absolute defect location in tunnel can then be determined. Finally, 3624 images with a resolution of (8192×4096) are collected.

Figure 4. Inspection process in a single hole double track railway tunnel.

Figure 5. Images collected by each module.

2.2 Data processing and annotation

Due to the powerful computation ability of GPU, though deep learning model can efficiently extract features from images, it is still difficult to directly analyse such a large image (8192×4096). Hence, a crop algorithm is performed on an image to obtain 8 images with a resolution of (2048×2048), indicating that the dataset is expanded by 8 times. In addition, each cropped image is named as ‘R_N_I_i_j’, where i and j represent the row and column number in the original image.

As shown in Figure 6, taking three common railway tunnel structural defects (leakage, crack, and block) as detection object, LabelMe, a general annotation tool, is utilized to label defect location and category in these cropped images through manual annotation. Finally, the railway tunnel structural defect dataset contains 4454 labelled images for training deep learning model.

Figure 6. Railway tunnel structural defect images.

2.3 Defects detection model

With the rapid development of computer vision technology in the field of deep learning, multiple models have been proposed to achieve the aim of fast and accurate recognition. Currently, YOLOv8 (Glenn, 2023) is a state-of-the-art (SOTA) model for various vision tasks, and thus is used in this study to detect railway tunnel structural defects.

The overall model architecture is shown in Figure 7. In the backbone, the input image is handled in a series of convolutional blocks to get a feature map containing abundant semantic information. Then a feature pyramid structure is constructed to combine feature maps of different granularity in the head, finally three feature maps are generated to separately detect targets at different scales. For more details, please refer to (Glenn, 2023).

The aim of training a deep learning model is to obtain a group of optimal model parameters, which can make model realize satisfactory detection performance. Thus, a loss function is necessary to perform gradient backpropagation. The loss function of YOLOv8 contains three parts, classification (L_{cls}), regression (L_{box}), and confidence (L_{conf}), as displayed in (1).

$$L_{cls} = -\frac{1}{b} \sum_{i=1}^b \frac{1}{n_i} \sum_{j=1}^{n_i} y_{ij} \ln(\hat{y}_{ij})$$

$$L_{box} = \frac{1}{b} \sum_{i=1}^b \frac{1}{n_i} \sum_{j=1}^{n_i} (1 - IoU(GT_{ij}, Pre_{ij})) \quad (1)$$

$$L_{conf} = -\frac{1}{b} \sum_{i=1}^b \frac{1}{n} \sum_{j=1}^{n_i} s_{ij} \ln(\hat{s}_{ij})$$

where b is the batch size; n_i is the number of positive samples; y_{ij} is the GT class label; \hat{y}_{ij} is the predict class label; IoU is the intersection over union between GT and Pre boxes; n is the size of feature map; s_{ij} is the GT foreground label; \hat{s}_{ij} is the predict foreground label.

The final loss function is formed as (2).

$$L = \lambda_{cls} L_{cls} + \lambda_{box} L_{box} + \lambda_{conf} L_{conf} \quad (2)$$

where L is the final loss function; λ_{cls} , λ_{box} , λ_{conf} are the balanced parameters.

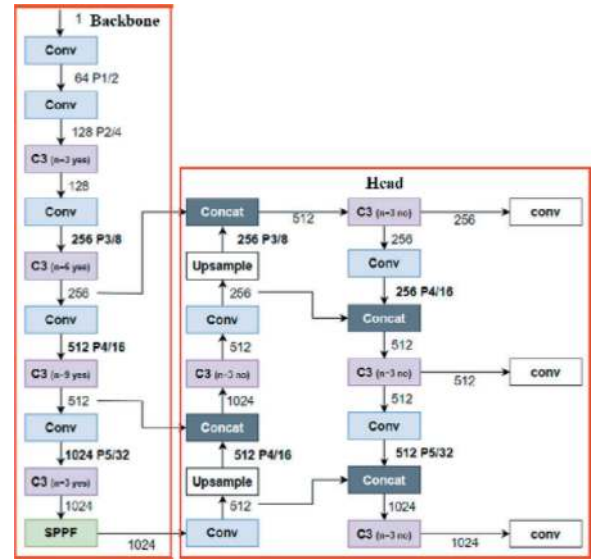

Figure 7. YOLOv8 detection model architecture.

3 KNOWLEDGE GRAPH FOR DEFECTS MAINTENANCE

Traditional methods mainly depend on workers to determine specific maintenance measures for different defects according to relevant standards. While the rationality of measures largely hinges on personnel experience, which may be low efficiency and insufficient to meet the operational requirements. Thus, a defects maintenance knowledge graph is constructed to realize information integration, query, and decision support analysis.

The knowledge graph was proposed by Google in 2012 and was established to improve the search engines performance. At present, knowledge graph (KG) has become one of the important ways for organizing and representing knowledge in the era of big data, and is a key technology for achieving cognitive intelligence (Peng et al., 2023). KG is a structured semantic knowledge base that uses network structures to describe concepts, entities, and their relationships in the real world. The basic unit of KG is an entity-relation-entity triple, as well as the entity and its related attribute value pairs. By pre-defining entities, relationships, and attributes, machines are able to understand and process data in this knowledge form, which is also called ontology design.

3.1 Ontology design

Ontologies represent a formal description of concepts and their relationships, allowing modelling a knowledge graph for a specific domain or task (Dimitrova et al., 2020). Hence, ontology design is to determine the concepts and attributes contained in the domain for the requirements of domain knowledge. Besides, the relationship between entities also needs to be defined, and different types of entities may have different relationships for specific domains. In this study, the ontology design for railway tunnel structural defects maintenance is completed in a top-down manner mainly through human knowledge and expert experience (Zheng et al., 2021).

Given that the aim of this KG is to perform maintenance decision for railway tunnel structural defects, the ontological classes are conceptual abstracts of similar entities within the tunnel defects maintenance. Therefore, it can be concluded that the knowledge required for tunnel structural defects maintenance includes the identification of operational tunnels, maintenance methods, and structural segments. Then the ontological classes needs be further categorized to satisfy the maintenance requirements. For instance, an operational tunnel contains several segments and some maintenance methods are defined in relevant standards. Thus, defects information is obtained for each segment with deep learning technology, and maintenance methods for different defect and severity are extracted by expert experience. In addition, the entity properties related to tunnel structural defects are also defined in the ontology design. As shown in Figure 8, the designed ontology displays the relationships between ontological classes by connecting edges in dashed line form, and the solid line represents ontological class properties.

3.2 Graph construction

Based on the above ontology design, structured data (i.e., defects detection results) and unstructured

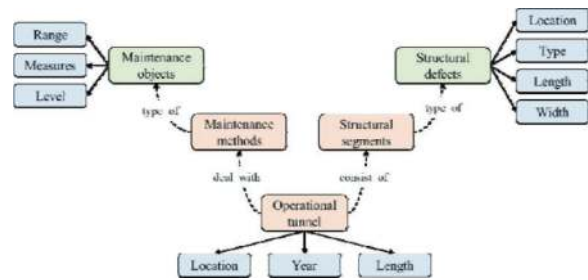

Figure 8. Ontology design for tunnel structural defects maintenance.

knowledge (i.e., maintenance standards) are transferred and stored in a unified knowledge base. For the structured data, after predicting defect location and category, the detection results are stored in the format required in the ontology design. While for the unstructured knowledge, it is mainly summarized and extracted from maintenance standards through human experience. Table 1 displays the severity definition of crack in standards, it is required to manually convert it into a structured storage format (e.g., json, csv).

At present, there are mainly three kinds of knowledge graph storage methods, traditional relational database, RDF triplet database and graph database. Since graph database is a kind of ideal KG management tool where knowledge is stored in graph structure and more intuitive, Neo4j graph database is adopted in this study to store data, which is open-source and uses Cypher language to operate, manage and visualize the graph (Pang et al., 2023).

Table 1. Evaluation standard of segment crack health.

Crack width (mm)	Evaluation standard
[0, 0.2)	Level 1
[0.2, 0.5)	Level 2
[0.5, 1.0)	Level 3
[1.0, 2.0)	Level 4
≥ 2.0	Level 5

4 RESULTS OF DSS FOR DEFECTS MAINTENANCE

4.1 Defects detection performance evaluation

Model training is a process of continuous iteration and updating, a regular evaluation is necessary to judge the training state and decide when to stop. Thus, Dataset is usually divided into three parts, train, validation, and test. During the training process, the train set is used to update model parameters and model performance is evaluated on validation set, the trained model can be further evaluated on test set by visualizing detection results. The ratio of three sets in this study is 8:1:1 shown in Table 2.

Table 2. Composition of three sets.

Name	Defect count			Image count
	leakage	crack	block	
train	2150	1980	362	3638
validation	414	156	26	450
test	210	151	23	366

As shown in Table 3, with comparing prediction with label, model detection results can be divided into four categories, and two evaluation indexes are formed as (3). However, given that the total number of targets is fixed, the two indicators show a state of fluctuation and growth. To this end, mean average precision (Lin et al., 2014; mAP) is adopted to comprehensively evaluate defects detection performance., which is also widely used in the filed of deep learning to compare and assess model performance.

Table 3. Model prediction categories.

Prediction	Label	
	Positive	Negative
Positive	TP	FP
Negative	FN	TN

$$Prediction = \frac{TP}{TP + FP} \quad (3)$$

$$Prediction = \frac{TP}{TP + FN}$$

As shown in Figure 9, to determine the optimal model parameters, the recognition performance is evaluated on validation set after each epoch. Finally, the loss and mAP values tend to be stable, and the optimal mAP value is 0.722 at a detection speed of 35 frames per second (FPS). Some model recognition results on test set are also displayed in Figure 10, indicating that the model achieves satisfactory accuracy.

4.2 Maintenance decision results

According to the above graph construction process, as shown in Figure 11, the defect detection results are automatically transferred and stored in structured format (csv in this study). While for the unstructured knowledge in maintenance standards, the entities and relationships are extracted and constructed

Figure 9. Defects detection model training process.

Figure 10. Model recognition results on test set.

Segment	Defect	Type	DefectLoc	SegmentLoc	DefectDirection	DefectInfo

manually in Neo4j (Figure 12). Finally, the railway tunnel structural defects maintenance knowledge graph is visualized in Neo4j (Figure 13), the entity properties and relationships are constructed as defined in Figure 8.

With the constructed knowledge graph, the semantic reasoning language (Cypher) is used to query, analyse, and make decision for railway tunnel structural defects. For example, as displayed in

Figure 12. Defects maintenance graph in Neo4j.

Figure 13. Defects maintenance knowledge graph visualized in Neo4j.

Figure 14, the code “match a=(Tunnel)-[:CONSIST_OF] →(:Segment)-[:HAD_DEFECT]→(:Defect {Type:‘crack’}) return a” returns all crack defect results. Then, to further realize maintenance decision for defects, the code needs to construct the relationship between defects information and maintenance standard, such as “match (a:Defect {Type:‘crack’}), (b:Level {name:‘cracklevel’}) where a.Width > b.rangemin and a.Width < b.rangemax return a.ID, b.num”. As shown in Figure 15, what (ID, Loc) and how (Level num) to maintain crack defects can be quickly and automatically decided, proving the efficiency of decision support system for railway tunnel structural defects maintenance.

5 CONCLUSIONS

In this study, an intelligent decision support system is constructed for tunnel structural defects maintenance. This system mainly contains two parts, a deep

Figure 15. Maintenance decision results for crack defects.

learning model for defects detection and a knowledge graph for maintenance decision making. It can store both structured detection results and unstructured maintenance standards and realize automatic defects maintenance decision making through a semantic reasoning language. The main conclusions are as follows.

- (1) A comprehensive detection device is designed to efficiently collect defect images by considering the characteristics of round-trip inspection, and the absolute image location in tunnel is determined in proper naming rules. Furthermore, the absolute defect location can be automatically obtained with YOLOv8 defects detection model.
- (2) Ontology design is the fundamental step of constructing knowledge graph and generally is developed in a top-down manner for domain task. For tunnel structural defects maintenance, based on three top classes, operation tunnel, maintenance segments, and maintenance methods, the ontology can be completed by extracting concepts from detection results and maintenance standards through expert knowledge.
- (3) Graph database is a powerful and intuitive knowledge graph form to store structured and unstructured data defined in ontology. According to the entity properties and relationships, semantic reasoning language is utilized to realize automatic decision making for tunnel structural defects maintenance.

ACKNOWLEDGMENTS

Prediction of disc cutter wear considering ground conditions and TBM operating parameters

Yun Seong Kang, Se Jin Park, Ji Hye Hwang, Ju Pyo Hong & Tae Young Ko*
Kangwon National University, Chuncheon, Korea

ABSTRACT: Tunnel boring machines (TBMs) are being exceedingly used in tunnel projects to minimize noise and vibrations during excavation. The disc cutter, which is a tool mounted on the cutterhead of a TBM, continuously interacts with the ground because of the rotation of the cutterhead, resulting in inevitable wear. Because replacing the disc cutter involves substantial time and cost, it significantly reduces the operation and excavation rates of the TBM and impacts the total time and cost of the TBM project. Thus, accurate prediction of cutter wear or lifespan is crucial. In this study, we estimated the coefficient bearing rate (mm/km), which is an index for quantifying wear, considering both the ground conditions and operating parameters of the slurry TBMs. To address the issue of insufficient uniaxial compressive strength (UCS) data, we first performed UCS prediction, followed by prediction of the Coefficient Wearing rate. The estimation of the Coefficient Wearing rate utilizes machine learning techniques, such as the k-nearest neighbors, Support vector machine, random forest, gradient XGBoost, LightGBM, and CatBoost. The entire dataset was divided into five training/test sets for the purpose of five-fold cross-validation. The model performance was evaluated using the coefficient of determination (R^2) and root mean square error (RMSE), with the hyperparameter optimization process conducted via five-fold cross-validation. The average R^2 and RMSE values for the LightGBM on the test data were 0.624 and 0.00791, respectively. Finally, to evaluate the feature importance of the prediction models, a SHapley Additive exPlanation (SHAP) analysis was conducted.

Keywords: Disc cutter, Wear, TBM, Operation parameter, Machine learning

1 INTRODUCTION

Nowadays, tunnel boring machines (TBMs) are being increasingly used in tunnel projects to minimize noise and vibration during excavation. One of the most critical aspects of the TBM projects is the lifespan and wear of the TBM disc cutters (Mahmoodzadeh et al., 2021). The disc cutter, which is a tool mounted on the cutterhead of a TBM, continuously interacts with the ground because of the rotation of the cutterhead, resulting in inevitable wear. Because replacing the disc cutter involves substantial time and cost, it significantly reduces the operation and excavation rates of the TBM and significantly affects the total time and cost of the TBM project (Kim et al., 2022). Thus, the accurate prediction of cutter wear and lifespan is crucial.

Recent studies have increasingly focused on utilizing artificial intelligence to predict the wear and lifespan of disc cutters in the TBMs. Mahmoodzadeh et al. (2021) employed geological conditions, TBM operating parameters, and machine-learning algorithms to predict the lifespan (H_f , $m^3/cutter$) of disc cutters in Gripper TBMs. Similarly, Elbaz et al.

(2021) used geological conditions, TBM operating parameters, and a group method of data handling (GMDH)-type neural network to predict the lifespan (H_f) of disc cutters in the earth pressure balance (EPB) TBMs. Kim et al. (2022) utilized the TBM operating parameters along with machine learning and deep learning techniques to predict the cutter lifespan and wear rate (%) of the Slurry TBMs. However, there is relatively limited research on predicting the wear of disk cutters in the Slurry TBMs considering both the TBM operating parameters and geological conditions. In this study, we estimated the Coefficient Wearing rate (mm/km), which is an index for quantifying wear, considering both the ground conditions and operating parameters of the Slurry TBMs.

2 DATASET ESTABLISHMENT

In this study, the data from the tunnel projects in Singapore were used. The project involved the excavation of an approximately 5.53 km long tunnel, which was divided into two sections. Both the sections were excavated using the TBMs with identical

*Corresponding author: tyko@kangwon.ac.kr

specifications, which are referred to as TBM #1 and TBM #2, respectively. The specifications of the TBMs are listed in Table 1. The overall geological composition of the tunnel predominantly consists of the Bukit Timah Granite, with some sections passing through the Kallang sediment and mixed ground (Figure 1). TBM #1 excavated a section of approximately 3.14 km, where geological investigation estimated that the rock, soil, and mixed zones were 2670 m, 377 m, and 94 m, respectively; TBM #2 excavated a section of approximately 2.21 km, with the rock, soil, and mixed zones estimated to be 2120 m, 44 m, and 44 m, respectively. The operational data from the TBM used in this study were collected at excavation intervals of approximately 20 mm. Geological conditions were characterized using the weathering grades (G1–G6) obtained from the face logging performed during the CutterHead interventions (CHIs) and uniaxial compressive strength (UCS) values obtained from the drilling investigations. The weathering grade for the entire tunnel section was classified based on Approach 2 of Section 6 in BS5930:1990, and the weathering grades and their characteristics by grade are described in Table 2 (BS 1999). The weathering grades for the entire tunnel section varied from G1 to G5; however, the G6 grade was not observed.

The wear of the disc cutters was measured in millimeters based on the reduction in the radius of each disc cutter observed during the CHIs.

The UCS is frequently used as an input variable in various studies to predict the disc cutter wear and serves as a key indicator of geological conditions (Agrawal et al., 2022; Ding et al., 2022; Elbaz et al., 2021; Kang et al., 2022). In the projects examined in this study, 27 UCS data points were obtained for the section TBM #1 and 22 for section TBM #2 through drilling surveys. This is significantly inadequate compared with the TBM operation data recorded every 20 mm of excavation and cutter wear data obtained from the 203 cutter head inspections (CHIs). To address this data scarcity issue, the UCS values for areas where operation data were recorded were first predicted using the available operation and UCS data. Subsequently, the predicted UCS data were utilized to predict the disc cutter wear.

3 UCS PREDICTION

To predict the UCS, a database was constructed under the assumption that the UCS values were consistent

Table 1. Summary of TBM and disc cutter specifications.

TBM type	Slurry
TBM diameter	6.9 m
Torque	0–6, 250 kN·m
Thrust force	0–51, 200 kN
Cutterhead rotation speed	0–6 rpm
Number of disc cutter	48
Disc cutter diameter	483 mm

Table 2. BS5930:1990 approach 2 weathering classification.

Geo-notation	Grade	Classifier	Typical characteristics
G1	I	Fresh	Unchanged from original state
G2	II	Slightly weathered	Slight discoloration, slight weakening
G3	III	Moderately weathered	Considerably weakened, penetrative discoloration; large pieces cannot be broken by hand
G4	IV	Highly weathered	Large pieces cannot be broken by hand; Does not readily disaggregate (slake) when dry sample immersed in water
G5	V	Completely weathered	Considerably weakened; Slakes; Original texture apparent
G6	VI	Residual soil	Soil derived by in situ weathering but retaining none of original texture or fabric

within an approximate 50 mm range centered around the points where the drilling surveys were conducted.

3.1 Data preprocessing

3.1.1 Selection of parameters

During the tunnelling process carried out by the TBM, approximately 2000 operation parameters, including the thrust force, torque, and cutter head rotation speed, were recorded at approximately

Figure 1. Geological profile of TBM tunnel project.

Figure 2. Variations in absolute torque during excavation.

20 mm advancement intervals. Using an excessive number of input variables can complicate the predictive models based on machine-learning algorithms and increase the computational time. Therefore, it is essential to eliminate the variables, which are not significant in predicting the UCS. In this study, the thrust force (TF), torque (TQ), cutterhead rotation speed (CHRS), and advance rate (AR) were chosen as the input variables to reflect the interaction between the cutterhead and excavation face. Additional variables like the bearing thrust force (BTF) and feed pressure (FP), which are related to the face pressure, as well as the feed flow rate (FFR) and discharge flow rate (DFR), which correlate with the stress state of the surrounding ground, were also selected (Xu et al., 2023). Furthermore, the field penetration index (FPI) is a performance evaluation metric for the TBM and can be calculated using Equation 1. Bejari and Hamidi (2013) and Hassanpour et al. (2011) demonstrated a significant correlation between the FPI and UCS. Based on these findings, the FPI was selected as the input variable for the UCS prediction model.

$$FPI(kN/cutter)/(mm/rev) = \frac{F_N(kN/cutter)}{penetration(mm/rev)} \quad (1)$$

Where, F_N is the normal force per disc cutter (kN/cutter).

3.1.2 Extraction of stable phase

During the excavation of a single ring, approximately 1.4 m in length, the TBM operation data typically vary continuously. These variations can be broadly categorized into the start-up, stable, and end phases (Figure 2). From the TBM operation data for a single ring, the start-up phase was removed because the TBM operates in an unstable condition, and the end phase was also removed because it corresponds to the periods when the TBM is not excavating (Xu et al., 2023). The start-up phase was defined as the interval from the beginning of the excavation cycle to the point where a 20 mm advance occurred. Records were removed if any of the input variables had a value of zero or less or if they were missing.

Descriptive statistics for the variables used in predicting the UCS are summarized in Table 3.

Table 3. Statistical summary of variables in UCS prediction model.

Variables	mean	std	min	max	count
TQ (kN·m)	1011	210	447	1780	242
CHRS (rpm)	3.12	0.59	0.83	3.99	242
TF (kN)	22940	3116	6280	29837	242
BTF (kN)	9212	2514	3546	13541	242
FP (kPa)	388	72	274	545	242
FFR (m ³ /min)	6.81	0.26	6.07	7.45	242
DFR (m ³ /min)	7.15	0.22	6.45	7.61	242
AR (mm/min)	9.14	3.98	2.08	25.33	242
FPI ((kN/cutter)/(mm/rev))	84.98	52.25	8.48	307.68	242
UCS (MPa)	78.28	32.97	17	144	242

3.1.3 Data splitting and scaling

For training and validation of the UCS prediction model using supervised machine learning algorithms, the entire dataset was randomly divided into five subsets. In each iteration, four subsets were used for the training data, and the remaining subsets served as the test data. This process led to the creation of five combinations of the train and test datasets. Some machine learning algorithms, such as the k-nearest neighbors and support vector machines, can be influenced by the differing magnitudes of the input variables. To mitigate this problem, the MinMax scaling was applied to each of the five train and test sets.

3.2 Methodology

In this study, various supervised machine learning algorithms, including the k-nearest neighbors (KNN), support vector machine (SVM), random forest (RF), extreme gradient boost (XGBoost), categorical boost (CatBoost), and light gradient boosting machine (LGBM), were employed for the UCS prediction models. Each model was individually trained using five training sets. Hyperparameters for each of these models were optimized using the tree-structured Parzen estimator (TPE) Bayesian

optimization. During the optimization process, each training set was divided into five folds, and five-fold cross-validation was conducted for optimization. The performances of the optimized prediction models were evaluated using the coefficient of determination (R^2) and root mean squared error (RMSE).

$$RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2} \quad (2)$$

$$R^2 = 1 - \left\{ \frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{\sum_{i=1}^n (y_i - \bar{y})^2} \right\} \quad (3)$$

Where, y_i is the i^{th} actual value; \bar{y} is the mean of the actual values; \hat{y}_i is the i^{th} value predicted by the model.

3.3 UCS prediction results

The performance evaluation results for each model are summarized in Table 4. The highest average prediction performance for the test set was observed for the KNN, followed by the CatBoost in the second place. Although both the KNN and CatBoost demonstrated high average predictive performance on the test set, the standard deviation of the prediction performance for the KNN model was relatively higher than that of the CatBoost, indicating that the CatBoost provides more stable predictions. To perform the UCS predictions for the entire range, both the high average prediction performance and model stability must be considered. Therefore, the CatBoost was selected as the final UCS-prediction model. Using the final model, UCS predictions were made for the entire range, in which the operation data were recorded. The average UCS values from the five models were used to determine the final UCS predictions.

Table 4. Performance summary of UCS prediction models.

Model	Test RMSE		Test R^2	
	mean	std	mean	std
KNN	9.36	2.310	0.91	0.042
SVM	26.94	2.597	0.30	0.174
RF	15.03	1.095	0.78	0.045
XGBoost	11.55	1.602	0.87	0.043
CatBoost	11.01	1.011	0.88	0.030
LGBM	13.52	1.522	0.83	0.048

4 DISC CUTTER WEAR PREDICTION

Disc cutter wear prediction considers only the normal wear of the face cutters. Using the data on the radius reduction for disc cutter numbers 13–36, as measured from the 203 CHIs, the Coefficient Wearing rate (CW) was calculated. The CW is obtained by dividing the reduction in the disc cutter

radius (mm) by the distance traveled by the specific cutter and expressed as:

$$CW(\text{mm/km}) = \text{Cutter wear}(\text{mm}) / \text{Cutter rolling distance}(\text{km}) \quad (4)$$

4.1 Data preprocessing

The TBM operation data were filtered to include only the stable states, as outlined in Section 3.1.2, and the average values for each CHI were utilized. Geological conditions were also averaged across the CHI to match the CW data. Owing to the measurement errors in assessing the cutter wear, the CW data may contain noise. To address this issue, data points with a CW value of 0.1 or higher were initially excluded, as they were not considered to be representative of normal wear-related data. Subsequently, within each CHI, outliers in the CW variable were identified using the isolation forest technique, and records deemed as outliers were removed. Amount et al. (2017) revealed that among the TBM operation data, parameters such as the TF, TQ, AR, and cutter rotation speed (CRS) significantly influence the cutter wear. Accordingly, these variables were selected as the input features. Additionally, the FP, which is related to the face pressure, normal force per disc cutter (Fn), cutter seal grease temperature front (CTF), and cutter seal grease temperature rear (CTR), which are relevant to the force and temperature acting on the disc cutters, were selected as the input features. For the geological conditions, the estimated UCS from Section 3 and the weathering Grade (G1–G5) were selected as the input variables. The categorical variable, the weathering grade, was converted into numerical data using one-hot encoding. Descriptive statistics for the variables used to predict the CW are summarized in Table 5.

Table 5. Statistical summary of variables in CW prediction model.

Variables	mean	std	min	max	count
CTF (°C)	42.98	11.92	25.28	89.16	1686
CTR (°C)	34.90	6.93	20.60	52.56	1686
TQ (kN·m)	1009	108	644	1502	1686
CRS (rpm)	26.82	8.47	4.68	46.56	1686
TF (kN)	22855	2904	12623	29470	1686
FP (kPa)	372.42	72.64	209.06	546.44	1686
AR (mm/min)	9.26	2.99	2.77	19.75	1686
Fn (kN/cutter)	209.38	44.66	84.85	319.16	1686
UCS (MPa)	81.12	14.02	38.56	108.89	1686
CW (mm/km)	0.02045	0.01294	0.00219	0.08870	1686

The complete dataset was divided into training and test sets, and MinMaxScaling was applied following the procedure detailed in Section 3.1.3.

4.2 Methodology

A CW prediction model was developed using the KNN, SVM, RF, XGBoost, CatBoost, and LGBM algorithms. Hyperparameter optimization and performance evaluation were conducted using the same methods employed for the UCS prediction.

To investigate the importance of the input variables used in the CW prediction model, a SHapley Additive exPlanation (SHAP) analysis was conducted. SHAP, proposed by Lundberg and Lee (2017), is a method for evaluating the importance of variables in predictive models, which utilize algorithms, such as machine learning. The SHAP value (ϕ_i) was calculated as:

$$\phi_i = \sum_{S \subseteq N \setminus \{i\}} \frac{|S|!(N-|S|-1)!}{|N|!} [f(S \cup \{i\}) - f(S)] \quad (5)$$

Where N is the set of all the features; S is the subset of N except for the i^{th} feature; $f(S \cup \{i\})$ is the conditional expectation of the predictive model when including the i^{th} feature; $f(S)$ is the conditional expectation of the predictive model when excluding the i^{th} feature.

Calculating the SHAP values requires substantial computational resources as the number of features increases. Methods, such as the Kernel SHAP and Tree SHAP have been proposed to approximate the SHAP values. The Tree SHAP method exploits the internal structure of tree-based models to calculate the SHAP values accurately and quickly (Lundberg et al., 2020).

4.3 CW prediction results

The performance evaluation results for each model are listed in Table 6.

Table 6. Performance summary of CW prediction models.

Model	Test RMSE		Test R ²	
	mean	std	mean	std
KNN	0.00833	0.000268	0.581	0.047115
SVM	0.00965	0.000730	0.440	0.060054
RF	0.00805	0.000472	0.611	0.03276
XGBoost	0.00783	0.000440	0.630	0.043621
CatBoost	0.00798	0.000451	0.617	0.038959
LGBM	0.00791	0.000398	0.624	0.034377

The XGBoost model exhibited the lowest average test RMSE of 0.00783 and highest average test R² of 0.630. The LGBM followed closely, with the second-lowest average test RMSE of 0.00791 and second-highest average test R² of 0.624. Regarding the standard deviation of the test RMSE, the KNN, LGBM, and XGBoost models were ranked in the ascending order. Similarly, for the standard deviation of the test R², RF was followed by the LGBM, and CatBoost. In conclusion, the LGBM model was found to have relatively high performance and stability compared with the other models. A comparison between the CW values predicted by the LGBM models and actual CW values is shown in Figure 3.

Feature importance analysis for the LGBM was conducted using the Tree SHAP. Figure 4 shows the mean absolute SHAP values of the input features used in the LGBM.

A higher mean absolute SHAP value indicates a more important feature of the prediction model. In the LGBM, the order was CTR > TQ > AR > CTF > FP. This indicates that the cutter grease temperature (rear and front sides), torque, advance rate, and feed pressure are utilized significantly in predicting the CW in the LGBM models.

Figure 3. Plots of LGBM models.

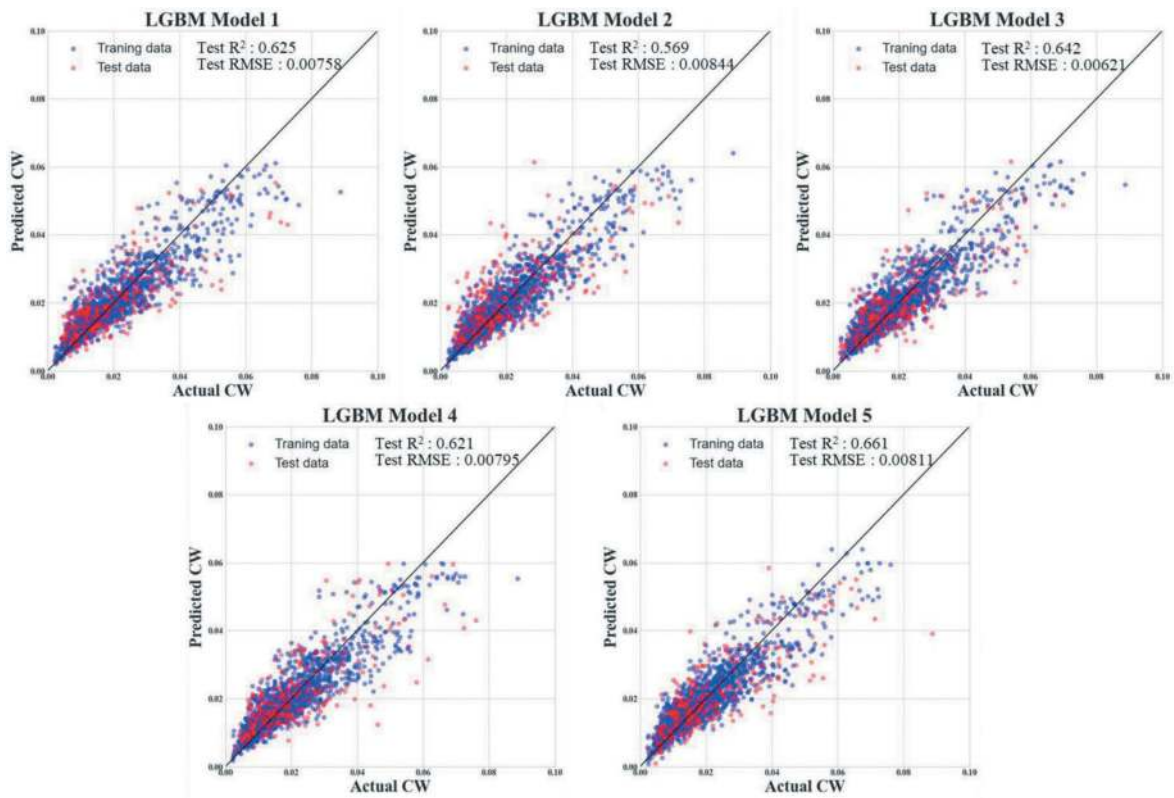

Figure 4. Mean absolute SHAP values of LGBM models.

5 CONCLUSIONS

In this study, we predicted the Coefficient Wearing rate (CW) of a slurry TBM by considering its operating parameters and geological conditions. Owing to the relative scarcity of the UCS data compared to other operations and CW data, we first predicted the UCS using the operation data and drilling survey results to address this data limitation. Subsequently, the CW predictions were performed using the complete dataset. The conclusions drawn are as follows:

- (1) For the UCS prediction, we performed data pre-processing activities, such as selecting the input variables, extracting the stable states, and partitioning the data, followed by the MinMaxScaling. We created the UCS prediction models using six supervised machine-learning algorithms (KNN, SVM, RF, XGBoost, CatBoost, and LGBM) and compared their average predictive performances. The CatBoost model displayed relatively high prediction accuracy for the test data, with an average RMSE of 1.001 and an R^2 score of 0.88. Owing to its superior predictive performance and stability, the CatBoost model was selected for the UCS prediction across the recorded sections of the operation data.
- (2) The CW prediction models were developed using the input variables CTF, CTR, TQ, CRS, TF, TQ, FP, AR, Fn, weathering grade (G1–G5), and UCS, employing algorithms, such as the

- KNN, SVM, RF, XGBoost, CatBoost, and LGBM. Upon comparing the performance of these models, the XGBoost model exhibited the lowest average test RMSE of 0.00783 and highest average test R^2 of 0.630. The LGBM followed closely, with the second-lowest average test RMSE of 0.00791 and second-highest average test R^2 of 0.624. Regarding the standard deviation of the test RMSE, the KNN, LGBM, and XGBoost models were ranked in the ascending order. Similarly, for the standard deviation of test R^2 , the RF was followed by the LGBM, and CatBoost. In conclusion, the LGBM model was found to have relatively high performance and stability compared with the other models.
- (3) Upon analyzing the feature importance using the Tree SHAP for the LGBM models, the top five important features were found to be the CTR, TQ, AR, CTF, and FP. This indicates that the cutter grease temperature (rear and front sides), torque, advance rate, and feed pressure are utilized significantly in predicting the CW in the LGBM models.
- (4) In this study, the mean values of the operation data and geological conditions for each CHI interval were utilized to predict the cutter wear. Therefore, it did not adequately account for the variability in the operating conditions. Future research could use algorithms capable of handling time-series data to properly consider such variability, potentially improving the accuracy of cutter wear prediction.

ABSTRACT: In the Himalayan region, tunnels are often constructed through complex and varying geological formations having rock mass with higher degree of jointing, faulting, folding, and weakness/shear zones. Such rock mass condition significantly increases the rock mass permeability which enables a higher possibility of water leakage into and out of the headrace tunnels built for hydropower projects and is a challenging situation for tunnel stability. Therefore, comprehensive leakage assessment and effective pre- and post-grouting application are essential in hydropower tunnels. In this research, the water leakage was predicted by using three machine learning approaches such as Support Vector Regression (SVR), Decision Tree (DT) regression, and K-Nearest Neighbors (KNN) models. The water leakage/inflow was predicted in one of the hydropower tunnels based on the geological condition of rock mass, rock mass quality, and hydro-geological conditions. The effective post-grouting method was applied to mitigate the potential water leakage and to enhance the rock mass quality and stability of the hydro-power tunnel. It was observed that the injection grouting technique helps to make tunnels less permeable, reduces instability conditions, and ensures the long-term safety and structural integrity of the hydropower tunnels.

Keywords: Complex geology, Machine Learning, Leakage, Stability, Post-grouting

1 INTRODUCTION

The tunnel construction in the Himalayan region faces severe tunneling challenges due to the complex geological conditions characterized by a higher degree of jointing, high degree of faulting, folding, weathering, and the presence of weakness/shear zones within the rock mass (Panthi 2006). These complex geological conditions are due to the consequence of active tectonic activities in the region. These conditions significantly increase rock mass permeability and make headrace tunnels of hydropower projects susceptible to water leakage. Thus, groundwater inflow and leakage are the most common and challenging issues in hydropower tunnelling projects in the Himalayan region (Panthi 2006). Water ingress into these tunnels not only affects the stability of the

tunnel but also poses operational and safety risks, which could lead to project delay and huge economic loss (Panthi and Nilsen 2010). Therefore, an accurate water inflow/leakage assessment is essential for timely measure and control of water inflow/leakage, and the selection of appropriate grouting techniques to enhance the strength of rock mass and to secure stability of water tunnels.

Many researchers highlight the use of analytical, empirical, and numerical techniques and theoretical frameworks for the prediction of water ingress and grouting capability. However, it is challenging to predict the accurate amount in tunnelling projects (Holmøy 2008 and Stille 2015). To mitigate these limitations, machine learning (ML) techniques could be an appropriate approach to predict the water inflow/leakage and to decide effective grouting

*Corresponding author: tek.b.katuwal@ntnu.no

measures. However, this is challenging due to the limited availability of field data related to rock mass properties, structural geology, groundwater level, project topography, and effective stresses.

This paper attempts to present different machine learning (ML) approaches for comprehensive assessment and prediction of water inflow/leakage, and the application of injection grouting to reduce water leakage and enhance tunnel stability in the headrace tunnel of 54 MW Super Dordi Hydropower Project (SDHEP).

2 PROJECT BACKGROUND

2.1 Brief about SDHEP

The Super Dordi Hydropower Project “Kha” (hereafter referred to as SDHEP) is a Run-of-River (ROR) project, which is located at Dordi Rural Municipality, Lamjung District, Gandaki Province of Nepal, which is about 188 km northwest of Kathmandu. Geographically, this project area is located between Longitudes 84°34’15” E and 84°31’00” E, and Latitudes 28°18’43” N and 28°16’20” N. The project is a high-head scheme with a gross head of 638 m and has a design discharge is 9.9 m³/sec. The total installed capacity of this project is 54 MW. The main components of this project are low-head diversion dam (18.5 m X 3.3 m), D – shaped gravel trap (36 m X 4 m X 2.3-4 m), double-chamber desander basins (123 m X 11 m X 13 m), D – shaped headrace tunnel (2.8 m Dia and 5.2 km length), surge shaft (6 m Dia. and 49 m height), pressure shafts (2.2 m dia. and 1052 m long including penstock branches to two turbines), underground powerhouse (51.3 m X 15 m X 29.6 m), tailrace tunnel, and access tunnel (PHCPL 2022). In order to address the challenges associated with frequently occurring high tectonic activity and the risk of landslides, and to ensure long-term stability, the major water conveyance structures such as the desander, headrace tunnel, surge shaft, penstock shaft, powerhouse cavern, and tailrace tunnel are strategically constructed underground.

2.2 Project geology

Geologically, the SDHEP area is located in the Higher Himalayan range. The major rock types are schist and gneiss as shown in Figure 1. Predominantly, the geological composition of the area consists of banded gneiss with schist partings (Adhikari et al. 2023, Katuwal et al. 2023). These geological formations extensively appear in the Higher Himalayan region, spanning from east to west across the entire Himalayan range.

The upper part of the headrace tunnel (HRT) encountered the slightly to moderately weathered and medium foliated strong gneiss. A relatively short stretch of the tunnel section encountered fresh to slightly weathered gneiss, which is more dominant with quartz content. Likewise, the downstream section of HRT, surge shaft, penstock shaft, and powerhouse

cavern encountered the slightly to moderately weathered and medium foliated strong gneiss. Mainly, the banded gneiss with occasional schist parting is encountered along the alignment of the headrace tunnel. The topography of the project area is covered by mainly two soil types, i.e., colluvial and alluvial soil. The colluvial soil consists high content of fine silt and clay which is exposed on the surface of the HRT alignment. Likewise, the surface of powerhouse and headworks are exposed to alluvial soil which consists of predominantly coarse-grained material such as sand, gravel, cobble, and boulder.

Figure 1. Longitudinal Profile of SDHEP.

3 MACHINE LEARNING TECHNIQUES

Nowadays, machine learning (ML) techniques have been widely applicable to predict water ingress in tunnel projects. The ML approach shows good performance in predicting water inflow/leakage in tunnel projects (Mahmoodzadeh et al. 2023). Therefore, in this paper, three ML regression models such as Support Vector Regression (SVR), Decision Tree (DT) regressor, and K-Nearest Neighbors (KNN) are used to predict the water inflow/leakage at the SDHEP headrace tunnel. These regression models help to predict the dependent variables from several features or independent variables. The most appropriate regression model has been established by comparing the eight statistical indices such as R-squared (R²), Mean Absolute Error (MAE), Mean Squared Error (MSE), Root Mean Squared Error (RMSE), Relative Root Mean Squared Error (RRMSE), Mean Absolute Percentage Error (MAPE), Mean Relative Error (MRE), and Variance Accounted For (VAF). For this purpose, the research methodology is set up mainly with four components such as dataset preparation, model selection, training and validation of selected model, and result analysis and discussions.

3.1 Database study

To predict the water ingress/leakage in the hydropower tunnels, it is necessary to collect the filed data and select the effective parameters. Therefore, in this case study, the number of datasets and types of effective parameters such as Rock Quality Designation (RQD), Joint number (Jn), Joint Roughness (Jr), Joint alteration number (Ja), Q-Classification value (Q), static head (h), overburden (H), shortest distance from the tunnel to topography (d), and specific discharge (q),

average Lugeon Unit (LU) are collected based on actual data received from the project. The summary of the field datasets is presented in Tables 1 and 2, which are used for training and testing parameters. These tables depict the statistical description of selected parameters by defining the minimum, standard deviation, maximum, mean values, and different percentile values.

Table 1. Field datasets for rock mass quality.

	RQD	Jn	Jr	Ja	Q
Count	175	175	175	175	175
Mean	62.17	6.19	1.57	1.55	7.77
Std	9.52	1.17	0.3	0.55	5.69
Min	30	3	1	1	1.1
25%	55	6	1.5	1	3.33
50%	65	6	1.5	2	6
75%	70	6	1.5	2	10.24
Max	80	9	3	3	30

75%	19.96	150	179	2.88	1.3
Max	20.56	191	231	59.51	27.3

3.1.1 Correlation analysis

In machine learning, the correlation heatmap is often used to establish and visualize the strength of relationship (multicollinearity) between the multiple feature variables and dependent variables. The accuracy of the predicted model is significantly influenced by the multicollinearity numerical values. In this heat map, Color-coding cells make it easy to see how variables are related with a quick look.

In this research, the correlation heatmap analysis (using the Pearson correlation coefficient) was performed between collected database from the head-race tunnel. This process illustrates the interrelation between independent features and dependent variable. The range of this analysis lies within [-1, 1]. A high value of [+1] means these variables are highly correlated and have a high positive effect and vice versa. In Figure 2, the positive correlation value of 0.62 is seen between the RQD and Q-value, which is remarkable since an increase in the RQD value will give an increased quality of rock mass. The Figure also depicts that the rate of water ingress/leakage positively correlated with the overburden, and joint alteration number. On the other hand,

parameters such as RQD, Q-value, and joint roughness are inversely correlated. Moreover, Figure 2 indicates that the correlation between the available datasets seems relatively low. This may be due to the fact that the water ingress and grout consumption are also influenced by variables such as persistence, joint volume, spacing of joints, and infilling material characteristics.

Figure 2. Correlation matrix for database.

3.1.2 Principal Component Analysis (PCA)

The PCA is a multivariate statistical approach that is used for the dimensionality reduction of project databases. For this purpose, the principal components have been established to describe the linear combination of features and to define the variation in the selected database. Figure 3 illustrates the screen plot of principal components for the ingress/leakage of water. This Figure clearly explains that 90% of selected database variance is explained by the six major principal components. The variability of each variable in these principal components are presented in Table 3.

Table 3. A Summary of principal components coefficients.

Variables	PC1	PC2	PC3	PC4	PC5	PC6
h	-0.27	-0.15	-0.44	-0.35	0.29	-0.54
H	0.15	0.04	-0.58	0.5	0.41	0.13
RQD	-0.4	0.23	0.31	0.01	0.23	0.45
Jn	0.19	-0.28	0.55	-0.13	0.53	-0.32
Jr	-0.21	0.62	-0.03	-0.2	-0.29	-0.34
Ja	0.16	0.34	0.26	0.63	0	-0.49
Q	-0.39	0.37	0.02	-0.01	0.54	0.07
LU	0.5	0.32	-0.06	-0.28	0.16	0.09
q	0.49	0.33	-0.06	-0.3	0.15	0.13
Eigenvalues	2.89	1.50	1.34	1.11	0.82	0.78
Variability (%)	31.88	16.52	14.78	12.26	9.08	8.57
Cumulative (%)	31.88	48.40	63.18	75.77	84.53	93.10

Figure 3. Screen plot for Principal Components.

3.1.3 Variance Inflation Factor (VIF)

Dimension of the given data set is primarily reduced by the PCA analysis without quantifying the multicollinearity. To address this limitation, the Variance Inflation Factor (VIF) has been applied. The correlation strength between the independent variables has been established by using the VIF. Moreover, the VIF can provide information about the severity and presence of multicollinearity in the databases, which is illustrated in Table 4. The VIF = 1 indicates no multicollinearity between the selected variables. When the value of the VIF is greater than 10, it is a sign of a high degree of multicollinearity between the variables and it will be problematic in the regression models, therefore, eliminating these features will be easier for regression analysis. However, the selection of independent variables depends upon the selection of the regression model (Cheng et al. 2022). In this research, all parameters are considered for the establishment of a regression model.

Table 4. A summary of Variance Inflation Factor (VIF).

For q	H	h	RQD	Jn	Jr	Ja	Q	LU
VIF	45.9	4.3	65.3	25.1	31.5	11.8	4.8	4.9

3.2 Data distribution

The selected datasets have been organized into distinct plots to enable quick visualization and enhance understanding. To accomplish this, box plots were initially generated for the chosen datasets. It was observed that the Jn, Jr, and Ja datasets displayed limited data variability and were not well-distributed. To address this limitation, the plot performance has been enhanced by incorporating both box and histogram plots for the selected datasets as shown in Figure 4. Histograms display how data is distributed in terms of shape and frequency. In contrast, box plots are useful for a rapid assessment of central tendencies, data spread, and the presence of outliers.

In Figure 4, except the box plot data of h, and RQD, the data are out of the middle of the box. Therefore, to address this issue and combine both of these distribution representations into a single plot,

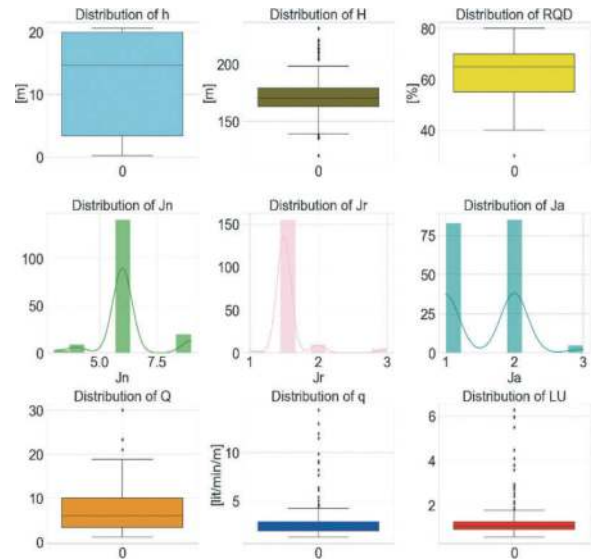

Figure 4. Multivariate data visualization of selected parameters.

the violin plot is found to be a more effective choice for visualizing of data that has multiple peaks or a skewed distribution. Likewise, a violin plot is the configuration of the data set that enhances clarity and understanding. Moreover, the violin plots illustrate the summary of statistics and probability density function (or density) of each feature and dependent variables. Figure 5 illustrates the distribution of the statical quartile summary of filed data set. In these Figures, a wider region of density plot indicates the more frequent occurrence and vice versa.

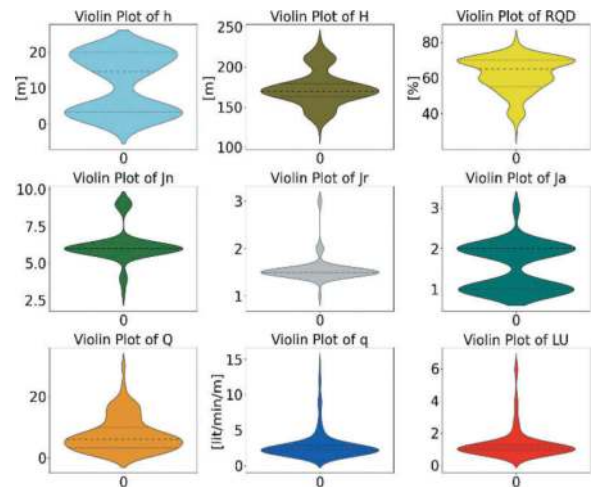

Figure 5. Datasets distribution in violin plot.

3.3 Data normalization

Data normalization constitutes a fundamental process within the domain of machine learning (ML). This procedure is essential due to the inherent variability in the dimensions and units of input data,

which can fluctuate with changing input data. The act of normalization serves to rescale all input features and variables to a uniform scale. Table 1 and 2 depicts that the range of specific discharge varies from 1.28 lit/min/m to 59.51 lit/min/m, whereas the joint alteration number (Ja) varies from 1 to 3 and the height of overburden varies from 120 m to 131 m. This indicates that the magnitude of input variables are in different scales. Therefore, data normalization should be conducted for better correlation and prediction of machine learning models.

3.4 Statistical analysis of selected model

Statistical evaluation of selected model plays a crucial role in understanding and predicting the efficient model for headrace tunnels of hydropower projects. Therefore, various statistical indices such as R-squared (R^2), Mean Absolute Error (MAE), Mean Squared Error (MSE), Root Mean Squared Error (RMSE), Relative Root Mean Squared Error (RRMSE), Mean Absolute Percentage Error (MAPE), Mean Relative Error (MRE), and Variance Accounted For (VAF) are calculated by using Equation 1 to Equation 8, respectively. The linear correlation between the predicted and actual values is established by using R^2 .

$$R^2 = 1 - \frac{\text{sum of squared regression (SSR)}}{\text{sum of squared total (SST)}} \quad (1)$$

$$\text{MAE} = \frac{1}{n} \sum_{i=1}^n |y_i^a - y_i^p| \quad (2)$$

$$\text{MSE} = \frac{1}{n} \sum_{i=1}^n (y_i^a - y_i^p)^2 \quad (3)$$

$$\text{RMSE} = \sqrt{\frac{1}{n} \sum_{i=1}^n (y_i^a - y_i^p)^2} \quad (4)$$

$$\text{RRMSE} = \sqrt{\frac{1}{n} \sum_{i=1}^n \left(\frac{y_i^a - y_i^p}{y_i^a} \right)^2} \quad (5)$$

$$\text{MAPE} = \frac{1}{n} \sum_{i=1}^n \left| \frac{y_i^a - y_i^p}{y_i^a} \right| * 100\% \quad (6)$$

$$\text{MRE} = \frac{1}{n} \sum_{i=1}^n \left| \frac{y_i^a - y_i^p}{y_i^a} \right| \quad (7)$$

$$\text{VAF} = 1 - \left| \frac{\text{var}(y_i^a - y_i^p)}{\text{var}(y_i^a)} \right| * 100\% \quad (8)$$

Where, actual and predicted values of variables are represented by y_i^a and y_i^p respectively, and n in the equations is the total number of datasets that are used in selected machine learning models.

4 WATER INFLOW PREDICTION MODEL AND RESULTS

In this study, Support Vector Regression (SVR), Decision Tress (DT), and K-Nearest Neighbors (KNN) models are applied for the assessment and prediction of water ingress in the headrace tunnel of SDHEP in Anaconda version 3.6 with computation in Python.

4.1 Support Vector Regression (SVR)

Support Vector Regression (SVR) is a machine-learning technique specifically adapted for predicting water ingress in the headrace tunnel. It connects the capabilities of support vector machines to model and predict water ingress into hydropower tunnels, which supports rock engineers to make well-informed choices for effective management and mitigation of water ingress challenges. The Figure 6 illustrates the water inflow prediction by using this SVR model.

Figure 6. SVR model for water inflow prediction.

As Figure 6 indicates, there is a good correlation between the model and different dependent variables. Table 5 provides information about the statistical indices R^2 , MAE, MSE, RMSE, RRMSE, MAPE, MRE, and VAF which are evaluated as 0.99, 0.09, 0.02, 0.12, 0.05, 3.47, 0.48, and 99.6, respectively, where the SVR model indicates high degree of accuracy. Therefore, this ML model has a good capacity for the prediction of water leakage/inflow in hydropower tunnels.

Table 5. A summary of statistical indices of SVR model.

R^2	MAE	MSE	RMSE	RRMSE	MAPE	MRE	VAF
0.99	0.09	0.02	0.12	0.05	3.47	0.48	99.6

4.2 Decision Tree (DT)

A Decision Tree (DT) is the most widely used predictive model for regression analysis in the context

of hydropower tunnels to forecast and assess the probability of water ingress. It's a visual representation of a decision-making process that considers various factors and their interactions to determine the probability of water inflow/leakage in/from the tunnels. This tool helps rock/tunnel engineers make decisions to prevent and manage water ingress effectively, ensuring the safety and efficiency of hydropower operations.

The Figure 7 illustrates the comparison between the actual field data set and the water inflow prediction by using this DT model. Likewise, Table 6 establishes the statistical indices R^2 , MAE, MSE, RMSE, RRMSE, MAPE, MRE, and VAF which are evaluated as 0.97, 0.14, 0.08, 0.29, 0.10, 4.67, 0.98, and 97.6, respectively, which indicate that the DT models have a good capacity for the prediction of water inflow. The static indices indicated that this model presents a good correlation with the features and dependent variables.

Figure 7. DT model for water inflow prediction.

Table 6. A summary of statistical indices of SVR model.

R2	MAE	MSE	RMSE	RRMSE	MAPE	MRE	VAF
0.97	0.14	0.08	0.29	0.10	4.67	0.98	97.6

4.3 K-Nearest Neighbors (KNN)

A K-Nearest Neighbors (KNN) is the most widely used predictive model for regression. Figure 8 illustrates the comparison between the actual field data set and the KNN prediction model for water inflow in the case tunnel project. Table 7 demonstrates the statistical indices R^2 , MAE, MSE, RMSE, RRMSE, MAPE, MRE, and VAF which are evaluated as 0.89, 0.45, 0.38, 0.61, 0.22, 17, -1.22, and 88.9, respectively. The static indices indicated that this model presents a good correlation with the features and dependent variables. All outcomes indicate that the KNN models have a good capacity and are acceptable for the prediction of water inflow in hydropower tunnels.

Figure 8. KNN model for water inflow prediction.

Table 7. A summary of statistical indices of SVR model.

R2	MAE	MSE	RMSE	RRMSE	MAPE	MRE	VAF
0.89	0.45	0.38	0.61	0.22	17	-1.22	88.9

5 GROUT CONSUMPTION

Post-grouting technique is very often used to control water leakage from headrace tunnels of hydropower projects in the Himalayan region. The measurement of the Lugeon value, which assesses rock permeability, plays a pivotal role to evaluate the effectiveness of post-grouting. At SDHEP, the post-grouting technique was used to control potential water leakage from the headrace tunnel. The post-grouting technique involves the injection of cement grout into the surrounding rock mass to achieve substantial sealing of joints and discontinuities and reduce permeability. A typical drill hole pattern adopted while post-grouting is illustrated in Figure 9. This Figure demonstrates the drill hole length, and drilling pattern in both the hill and valley sides of the headrace tunnel. Likewise, a detailed description of the parameters associated to post-grouting is illustrated in Table 8.

Figure 9. Detail illustration of drill hole arrangement.

At SDHEP the post-grouting not only enhanced the structural integrity of the rock mass but also established a water-resistant barrier, thereby minimizing the risk of water leakage from the tunnel. Consequently, the combination of post-grouting and the reduction in Lugeon value ensured the long-term structural integrity and operational reliability of the water tunnel.

Table 8. Parameter for Injection Grouting.

Parameters	Values
Drill hole length (m)	4
Drill hole diameter (mm)	45-48
Packer diameter (mm)	42
Placement of Packer inside (m)	2
Minimum Grouting Pressure (bar)	4-6
Grout pressure at seepage area (bar)	15
Bentonite (%)	5
Plasticizer (%)	1.5-3
Retarder (if mixed outside) (%)	1.5
W/C ratio	1:1

5.1 Grout consumption assessment

The effective post-grouting work is very challenging since it is extremely difficult to achieve targeted pressure without losing unnecessary extra grout material. Therefore, the effective post-grouting work is a challenging task since the grout take is significantly affected by the rock mass properties, topographical condition, structural geology, joint infilling material, groundwater level and effective rock stress conditions. The summary of the field datasets is presented in Table 9, which illustrates the rock mass class (RMC) count and statistical variation of selected parameters that defines minimum, maximum, mean values, standard deviation, and different percentile values.

The pairwise data relationships between different parameters used in grout consumption assessment are illustrated in Figure 10. The Figure shows pairwise plot or scatterplot matrix. This plot helps to visualize and explore different independent and dependent variables. The plot can describe how different variables are relative to each other based on different types of rock mass classes. Moreover, the plot provides a quick overview of the relationship between grout consumption (GC), joint aperture (e), hydraulic

permeability (K), Lugeon unit (LU), and water ingress (q) for rock mass class (RMC) II, III, IV, and V. For example, in the context of rock mass classified as Type IV, a high degree of fracture aperture can significantly increase the hydraulic permeability of the rock mass. As the Lugeon unit, a measure of permeability increases, it signifies a higher propensity for water ingress from the hydropower tunnel. Consequently, to mitigate this condition and ensure the stability of the tunnel, large quantities of grout material may be necessitated to seal the fractures and reduce water leakage. Therefore, the matrix is a valuable tool for gaining insights and is particularly useful when dealing with multivariate data, as it offers a quick and comprehensive overview of the relationships between variables, helping in the initial stages of data exploration.

The relationship between water leakage, Lugeon unit, and grout consumption is shown in Figure 11. Likewise, the relationship between hydraulic permeability, hydraulic aperture, and grout consumption is illustrated in Figure 12.

Figure 11. Relationship between water inflow, Lugeon unit, and grout consumption.

6 RESULT ANALYSIS AND DISCUSSION

The water leakage and grout consumption assessments were made on the headrace tunnel of SDHEP. The assessment was conducted using field datasets

Figure 12. Relationship between hydraulic permeability, hydraulic aperture, and grout consumption.

related to the rock mass quality, hydro-geological conditions, Lugeon unit, and grout consumption.

6.1 Result comparison of water inflow prediction

Various machine learning models were employed to predict water leakage from the headrace tunnel. The prediction was then compared to actual datasets. All models demonstrated acceptable and good predictive performance individually. However, it is essential to compare and rank these models to enhance the reliability of selected models. To achieve this, statistical indices were used to evaluate and categorize the performance of each model as good, better, or best, with respective weightings of 1, 2, and 3. The overall ranking of each model was determined by summing assigned weights. Table 10 illustrates the comparative ranking of selected models. The table shows that the SVR, DT, and KNN models perform best, better, and good performance, respectively to predict the ingress of water.

Table 10. Comparison of Water inflow predicted models.

Parameter/Model		SVR	DT	KNN
R ²	Value	0.99	0.97	0.89
	Weightage	3	2	1
MAE	Value	0.09	0.14	0.45
	Weightage	3	2	1
MSE	Value	0.02	0.08	0.38
	Weightage	3	2	1
RMSE	Value	0.12	0.29	0.61
	Weightage	3	2	1
RRMSE	Value	0.05	0.10	0.22
	Weightage	3	2	1
MAPE	Value	3.47	4.67	17
	Weightage	3	2	1
MRE	Value	0.48	0.98	-1.22
	Weightage	3	2	1

	Weightage	3	2	1
Remarks	Total Weightage	24	16	8
	Rank	1	2	3

Figure 13. Actual and prediction results in comparisons.

The performance of the selected models is compared using statistical tools such as R-squared, Adjusted R-squared, and Pearson's r value. The actual test database and predicted results of the selected ML models are presented in Figure 13. In the Figure, SVR shows the strongest correlation between the predicted and actual databases, followed by the DT and KNN regression models. Moreover, Pearson's r measures how closely the data points in the scatterplot cluster around a straight line. The authors found that the SVR model quantifies a strong linear relationship between variables, followed by the DT and KNN models. However, all selected ML models establish a strong relationship between actual and predicted variables.

6.2 Result comparison of grout consumption

In the above section, the relationship between different independent variables such as water inflow, Lugeon unit, hydraulic permeability, and hydraulic aperture are plotted with grout consumption volume. These curves show fairly good correlations between these parameters in most of the chainage and rock mass conditions. In some parts, the results show unusual tendencies. However, after injection grouting the ingress of water is fully controlled and the headrace tunnel is well-functioning. Hence, the post-injection grouting was successful and has significantly reduced the water leakage potential and rock mass permeability and improved the rock mass strength, and enhanced tunnel stability.

7 CONCLUSION

A comprehensive overview of water ingress/leakage in the headrace tunnel of SDHEP was conducted based on the field data consisting of geology, hydrogeology, and injection grout parameters. After that, thorough data interpretation, statistical correlation, and regression analysis were performed using machine learning algorithms to predict water leakage from the headrace tunnel. It has been observed that machine learning techniques may be successfully used to assess the water ingress potential of the headrace tunnels of hydropower projects. Different machine learning

regression models, such as Support Vector Regression (SVR), Decision Tree (DT), and K-Nearest Neighbors (KNN), have demonstrated the ability to predict water inflow/leakage in the water tunnel. As the field continues to evolve, the integration of machine learning in the management of water tunnels may prove to be a helpful tool for assessing tunnel stability challenges.

ABSTRACT: The replacement of damaged or worn disc cutters in tunnel boring machines (TBMs) leads to significant costs and downtime, affecting TBM utilization and advance rates. Therefore, accurately estimating disc cutter lifespan is crucial for efficient TBM deployment in tunnelling projects. In this study, a novel machine-learning-based prediction model designed to forecast disc cutter wear, taking into account individual cutter travel lengths was proposed. The model was implemented using the cutter head intervention (CHI) report from the hard rock excavation section of Daegok-Sosa tunneling project in Korea. Incorporating 9 wear-inducing factors, the developed model demonstrated exceptional prediction accuracy for the single-ring excavation lengths. The proposed model is expected to improve existing disc cutter lifespan prediction methodologies and reduce associated costs and time impact.

Keywords: Disc cutter wear prediction, Machine Learning, EPB TBM Tunnelling

1 INTRODUCTION

The global use case of tunnel boring machines (TBMs) in the tunnelling industry has surged, attributed to their superior performance in ensuring safety and environmental sustainability. Earth Pressure Balance (EPB) TBMs, in particular, are utilized in fine-graded ground conditions where the balance of earth pressure is maintained to prevent ground collapse and to control the advancement of the machine. One of the critical components of TBM is the disc cutter, which plays a pivotal role in the excavation process. These cutters, essential for rock-breaking, undergo wear during TBM operations, necessitating timely replacements to maintain efficiency. Thus, accurately predicting cutter lifespan is crucial for cost-effective tunnelling (Hassanpour et al., 2015).

Several researchers developed disc cutter wear prediction models in TBMs, primarily based on empirical

data from past tunnelling projects. Notably, the Colorado School of Mines (CSM) and the Norwegian University of Science and Technology (NTNU) models are well-known. The CSM model, grounded in the Cerchar abrasivity index (CAI), offers a semi-theoretical approach (Rostami, 1993; 1997), while the NTNU model is more empirically driven, utilizing extensive field data (Bruland, 1998). Despite these models, predicting cutter wear remains challenging due to the variability in geological conditions and TBM specifications. Many models, while effective in specific projects, falter in broader applications, emphasizing the absence of a universally applicable model.

Given the complexities of disc cutter wear, influenced by diverse geological conditions and TBM operational nuances, there's a growing interest in applying machine learning (ML) for predictions. Recent advancements in ML, as showcased by studies like Kim et al. (2020) and Mahmoodzadeh et al. (2021),

*Corresponding author: dkkim22@kict.re.kr

have demonstrated promising results in predicting cutter wear. Specifically, the Random Forest(RF) method has shown high accuracy in wear predictions. However, a gap remains in predicting wear across different disc locations, highlighting the need for more comprehensive models to predict the individual cutter wear amount instead of the average disc cutter wear.

This research investigates into machine learning-based prediction models, focusing on the random forest (RF) method, to predict the individual cutter wear amount accumulated during a single ring excavation length. Specifically, the wear of individual disc cutters were incorporated for the first time to factor the travel lengths of each disc cutter. Encompassing geological conditions, TBM operational data, and cutter wear records, total of 17,947 datasets were employed to train and test the cutter wear predicting model.

2 SITE DESCRIPTION

2.1 Overview of project and machinery

The Daegok–Sosa railway project spans 18.4 km, linking the Sosa–Wonsi railway to the western coast and enhancing the railway grid in northwest Seoul, as shown in Figure 1. It encompasses two parallel tunnels, each 2.7 km, with a section of 1.2 km beneath the

Figure 1. Construction plan overview.

Han River at depths between 25–55 m. To navigate these challenging terrains, two earth pressure balance (EPB) shield TBMs were employed, featuring inner and outer diameters of 7.0 m and 7.7 m. Key TBM specifications are demonstrated in Table 1.

Table 1. Key specifications of EPB TBM.

Specification [Unit]	Range
Torque [kNm]	7510-12,843
Maximum thrust force [kN]	66,523
Rotational speed [rpm]	0-3.7
Segment length [m]	1.5
Power [kW]	2080 (13x160)

2.2 Geological conditions

Situated in the Gyeong-gi massif, the tunnel area is characterized by a Precambrian gneiss complex and granite intrusions from the Jurassic era. The alignment reveals a mix of alluvial deposits, including sand, silt, and clay, with granite and gneiss layers, as shown in Figure 2. Notably, the gneiss and granite exhibit high abrasiveness, indicated by Cerchar abrasivity index (CAI) values of 4–6. The tunnelling encountered mixed geological formations, segmented into mixed ground, hard rock, and soft ground sections. This research primarily delves into the hard rock sections located between chainage 4800–5600, to analyse on the abrasive wear rate of disc cutters during the hard rock zone excavation.

Figure 2. Geological layout along the alignment.

3 DISC CUTTER WEAR CHARACTERISTICS

The Daegok–Sosa tunnelling project utilized a dome-shaped cutterhead, as depicted in Figure 3. This cutterhead was fitted with a mix of disc cutters, scrapers, and buckets. Fifty disc cutters were positioned at the cutterhead’s forefront, with three distinct types based on their location: center, face, and gauge cutters. The majority were face cutters, spaced 90 mm apart. All single cutters were 18 inches, with a hardness of 55–58 kN on the Rockwell hardness C scale (HRC).

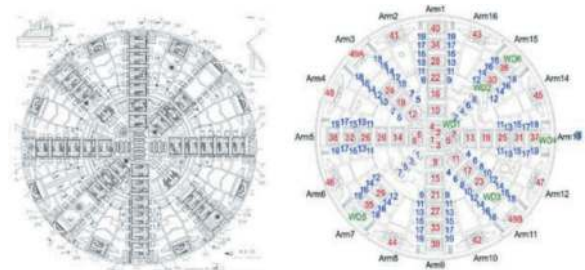

Figure 3. Cutter shape of the EPB TBM.

During the TBM tunnelling, cutting tools wear out due to ground interaction. Disc cutters apply force to rocks, causing chipping. They’re also equipped to manage boulders in soil sections. While disc cutters excel in hard rock and dense soils, scrapers are suited for softer grounds, and rippers for medium-dense

terrains. These tools face wear from abrasive materials, leading to both normal and abnormal wear patterns. In mixed geologies, disc cutters undergo varied conditions in a single rotation, causing unbalanced loads and potential abnormal wear. Wear severity relates to the cutter's travel length and penetration rate. If not replaced timely, a damaged cutter can hinder construction progress (Wang et al., 2015).

Figure 3 showcases the locations of disc cutters (marked in red), which can relate to the travel length of each disc cutter. Wear is proportional to penetration and travel length. The travel length is derived from the cutter's radial positions and tunnel advancement. In theory, center and face cutters need more replacements with increased travel length, while gauge cutters wear out faster due to their design (Liu et al., 2017). The CHI interval is vital as TBM excavation downtime occurs during inspections. Sometimes, downtime costs surpass cutter replacement costs. Hence, cutters might be replaced before reaching their wear limit to maintain efficient cutterhead performance.

4 DISC CUTTER WEAR DATABASE

The predictive database for TBM cutter wear was developed by integrating data from the CHI reports, geological survey reports, and TBM operational logs. Due to discrepancies in the data sources, data preprocessing was essential to ensure the consistency in the type and measurements of the input data. For the purposes of this study, the target database was formulated based on the wear amount for each disc cutter per ring. The input database encompassed factors affecting disc cutter wear, including TBM operational metrics and geological factors.

4.1 Disc wear measurements

Data on the wear of face and gauge cutters in hard rock sections were sourced from the CHI reports between 30–65. For the consistency of the input data, eight center disc cutters replacement data were removed from the analysis. In addition, abnormal wear data such as the flat wear, chipping, and mushrooming were omitted. Similarly, four CHI reports with major errors were ignored. Lastly, occasional missing data were filled using the linear interpolation method. The interquartile range (IQR) technique was applied to the final database to remove outliers. As the result, the disc cutter wear amount of the face and gauge cutters for each ring excavation length was obtained. The final filtered database has 17,947 entries with wear data varying between 0–1.091mm per ring excavation.

To relate the disc cutter wear per ring excavation, this study identified 9 significant factors rooted in correlations established by prior research (Frenzel et al., 2008; Amoun et al., 2017; Plinninger et al., 2018; Mahmoodzadeh et al., 2021). The operational

factors of the EPB TBM encompass five primary controls: rotational speed, torque, thrust force, advance rate, and chamber pressure. Geological aspects at the excavation forefront are captured by the rock quality designation (RQD) values taken at the tunnel's crown. Further geological data includes the distances from the tunnel crown to the groundwater table level (GWL) and the cover depth. This geological information was sourced from a longitudinal profile containing 54 borehole survey reports.

5 MACHINE LEARNING MODEL IMPLEMENTATION

5.1 Random forest algorithm

The model to predict disc cutter wear was designed using the Random Forest (RF) algorithm. This ensemble machine learning strategy derives its predictions by averaging the results of multiple decision trees. When benchmarked against other machine learning approaches, the RF model showcases enhanced generalization and a robust mechanism to prevent overfitting. This is largely due to its bagging technique, which synergizes bootstrap sampling with aggregation, repeatedly drawing n random subsets from the main dataset to craft a variety of decision trees. The cumulative result from these trees, represented in Equation 1, offers the final prediction.

$$y = \frac{1}{n} \sum_{i=1}^n y_i(x) \quad (1)$$

The efficacy of a machine learning model's prediction is influenced by its input data and hyperparameters—internal configurations that steer the learning journey. This research fine-tuned the RF model by adjusting four key hyperparameters, which are `n_estimators`, `max_depth`, `min_samples_split`, and `min_samples_leaf`. Furthermore, a grid search approach was utilized to determine the most suitable hyperparameter blend, with the potential combinations.

5.2 Model implementation

To implement the wear predicting RF model, the disc cutter abrasion prediction database was reconfigured to align with the abrasion data per unit ring distance. This involved integrating data from CHI reports, geological surveys, TBM operational logs, and tunnel design documentation. The consolidated database housed 17,947 entries, each comprising 9 wear-influencing factors and wear metrics per ring. Subsequently, the RF model was developed, optimizing hyperparameters based on the input datasets. The database was split, allocating 80% for model training and the remaining 20% for performance evaluation.

During the training phase, a 5-fold cross-validation method was adopted to neutralize any potential biases in the input data. This entailed partitioning the training data into five segments. While four segments served as training data, the remaining segment was used for model validation. This validation rotation was conducted five times, ensuring each segment had a turn in the validation role.

The performance of the ML regression models was evaluated using three metrics: RMSE, MAE, and R^2 , as depicted in Equations (2)–(4). RMSE provides the square root of the averaged squared errors, whereas MAE computes the average disparity between predicted and true values. A lower RMSE or MAE signifies a more precise prediction of disc cutter wear. On the other hand, R^2 measures the linear association between the predicted and true values, with its value ranging between 0 and 1. A higher R^2 suggests enhanced prediction accuracy of the ML models.

Figure 4. Prediction performance on the training and testing data.

Figure 5. Feature importance scores.

$$\text{RMSE} = \sqrt{\frac{1}{N} \sum_{i=1}^N (y_i - \hat{y}_i)^2} \quad (2)$$

$$\text{MAE} = \frac{1}{N} \sum_{i=1}^N |y_i - \hat{y}_i| \quad (3)$$

$$R^2 = 1 - \frac{\sum_{i=1}^N (y_i - \hat{y}_i)^2}{\sum_{i=1}^N (y_i - \bar{y})^2} \quad (4)$$

5.3 Feature importance

Feature importance analysis delves into the relative significance of each attribute in determining an ML model's performance. By pinpointing dominant predictors, it sheds light on inherent data patterns. Within the framework of the RF model, the significance of each feature is ascertained by assessing the reduction in data impurity when the feature is split. In this research, we scrutinized the feature importance scores from the RF model to discern the impact of each factor inducing disc cutter wear.

6 RESULT AND DISCUSSION

The RF model's predictive capability was assessed by experimenting with various hyperparameter combinations, identified through the grid search technique. As the result from RF training, the ideal hyperparameter combination was identified as `max_depth = 20`, `min_samples_leaf = 1`, `min_samples_split = 2`, and `n_estimators = 105`. Figure 4 illustrates the precision in predicting cutter wear for training and testing datasets, respectively. Results using three metrics, RMSE, MAE, and R^2 , are 0.024 mm, 0.012 mm, and 0.987 for training and 0.059 mm, 0.031 mm, 0.918 for test, respectively. The proposed model's predicted the disc cutter wear per ring

excavation with accuracy of 0.059 mm, which surpasses the RMSE result of 107.3554 m³/cutter noted in Mahmoodzadeh et al.'s 2021 study.

Considering the average CHI range in the hard rock layer (CHI from 30 to 65) is 16 rings, the test RMSE implies the RF model can predict cutter wear between each CHI with a precision close to 1 mm; specifically, 0.059 mm multiplied by 16 rings equals 0.944 mm. Moreover, the R² value for the test outcomes stood at 0.918, markedly superior to values presented in prior research (Delisio and Zhao, 2014; Hassanpour et al., 2014; Koppl et al., 2015; Liu et al., 2017; Ren et al., 2018).

Figure 5 depicts the feature importance scores obtained from the RF model. The cutter travel length took the lead with a score of 0.54, suggesting the highest potent link to disc cutter wear. Geological elements, namely the cover depth, GWL, and RQD, secured scores above 0.11. This hints at a more pronounced association with disc cutter wear in contrast to the TBM operational metrics. Within the realm of TBM operational factors, rotation speed ranked highest, trailed by thrust force, chamber pressure, torque, and advance speed sequentially. It's noteworthy that the geological data employed in this study was sourced from a restricted set of sites. Consequently, the geological data gaps between survey points were bridged using linear interpolation.

7 CONCLUSION

This research employed the RF algorithm to implement a machine learning-driven model for predicting disc cutter wear per ring excavation. The formulated model provides forecasts of cutter wear for each ring excavation, taking into account the specific travel lengths of individual disc cutters. Using 17,947 datasets from the Daegok-Sosa EPB TBM project and considering 9 factors influencing cutter wear, the model underwent training and validation. From the findings, following conclusions are driven:

- 1) The RF-based disc cutter wear prediction model showcased superior predictive prowess, registering an RMSE of 0.059 mm and an R² of 0.918 for the test set. By factoring in each disc cutter's travel length, along with 14 other wear-influencing elements, the model adeptly predicts cutter wear over a singular ring excavation span.
- 2) The feature importance analysis pinpointed the cutter travel length as paramount in forecasting disc cutter wear. This was followed by geological and TBM operational elements. The notable gap in importance scores between the cutter travel length and other factors underscores its pivotal role in wear prediction.
- 3) This paper introduces a model for predicting disc cutter wear that integrates individual cutter travel lengths through machine learning. It's recommended to deploy this model across a broader

spectrum of projects, refining it based on outcomes to bolster its universality. Subsequent research can evolve the model to encompass irregular wear patterns in disc cutters and cater to other tunnel segments like mixed-face areas.

ACKNOWLEDGMENTS

Research for this paper was carried out under the Development of advanced management technology (Total care) for infrastructure (project no. RS-2022-00142566) funded by Korea Agency for Infrastructure Technology Advancement.

ABSTRACT: Scanned point clouds are high-value digital assets for the inspection and evaluation of tunnel structures. Segment segmentation of scanned point clouds is a prerequisite for measuring the deformation of segments. However, the semantic enrichment of point clouds can be time-consuming and labour-intensive. 3D deep learning (DL) has emerged as a viable means of analysing point clouds. To that end, this paper describes the development of an annotated high-quality and large-volume point cloud dataset for subsequent training and evaluation of 3D DL models. Data augmentation methods, including rotation and feature extending, are proposed to prepare the dataset, ensuring that features of the point clouds can be effectively captured by the 3D DL models. Data experiments are carried out using the popular 3D DL network 'PointNet++' to compare the influences of different data augmentation methods and network parameters. Satisfactory segmentation accuracy (mean intersection over union ~ 90%) is achieved by optimizing data augmentation methods and network parameters. The proposed automatic segmentation method shows promise to improve the efficiency of tunnel ring point cloud processing and facilitate the deformation inspection of segments.

Keywords: Point cloud, Segmental tunnel lining, 3D deep learning, Segmentation

1 INTRODUCTION

Segmental tunnel linings are common support structures for metro tunnels and other large-diameter utility tunnels. Segmental linings are prone to deformation (Lin, Xie, *et al.* 2022, Lin, Li, *et al.* 2023) arising from intensive adjacent construction and uncertain soil properties which can be difficult to predict. An accurate assessment of existing deformations is

fundamental to rigorous structural analysis of these assets (Chang *et al.* 2023, Xie *et al.* 2023). However, the traditional methods, such as total stations (Lin, Li, *et al.* 2022), settlement gauges (Xie and Tang 2018), and convergence gauges (Wang *et al.* 2021) can only capture limited point-wise displacements which do not always reflect the full deformation field.

Laser scanning is a powerful means of capturing abundant spatial data. The reliability of extracting

*Corresponding author: linwei9612@outlook.com

deformations of segmental tunnel linings from point clouds has been well-documented (Roca-Pardiñas *et al.* 2014, Xie and Lu 2017, Lin, Xie, *et al.* 2023). The semantics of point clouds are prerequisites for automated deformation calculation. Heuristic algorithms have been developed to segment tunnel point clouds but are highly dependent on tunnel design and construction information (Yi *et al.* 2019, Duan *et al.* 2021). The emergence of 3D deep learning (DL) provides a promising fully automatic way to realize semantic segmentation of point clouds without any project-/site-specific algorithms (Soilán *et al.* 2020, Xie *et al.* 2020). Although applying 3D DL networks to tunnel point clouds is gaining attention (Ji *et al.* 2023, Zhou *et al.* 2023), the application of 3D DL to segment-wise segmentation has not yet been achieved.

To realize automatic segment segmentation of point clouds, a well-annotated point cloud dataset is proposed and utilized to train and evaluate 3D DL models. Data normalization and sampling are adopted to ensure the effective utilisation of point cloud features. Using the popular 3D DL network, ‘PointNet++’ (Qi *et al.* 2017), experiments are performed to compare the influences of data augmentation methods and network parameters on the segmentation performance.

2 DATASET

The point clouds in the present dataset are scanned by terrestrial laser scanners (TLS) from two in-service shield tunnels located in Wuxi, China and denoted T1 and T2 (see Figure 1). The shield tunnels are hierarchically composed of rings and segments. Each ring consists of six segments, including one key segment, two adjacent segments, and three standard segments. The rings are connected by staggered circumferential joints (Liu *et al.* 2017). The inner diameter and length per ring are 5.5 m and 1.2 m respectively.

The TLS used for scanning is the Leica C10 which acquires high-quality point clouds with a scanning noise (root mean square error) of < 0.5 mm for scanning distances < 50 m. The point clouds are scanned from 31 scanning stations without overlaps. All possible elements and noise, including cables, pipes, rails, walkways, and other non-structural elements, are considered in the present dataset. The total number of scanned rings is 738 equating to a total length of 885.6 m. The total number of scanned points is 439,178,993. Each point comprises the following features: (a) three values for the Cartesian coordinates and (b) one value for intensity (ranging from 0 to 1). The Cartesian coordinates are recorded as the relative positions of scanned elements to the laser scanner (original point).

To train and evaluate the performance of 3D DL networks on segment segmentation, the scanned point clouds are manually annotated. The point cloud annotation follows a top-down workflow, as shown in

Figure 1. The field scanning of segmental tunnel linings.

Figure 2. For the annotated point clouds, $Tl-m-n$ is adopted to denote each subset of the data where l , m and n refer to the tunnel number, scanning station number, and ring number, respectively. An exemplar annotated point cloud is presented in Figure 3, where all the labels are displayed in different colours. Label 0 denotes the points of non-structural elements and noise. Label 1 to label 6 represent different segments within each ring. Label 1 stands for the key segment and the rest of the segments are all assigned non-zero labels sequentially according to the installation positions (counterclockwise). The class proportion of all the point clouds in the dataset is shown in Figure 4, where the imbalance distribution of classes can be observed due to the complex environment of in-service tunnels.

Figure 2. The adopted point cloud annotation workflow.

Figure 3. An exemplar annotated point cloud (T2-4-301).

Figure 4. Class proportion of the dataset.

3 METHODOLOGY

3.1 Data normalization

Data normalization (Garbin *et al.* 2020) is critical to ensure the DL networks learn the features without being affected by possible disturbances, such as scale effects. Hence, the annotated point clouds are normalized for both Cartesian coordinates and intensity. The Cartesian coordinates are proportionally scaled to ensure that the values are within the interval -1 to 1 . The values of intensity are normalized by applying a min-max filtering scaler as follows:

$$i_a = \begin{cases} 0, & i_0 < i_{\min} \\ \frac{i_0 - i_{\min}}{i_{\max} - i_{\min}}, & i_{\min} \leq i_0 \leq i_{\max} \\ 1, & i_0 > i_{\max} \end{cases} \quad (1)$$

where i_0 is the original intensity value, i_a is the augmented original value, and i_{\min} and i_{\max} are the given thresholds (1% percentile and 99% percentile are adopted here respectively). The results of this exercise for intensity normalization are shown in Figure 5. It is demonstrated that the intensity values are more diversly distributed in the interval -1 to 1 after the intensity normalization.

3.2 Data sampling

Point cloud sampling is usually adopted before training and evaluation to improve computational efficiency. Algorithms for data sampling require careful consideration to strike a balance between efficiency and fidelity (avoiding excessive information loss).

Two sampling algorithms are popular in the literature (Qi *et al.* 2017, Hu *et al.* 2022): ‘random sampling’ (RS) and ‘farthest point sampling’ (FPS). RS randomly selects individual points for removal where each point has the same probability of being sampled. FPS iteratively returns the farthest point from the sampled points and performs distance

(a)

(b)

Figure 5. The intensity distribution of ring-wise point cloud (T1-1-21): (a) before normalization and (b) after normalization.

updating. However, the two algorithms have significant drawbacks: (a) RS does not ensure spatial homogeneity of the sampled points and (b) FPS causes high computational costs. Another sampling algorithm, ‘grid sampling’ (GS) (Sun *et al.* 2022), achieves a good balance between spatial homogeneity and computational efficiency while the sampled number of points can not be determined for GS. By GS, the point clouds are divided into voxels of the same size, and then the point closest to the centre of each voxel is returned as the sampled point. To take advantage of GS whilst controlling the sampled number of points, the ‘grid-random sampling’ (GRS) approach is proposed. The GRS algorithm is performed in two stages: (a) The point clouds are sampled with the GS algorithm given an approximated voxel size and (b) the sampled point clouds are then randomly sampled to the required number of points.

RS, FPS, and GRS are applied to ring-wise point clouds to compare the influence of the sampling methods on information loss, as shown in Figure 6. The same exemplar ring-wise point cloud consists of 3,694,229 points and is downsampled to 12,288 points. The voxel size selected for GRS is 37.5 mm. It can be observed that the RS returns unevenly distributed points while FPS preserves the most information. GRS outperforms RS as it preserves more details. The computational time of the three algorithms is provided in Table 1. FPS takes about 17 times the computational time of GRS. Considering both efficiency and fidelity, GRS is adopted for sampling point clouds before model training and evaluation.

Figure 6. Sampling results of the ring-wise point cloud (T1-1-20): (a) the raw ring-wise point cloud, (b) RS, (c) FPS, and (d) GRS.

Table 1. The computational time of sampling algorithms on the ring-wise point cloud (T1-1-20).

Sampling algorithm	Computational time*/s
RS	3.39
FPS	87.11
GRS	5.12

* The computational time is calculated on AMD Ryzen 7 5800H CPU.

3.3 Data augmentation

For point clouds, rotation is the most common way to augment data (Qi *et al.* 2017). After sampling, the ring-wise point clouds are randomly rotated to generate augmented point clouds. The number of point clouds augmented from each original point cloud is denoted C_a .

The rotation can be performed within the x-y plane only or arbitrarily in 3D space, as follows:

$$\begin{pmatrix} x_r \\ y_r \\ z_r \end{pmatrix} = R_z(\alpha)R_y(\beta)R_x(\gamma) \begin{pmatrix} x_0 \\ y_0 \\ z_0 \end{pmatrix} \quad (2)$$

$$R_z(\alpha) = \begin{pmatrix} \cos \alpha & -\sin \alpha & 0 \\ \sin \alpha & \cos \alpha & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (3)$$

$$R_y(\beta) = \begin{pmatrix} \cos \beta & 0 & \sin \beta \\ 0 & 1 & 0 \\ -\sin \beta & 0 & \cos \beta \end{pmatrix} \quad (4)$$

$$R_x(\gamma) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \gamma & -\sin \gamma \\ 0 & \sin \gamma & \cos \gamma \end{pmatrix} \quad (5)$$

where x_0 , y_0 , and z_0 denote the original Cartesian coordinates, x_r , y_r , and z_r denote the rotated Cartesian coordinates, R_z , R_y , and R_x are the rotation matrix along axes z, y, and x, respectively, and α , β , and γ are random rotation angles along axes z, y, and x, respectively (β and γ equal 0 for 2D rotation).

Another rotation strategy denoted 2.5D rotation, is proposed for comparison, which performs the rotation within the x-y plane first and then rotates the ring-wise point clouds along the fitted cylindrical axis of tunnel rings. The 2.5D rotation is performed as follows:

$$\begin{pmatrix} x_r \\ y_r \\ z_r \end{pmatrix} = R_z(\alpha)R_n(\delta) \begin{pmatrix} x_0 \\ y_0 \\ z_0 \end{pmatrix} \quad (6)$$

$$R_n(\delta) = \begin{pmatrix} n_x^2(1 - \cos \delta) + \cos \delta & n_x n_y(1 - \cos \delta) - n_z \sin \delta & n_x n_z(1 - \cos \delta) + n_y \sin \delta \\ n_x n_y(1 - \cos \delta) - n_z \sin \delta & n_y^2(1 - \cos \delta) + \cos \delta & n_y n_z(1 - \cos \delta) + n_x \sin \delta \\ n_x n_z(1 - \cos \delta) - n_y \sin \delta & n_y n_z(1 - \cos \delta) + n_x \sin \delta & n_z^2(1 - \cos \delta) + \cos \delta \end{pmatrix} \quad (7)$$

where R_n is the rotation matrix along the fitted cylindrical axis and δ is the random rotation angle along the fitted cylindrical axis. Different ranges of random δ are compared, i.e., -180° to 180° , -15° to 15° , and -7.5° to 7.5° , denoted group L, group M, and group S respectively.

To fully exploit the implicit features in the point clouds for model training, the normals of individual points are provided as expanded features. Given a point in the point cloud, the normals are calculated using the following steps: (a) search the five points nearest to the given point, (b) fit the local plane described by these five nearest points, and (c) calculate the of the fitted plane.

Each ring-wise point cloud is rotated C_a times to generate several point clouds for training. To determine the effects of rotation strategies on the segmentation performance, five experiments are performed, where C_a equating to six is adopted. Then, different values of C_a — 6, 9, and 12 — are compared to further determine the best implementation of the data augmentation.

3.4 Network parameter

There are two main network parameters in PointNet++, namely the neighbour radius and the number of neighbours, which control the receptive field of the network. The neighbour radius defines the region of sampling in each feature aggregation layer whilst the number of neighbours defines the number of points to be sampled. With a set of network parameters as the baseline, neighbour radius and neighbour number are both varied as shown in Table 2.

Table 2. The compared perception field parameters.

Model No.	Compared parameter	Layer	Neighbour radius	Neighbour number
P1	Baseline	1	0.1, 0.2, 0.4	32, 64, 128
		2	0.4, 0.8	64, 128
P2	Neighbour radius	1	0.05, 0.1, 0.2	32, 64, 128
		2	0.2, 0.4	64, 128
P3		1	0.01, 0.02, 0.04	32, 64, 128
		2	0.04, 0.08	64, 128
P4	Neighbour number	1	0.1, 0.2, 0.4	16, 32, 64
		2	0.4, 0.8	32, 64
P5		1	0.1, 0.2, 0.4	64, 128, 256
		2	0.4, 0.8	128, 256

3.5 Model training and evaluation

All models in the present experiments are trained and evaluated using NVIDIA A100-SXM-80GB GPUs. The training set and test set are split randomly, following the 80/20 rule to ensure rigorous model evaluation, as shown in Table 3. All the trained models are evaluated on the test set.

Table 3. The split of the training set and test set.

Tunnel No.	Scaning station No. in the training set	Scaning station No. in the test set
T1	1, 2, 3, 5, 6, 7, 8, 9, 10, 11, 13, 14, 16, and 17	4, 12, and 15
T2	1, 3, 4, 5, 6, 7, 8, 9, 11, 12, and 13	2, 10 and, 14

OA (overall accuracy) and mIoU (mean intersection over union) are employed to evaluate model performance, calculated as follows:

$$OA = \frac{\sum_{j=1}^M (TP)_j}{N} \quad (8)$$

$$mIoU = \frac{1}{M} \sum_{j=1}^M \frac{(TP)_j}{(TP)_j + (FP)_j + (FN)_j} \quad (9)$$

where M is the number of classes, N is the number of points, and TP , FP , and FN denote true positive, false positive, and false negative predictions respectively. Among the two metrics, mIoU represents the most reasonable evaluation for class-imbalanced datasets and is thus adopted as the priority metric.

4 RESULTS

Table 4 presents the OA and mIoU of PointNet++ trained with different rotation strategies. Using 2D (x-y) rotation, the mIoU reaches 0.869, outperforming other rotation strategies. This may be due to the most realistic augmented point clouds generated by 2D rotation since the tunnel axis is usually within the horizontal plane. By providing the normals of each point in the point clouds, the OA and mIoU further increase to 0.936 and 0.874 respectively, boosting the segmentation performance.

Table 4. The evaluation metrics of PointNet++ trained with different rotation strategies.

Model No.	Rotation strategy	OA	mIoU
R1	3D rotation	0.919	0.836
R2	2D rotation	0.933	0.869
R3	2.5D rotation — L	0.921	0.838
R4	2.5D rotation — M	0.929	0.858
R5	2.5D rotation — S	0.931	0.864

The evaluation metrics of different augmented point cloud numbers are listed in Table 5, where the normal are included as features. The larger number of augmented point clouds leads to better segmentation performance whilst the time consumed for training increases proportionally to the training set size, as indicated by the corresponding OA and mIoU values. By increasing the number of augmented point clouds to 12, the mIoU improves to 0.883.

Table 5. The evaluation metrics of PointNet++ trained with different numbers of augmented point clouds.

Model No.	C_a	OA	mIoU
N1	6	0.936	0.874
N2	9	0.939	0.880
N3	12	0.940	0.883

The best-performing data augmentation strategy — 2D rotation, C_a equating to 12, and using normals as expanded features — is adopted when comparing network parameters. Table 6 presents the segmentation performance for different network parameters. By narrowing the neighbour radius (Model P2), the mIoU is increased to 0.897 compared to the baseline. A similar improvement is observed when increasing the number of neighbours (Model P5). Additionally, an experiment adopting the neighbour radius from Model P2 and neighbour number from Model P5 results in a mIoU of 0.887. This shows that the combination of optimised individual parameters does not necessarily guarantee an optimised overall result. Figure 7 presents the visualized segmentation results for Model P1 (baseline), Model P2, and Model P5. Compared to the baseline, the segmentation performance is improved around the segment boundaries by adjusting the network parameters.

Table 6. The evaluation metrics of PointNet++ trained with different network parameters.

Model No.	Network parameter	OA	mIoU
P1	Baseline	0.940	0.883
P2	Neighbour radius	0.947	0.897
P3		0.941	0.889
P4	Neighbour number	0.934	0.871
P5		0.945	0.894

Figure 7. Exemplar segmentation result (T1-4-203) of (a) ground truth, (b) Model P1, (c) Model P2, and (d) Model P5.

The ovalisation fitting (Xie and Lu 2017) is performed and the error between manually processed and automatically processed point clouds is shown in Figure 8. It is observed that ovalisation fitting on both the long axis and short axis achieves submillimeter accuracy. The mean error of ovalisation orientation is 0.7° , showing satisfactory results. Further,

the segment segmentation of point clouds enables the per-segment deformation fitting. The per-segment deformation fitting result is shown in Figure 9. The overall trend of per-segment deformation is in line with the ovalisation pattern. However, the per-segment deformation fitting reveals a more high-fidelity deformation description since the differential deformation between segments is captured.

Figure 8. Ovalisation fitting error on the point cloud (T1-4) segmented by Model P2.

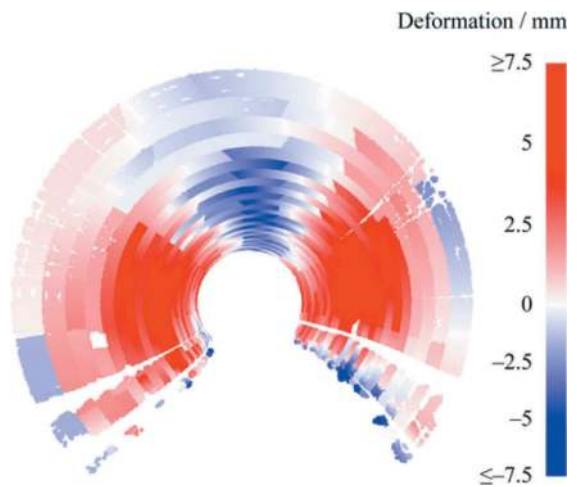

Figure 9. Deformation fitting result of per-segment deformation on the point cloud (T1-4) segmented by Model P2.

5 CONCLUSIONS

Using a richly annotated tunnel point cloud dataset, experiments were conducted to explore the feasibility of 3D DL for segment-wise segmentation. The influence of data augmentation methods and network parameters on the segmentation performance was also investigated by comparative experiments.

A novel sampling algorithm, GRS, was proposed, to an optimal trade-off between fidelity and efficiency. GRS shows the advantages of low computational costs whilst providing a fidelity-preserving performance similar to FPS. It is noted that GRS is computationally extremely efficient, representing only 5.9% of FPS.

2D rotation was shown to be the most effective data augmentation strategy, outperforming 3D rotation and the proposed 2.5D rotation. By calculating the normals of points as expanded input features, the segmentation performance was also improved. Besides data augmentation, the network parameters have a notable influence on the segmentation performance of 3D DL models. smaller neighbour radius and larger number of neighbours, both related to the receptive field, resulted in superior segmentation performance.

In this paper, a viable method for tunnel point cloud segmentation using 3D DL was demonstrated and ways to improve the segmentation performance were also provided. The present study enables the automatic segmentation of ring-wise point clouds, allowing the per-segment deformation fitting and providing high-fidelity deformation inspection.

The proposed method applies to per-ring point clouds, which means that efforts for segmentation between rings remain to be addressed. The segmentation of the original point clouds will lead to the fully automation segmentation of segmental tunnel lining point clouds while involving the challenge of segmenting more large-scale and complex scenes.

ABSTRACT: This article explores the possibility of using machine learning algorithms to predict the speed of a tunnel shield complex. The description and principles of the algorithms are presented. The dataset obtained from the Ziyang Line Project was adapted for the set purpose by means of preprocessing operations. From the results obtained, it is evident that the XG Boost algorithm demonstrates the best predictive ability ($R^2=0.809$; $RMSE=5.708$) for the stated problem.

Keywords: TBM, Driving speed prediction, Machine learning

1 INTRODUCTION

Tunnel boring machines (TBMs) have revolutionized the way underground tunnels are constructed, allowing for faster and more efficient excavation than by

Figure 1. TBM ZTSE82000.

using traditional methods. However, the speed of a TBM depends on a variety of factors, such as the type of soil, rock, and water encountered during excavation, as well as the machine's design and operational parameters. Accurately predicting the speed of a TBM can help optimize its performance, reduce costs, and improve safety during tunnel construction.

In recent years, machine learning (ML) algorithms have shown great potential in predicting the performance of TBMs. By analyzing large amounts of data from previous tunneling projects, ML models can identify patterns and correlations between various parameters and the TBM's speed, enabling more accurate predictions.

2 PROJECT DESCRIPTION

The Ziyang line project starts from Futian Station on the south side of Tianfu International Airport and ends at Ziyang North High-speed Railway Station in Ziyang

City. The total length of the line is 39.37 km, of which the underground section is 9.77 km, including 4 stations and 4 tunnels. The strata where the tunnel passes through are mainly moderately weathered mudstone and sandstone, and locally strongly weathered mudstone and sandstone. The outer diameter of the shield tunnel lining is 7900 mm, the inner diameter is 7100 mm and the thickness of the tunnel segment is 400 mm. ZTSE8200 TBM (Figure 1) is used for the tunnel construction.

3 MACHINE LEARNING

Machine learning is a branch of the science of artificial intelligence that studies methods for constructing algorithms capable of learning. It is based on the idea that a system of such algorithms can learn to identify patterns and make decisions with minimal human involvement. Machine learning is at the intersection of mathematical statistics, optimization methods and classical mathematical disciplines, but also has its unique field of research related to the problems of computational efficiency and retraining. Many methods have been developed as an alternative to classical statistical approaches and are closely related to information extraction and data mining.

Within the framework of TBM driving speed prediction, the ability of machine learning to solve a regression problem is used, in which an algorithm based on an initial dataset predicts the value. Moreover, machine learning methods have been widely used in various fields of civil engineering, such as tunnel settlement prediction (Yan et al., 2020; Hu et al., 2019.), intelligent surrounding rock classification (Liu et al., 2018; Yang et al., 2021; Zhao et al., 2022) and tunnel crack identification (Liao et al., 2022; Dang, L. et al., 2022).

3.1 Linear models

3.1.1 Ordinary least squares

Ordinary Least Squares (OLS) linear regression is a statistical method used for modeling the relationship between a dependent variable and one or more independent variables by fitting a linear equation to observed data. The goal is to find the line of best fit, which minimizes the sum of squared differences between the observed response and the response predicted by the linear model. The method provides an estimate of the coefficients of the linear equation, which can be used to make predictions about the response variable based on new observations of the independent variables.

3.1.2 Lasso regression

Lasso regression is a type of linear regression that adds a regularization term to the loss function being optimized. This term, known as *L1* regularization, helps to prevent overfitting by penalizing large coefficients in

the model. The objective function in Lasso regression is defined as follows (McNeish, 2015):

$$L^{Lasso}(\beta) = Y - X\beta^2 + \lambda W^T \beta \quad (1)$$

Where L is the loss function, Y is the target vector, X is the design matrix, β is the vector of coefficients, n is the number of observations, and λ is the regularization parameter. The first term of the objective function is the mean squared error, which is the standard loss function for linear regression. The second term is the *L1* regularization term, which is the sum of the absolute values of the coefficients. The regularization parameter, λ , determines the strength of the regularization and is typically chosen using cross-validation.

Lasso regression has the property that some coefficients equal to zero. This means that Lasso can be used for feature selection, as it effectively removes the least important variables from the model. The *L1* regularization term also has the effect of shrinking the coefficients towards zero, which can help to reduce the variance of the model.

In practice, Lasso regression can be implemented using optimization algorithms such as coordinate descent, sub-gradient descent, or the LARS (Least Angle Regression) algorithm. Lasso regression can also be used in combination with other types of regularization, such as ridge regression, to create an elastic net model.

Lasso regression is a useful tool for linear models with many features, particularly when the number of features is larger than the number of samples. However, it is important to keep in mind that Lasso can be sensitive to the scaling of the features, thus it is often recommended to standardize the variables before fitting the model.

Figure 2. Simplified model of an artificial neuron.

3.1.3 Ridge regression

Ridge Regression is a type of regularized linear regression algorithm that aims to minimize the residual sum of squares between the predicted response and the true response by adding a penalty term to the loss function. This penalty term, called "*L2* regularization", helps to reduce the model complexity and avoid overfitting. The regularization term is the sum of the squares of the coefficients, multiplied by a hyperparameter alpha, which determines the strength of the regularization. Larger values of alpha result in a more restricted

model with smaller coefficients, while smaller values result in a less restricted model with larger coefficients. The optimal value of alpha is usually determined by cross-validation. Ridge regression is well-suited for cases where the number of predictors is large compared to the number of observations, or where some predictors are highly correlated.

3.1.4 Polynomial regression

Polynomial Regression is a form of regression analysis in which the relationship between the independent variable x and the dependent variable y are modeled as an n th degree polynomial. In polynomial regression, the independent variable is raised to a power to create a new set of predictors, which can model non-linear relationships between the dependent and independent variables. The model is trained using a training dataset, and the coefficients of the polynomial are estimated using optimization techniques such as gradient descent. The goal is to find the polynomial that best fits the data, as measured by an appropriate error metric. Once the model is trained, it can be used to make predictions for new data points.

3.2 Artificial neural network

Artificial neural network (ANN) is formed by several neurons as an information processing unit serving as the basis for the performing of a function in accordance with its task (Fausset L., 1994.). A neuron is an element that calculates an output signal using a particular rule from a set of input signals. It consists of weights inputs, a function of summation, a function of activation and output (Figure 2). Neurons can be connected to each other in different ways, but the essence of the neural network always remains the same — transmitting information ahead.

Thus, the input data is sent to the hidden layers for computing. Finally, the last hidden layer sends the processed information to the output layer. In this study, fully connected neural network is used, in which each neuron of one layer is sequentially connected to each neuron of the subsequent layer, including the input, hidden and output layers (Figure 3). Different weights describe the different influence of neighboring neurons on a particular one. These parameters are configured by the network itself during training. The weighted sum of the input data is transmitted to the hidden neurons, where it is transformed using the activation function. The process of obtaining output data is described by the equation:

$$Y_k^{n+1} = f \left(\sum_{i=1}^N X_i^n w_{ki}^n + b_i^n \right) \quad (2)$$

where Y_k^{n+1} is output of unit k in the n th layer, f is the function of activation, X_i^n is the input vector, w_{ki}^n is a weight vector, b_i^n is the bias weight.

The initial values of the weights are often set randomly, and the training of the neural network is the selection of weights — backpropagation algorithm.

Figure 3. Schematic of an artificial neural network.

Application of the network training rules for backpropagation consists of two stages: feedforward and backward propagation. A set of training examples called training set is given on the network. This training set is represented by a feature vector called the associated input vector with an output that is the target of the training. In other words, the training set consists of an input vector and a target output vector. Exodus from the network is an actual output vector. Next, a comparison is made between the actual output produced and the target output by reducing the two outputs. The result of the reduction is an error. Errors are used to make changes to each weight by re-propagating it. Any weight changes that occur can reduce errors. Cycle weight changes (epochs) are carried out in each training set so that the 50 stop is reached, when the set number of epochs is reached or when a set threshold value is passed. The backpropagation network training algorithm consists of 3 stages:

1. The feedforward stage. The input layer is first calculated by summing the weight and bias values up to the output layer using a predetermined activation function.
2. The stage of feedback (backpropagation). The difference between network output with the desired target is calculated, which is then referred to as an error. Next is the back-propagation phase, the error factor is propagated backward, starting from the corresponding line directly with the units in the output layer.
3. The stage of updating the weights and biases. The last phase is modifying the weights to reduce occurred errors (Afandi et al., 2022).

3.3 Decision tree

The decision tree is an effective tool for data mining and predictive analytics. It helps in solving

classification and regression problems. The decision tree is a hierarchical tree structure consisting of a “If ... then ...” rule. Due to use the training set, the rules are generated automatically during the training process. The rules are generated by generalizing a set of individual observations (training examples) describing the subject area. Therefore, they are called inductive rules, and the learning process itself is called the induction of decision trees. In the training set, a target value should be set for the examples, since decision trees are models created based on supervised learning. Two types of trees are distinguished by the type of variable: classification tree, when the target variable is discrete, and regression one, when the target variable is continuous.

The root node, or the decision node, represents an option that will occur in splitting all records into two or more mutually exclusive subsets. Internal nodes, or random nodes, are one of the possible options available at this stage of the tree structure; the upper edge of the node is connected to its parent node, and the lower edge is connected to its child nodes or leaf nodes. Leaf nodes, or end nodes, are the final result of a combination of decisions or events (Figure 4).

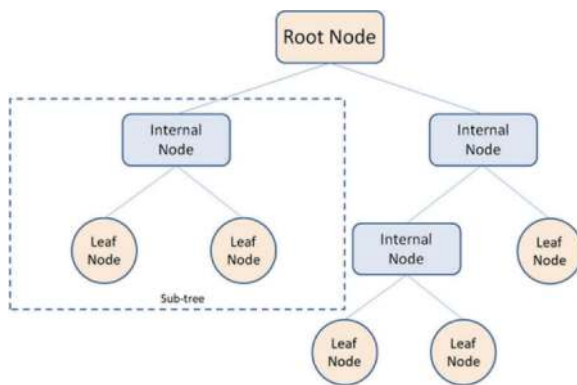

Figure 4. Schematic of a simple decision tree.

Before compiling the model, the most significant input variables shall be identified first, and then based on the status of these variables the records at the root node and at subsequent internal nodes shall be divided into two or more categories or “bins”. Characteristics entropy, Gini index, classification error, information gain, gain ratio and twoing criteria (Patel, Upadhyay, 2012.) are related to the degree of “purity” of the resultant child nodes (i.e., the proportion with the target condition) and used to select between different potential input variables. This splitting procedure continues until pre-determined homogeneity or stopping criteria are met. In most cases, not all potential input variables will be used to build the decision tree model and in some cases a specific input variable may be used multiple times at different levels of the decision tree (Song, Ying, 2015.).

3.3.1 Classification and regression tree (CART)

The CART (Classification and Regression Tree) algorithm recursively divides the original data set into subsets that become more and more homogeneous with respect to certain features, resulting in a tree-like hierarchical structure (Breiman et al., 1984.). Division is carried out on the basis of traditional logical rules in the form of IF (A) THEN (B), where A is some logical condition, and B is the procedure for dividing a subset into two parts, for one of which condition A is true, and for the other it is false.

At the first iteration, the root node of the tree is associated with the most optimal conditional judgment, and the entire set of objects is divided into two groups. Two branches can also branch off from each subsequent parent node to the descendant nodes, which in turn are associated with the boundary values of other most suitable variables and determine the rules for further splitting (splitting criterion). The final nodes of the tree are the “leaves” corresponding to the solutions found and combining all the objects of the training sample divided into groups.

The described process refers to the so-called “greedy” algorithms that strive, regardless of anything, to build the most “bushy” tree (also “deep tree”). Naturally, the more extensive and bushier the tree, the better the results of its testing will be on the training sample, but not as successful on the test sample. Therefore, the constructed model must also be optimal in size, i.e. contain information that improves the quality of recognition, and ignore the information that does not improve it. To ensure this, it is common to “prune” the tree (tree pruning) – to cut off branches where this procedure does not lead to a serious increase in errors.

It is impossible to find an objective internal criterion that leads to a good compromise between error-free and compact, thus the standard mechanism for optimizing trees is based on cross-validation (Loh, Shih, 1997). To do this, the training sample is divided, for example, into 10 equal parts: 9 parts are used to build a tree, and the remaining part plays the role of verification aggregate. After repeating this procedure many times, the tree that showed the best result during cross-validation is selected from a certain set of candidate trees that have a practically acceptable range of model quality criteria.

$$RMSE(y, \hat{y}) = \sqrt{\frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2}$$

3.3.2 Random forests (RF)

Random forest is a method invented after CART by Leo Breiman, which is based on the use of a committee (ensemble) of decision trees (Breiman, 2001.). The essence of the algorithm is that at each iteration a random sample of variables is made, after which, on this new sample, the construction of a decision tree begins. At the same time, “bagging” is performed — a sample of random two-thirds of observations for

training, and the remaining third is used to evaluate the result. This operation is performed hundreds or thousands of times. The resulting model will be the result of a “vote” of a set of trees obtained during modeling.

3.3.3 XGBoost regression

XGBoost (short for eXtreme Gradient Boosting) is a popular implementation of the Gradient Boosting algorithm. It is an efficient and effective machine learning algorithm for solving regression and classification problems. XGBoost is a tree-based ensemble model that works by building a sequence of decision trees. The model makes an initial prediction based on the mean of the target variable. It then adds a new decision tree that is trained to predict the residuals of the previous trees.

The process is repeated until the residuals are reduced to a minimum or until a predefined maximum number of trees is reached. The final prediction is the sum of the initial prediction and the predictions of all the decision trees. To avoid overfitting, XGBoost uses regularization techniques like *L1* and *L2* regularization and also incorporates early stopping, which allows the model to stop building new trees when it is no longer improving the performance on the validation set.

3.4 Statistical accuracy measurement

When using forecasting machine learning models, there is always some degree of uncertainty. The accuracy and correctness of the prediction results are characterized by the magnitude of the prediction error, which shows the difference between the actually measured value and the predicted one. In this study, the accuracy and forecasting power of the models were measured by two indicators: the predictive coefficient of determination *R*² and the root mean square error (RMSE):

$$R^2(y, \hat{y}) = 1 - \frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{\sum_{i=1}^n (y_i - \bar{y})^2}, \text{ where } \bar{y} = \frac{1}{n} \sum_{i=1}^n y_i \quad (3)$$

$$RMSE(y, \hat{y}) = \sqrt{\frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2} \quad (4)$$

Where, \hat{y} are actual and predicted value, respectively.

3.5 Dataset

The dataset is recorded by a computer using data from a TBM during its operation. Initially, the dataset was a table with 280 columns and 212,000 rows for tunnel lining rings numbered 0 to 777, representing various parameters of the TBM and its operation. After applying the data preprocessing procedure, a table with 14

columns (13 features and the speed rate column) and 11169 rows is obtained. Preprocessing operations include removing 5% of the data from the beginning and end of the set to exclude the possible influence of the initial and final conditions at the start and end point of the record. Further, since the regression problem is being solved to predict the speed of the TBM, all rows with zero speed value are also removed from the data set. Finally, out of 280 features, the main 13 ones are used, which have the greatest impact on the speed value. The main selection criterion is the condition under which the value of the correlation score of a particular feature for the speed should be greater than or equal to 0.3. The most significant features are total thrust (correlation score is 0.78 with the driving speed of the TBM), propulsion pump outlet pressure (0.75), speed of the screw conveyer (0.75), working status of shield machine (0.7), screw conveyer blade torque (0.6) and screw engine cylinder pressure (0.6). The distributions of these features and of the TBM's driving speed are illustrated in Figure 5.

Figure 5. Density distributions of the data.

3.6 Results

To determine the reliability of the proposed machine learning solutions, solving algorithms are trained with a training set. The entire volume of data is randomly divided in training (80%), validation (10%) and test (10%) sets by leave-one-out method.

Figure 6 shows the results of comparing actual measurements and predicted values. Each graph contains dot diagrams, which are plotted relative to the line $y=x$ and show correlation between predictions of the models and measured shield driving speed. XG Boost regression model has the best predictive ability with the values $R^2=0.809$ and $RMSE=5.708$; worst of all, as expected, the decision tree model copes with the prediction with the values of $R^2=0.626$ and $RMSE=7.979$.

It should be noted that the dataset used by the algorithms is compiled in such a way that each row contains the values of the features and the target

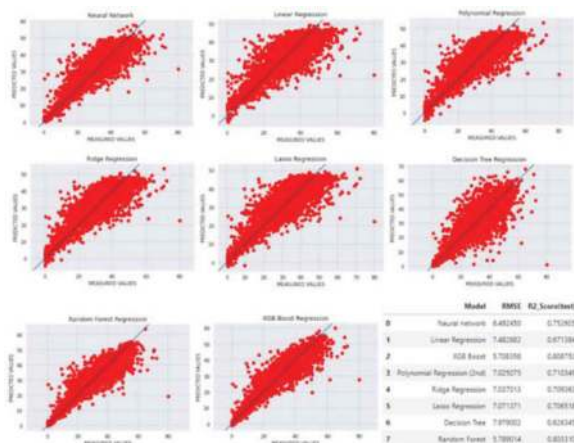

Figure 6. Predictions, R2 score and RMSE values.

variable at a specific time t_i , for which the correlation coefficients are described above. For successful forecasting, a condition is necessary under which the features obtained at time t_i allow obtaining the value of the TBM driving speed at time $t_j = t_i + \Delta t$.

The dataset was modified in such a way that the features at t_i are compared with the target variable at t_j with $\Delta t = 10$ mins, which led to a redistribution of the correlation matrix: the coefficient for thrust force decreases dramatically, while the coefficients bentonite flow increases significantly. For a more detailed study of these dependencies and the derivation of general patterns, it is necessary to use more data from various construction sites.

4 CONCLUSIONS

This study shows that machine learning techniques can be used to accurately predict TBM driving speed, thereby improving tunnel excavation efficiency. A theoretical description of machine learning algorithms is given. The data collection process for the study is discussed, which involved collecting in-situ data from a TBM excavation project in China. Then the data is processed, polished and prepared for machine learning analysis. Finally, several machine learning algorithms are applied to the data, including linear regression models, decision trees models, and neural network to predict TBM driving speed. The results show that XG Boost algorithm outperformed the other algorithms in terms of accuracy, achieving an R2 score of 0.809. Overall, the study highlights the potential of machine learning for improving the efficiency and accuracy of tunnel excavation. Authors hope that presented findings will encourage further research in this area and help to advance the field of tunnel engineering.

ABSTRACT: Maintenance strategy and routine inspections play a crucial role in the management of the large-scale infrastructures built at the European Laboratory for Particle Physics (CERN), which hosts more than 80km of underground tunnels with particle accelerators and beam lines. Most tunnels are not accessible during beam operation. Signs of ageing tunnel defects have been observed during tunnel inspections, particularly in tunnels constructed many decades ago. In the light of the safety of CERN personnel and the operational lifetime of CERN tunnels, the implementation of smart monitoring tools is essential for data automation and remote inspections.

In this paper, an overview of the advanced monitoring technologies that are implemented for the inspection of CERN underground tunnels is presented. This includes the state-of-the-art monitoring tools, robotic mounted imaging, unmanned aerial vehicles (UAV) and fibre optic sensors. The frontier analysis is conducted via artificial intelligence technology, machine learning, graphic based deep learning, and photogrammetry. The feasibility of the above-mentioned methodologies has been tested in CERN underground areas, providing instrumental data for the CERN's tunnel asset management.

Keywords: Monitoring, Tunnel Asset Management, Artificial Intelligence

1 INTRODUCTION

The European Laboratory for Particle Physics (CERN) located on the Franco-Swiss border, hosts the most powerful particle accelerator ever built, the Large Hadron Collider (LHC) (Figure 1). Physics experiments with high energy particle collisions are carried out in 100m deep tunnels, excavated in a sedimentary rock, called the red molasse, which comprises irregular sub horizontal bedded sequence of marls and sandstones (Fern et al., 2018) (Figure 2).

Due to the radioactive environment created in the particle collisions, most CERN's underground areas are inaccessible throughout the year. Only during scheduled periods, such as the Year End Technical Stop (YETS), tunnel access is allowed, which enables upgrades and maintenance activities to be carried out. As a result, it is very challenging to visually inspect

CERN infrastructures, calling for exploiting smart and remote tools for comprehensive geotechnical analysis.

This paper presents the state-of-the-art monitoring technologies used in tunnels at CERN. It also describes the emerging technologies in the field of structural health monitoring and focuses on their benefits and challenges.

2 CERN UNDERGROUND FACILITIES

The underground network built at CERN comprises of around 80km of tunnels, shafts and experimental caverns with some structures built more than 50 years ago, thus exceeding their structural design life.

Recent inspections have clearly shown signs of tunnel lining deterioration with time due to tunnel distress, water leakage and concrete spalling.

*Corresponding author: vanessa.di.murro@cern.ch

Several challenges are encountered by the Tunnel Asset Management (TAM) team at CERN during the inspection campaigns:

- Very large-scale underground infrastructure with short inspection window.
- Unavailability of tunnels during operations of particle accelerator experiments, which make the tunnel environment radioactive during operation. For safety reasons, civil engineers can only inspect the underground areas and undertake repairs during the YETS, of 1-2 months duration.
- The radiation environment also limits the use of electronic devices for monitoring CERN infrastructures, as most commercial devices are not radiation tolerant.
- Restricted access: underground areas can only be accessed by CERN personnel equipped with personal safety protection kit and specialized training.

The implementation of remote and automated monitoring techniques plays therefore a crucial role for the management of large underground assets such as those found at CERN.

Figure 2. Swiss geology: CERN location (Fern et al., 2018).

3 MONITORING TECHNOLOGIES

The use of intelligent defect detection of tunnel lining surfaces has enabled CERN engineers to overcome a series of challenges related to the limited accessibility to underground areas and obtain instrumental data using different innovative methodologies. The overview of technologies and results are presented hereafter.

3.1 Computer-vision based remote crack detection system

Cracks serve as an early sign of deterioration of aging underground infrastructure. Cracks are the main defect encountered at CERN. To undertake remote inspection and enable monitoring during the accelerator experiments, advanced robotic solutions or image-based crack monitoring methods were developed at CERN (Ouyang et al., 2023, O'Brien et al., 2023).

Two robotic solutions are used to collect image data remotely in different scenarios. For monitoring the tunnels, the telemanipulated robot, the CERNbot, mounted with a coordinated camera rigs can be used. This is a modular robot developed by the Robotics team at CERN, enabling real time collection of tunnel lining images at different vertical tunnel positions (Di Castro, 2019) (Figure 3a). In the LHC 27km ring, the customised Tunnel Inspection Monorail (TIM) can also be used for image collection (Figure 3b).

For the monitoring of CERN shafts, an unmanned aerial vehicle (UAV) is adopted, which will be discussed in more detail in Section 3.2.

Figure 3. The customised advanced robotic solution (CERNbot) used for crack detection (Ouyang et al, 2023), (b) Tunnel Inspection Monorail (TIM).

Images are taken with overlaps and those images captured by the coordinated camera set in consecutive inspection spots are utilized for the creation of the panorama.

The mosaicking process is conducted by the Speeded-up Robust Features (SURF) algorithm which extracts invariant points in the overlap areas of adjacent images and stitches them all together. The stitched panorama enables a wider field of view, as shown in Figure 4.

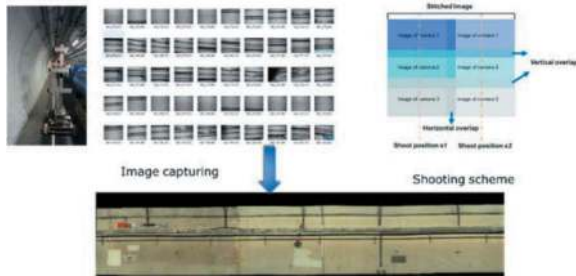

Figure 4. Image stitching for panorama (Ouyang et al., 2023).

To achieve automated crack detection at pixel level, the deep learning model, Deeplab V3 plus, is finetuned on the collected image data base, using transfer learning. As shown in Figure 5, cracks of small patch images are segmented out at pixel level. The cracks on the high-resolution panoramas are separated out with the smooth blending method, as shown in Figure 6. More details of this research can be found in Ouyang et al. (2023).

Figure 5. Deeplab V3 plus for automated crack segmentation.

Figure 6. Crack spatial layout after the detection.

Overall, the adoption of a computer-vision based study has reduced the need for human presence in the tunnels as it automates the image collection.

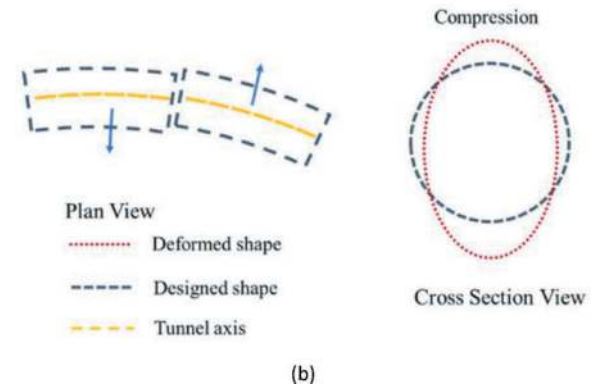

This tool also enables a quick assessment of the general condition of CERN tunnels, it facilitates the identification of the most severe crack

damaged tunnel chainages, with sectional crack percentage, as shown in Figure 7a. In addition, the crack spatial patterns also reveal two different tunnel deformation modes for the circular LHC tunnel and the straight TT1 tunnel (Figure 7b).

The assessment of the tunnel structural behaviour enables the TAM team to plan well in advance of any mitigation measures to be implemented during the YETS and, hence, minimise the time on site and inform in the decision-making process for maintenance activities.

(a)

(b)

Figure 7. Crack statistics: (a) crack density distribution and (b) two observed tunnel deformation modes (Ouyang et al., 2023).

3.2 Unmanned Aerial Vehicle (UAV) for defect detection

The CERN underground infrastructure also includes several shafts, which cannot be visually inspected by the CERN TAM team. It is therefore crucial to adopt innovative monitoring solutions to assess the condition of the shafts.

The use of an unmanned aerial vehicle (UAV) enables to inspect the condition of CERN shaft efficiently and quickly.

A pilot monitoring trial using a drone was carried out in March 2023 for a 10m diameter shaft (PX84) at the Large Hadron Collider Point 8 (LHCb experiment site) by using one of the latest version of the

Elios 3 drone produced by the Flyability company (Figure 8a, b).

The Elios 3 drone was driven remotely by an experienced team from Flyability. The collected images showed the cracks and calcite deposits on the shaft lining (Figure 8c). Water leakages were also visible through a thermal analysis (Figure 8b).

Figure 8. Drone trial of CERN shaft PX84: (a) drone image, (b) image of the shaft, (c) calcite deposits on the shaft lining, (d) thermal analysis (Flyability).

Processed images taken by the drone allow for automated fault detection of the shaft structural condition, with the aim of assessing its status and, hence, plan any repair works needed.

3.3 Distributed Fibre Optic Sensors (DFOS) for strain and temperature measurements

Distributed fibre optic sensors (DFOS) have been extensively used in various projects for monitoring the performance of civil engineering infrastructures such as tunnels (Di Murro et al. 2019, Mohamad et al., 2012, Soga et al. 2017). Among the different monitoring technologies, the use of DFOS seems to be the most appropriate for understanding the behaviour of CERN tunnels. Optical fibres have the advantage of being small in size, as well as being immune to the electromagnetic influence associated with the high energy of the LHC. They also enable the monitoring of long tunnel distances. However, the properties of the optical fibre and its behaviour can change depending on radiation levels. For such environments, an accurate study is required, and radiation resistant optical fibres may need to be adopted.

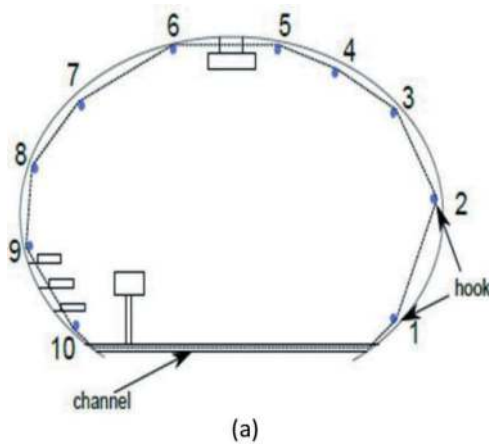

A monitoring installation using DFOS was trialed for the long-term performance of the concrete-lined tunnel TT10 (Figure 9). Several circumferential fibre optic loops have been deployed (Di Murro, 2019).

Figure 9. View of TT10 tunnel (Di Murro, 2019).

Figure 10. Omnisens FO analyser used in CERN tunnel.

(b)

Figure 11. FO field installations: (a) Cross-section of the circumferential strain cable loop, (b) Method of attachment of optical fibre: pulley wheels (Di Murro, 2019).

The FO strain data was collected by attaching both ends of each FO installation to a Brillouin optical time domain analysis (BOTDA) interrogator, manufactured by Omnisens company (Figure 10).

The FO cable was attached to the tunnel lining at discrete locations by using a gauge-length method which makes use of a series of hook-and-pulleys, with the hook screwed into the tunnel lining surface and the FO cable passing along the pulley (Figure 11a, b). The gauge length method can only measure strain if the optical fibre is sufficiently pre-tensioned, without leaving any slack sections.

An example of FO data results is shown in Figure 12. The continuous axial strain measurement along the tunnel circumference is plotted against the cable distance for a monitoring period of 3 years. A sinusoidal-shaped strain profile with tension (positive strains) at tunnel spring line and compression (negative strains) developed along the tunnel lining, suggesting a vertical tunnel ovalisation as the mechanism of deformation many years after construction.

Overall, the research carried out by Di Murro (2019) shows that the examined tunnel sections exhibit a slow development of strain continuously with time over the monitored period of three years.

Figure 12. FO data results: strain measurements along the tunnel circumference (Di Murro, 2019).

4 CONCLUSIONS

This paper presented an overview of the smart and emerging monitoring technologies implemented at CERN for the monitoring of CERN underground assets. Ageing tunnels are exhibiting some structural distress over time, resulting in tensile cracks, spalling and water leakages.

Given the large extent of CERN's underground network, the use of intelligent monitoring technologies plays an important role. Advanced robotic solutions have shown that automated images of the tunnel lining surfaces can be collected for crack detection and quantification.

Moreover, to assess the structural condition of shafts, the use of an unmanned aerial vehicle (UAV) has enabled efficient and quick inspection of the shaft defects.

Additionally, the benefits of distributed fibre optic sensors for the strain measurements of a tunnel were also presented and discussed. Optical Fibres used in the structural health monitoring field not only provide continuous strain and temperature data with time, but also allow to understand the mechanism of tunnel deformation remotely.

Overall, by adopting automated and remote monitoring tools, large data sets can be collected and processed, minimising the subjectivity of visual inspection by engineers and overcoming the limited access to CERN areas.

The implementation of the above-mentioned monitoring technologies has improved the inspection of CERN facilities with time and has enabled better planning of repair works.

ABSTRACT: With the development of machine learning and intelligent control technology, shield self-driving technology is gradually moving from the laboratory into the engineering field. However, tunnel construction is a systematic project. Highly efficient, high-quality construction must be achieved by improving the shield tunnelling capacity and strengthening the synergy of equipment performance, material supply, transportation capacity, and other aspects. Based on analysing the critical problems of shield tunnel construction management, this paper proposes the idea of adopting lean construction to improve the tunnel construction management level. By taking advantage of shield self-driving technology and digital platform, the paper builds a tunnel digital lean construction mode by optimizing the processes, materials, equipment, personnel, and space, tracking and evaluating the effect in real-time, analysing the cause and coordinating various aspects to ensure that the entire construction is always in an efficient state of operation. The tunnel digital lean construction mode has been applied to the JCXSG-12 tunnel section of Shanghai Airport Line. Compared with the traditional construction mode, it can significantly reduce the influence of various human factors, lower labour costs, accelerate the construction process, decrease environmental pollution and mechanical loss during the construction process, and improve project safety, quality, and efficiency. It provides a new way for underground space construction and development.

Keywords: Tunnel, shield self-driving, digitalization, lean construction

1 INTRODUCTION

With the increasing demand for underground space development, there is a new demand for safety, quality, and efficiency in tunnel construction. Therefore, the research of self-driving of shield machines has become a hot spot in recent years to realize the goal of efficient, high-quality, and safe construction during shield tunnelling. However, the self-driving of the shield machine can only partially solve the tunnelling problem because tunnel construction is a systematic project. In addition to shield tunnelling,

it also requires the cooperation and support of other links, such as segment transportation, muck transportation, and equipment maintenance. Problems in any one section or step will lead to decreased construction efficiency and increased project risk. Therefore, how to carry out scientific tunnel construction management has become the focus of attention. From the perspective of construction management, there are two types of problems in tunnel construction management: 1) Deviation in the implementation of the technical plan, such as poor supervision of construction quality and risk, which causes various types of

*Corresponding author: minahu@shu.edu.cn

accidents, such as axial deviation, ground settlement, and tunnel leakage. 2) Inadequate management of resources, such as a mismatch between the equipment configuration and the production schedule, and the project suffers from unnecessary waiting situations. 3) Inefficient synergy among the project personnel: personnel's differences in access to information lead to problems in cooperating.

To solve the problems of tunnel project management, researchers have worked from information sharing, risk management, schedule management, and multiple perspectives. Breaking the barriers of communication and synergy among various links around information sharing has been a hot research topic in recent years. People adopt the Internet (Li, 2013), BIM (Yu, 2016; Zhou, 2021), and GIS (Zhang, 2021) technologies to converge and visualize construction data from various sources and different data structures, which promotes the flow and understanding of information and facilitates analysis and supervision. Risk management is the critical point of tunnel construction. People use failure knowledge (Junichi, 2005), risk database (Huang, 2006), WBS-RBS theory (Zhao, 2023), and other methods to establish risk identification, assessment, tracking, and decision-making for the construction process and build a risk management system for tunnel construction. Quality, schedule and cost management are the core of engineering project management. People carry out process supervision and control around the quality control target (Zhou, 2021; Chen, 2004) and introduce the PDCA method for quality management (Song, 2010). Combined with the process flow and technical points of the shield method, technicians monitor, analyse, and control the construction process according to the requirements of construction quality control (Wang, 2021), budget and cost settlement (Xiao, 2018), and optimize the progress and resources of the project by using the construction simulation software (Yang, 2007) and the network planning diagrams (Han, 2019) to improve the construction progress and cost control of tunnelling project. These studies have promoted the improvement of tunnel construction management. However, the current research results still have many problems in practical application: 1) The research is often only from a certain point of view, and the scope of monitoring, evaluation, management, and decision-making is too broad to refine the description and consideration of the complex correlation between various types of information, various steps, and various kinds of goals. 2) The simple sharing of information lacks the deep integration of the task execution and resource layers and cannot promote work implementation. 3) Accurate management decisions must rely on timely and complete information and accurate and reliable forecasts, which traditional project management techniques do not have. As a result, the bottlenecks in tunnel construction management have yet to be effectively solved.

To solve the above problems, the most critical is around the tunnel construction tasks, accurate planning,

dynamic scheduling of resources, and strict task implementation. Lauris Koskela proposed to apply lean management to the construction industry, and in 1993, he first proposed "Lean Construction" at the IGLC (International Group of Lean Construction) conference. Lean construction (Koskela, 2002) emphasizes more accurate scheduling, effective work distribution, closer collaboration, refined budgeting, and more humanized project management processes. Traditional shield construction is limited by technology, and lean construction is difficult to implement in actual projects due to the lack of process delicate and precise capabilities. Therefore, we adopt the lean construction management idea with the digital technology of the shield self-driving system to realize accurate prediction and execution and promote the implementation of the lean construction management mode. Taking workflow as the core of project management, we connect the three links of planning, scheduling, and execution to establish a new tunnel construction organization and management system with accurate judgment, rapid response, and smooth execution so that the tunnel construction process can adapt to all kinds of changes, realize the optimal integration of resources, lower costs, ensure quality, shorten the construction period, strengthen collaboration, reduce all unnecessary waste, and create more project value of the project.

2 RELATED WORKS

2.1 *Lean construction*

Lean Construction (LC) originates from Lean Manufacturing, which is the application of Lean Manufacturing theory in the construction industry. The Transformation-Flow-Value (T-F-V) theory is the basis of Lean Construction (Koskela, 2000). It states that: 1) Production can be seen as a transformation process from input to output, and production management is to break down this process into a number of basic elements and realize these elements as efficiently as possible. 2) Production is seen as a flow including waiting, inspection, movement, and other ineffective activities, so production management is to minimize the ineffective flow. Production management is to reduce the ineffective flow. 3) Production is the realization of customer needs (Value), then production management is equivalent to the customer's requirements accurately reflected in the design and to make the production and design based on requirements to maintain consistency. It can be seen that lean construction needs to achieve is to meet or exceed the design requirements in the project implementation, eliminate waste, and pursue the perfect process centered on the value stream.

2.2 *Shield self-driving*

Shield self-driving refers to a series of means, such as independent perception, autonomous planning,

assessment decision-making, and automatic control, in which the shield machine automatically performs operational steps such as rock and soil excavation, shield tunnelling, synchronized grouting, and shield tail grease pressure injection, and completes the tasks of tunnel axial control and ground settlement control while ensuring the safety of the project (Hu, 2022). Shield self-driving is centred around project design requirements and value realization and is a core part of the tunnel construction workflow. Therefore, with self-driving as the core, it can provide timely and refined decision-making and execution support for tunnel lean construction.

Table 1 shows the relationship between shield self-driving and construction management's production elements, workflow, and value realization, using a common earth pressure balance shield as an example.

As can be seen from Table 1, through the prediction and planning of critical elements based on shield self-driving technology, it is possible to refine the quantity, time, and location of production elements such as equipment, materials, and labour, and make a detailed plan for the maintenance of equipment, materials, personnel arrangements and the execution of ancillary tasks. By digital means, it can compare the deviation between the refined plan and the actual execution, quickly detect unnecessary waiting and waste in the workflow, and combine with value assessment, timely detection, and early warning of quality and safety

problems in the construction process, and dynamically optimize and correct the entire workflow.

3 LEAN CONSTRUCTION FOR SHIELD TUNNELLING

3.1 *Shield construction process analysis*

Shield tunnelling is a cyclic, assembly-line operation process. The most central processes are soil cutting, segment assembly, slurry injection, and Muck transportation. Figure 1 shows the back-and-forth relationship within and between these four processes. As can be seen from the figure, there are many conditional nodes in this process, and the status of the nodes will directly affect the efficiency of the shield construction. The tasks in the orange background of the figure are affected by these nodes, in other words, constrained by various types of space, resources, and equipment. The tasks in the blue background of the figure are provided by the self-driving control system, including tunnelling planning, segment selection and assembly solution, slurry and grease injection plan, and soil transportation plan, which is calculated based on the tunnelling planning. It can be seen that with self-driving technology, the forecast of the amount of resources, time, and space requirements can be depicted in more detail than before, which means that the

Table 1. T-F-V in the perspective of shield self-driving.

	Transformation			Flow	Value
	Task Element Prediction and Plan (Quantity,Time,Space)				
Shield Self-driving Task	Materials	Equipment	Labor	Process Evaluation and Improvement	Value Goal and Realization

Soil Conditioning	materials for soil improvement, such as foaming agents.	/	Materials Clerk	Waiting Time, Failure Duration	Improving Advancing Speed Decreasing Energy consumption
Muck Discharge	/	Crane, Vehicle in Tunnel, Off-site transportation	Transportation team, lifting team, Materials Clerk	Transfer Duration	Improving Advancing Speed
Slurry Injection	Slurry	crane vehicle in Tunnel Off-site transportation	Transportation team, lifting team, Materials Clerk	Waiting Time, Slurry usage and effectiveness	Improving Environmental safety, Reducing Material Cost
Shield tail grease Injection	Grease	crane. Vehicle in Tunnel, Off-site transportation	Transportation team, lifting team, Materials Clerk	Waiting Time, Slurry usage and effectiveness	Improving Tunnel Safety Reducing Material Cost

supporting things can be arranged earlier and more accurately according to the plan. This reduces the unnecessary waiting of each conditional node due to unsatisfied states.

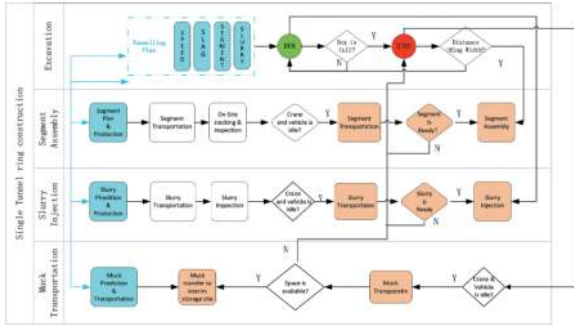

Figure 1. Tunnelling process by shield self-driving.

3.2 Material requirement planning

As seen in Figure 1, resources are the most crucial issue affecting the continuity of shield tunnel construction. Three main types of resources are needed for shield construction: materials, equipment, and space. Materials include tube sheets and slurry, equipment includes crane, vehicle, and truck, and space refers to the location needed for temporary stacking of segments and slurry. Therefore, it is essential to determine each resource's preparation time and amount based on forecasting and planning.

Shield self-driving system can predict a reasonable advancement speed based on the surrounding strata, tunnel alignment, and shield machine efficacy, combines historical or pre-engineering data, defines the advancement plan for the next phase (50-100 rings), calculates the types and quantities of each type of resource and constructs an information list table. Based on the tunnel tunnelling plan and resource list table, determine the uncertainty of the advancement speed and resource status, analyse the probability of their occurrence, and further adjust the resource ordering and equipment maintenance plan. The resource requirement planning process is shown in Figure 2.

3.3 Tunnelling plan optimization

Another constraint of shield tunnelling comes from the working space because the space inside the tunnel is limited. Even if there are enough resources, many jobs can not be carried out simultaneously in the same working space, which will cause conflicts. Therefore, this paper adopts the line of balance method (LOB) (Sarraj,1990), which is a resource-driven scheduling system for projects with repetitive activities to analyse the occupancy of the construction workspace. Meanwhile, we designed two indicators, Workflow-Idle-Rate and Equipment-Load-Unbalance-Rate, to evaluate the continuity and smoothness of the advancement process.

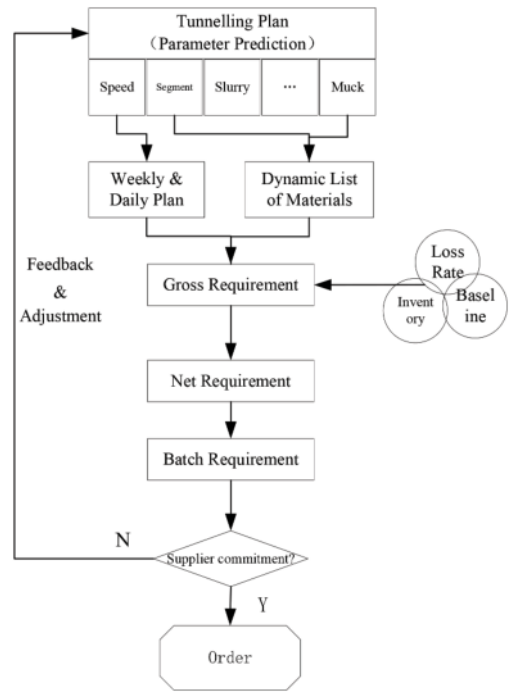

Figure 2. Resource requirements under shield self-driving.

3.3.1 LOB graph

In contrast to the critical line method and Gantt charts, the LOB method utilizes clear and easy-to-understand graphics that consider the flow process of tasks through different construction units while showing the productivity and time period of each task. Figure 3 shows the flow of tasks in different workspaces during tunnelling construction. As seen in Figure 3, due to the workspace limitations and the different work efficiency of each task, there will inevitably be the problem of task discontinuity, which will significantly impact the project's progress and cost. Therefore, from the perspective of lean construction, the process or technology of the tasks must be appropriately modified to reduce the waiting time between tasks so that the whole excavation process is always in a stable and smooth state, which is also beneficial to reduce the equipment failure rate and improve the quality of the project.

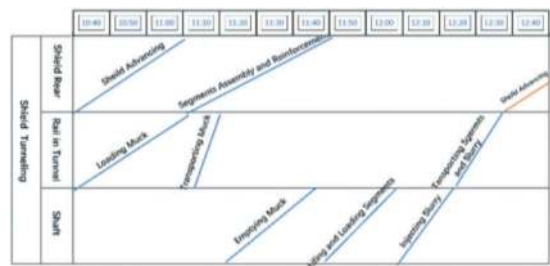

Figure 3. LOB graph of shield tunnelling.

In Figure 3, although the working space shows that the processes are connected as seamlessly as possible,

in reality, the disposal of muck and slurry injection at the shaft occupied a long time, leading to a long waiting time for the shield machine and the vehicle and a lack of production efficiency. Therefore, improving the process flow in the working shaft area is very important.

3.3.2 Optimization indicator

1) Workflow-Idle-Rate

Workflow-Idle-Rate (IR) is used to measure the idleness (degree of continuity) of the workflow in the ring, see Equation 1. It is mainly used to analyse the relationship between the ring's tunnelling processes and reduce the single-ring tunnelling time.

$$IR = it/t \times 100\% \quad (1)$$

where.

t : working time, is the time interval from the start of a single-loop workflow to the end of all processes in a single loop; idle time,

it : waiting time is the total waiting time during the working time.

2) Equipment-Load-Unbalance-Rate

Equipment-Load-Unbalance-Rate (UBR) is used to measure workflow equipment workload. On the premise that the advancement time in the ring has been optimized, it ensures the balance of daily, weekly, and monthly planned tasks, which makes the operation of the equipment and workforce in a stable state, reduces the equipment failure rate and improves the quality of the project.

$$UBR = \frac{\sqrt{\frac{\sum_{i=1}^N (t_i - \bar{t})^2}{N}}}{\bar{t}} + \frac{\sqrt{\frac{\sum_{i=1}^N (tw_i - \bar{tw})^2}{N}}}{\bar{tw}} \quad (2)$$

Where,

t_i : is the working time of the i th ring,

tw_i : is the interval time between the i th and the $(i+1)$ th ring,

\bar{t} : is the average time to complete a single ring of N rings,

\bar{tw} : is the average waiting time between rings of N rings,

N : total tunnelling rings,

\bar{t} : is the standard time to complete a single ring,

\bar{tw} : is the standard waiting time between two rings.

In this way, according to the LOB graph, with the optimization goal of minimizing the combined idle rate and imbalance, we optimize the processes in the tunneling process and, based on the standard advancement time determined by the automated advancement system, and in conjunction with the current status of the resources, we arrange for the ordering of materials, the maintenance of the equipment, as well as the personnel and vehicle schedules into the determination of the shield advancement plan, to achieve the fine-tuning cooperation of the various collaborating parties.

4 ENGINEERING APPLICATION

4.1 Engineering background

The Airport Line of Shanghai Rail Transit City Line, with a total length of 68.627km, is a fast-track Corridor of Shanghai that connects the two airports, and it is also a crucial railroad between Shanghai and the outside of the town. The JCXSG-12 tunnel section of the Airport Line from 7# wind shaft to Lingkong Road conversion shaft, which is 5.7km long, and the shield will cross 48 Class I and Class II risk points along the tunnel designed axis. The geographic graph of the section is shown in Figure 4, and the tunnel is constructed with a 9.3m "Zhiyu" self-driving earth pressure balance shield (Figure 5). Compared with the traditional shield, the "Zhiyu" Shield can quickly judge its state and recognize the surrounding environment, autonomously carry out propulsion planning, determine the advancing speed, thrust, torque, zonal oil pressure, and grouting volume, and other vital parameters, dynamically control the shield to do a series of actions such as cutting, attitude correction, pressure balance, grouting, improvement, etc., to complete the whole process of automatic tunnelling.

Figure 4. Shanghai airport line (JCXSG-12).

Figure 5. "Zhiyu" shield.

4.2 Other supporting methodology

In addition to planning and optimizing the tunnelling process and resources using "Zhiyu" shield self-driving techniques, some management tools are required to ensure that lean construction becomes a reality from concepts. The following supporting methods were adopted in the project:

4.2.1 Last Planner System (LPS)

Considering the shield advancing as the last process, and according to the idea that the demand of the latter process pulls the former process, we gradually determine the space, equipment, and material demand of the former process based on the needs of the advancement process. The “last planner system” emphasizes pull-type management, releasing daily, weekly, and monthly demand plans through the project cooperative group, coordinating all relevant divisions to participate in the execution of the project plan in depth, thus reducing unnecessary work and waiting time, and maximizing the speed of construction progress. In this way, the tunnel segment production company carries out more accurate production and scheduling, the shield machine and vehicle maintenance team do maintenance according to the downtime gap to minimize unnecessary waiting time, and the project management department contacts the muck transportation service provider in advance according to the production plan to avoid affecting the project schedule because of the problem of muck discharge.

4.2.2 Just in Time (JIT)

The just-in-time production system is based on a refined advancement plan, and standardized personnel time, location, and operation requirements are established in project management, preventing redundant operations from interfering with engineering work. With people, materials, and machines arriving on time and a stable work rhythm in each section, not only are workers able to operate more skillfully, but also various types of waste, such as unnecessary movement of items, are reduced, and high quality, low cost, and low resource consumption are realized.

4.2.3 Activity-Based Costing Management (ABCM)

The project brings cost management together in every live operation of tunnel tunnelling. Through continuous operation improvement, waste can be reduced, and project costs can be lowered. The operation cost is managed along with the tunnelling process. According to the self-driving system’s evaluation system, the effect and cost of soil improvement, shield propulsion, synchronized grouting, and grease injection operations are continuously adjusted. During the advancement process, the automatic control model is dynamically optimized, and the operation cost calculation and analysis are integrated into the whole construction process to continuously transform and maximize self-driving decision-making and control ability. In this project, the average shield propulsion speed was increased from 75mm/min at the initial stage to 95mm/min at the later stage, while the energy consumption of shield propulsion per unit distance was reduced by 25%.

4.2.4 6S on-site management

Site management is the guarantee of lean construction. Therefore, the 6S on-site management theory is adopted in the project through organizing (SEIRI):

discard unwanted items; reorganizing (SEITON): make it possible to get the things you want at any time; cleaning (SEISOU): always keep tidy; cleaning (SEIKETSU): always maintain the state of organizing, cleaning, reorganizing; quality (SHITSUKE): comply with the established rules; safety (SAFETY): establish the concept of safety first to ensure the smooth implementation of the project.

4.3 Application effects

The whole tunnel was propelled by self-driving, with an average speed of 84.8 mm/min throughout the tunnel, and created a record for the fastest single-day and single-month shield tunnelling of the same class in March 2023, with 19 rings in a single day and 829.8 m (461 rings) in a single month (Figure 6). As can be seen from the Figure 6, the shield machine always maintains a high advancement mileage, and only on March 9, 27 and 28 the number of advancement rings was less. This was due to the fact that the shield machine and the vehicle had reached the required maintenance time and mileage, and needed to be shut down for maintenance, which is a normal part of the production schedule.

During the shield advancing process, the absolute average value of shield attitude deviation is less than 40mm, and the maximum value of cumulative ground settlement is less than -13mm-3mm. The quality of the formed tunnel is good, the tube sheet misalignment and tube sheet gap are controlled within 3mm, and the amount of tube sheet uplift is controlled stably, ensuring “zero accident” in tunnel construction and “zero leakage” in the tunnel of 78,000 square meters. In addition, the energy consumption of the cutting part of the automatically controlled unit advance distance is 25% lower than that of the manual control, and the overall failure rate of the shield machine is 0.48%. After tunnel construction, when the shield was returned to the factory for maintenance, it was found that the shield machine had a good performance, and the wear and tear of each component was very small.

Figure 6. Shield daily advancement rings (March 2023).

5 CONCLUSION

Shield self-driving technology not only solves the problem of lack of experienced technicians and reduces the labor intensity of site operators but also

is an opportunity to change the production mode of the tunnel industry. This paper fully uses the advantages of self-driving technology, combining digital technology with lean construction methods in tunnel engineering project management. Through construction process standardization, resource demand plan refinement, and promotion plan optimization, together with the LPS, JIT, ABCM, and 6S on-site management, this paper significantly improves the production efficiency and quality, reduces the cost and energy consumption in JCXSG-12 tunnel construction of the Shanghai Airport Line, which reflects the advantages of combining the self-driving technology and the lean construction.

This research is just a beginning. The continuous development of digital and intelligent technology not only promotes the improvement of tunnel construction technology but also changes the tunnel construction management mode and injects new vitality into the development of underground engineering.

Study on machine learning method for supporting conventional tunnel engineering judgement

Kazuo Sakai*, Shuntaro Miyanaga & Masahito Yamagami
Taisei Advanced Center of Technology, Taisei Corporation, Kanagawa, Japan

ABSTRACT: The authors have been studying design methods in the conventional tunneling for rational and economical selection of support structures and optimal blasting using machine learning algorithm. In the methods, Measurement While Drilling (MWD) data of charging holes on the face are used as input variables. Those data are recognized as “big data” and are automatically collected at several centimeter intervals by the computer-assisted drilling rigs. The proposed method using quantitative MWD data could realize those designs with more consistency and swiftness than conventional ways where decision is emphasized by site engineer’s subjective observations of rock mass appearance. This paper reports a case study of analyzing geotechnical information and the MWD data obtained from an actual tunnel project. First, neural network algorithm learning MWD data were constructed. That made it possible for rock mass classification to be used as a basis for the tunnel support selection. The method provided the classifications consistent with geologist’s interpretation with more than 70 % regarding rock mass strength, weathering and alternation, and fracture spacing. In addition, random forest algorithm learning MWD data were tested to estimate the explosive volume for a round of blasting. As a result, using both averaged MWD data on each hole and their statistical analysis results, it was confirmed that the explosive volume was predicted with 90 % accuracy.

1 INTRODUCTION

In recent construction industries, productivity enhancement has been one of the high-priority issues as a measure against the prolonged work environment and the labor shortage resulted from declining birthrate

and aging population problem in Japan. We, Taisei Corporation, have been developing a remote control or automation system of heavy machinery for the tunnel excavation, making use of the recent enhancement of in in-tunnel network environment and up-to-date sensing technologies with the aid of IoT. In future, we believe that those developments will contribute to realizing excavation and support works only by a single miner, which are normally conducted by a group of people consisting of 5 to 6 workers today in Japan.

Figure 1 conceptually represents the Taisei’s current development status for the remote or automated tunnel excavation works. It consists of drilling, charging, blasting, mucking, scaling, installing steel supports, shotcreting, and rockbolting. For the drilling of explosive charging (and occasionally rockbolt) holes, the computer-assisted drilling rigs are applied. The rigs and drifters can be automatically operated as designed beforehand. In addition, the rigs are equipped with the Measurement While Drilling (hereinafter called MWD) function which records positions of drilling bits and loads acting on the drifters. Though recordable data may vary depending on manufactures the rigs, they are represented by the parameters, such as

Figure 1. Taisei’s current development status for the automation of tunnel excavation.

penetration rate (m/min), feed pressure (MPa), rotation pressure (MPa), and so on. These parameters are considered effective for assessing the rock mass conditions to be blasted and excavated.

For example, Schunnesson (1996) showed the correlation between the MWD data and RQD observed at rock masses in Glödborget, Sweden. Schunnesson (1998) also discussed the necessity of parameter normalization to take influences from the operator and drill control system into consideration, so that remaining data used to characterize the ground conditions only reflect variations of rock mass properties, such as hardness, fracturing and weathering. Eldert et al. (2022) analyzed the correlation between normalized MWD data and Q-parameters with the multilinear regression analysis. They also proposed a prediction method for rock supports by the holistic visual approach on the MWD data. Commonly applied in Japan is the estimation for rock mass conditions ahead of the tunnel face with the drilling energy (specific energy of cutting) calculated from MWD data (Yamashita, 2008). The drilling energy is defined as the specific energy to break one unit volume of rock. In the meanwhile, the rock mass classification with another

index of normalized drilling velocity ratio has also been proposed (Kuwabara, et al. 2008). Furthermore, the drilling energy is calculated from the MWD data of a computer-assisted drilling rigs and used not only for rock mass classification on the face but also for blasting design in the subsequent excavation rounds (Fukuda et al., 2020). These studies indicate that the MWD data can support the quantitative engineering judgment for the tunnel construction. The MWD data obtained by the computer-assisted drilling rigs are regarded as “big data”: with several centimeters interval in the depth direction for every drilling hole in every blasting round. Therefore, the authors have been developing the design methods in the conventional tunneling for rational and economical selection of support structures and the optimal blasting using machine learning algorithm which is considered suitable for effectively analyzing big data and identifying uncertain correlations. The proposed method using the quantitative MWD data could realize those designs with more consistency and swiftness than conventional ways where the decision is emphasized by site engineer’s subjective observations of rock mass appearance. Using the MWD data obtained by a computer-assisted drilling rigs produced by Epiroc, this paper reports two case studies to evaluate rock mass classification which is a basis for the tunnel support system, then to estimate explosive volume for a single blasting round, which is a key parameter in the appropriate blasting design.

2 COMPUTER-ASSISTED DRILLING RIGS AND MWD DATA

To realize the efficient drilling and the minimum over-excavation blasting leading to the reduction of required concrete for tunnel support, the computer-assisted drilling rigs called XE3C manufactured by Epiroc was applied to the Atoda tunnel construction project where the tunnel mainly passed through the tuff breccia in the Southern part of Japan. Table 1 shows the representative specifications of XE3C. The MWD function software called Underground Manager records the following MWD data which are also conceptually shown in Figure 2:

- Hole position and depth (m)
- Penetration rate (*PR*) (m/min)
- Hammering pressure (*HP*) (bar)
- Feed pressure (*FP*) (bar)
- Dumper pressure (*DP*) (bar)
- Rotation speed (*RS*) (rpm)
- Rotation pressure (*RP*) (bar)
- Water flow rate (*WF*) (l/min)
- Water pressure (*WP*) (bar)

Prior to the machine learning analysis, distribution of the raw MWD data was investigated. Through the daily face observation and documentation in the Atoda tunnel project, the rock mass conditions were classified as CII and DI in compliance with the rock classification system for road tunnels in Japan (JSCE, 2007). In the first half

Figure 3. Construction records (top: geological profile, middle: rock mass classification, bottom; explosive volume distribution).

Figure 4. Frequency distribution of MWD data (average data in each area: top, left bottom, and right bottom).

of the excavation length, the tunnel encountered relatively stiff andesite and tuff breccia classified CII and a round length of 1.2 m was applied. After the tunnel face passed the location 471 m from the portal, the tunnel encountered weathered rock repeatedly crossed by vertical discontinuities with slickenside, potentially leading to face instability problems. Therefore, the round length decreased to 1.0 m and the support system corresponding to class DI was selected. Figure 3 represents the geological profile of the Atoda tunnel in the investigation phase together with the construction results of the rock mass classification and the distribution of used explosive volume along the tunnel chainage. Figure 4 shows frequency distributions of the MWD data obtained for 159 observed and documented excavation faces. Each face was separated into three parts: top heading, left and right bottoms. It should be noted that the MWD data in those graphs are averaged values for holes drilled in those three parts. Also note that the data deeper than 50 cm only were analyzed. This is because the computer program is set to work at low speed and low pressure regardless of rock mass conditions to restrict harmful vibration effect from the drilling bit at the initial drilling stage. The normal drilling began at least after the bit reached a depth of 50 cm.

The graphs of penetration rate and feed pressure in Figure 4 indicate that slower rate and lower pressure were recorded in stiffer rock mass conditions (CII) than those in softer rock mass conditions (DI). Meanwhile, the peak of rotation speed in class DI was lower than that in class CII. Clear differences were not identified in the other indices.

In the following chapters, machine learning algorithms using the raw MWD data with characteristics explained above are experimentally constructed to examine the accuracy of estimation for the rock mass classification and explosive volume in the Atoda tunnel where the actual judgement was made based on the observations by site engineers and miners.

3 ROCK MASS EVALUATION BY ARTIFICIAL NEURAL NETWORK ALGORITHM

3.1 Conditions of Artificial Neural Network

Artificial Neural Network (hereinafter called ANN) generally consists of input, intermediate, and output layers. It provides objective output variables evaluated from explanatory variables in the input layer through intermediate layers. Neurons in the input and

output layers denote the numbers of explanatory and objective variables respectively. In this study, the explanatory variables are 8 MWD data, and objective variables are 6 face observation items for rock mass classification (Table 2): compressive strength, weathering and alternation, crack intervals, crack conditions, water inflow and water induced deterioration. Strike and dip in is not an objective variable in this study, since it can be judged only by visual inspection on the face. The number of layers and neurons in the intermediate layers can be arbitrary determined. In this study, 4 layers and 50 neurons were experimentally applied. An ANN algorithm was constructed in TensorFlow, one of the machine learning libraies. The activating function was a ramp function (ReLU). The ratings of each observation item in the output layer were classified by the Softmax function.

The Softmax function is often used in multiclass classification problems and gives probabilities of the answer that belongs to each rating. Therefore, the rating of each observation item with the highest probability is regarded as the estimation result in this study.

Table 2. Observation items for rock mass classification (JSCE, 2007).

Observation item	Rating					
A. Compressive strength (N/mm ²)	100 or more	100 - 50	50 - 25	25 - 10	10 - 3	3 or less
	Point load	4 or more	4 - 2	2 - 1	1 - 0.4	0.4 or less
	Rough guide for strength by hammering	Hard to break when placed on the ground and strongly hammered	Breakable when placed on the ground and strongly hammered	Breakable when held by hand and hammered	Breakable when hit with another rock of the same type	Partially breakable using two hands
B. Weathering and alternation	Rough guide for weathering	Generally fresh	Weathered or altered along the cracks	Weathered or altered to the rock core	Weathered into soil or unconsolidated soil	
	Rough guide for hydrothermal alteration	No alteration observed	Clay observed in the crack due to alteration	Decreased strength observed at the rock core due to alteration	Remarkable alteration into soil or clay	
	Rating	1	2	3	4	
C. Crack intervals	Crack intervals	d ≥ 1 m	1 m > d ≥ 50 cm	50 cm > d ≥ 20 cm	20 cm > d ≥ 5 cm	5 cm > d
	RQD	80 or more	80 - 50	60 - 30	40 - 10	20 or less
	Rating	1	2	3	4	5
D. Crack conditions	Crack opening	Tightly closed	Some of the cracks open (less than 1 mm wide)	Many of the cracks open (less than 1 mm wide)	Open (1-5 mm wide)	Open to the width of 5mm or more
	Substance in cracks	None	None	None	Thin clay (5 mm or less)	Thick clay (5 mm or more)
	Crack roughness and slickensides	Rough	Smooth	A limited slickenside	A highly polished slickenside	
	Rating	1	2	3	4	5
	Strike and dip perpendicular to tunnel axis	1. Reverse dip of 45 to 90 degrees	2. Reverse dip of 20 to 45 degrees	3. Regular/reverse dip of 0 to 20 degrees	4. Regular dip of 20 to 45 degrees	5. Regular dip of 45 to 90 degrees
E. Strike and dip parallel with tunnel axis	Parallel with tunnel axis		1. Dip of 0 to 20 degrees	2. Dip of 20 to 45 degrees	3. Dip of 45 to 90 degrees	
	Rating					
F. Water inflow	Status	No inflow or water seeping out surrounding 1 m	Water dripping at 1 to 20 l/min	Water locally flowing at 20 to 100 l/min	Water extensively flowing at 100 l/min or more	
	Rating	1	2	3	4	
G. Water induced deterioration	Water-induced deterioration	None	Loosened	Weakened	Washed out	
	Rating	1	2	3	4	

Figure 5. ANN for estimating the rating of observation items.

For the training and validation process, the complete data set which consists of 469 data from 139 cross-sections (131 data in class CII and 338 data in class DI) were divided into 332 data for training (CII: 66 data, DI: 266 data) and 137 data for validation (CII: 65 data, DI: 72 data). The number of trainings was 1000 times. Figure 5 conceptually represents the ANN structure in this study.

3.2 ANN results of rock mass quality estimation

Table 3 shows the accuracies of ANN in each observation item. They are calculated by all validation data, by data in class CII, and by data in class DI, respectively. Note that accuracy is defined as the ANN in the validation process that gives corresponding answers to actual observation results judged by engineers at the site. The result of ANN in each observation item can be interpreted as follows.

The accuracy of compressive strength was 73.7 % in total. However, there was a considerable difference between accuracies in class CII (56.9%) and class DI data (88.9%). The difference in accuracies of weathering and alternation was similar. The accuracy was 83.3 % in the class DI data, relatively higher than 64.6 % in the class CII data. Accuracy of crack intervals was also in the same tendency. One of the reasons accuracies in class CII did not reach that in class DI might be that the number of training data in class CII was not sufficient to acquire satisfying accuracy. In other words, additional training data included in class CII class could improve accuracy. On the other hand, the accuracy of water inflow in class CII was 84.6 %, close to the accuracy in total, and exceeded that in class DI (76.4 %). The preferable score of accuracy could however be derived from the conditions that all the observation results in class CII and most in class DI were categorized in rating “1” meaning “No inflow or water seepage not exceeding 1 liter/min” (refer to Table 2). The ANN using drilling data obtained in the tunnel with varying water inflow should be further studied in terms of its accuracy. Accuracy in crack conditions and water induced deterioration were 35.0 % and 54.0 % respectively, and neither were satisfactory. It might have come from more similar distributions in classes CII and DI than those of other items. Meanwhile, it has been proposed in existing research (Schunnesson, 1996 and 1998) that the quantitative fracturing index calculated from the MWD data variation indicates the existence of fractured zone. Further investigations are required, especially in crack conditions as to whether the increasing input data in other tunnels, change in data preprocessing methods, and change in ANN structures can contribute to accuracy improvement.

3.3 Evaluation of softmax

Table 4 shows accuracy difference according to the maximum Softmax value. Here, the maximum

Softmax value is the largest figure in Softmax among ratings in each observation item. Whereas accuracy is the probability is in which the rating with maximum Softmax value is consistent to the actual observation result. For example, in the compressive strength column, there were 117 ANN results with the maximum Softmax values higher than 0.900. Ninety-one out of 117 results, *i.e.*, 77.8 % provide right answers. In the same manner, 66.7 % of results with maximum Softmax value of 0.700 to 0.899 and 36.4 % of those with the values lower than 0.699 give right answers.

It could be interpreted the higher the maximum Softmax value the ratings have, the more reliable the ANN results. Accuracies of weathering and crack intervals which were relatively high in total as discussed in previous section scored good, such as 76.0 % and 68.8 % respectively when the maximum Softmax value is higher than 0.900. There was a similar tendency in the accuracy of compressive strength. The site engineer could therefore judge whether it is possible to apply the ANN results to the final decision for actual construction strategy on the basis of the

Table 3. The accuracy of ANN in each observation item.

		Observation items					
Accuracy		Compressive strength	Weathering/ Alternation	Crack intervals	Crack conditions	Water inflow	Water induced deterioration
Rock mass class	Total (137 data)	73.7% (101)	74.5% (102)	65.7% (90)	35.0% (48)	80.3% (110)	54.0% (74)
	CII (65 data)	56.9% (37)	64.6% (42)	56.9% (37)	30.8% (20)	84.6% (55)	75.4% (49)
	DI (72 data)	88.9% (64)	83.3% (60)	73.6% (53)	38.9% (28)	76.4% (55)	34.7% (25)

* The figures in parentheses are the number of data to which ANN gives correct answers for each observation item.

Table 4. The difference of accuracy in Softmax value.

		Observation items					
Softmax value		Compressive strength	Weathering/ Alternation	Crack intervals	Crack conditions	Water inflow	Water induced deterioration
Softmax value	Higher than 0.900	77.8% (91/117)	76.0% (95/125)	68.6% (83/121)	33.3% (42/126)	81.7% (107/131)	53.9% (69/128)
	0.700 to 0.899	66.7% (6/9)	50.0% (4/8)	66.7% (6/9)	50.0% (3/6)	33.3% (1/3)	66.7% (4/6)
	Lower than 0.699	36.4% (4/11)	75.0% (3/4)	14.3% (1/7)	60.0% (3/5)	50.0% (1/2)	33.3% (1/3)

* The figures in parentheses are the number of data in which Softmax showed the values higher than the indexed value, over the number of data to which ANN gives correct answer for each observation item.

Table 5. Correlation matrix for randomly selected holes.

Correlation analysis result								
	PR (dm/min)	HP (bar)	FP (bar)	DP (bar)	RS (r/min)	RP (bar)	WF (l/min)	WP (bar)

Softmax value. On the other hand, in the observation items of crack conditions and water induced deterioration with relatively low accuracies in total, the effectiveness of the Softmax value in supporting engineers' judgement could not be clarified, as indicated in the case of crack conditions where the evaluated accuracy was only 33.3 % even when the maximum Softmax value was higher than 0.900.

4 EXPLOSIVE VOLUME ESTIMATION BY RANDOM FOREST REGRESSION

4.1 Data processing

Data processing includes some statistical analyses of the data to determine possible constraints in applying various analytical methods and to detect data imbalance. Specifically, correlation analysis and principal component analysis (hereinafter called PCA) were conducted and the results are described in this section.

The correlation analysis was performed to discover and quantify the degree of dependence in the drilling parameters during drilling operation effort (single borehole). The knowledge gained from the correlation analysis could help to prepare the data to meet the expectations of machine learning algorithms, such as linear regression, whose performance will degrade if the input data are significantly correlated.

Table 5 shows the correlation matrix for MWD data (except for drilling positions) constructed by randomly selected 1000 drilling holes from cross-sections 122 to 1026 m of tunnel chainage. Note that the correlation coefficients in the matrix were calculated only in the normal drilling stage (deeper than 50 cm) of each drilling hole. The highest correlation coefficient in Table 5 was 0.699 between the dumper pressure and the rotation speed. Thus, it is not able to conclude that the MWD variables are strongly correlated each other. Therefore, the correlation coefficients in the lower red triangle in Table 5 were extracted and used as explanatory variables together with raw/averaged MWD data for the Random Forest Regression analysis to be described in next section.

Data clustering was performed with PCA. The method is one of the most popular methods to reduce the data attributes to a smaller (and therefore more manageable) number of components (or variables) by obtaining the most significant parameters for variations and preserving as much of the data's variation as possible. It seems to be the most commonly applied method for any MWD data analysis (Qiu et al., 2022).

Table 6 compares the PCA (Principal Component Analysis) variance ratios of the raw and averaged

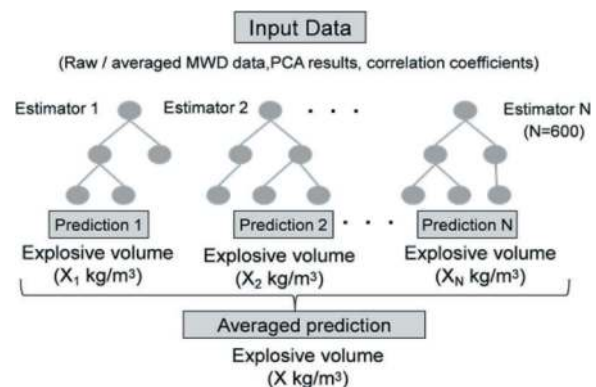

Figure 7. RFR structure for estimating explosive volume.

Table 7. Summary of RFR.

Input variables	Performance		
	RMSE (kg/m ³)	MAPE (%)	Accuracy (%)
Raw MWD data	0.05	13.4	86.6
PCA outputs	0.09	22.1	77.9
Raw MWD data & PCA outputs of raw MWD	0.06	14.3	85.7
Averaged MWD data	0.05	11.2	88.8
PCA outputs of averaged MWD	0.08	21.1	78.9
Averaged MWD data & PCA outputs of averaged MWD	0.03	7.5	92.5
Correlation analysis results	0.05	12.1	87.9
Averaged MWD data & Correlation analysis results	0.03	7.4	92.6

MWD data for explanatory variables. Referring to the complete data set column in the table, first three principal components (PC1, 2 and 3) explain 68.3 % (= PC1 + PC2 + PC3) of data variation with the use of the raw MWD, while this becomes 82.1 % when the averaged data are used. From the comparison, it is clear that the low dimensional representation could be achieved better when the analysis is done on the drilling data averaged per drilling hole. Results from one PCA on the averaged MWD

variables were color-coded to the target variable, that is explosive volume as shown in Figure 6. The visualization shows a good separation between the two cross-sections where considerably different volume of explosives were used, even the first three PCs only explain a input data variation of 70%. Therefore, those first three PCs were further used for RFR together with the original MWD data and correlation coefficients.

4.2 Random Forest Regression (RFR)

Random Forest (RF) is one of the most popular machine learning methods and helps to reach a predicted result through the combination of outputs from several decision trees. RF is normally applied to two problems such as classification and regression problems. To check whether it's feasible to use the MWD data to optimize the volume of explosive materials used in tunneling, a predictive random forest regression model was developed. The model predicts the total volume of explosive material per m³ of the excavation in 147 cross-sections at tunnel chainages between 579 and 777 m. Different combinations of inputs were set up for the predictive model training, including a set of inputs with results from the correlation analysis and PCA. For the training and validation process, the complete dataset, which consists of the 147 cross-sections, was divided into input and validation groups randomly with a ratio of 9:1. To guarantee that sections with varying amounts of explosives are included in the validation set, the split-train RF, prediction, and validation procedure were performed multiple times.

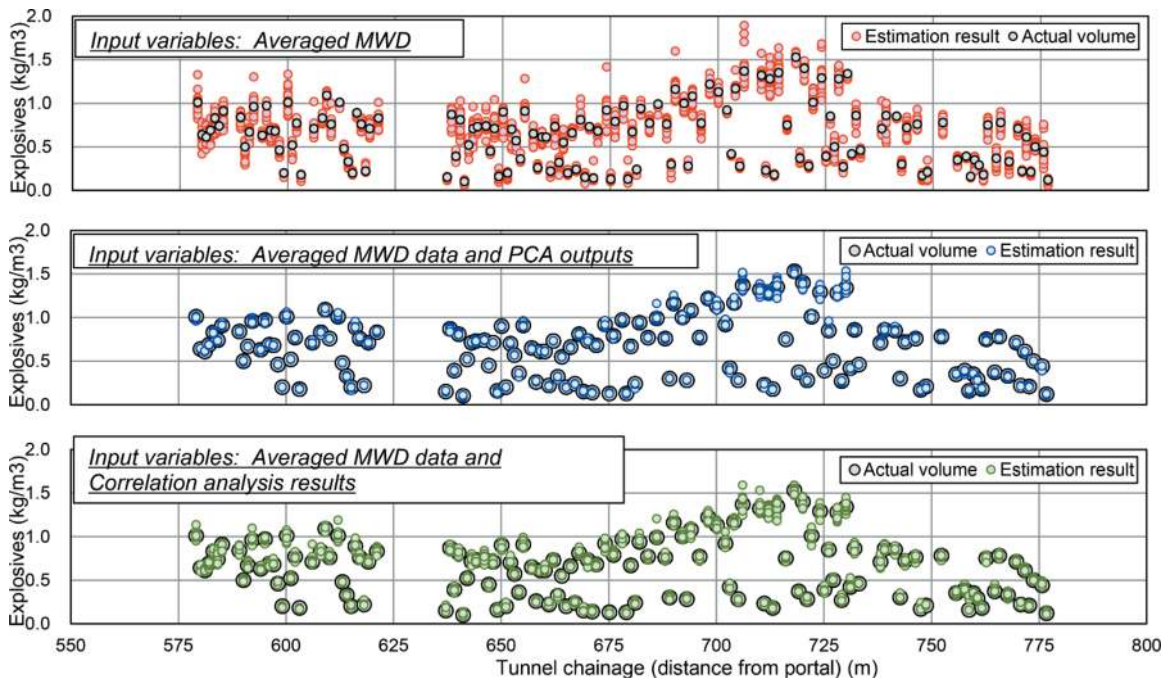

Figure 8. Comparison between estimation results of RFRs and actual explosive volume.

That resulted in multiple outputs for each section. For the settings of RFR, almost the default setting of SciKit Python library was used. The number of estimators was set to 600 because the greater number of estimators did not necessarily improve the result. Figure 7 conceptually explains the constructed RFR model in this study.

Table 7 shows the summary of the RFR analyses. The root means square error (RMSE), mean absolute percentage error (MAPE) and accuracy are calculated as follows and are used to evaluate the models' performance.

$$RMSE = \sqrt{\sum_{i=1}^n \frac{(\hat{y}_i - y_i)^2}{n}} \quad (1)$$

where, \hat{y}_i is an estimated i -th value, y_i is actual i -th value and n is the number of samples.

$$MAPE = \frac{1}{n} \sum_{i=1}^n \left| \frac{\hat{y}_i - y_i}{y_i} \right| \quad (2)$$

$$Accuracy (\%) = 100 - MAPE \quad (3)$$

First, comparing the accuracy of "Raw MWD data = 86.6 %" and "Averaged MWD data = 88.8 %" in the table 7, the input variables using averaged data gave better accuracy. The same tendency was also observed in the comparison between "Raw MWD data & PCA outputs of the raw MWD data = 85.7 %" and "Averaged MWD data & PCA outputs of the averaged MWD = 92.5 %". These outcomes might come from the fact that the PCA results using the averaged MWD data on each drilling hole had higher summation of the first three principal components and that the variation in inputs explained better than by the PCA results using raw MWD data.

Second, comparing the accuracy of "Averaged MWD data = 88.8 %" and "Averaged MWD data & PCA outputs of averaged MWD = 92.5 %" or "Averaged MWD data & correlation analysis results = 92.6 %", the latter cases using statistical values in addition to the averaged MWD data give greater accuracies. These indicate that the statistical values of PCA or correlation analysis contribute to improving the prediction because they might be regarded as additional variables explaining and characterizing MWD data well.

Figure 8 compares the actual and the predicted explosive volume distribution along the tunnel chainage in three cases of RFR using averaged MWD data and statistical inputs. Note that, in the graphs, there are some estimated results in each case (as clearly seen results using the averaged MWD data) because different combinations of input variables were set up for predictive model training, dividing the training and validation data into two groups with a ratio of 9:1. It is clear that the explosive volume can be estimated better when the statistical values of PCA and the correlation analysis are combined with the averaged MWD data, than using the averaged MWD data only in the prediction analysis.

5 CONCLUSIONS

In this study machine learning algorithms were constructed, and their accuracies were examined in which the objective variables of rock mass classification on the tunnel face and the required explosive volume for blasting were estimated by the explanatory variables of the MWD data obtained by the computer-assisted drilling rigs. Those engineering judgements for the conventional tunnel construction used to be conducted by fully trained engineers and miners. ANN for estimating rating of observation items from the MWD data by XE3C produced accuracy of more or less 70 % for the parameters such as compressive strength, weathering and alternation, and crack intervals. However it gave low accuracy on the parameters such as crack conditions and water induced deterioration. This result may suggest that the MWD data mainly consisting of speeds of drilling bits and loads on drifters could be related with strength related parameters of drilled object, but might difficulty in predicting water or crack conditions.

In addition, the RF algorithm could also estimate the actual explosive volume with a small error when the statistical values like principal component analysis results for explanatory variables are applied with the original MWD data. Taking these learned results into consideration, the authors believe that a machine learning algorithm could possibly assist quantitative MWD data acquisition for engineering judgements in tunnel construction which used to be carried out by site engineers and miners.

In this study site engineers' qualitative face observation records and actual explosive volume on the basis of visual inspections and previous experience were regarded as objective variables for respective training of the machine learning algorithms. Therefore, they may still include inaccurate observation records or excessive blasting results which could lead to unnecessary over-excavation in cross-sections and inappropriate advance in the longitudinal direction. In the future studies, applying quantitative data like physical properties of rock or over-excavation measurement results by a 3-D laser scanner as objective variables, the authors would like to improve supporting tools for conventional tunnel engineering judgement which can contribute to construction productivity and safety.

ACKNOWLEDGMENTS

The authors are grateful to Ass. Prof. Takafumi Kitaoka at Kansai University for fruitful discussions and great assistance with the development of Neural Network algorithm in this study. We also thank to Prof. Thomas Marcher and Ass. Prof. Alla Sapronova at Graz University of Technology for estimating the explosive volume by Random Forest Regression algorithm.

ABSTRACT: Precise and reliable evaluation of the performance of tunnel boring machine (TBM) is of utmost importance in order to mitigate the risks associated with the substantial capital costs and intricate planning involved in tunnel construction. To address this issue, a total of ten distinct computational techniques have been developed, encompassing supervised and unsupervised learning models based on statistical, machine learning, fuzzy-based, genetic approaches, and deep learning algorithms. The models were implemented using a comprehensive database consisting of five features, namely cutterhead rotation speed, rate of penetration, cutter load, uniaxial compressive strength, and rock quality designation. The data utilized in these models was collected and generated from a specialized database containing multiple tunnel sections from five selected projects, encompassing a wide range of lithological units with varying compressive strength of sedimentary, igneous, and metamorphic rocks. The results of the analysis revealed significant correlations between variables geomechanical properties of rocks and operating machine parameters with TBM performance (TBM-ROP). Various loss functions and evaluation metrics were employed to assess the performance and accuracy of the applied methods. Notably, the outcomes of the proposed models exhibited satisfactory and reliable accuracy, with all models exhibiting an R-squared value above 0.70 and loss function values approaching zero. The results demonstrated that the supervised learning algorithms, particularly the DNN model, yielded the most precise outcomes for ROP ($R^2 = 0.97$; RMSE = 0.00004; MAPE = 0.00000).

Keywords: Hard rock TBMs, TBM performance prediction, Supervised and unsupervised learning, Computing machinery techniques

1 INTRODUCTION

In the context of planning tunnelling activities involving tunnel boring machines (TBMs), it is imperative to make well-informed assumptions and judgments at various stages of the project. Of particular importance is the rigorous evaluation of TBM performance, as this assessment greatly influences critical aspects such as project planning, cost management, and the overall viability of the project for decision-makers. Any miscalculations in project performance can lead to unexpected expenses, project delays, and diminished profitability (Gokceoglu, 2022) and even viability of the whole project cost and schedule.

The process of tunnelling involves inherent risks and uncertainties, which are influenced by factors such as the characteristics of the TBM, the geological conditions of the rock mass, and the operational parameters. Consequently, successful tunnelling projects necessitate meticulous decision-making and planning processes (Adoko et al., 2017).

Numerous researchers have highlighted the significance of predicting metrics such as the rate of penetration (ROP), advance rate (AR), and penetration per revolution (PR) for accurate estimation of TBMs operating in hard rock conditions. In order to achieve this objective, studies have focused on three prediction techniques: theoretical, empirical, and

*Corresponding author: hassanpour@ut.ac.ir; rostami@mines.edu

soft computing approaches (Rostami and Ozdemir, 1993; Gong and Zhao, 2009; Hassanpour et al., 2011).

Theoretical models employ cutting forces and laboratory cutting tests to establish formulas based on force equilibrium. While these models provide a fundamental understanding of rock fragmentation, they do not entirely capture the complexities of real-world rock conditions (Rostami and Ozdemir, 1993; Bilgin, 2016; Elmo and Stead, 2021).

One highly utilized model for predicting TBM performance is the NTNU model, developed by Blindheim (1979) based on research conducted at the Norwegian University of Science and Technology. Bruland (1998) updated the NTNU model with field data, resulting in one of the most extensively used empirical models for TBM tunnelling. Rostami and Ozdemir (1993) developed a predictive model for estimating the cutting force of disc cutters, which was subsequently enhanced by Rostami (1997, 2013), and by Yagiz (2002) to account for rock mass properties. Barton (2000) conducted a comprehensive review of various TBM tunnelling projects and developed the Q_{TBM} model, which utilizes the Q rock mass classification system to estimate TBM performance parameters including ROP, utilization factor ($U\%$), and AR.

The second approach, based on field performance observations, takes into account the geomechanical conditions at the excavation site (Hassanpour et al., 2011). Researchers have proposed and implemented various statistical methods, grounded in mathematical principles, for predicting TBM performance. Sapigni et al. (2002) and Gong and Zhao (2009) conducted nonlinear regression analyses to explore the empirical relationship between the rock mass rating (RMR) and penetration rate. Hassanpour et al. (2011) established multiple relationships between rock mass parameters such as RMR, rock quality designation (RQD), joint spacing, and uniaxial compressive strength (UCS), and found that a combination of RQD and UCS provides the most accurate prediction of TBM performance. However, Grima and Verhoef (1999) pointed out that statistical methods lack reliability in accurately defining complex and non-linear systems, and their predictability is affected by outliers and distant points in the database.

The third approach, which utilizes artificial intelligence (AI) and computing techniques, has gained significant popularity in recent years to address the complexity of predicting TBM performance (Benardos and Kaliampakos, 2004). The identification of factors influencing TBM performance and its parameters is a common challenge that can be effectively addressed using AI and machine learning (ML) methods. The use of these techniques, such as artificial neural networks (ANNs) has become extensively employed in tunnelling projects to predict TBM driving and operational parameters, and have shown

promising and reliable outcomes (Zhao et al., 2007; Gao et al., 2020).

Several models have been proposed for predicting TBM-ROP using support vector regression (SVR) (Okubo et al., 2003; Minh et al., 2017). Furthermore, other successful approaches described in previous studies include ANN, fuzzy logic, and particle swarm optimization (PSO) (Khandelwal and Singh, 2009; Jain et al., 2014). Liu et al. (2019) introduced a tailored version of SVR (single-purpose SVR) for TBM performance forecasting, and their proposed model outperformed the basic SVR model. Zhou et al. (2021) proposed innovative composite predictive models, drawing inspiration from the extreme gradient boosting (XGB) mechanism, to forecast TBM-ROP. They explored various optimization algorithms to enhance the XGB model, and their findings indicated that the PSO-XGB model is the superior predictive model for TBM-ROP prediction.

The present research endeavours to develop, train, test, and analyse the capabilities of ML, DL, fuzzy-based, and genetic approaches. The present study introduces the following novel contributions:

- The research investigates the effectiveness of ten types of supervised and unsupervised learning techniques included radial basis function, k-nearest neighbourhood neural network, multi-layer perceptron, support vector machine, support vector regression, gene expression programming, fuzzy inference system, deep neural network, extreme learning machine, and multivariable regression in the reliability analysis of TBM penetration rate in different rock conditions (a wide range of lithological units with varying compressive strength of sedimentary, igneous, and metamorphic rocks).
- This research examines the impact of multicollinearity in the database on the performance, accuracy, and overfitting of the developed models.
- The study formulates the hypothesis statement for reliability analysis and employs hypothesis tests to select the appropriate research hypothesis.
- Various analyses, including importance ranking, score analysis and regression error characteristics curve, are conducted to identify the optimal performance soft computing models for the reliability analysis of TBM performance.

Generally, the study aims to utilize supervised predictor models to predict TBM-ROP. To accomplish this, a big database comprising necessary data from five tunnelling projects is employed to predict and calculate the target driving TBM parameter based on input parameters, including operational parameters of the boring machine and geomechanical properties of intact rocks and rock masses. The performance of the models is evaluated using superior loss functions associated with artificial intelligence.

The significance of this research lies in its ability to effectively address a range of concerns faced by

operators in the construction of deep tunnels in hard rock conditions. By considering various factors such as the selection of an appropriate TBM, geotechnical characteristics along the tunnel face, and ensuring safe construction practices, this study provides valuable insights and guidance for operators.

2 PROJECT DESCRIPTION

The data utilized in this research was collected and generated from a specialized database containing multiple tunnel sections from several selected projects, encompassing a wide range of lithological units with varying compressive strength of sedimentary, igneous, and metamorphic rocks. A comprehensive investigation was conducted using geomechanical and machine data from five tunnelling projects, including the Zagros water conveyance tunnel lot 2, Manapouri second tail-race tunnel, Ghomrood water conveyance tunnel lots 3 and 4, Karaj water conveyance tunnel lot 1, and Kerman water conveyance tunnel, southern lot. The combined length of these projects amounts to 92.6 km.

A summary of the primary characteristics of these TBM tunnelling projects is presented in Table 1, while the geomechanical parameters of tunnelling projects are presented in Table 2.

Table 1. Main characteristics of tunnelling projects.

Projects	Tunnel length (km)	Available data (km)	TBM type	TBM diameter (m)
Zagross WCT (Lot 2)	26	5	Double shield	6.73
Ghomrood WCT (Lots 3 & 4)	21.5	15.7	Double shield	4.52
Karaj WCT (Lot 1)	15.9	8.2	Double shield	4.66
Kerman (Southern Lot)	19.2	6	Double shield	5.27
Manapouri Project	10	9	Open TBM	10.05

3 DATABASE DEVELOPMENT OF TBM FIELD PERFORMANCE

This section provides a principal component analysis (PCA) to develop the database. PCA is a statistical procedure used for analysing multivariable data in order to identify the principal components. It is common to highlight variations and reduce the dimensionality of the data. In this study, the PCA was conducted on both the output and input parameters to calculate the variance ratio, which indicates the extent to which TBM performance parameter is influenced by geomechanical properties and other operating parameters affecting TBM driving factors. Figure 1 represents the variance ratio of each

component. It is noteworthy that the utilization of four features demonstrates the highest variance ratio (above 84%), signifying that it is the most favourable model for calculating TBM driving parameter (TBM-ROP) in terms of statistical analysis. In addition, Figure 2 displays the component transformation matrix using the Varimax with the Kaiser normalization rotation method and component plot in rotated space.

Table 2. Geomechanical parameters of tunnelling projects.

Projects	UCS (MPa)	RQD	GSI	RMCI	RMR
Zagross WCT (Lot 2)	15-150	45-95	30-70	12-120	39-65
Ghomrood WCT (Lots 3 & 4)	25-150	10-100	30-80	4-170	43-76
Karaj WCT (Lot 1)	30-150	10-100	15-85	6-150	27-73
Kerman (Southern Lot)	170-300	100	90-92	160-300	87-89
Manapouri Project	100-225	70-100	-	71-239	51-76

Figure 1. Variance ratio of each component and groups of defined features.

Table 3. Summary results of statistical analysis of parameters recorded in the database.

	Unit	Min.	Max.	Skew.	Med.	Var.
RPM	-	2.5	11.9	1.27	5.48	4.2
UCS	MPa	20	300	0.629	98	4792.4
RQD	%	10	100	-0.85	79.25	736.3
Fn	tonf	24.8	2919.5	-0.16	15.83	28.03
ROP	m/h	0.35	5.88	0.371	2.39	2.172

Thus in order to construct the database for this study, various machine operational and driving parameters, as well as geomechanical properties, were defined. The operational parameters consisted of the cutterhead rotation speed (RPM) and cutter load (Fn), while the geomechanical properties of the rocks were represented by the uniaxial compressive strength (UCS) and rock quality designation (RQD).

Additionally, the mechanical properties of the boring machine were represented by the cutterhead diameters. The collected dataset was categorized into five lithological units based on the formation and engineering geological properties. Table 3 presents statistical indices derived from the dataset under investigation.

Figure 2. The component transformation matrix using the Varimax and component plots in rotated space.

Subsequently, laboratory tests, daily operating records, and TBM data logger were recorded for each excavation ring and engineering geological units, resulting in a dataset of 177 data points (collected from five tunnelling projects which indicates in Table 1) that included four parameters influencing the TBM performance. The dataset was divided into 90% for training and 10% for testing the supervised learning

models. Figure 3 presents boxplots that categorize the defined parameters within the database. This visualization allows for a comparative analysis of these parameters across different strength, enabling researchers to identify any variations or outliers that may exist.

4 EMPIRICAL MODEL

The scatterplot matrix of specified parameters in the database of TBM-ROP is shown in Figure 4 to visualize the linear correlations between the dependent and independent variables, including operating parameters of machine and rock geomechanical properties.

In case of multi-variable regression analysis, four parameters (refer to Table 3) are employed as independent variables and the TBM performance parameter as dependent value to assess the influence of each variable on the TBM-ROP using forward stepwise regression analysis (FSR). The proposed empirical formula to calculate TBM-ROP is presented in Equation 1.

$$ROP(m/h) = \zeta + MP + GP \quad (1)$$

Where ζ is a constant factor: 3.661

MP, operating machine parameters: $MP = 0.264 RPM - 0.019 Fn$

GP, geomechanical properties: $GP = -0.01 UCS + 0.021 RQD$

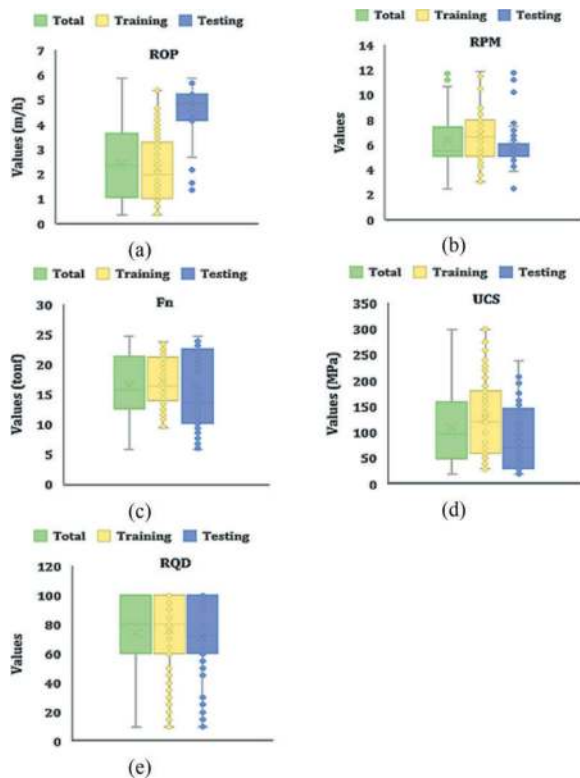

Figure 3. Boxplots diagrams based on each defined parameters within the database (total data, training and testing subsets).

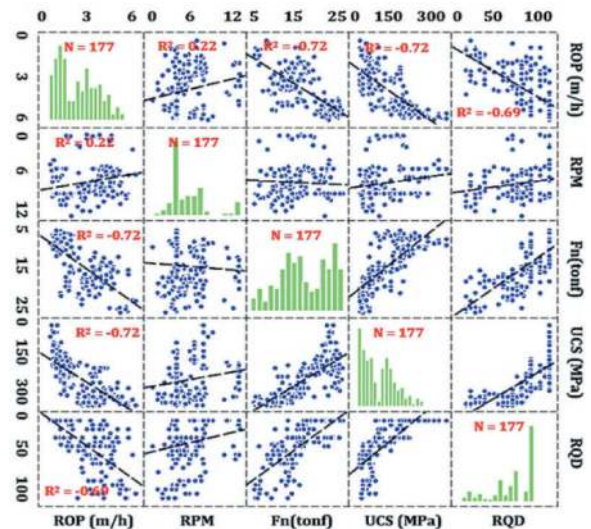

Figure 4. The scatterplot matrix and histograms of considered parameters in the estimation of TBM-ROP.

Figure 5 provides the correlations between the measured TBM-ROP with the calculated results based on the developed empirical formula. The predicted and measured results of this parameters is plotted in Figure 6 showing a good agreement between measured and predicted values for TBM-ROP.

Figure 5. Correlation between measured and predicted values of TBM-ROP.

5 SUPERVISED LEARNING ALGORITHMS

In tunnelling projects with complex physical and geological conditions and multiple input factors, supervised learning techniques such as machine learning, deep learning, genetic approaches, neural networks, and fuzzy-based models have become increasingly popular. The incorporation of these supervised learning algorithms has proven effective in enhancing the accuracy and efficiency of TBM performance estimation models in mechanized tunnelling applications.

This section presents the results of several utilized algorithms for TBM penetration rate, including least-squares support-vector machine (LS-SVM), support vector regression (SVR), Takagi-Sugeno fuzzy model (TSF), gene expression programming (GEP), extreme learning machine (ELM), deep neural network (DNN), multi-layer perceptron neural network (MLP), k-nearest neighbors (KNN), and radial basis function (RBF). Detailed information regarding the tuned parameters and hyper parameters for each applied technique for TBM-ROP is presented in Table 4.

The selection of these algorithm for analysis is justified by several reasons.

- They offer an innovative solution to complex problems through its novel approach to encoding and decoding information.

- They reduce the risk of overfitting by employing a regularization parameter that controls the model's complexity and prevents it from fitting noise in the data.
- These algorithms are well-suited for handling large datasets, as employ a kernel and non-linear trick that allows for data transformation into a higher-dimensional space. This flexibility enables them to effectively handle non-linearly separable datasets.
- The bilingual notation employed in following models provide a unique and effective strategy for addressing complex problems. As another point, these algorithms are renowned for their fast and efficient learning speed, which is particularly essential in tunnelling projects, where timely predictions are crucial for decision-making.
- These algorithms exhibit fast convergence, requiring fewer iterations compared to other machine learning algorithms to achieve the desired level of accuracy.
- They boast a strong theoretical foundation that guarantees convergence and optimality under specific conditions.
- These algorithms are applicable to various learning scenarios, including batch learning, sequential learning, and incremental learning, making them versatile tools for predicting target parameters in diverse tunnelling settings and experimental setups.
- They are valuable tool in various applications in time series forecasting.

To evaluate the performance of the developed models, various loss functions and evaluation metrics have been proposed. These metrics serve the purpose of quantifying the disparity between the predicted and actual TBM-ROP values, as well as assessing the predictive capability of the algorithms.

Figure 7 depicts the correlation between the actual and predicted values of TBM-ROP. As a sensitivity analysis, Figure 8 presents the predicted importance ranking for TBM-ROP using three machine learning algorithms (KNN, RBF, MLP). Also, the lower-dimensional projection of the predictor space considering three input factors (Fn, RPM, RQD) based on KNN network is indicated in Figure 9.

To assess the accuracy of the machine learning networks, loss functions were utilized to measure the deviation between the predicted outcomes and the actual measured values. These measures include the normalized root mean square error (NRMSE), root relative squared error (RRSE), relative root mean square error (RRMSE), mean bias error (MBE), root mean squared logarithmic error (RMSLE), and log cash loss (LCL). These loss functions enable a quantitative evaluation of the predictive capabilities of the machine learning models (Table 5). The evaluation of these loss functions consistently yielded excellent results for the TBM-ROP in the

training and testing subsets, indicating the models' ability to predict TBM performance based on input data derived from input features. These evaluations are integral in determining the potential of machine learning techniques in tunnelling engineering. The findings demonstrate a strong agreement between the predicted TBM performance values generated by the machine learning networks and the measured data.

Overall, this study showcases the use of loss functions and subsequent evaluation of machine learning models' accuracy in predicting parameters for future TBM performance analysis. These techniques can serve as a basis for further research that incorporates machine learning models into tunnelling applications.

Figure 10 effectively illustrates the overall ranking results of the various machine learning models. It is evident that the DNN and ELM models emerge as the most robust and accurate models when considering both the training and testing comprehensive ranking, in contrast to the other machine learning models for TBM-ROP.

Further comprehensive evaluations of the prediction results of multiple soft computing techniques for TBM-ROP was conducted using normalized error analysis, as depicted in Figure 11. This Taylor diagram assesses the performance of the applied algorithms based on the method prediction results, normalized standard deviation, normalized root mean square error, and variance.

Table 6 was presented to enhance its content by providing summaries and detailed information on various soft computing methods found in the literature. As depicted in the table, numerous studies have employed machine learning and deep learning techniques to predict the penetration rate of tunnel boring machines (TBM) using a limited number of models, while this study employs several intelligent networks. This present investigation has yielded more accurate and reliable results compared to previous research. The training and testing subsets of this study exhibit an RMSE range of 0.00 to 0.58 and 0.00 to 0.61, respectively, whereas previous studies have reported an RMSE range of 0.02 to 1.02. It is worth mentioning that the detailed review and analysis of the aforementioned studies can be found in their respective articles listed in the references section.

It is necessary to mention that the physical and mechanical characteristics of machines, including the diameter of the cutterhead, disc cutter diameters and spacing, back-up systems, number of disc cutters, and distance of cutters from the center of the cutterhead, remain unchanged

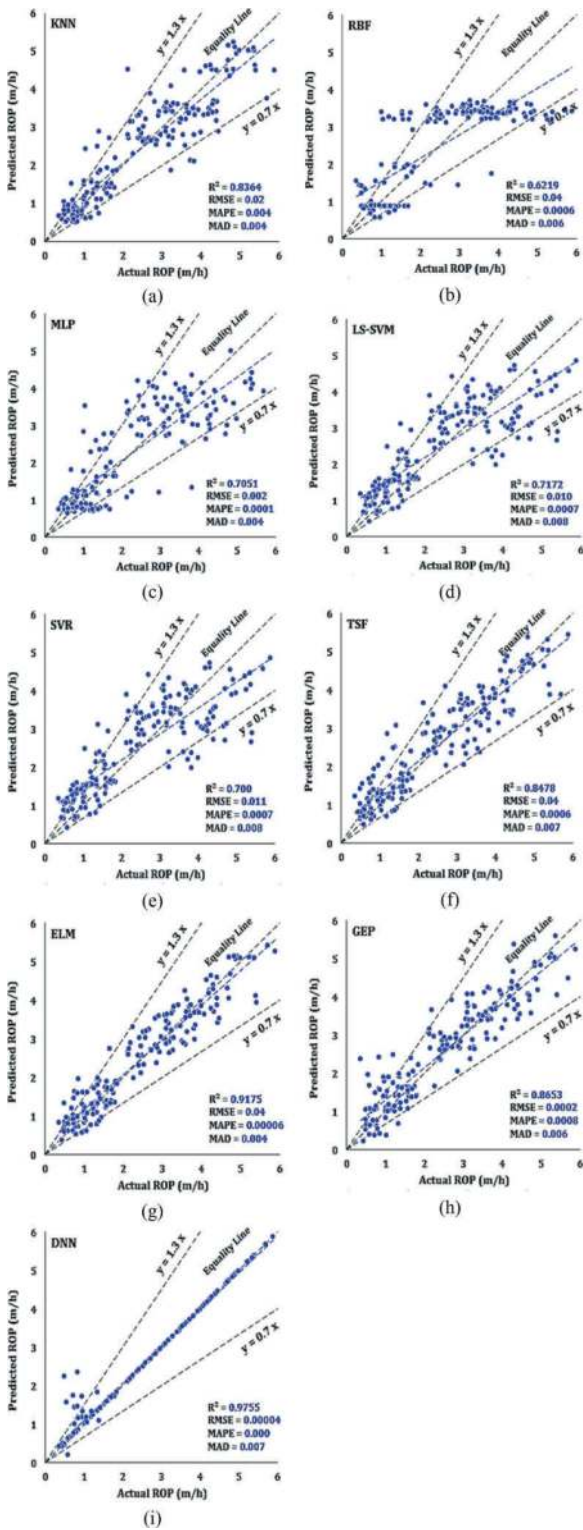

Figure 7. Comparison of the supervised learning predictions with the actual monitored data for TBM-ROP.

during excavation. Consequently, these factors are not suitable for incorporation into smart models that rely on machine learning or deep learning algorithms. In general, constant factors cannot be effectively utilized in the development of

intelligent networks, as these networks are unable to be trained using constant factors.

6 CONCLUSIONS

This study primarily aimed to predict the TBM-ROP within diverse rock types, ranging from sedimentary to igneous and metamorphic, with varied uniaxial compressive strengths. To achieve this, statistical analysis and supervised learning algorithms were employed to develop computational models for estimating TBM performance. These models relied on a variety of geomechanical parameters and operating factors pertaining to the machine. The dataset was carefully categorized by rock type, ensuring rational distribution intervals were defined for the geomechanical factors considered. Relationships between chosen parameters were thoroughly examined, leading to the formulation of new equations using the unsupervised regression statistical method. Additionally, machine learning, deep learning, genetic approaches, and fuzzy-based algorithms were developed to predict TBM performance.

By evaluating the performance and accuracy of models using various evaluation metrics, reliable and satisfactory results across all models were observed. These results were evident in R-squared

values exceeding 0.70 and the convergence of loss function values towards zero. Remarkably, supervised learning algorithms, particularly the DNN exhibits exceptional precision and reliability in predicting TBM-ROP.

These findings, coupled with the potential application of computing machinery techniques, offer promising avenues for accurately estimating TBM performance. Furthermore, they enhance our understanding of machine driving parameters within different rock types, spanning a wide range of strength levels. It is important to note that the proposed prediction algorithms effectively estimated TBM performance, aligning consistently with the measured data.

In conclusion, this research has effectively demonstrated the efficacy of employing computational techniques to evaluate TBM performance. The insights gained from this study are valuable for mitigating risks, optimizing construction

ABSTRACT: Traditional tunnel lining strength detection techniques are mostly contact-based and have lower detection efficiency. This study introduces hyperspectral imaging technology to rapidly identify lining strength from machine vision perspective. It involves collecting spectral data of samples with different strengths using two different wavelength hyperspectral cameras and employs machine learning algorithms to identify concrete compressive strength. Hyperspectral imagery was acquired from the surfaces of concrete specimens, resulting in spectral datasets encompassing both the [400-1000nm] and [900-1700nm] spectral ranges. Machine learning models were formulated to predict concrete compressive strength, both with raw spectral data and data that had undergone Savitzky-Golay (S-G) pre-processing. The findings indicate that satisfactory outcomes were achieved, either without pre-processing or through S-G pre-processing in isolation. Furthermore, the research explored the impact of different spectral wavelength ranges on concrete compressive strength assessment. Notably, the [900-1700nm] dataset exhibited a significant enhancement in the model's determination coefficient (R²) in comparison to the [400-1000nm] dataset. Lastly, a comprehensive analysis of the performance of Principal Component Regression (PCR), Partial Least Squares Regression (PLSR), and Least Squares Support Vector Machine (LSSVM) models was undertaken across various datasets. This culminated in the identification of the most suitable predictive model for concrete compressive strength assessment, accompanied by the computation of model evaluation metrics. This study has opened up new avenues for non-destructive testing of tunnel lining structure strength.

Keywords: Hyperspectral imaging, Tunnel lining, PCR, PLSR, LVSSVM, Compressive strength

1 INTRODUCTION

Concrete compressive strength plays a pivotal role in determining the mechanical performance of concrete. Variations in the source of concrete components, changes during the production process, and the physical properties of concrete directly impact its mechanical performance (Bullard et al., 2019). Among the methods for measuring concrete compressive strength, the uniaxial compressive strength test is considered the most accurate approach. On construction sites, core extraction and pull-out tests are two commonly used methods for testing the compressive

strength of concrete (ASTM C42/C42M-18a., 2018). With the core extraction method, a concrete core is obtained by drilling into the concrete structure at a selected location, and its compressive strength is tested (ASTM C1583/C1583M-13., 2013). During a pull-out test, a metal disk is attached to the concrete surface using a strong adhesive. After a short curing period, the metal disk is vertically pulled out from the surface, and the pull-out force can be used to calculate the compressive strength of the concrete structure. Both core extraction and pull-out tests are destructive and have the potential to damage the integrity of the concrete structure.

*Corresponding author: 2211053@tongji.edu.cn

In addition to these methods, the quality and compressive strength of concrete can also be assessed through non-destructive and non-invasive methods (Qasrawi et al., 2000), including ultrasonic pulse velocity (Hassan et al., 2012) and Schmidt hammer tests (Szilágyi et al., 2011), among others. However, after the rebound hammer test (Rojas-henao et al., 2012), the concrete surface exhibits numerous small indentations (Mesbah et al., 2002), which can have a noticeable impact on the appearance of the concrete. Ultrasonic testing (BS 1881-203 1986), on the other hand, is limited in on-site applications due to the influence of voids, cracks, and reinforcement (Popovics et al., 2005). While these methods aid in predicting estimates of compressive strength, the data obtained does not directly provide information about the physical properties and performance values of concrete (Malhotra et al., 2004).

Hyperspectral imaging (HSI) has been introduced as a non-invasive detection technique for characterizing the composition of materials in civil engineering (Eismann et al., 2012). HSI is a subclass of spectral imaging. Spectral imaging typically involves capturing the reflected spectral information from objects to acquire their characteristics (Zaini et al., 2016). For example, a common camera captures visible RGB (Red, Green, Blue) light to gather information about objects, representing simple broadband spectral imaging. In contrast, hyperspectral imaging is based on the use of numerous narrow spectral bands in image data technology (Arita et al., 2001). Unlike the broad channels of broadband imaging, hyperspectral imaging divides a particular spectral band into many very narrow channels, providing detailed spectral information across many bands that the human eye cannot perceive. Hyperspectral cameras effectively collect three-dimensional data cubes, as shown in Figure 1. When imaging concrete structures in a two-dimensional space, hyperspectral systems simultaneously acquire one-dimensional spectral information (Kohri et al., 2010). For each pixel, hyperspectral information is collected through multiple channels. Using machine

learning methods to analyze concrete hyperspectral data, we can rapidly and cost-effectively determine concrete compressive strength (Brook et al., 2011).

The goal of this study is to rapidly identify the compressive strength of concrete lining structures by using a portable hyperspectral camera to capture the optical reflectance spectra. The focus of this paper is on developing a compressive strength recognition model based on hyper-spectral data of concrete in different wavelength ranges. Various machine learning algorithms are employed to establish the correspondence between optical reflectance spectra and concrete compressive strength. Specifically, concrete samples of five different strength gradients are prepared using different types of silicate cement. For each group, hyperspectral information is collected after standard curing for 28 days, and the compressive strength of the samples is tested. This data is used to establish regression models linking hyperspectral data of different types of concrete samples to their compressive strength.

2 EXPERIMENT SETUP

2.1 Sample preparation

Five concrete samples with different strengths were prepared using ordinary Portland cement labelled C20, C30, C40, C50 and C60, as shown in Figure 2. They are a mixture of water, Portland cement and river sand with a water-cement ratio of 0.5. Pour the mortar mixed with cement of different grades into a standard cubic mold with a size of 100 mm × 100mm × 100mm. Two samples of each strength are made, for a total of 10 samples. Use plastic cloth to pad the mold to prevent surface cracking due to shrinkage. All samples were cured in a standard curing cabinet at a temperature of 23 ± 3.0 °C and a relative humidity (RH) of 90 ± 5%. After curing for 28 days, remove the mold and check the size and shape of the sample. Wipe and polish the surface of the specimen to avoid surface stains affecting the collection of hyperspectral information.

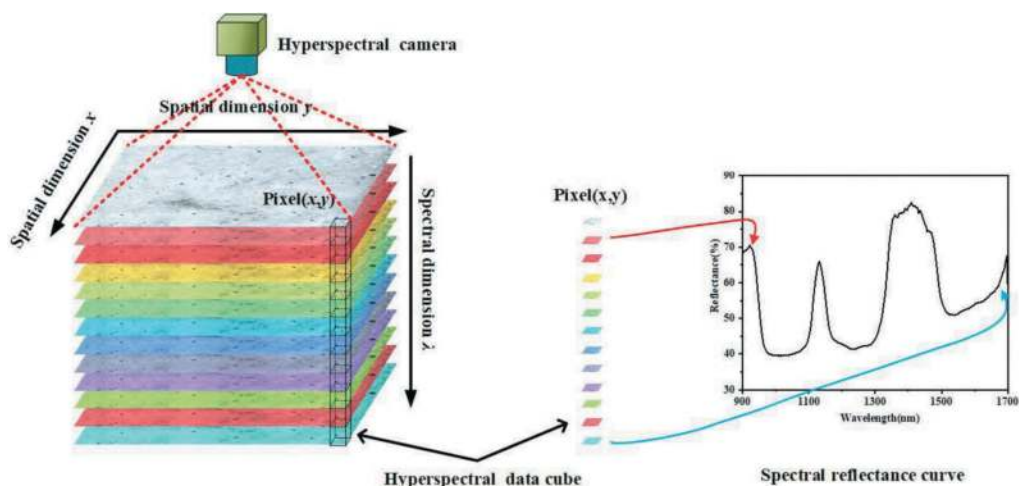

Figure 1. The working principle of hyperspectral imaging.

Figure 2. Concrete specimens used in experiments.

Hyperspectral camera scans and uniaxial compression tests followed. For each type of mortar mixture, uniaxial compression testing was performed according to ASTM C39/C39M-18.2018 to obtain the uniaxial compressive strength of each sample.

2.2 Hyperspectral scanning

Figure 3 shows the test setup for hyperspectral scanning of a sample using two hyperspectral cameras with different spectral ranges. The spectral range of the FS-23 camera is 400-1000nm and the spectral resolution is 2.5nm. The spectral range of the FS-25 camera is 900-1700nm and the spectral resolution is 8.0nm. The camera was fixed on a tripod, and the hyperspectral camera was set directly in front of the concrete sample at a distance of 1.2 m from the sample surface to obtain better resolution for close-range imaging. A white calibration plate with 80% reflectance is placed above the sample. The hyperspectral camera is calibrated by collecting and processing white reference data. The camera is connected to a laptop with data collection software

for setting camera parameters and collecting Scan data. After obtaining the corrected reflection hyperspectral image data, ENVI software is used to extract the reflection spectrum of each pixel in the image for subsequent analysis.

Before hyperspectral scanning, the hyperspectral image is calibrated by collecting and processing reflectance data from a white reflectance calibration board, which provides an 80% reflectance curve across the entire wavelength range. As the principles behind hyperspectral imaging resemble those of conventional cameras but with an expanded wavelength range, the impact of temperature and sample smoothness on spectral data is minimal. Subsequently, adjustments to the camera distance and light source are made based on the calibration board until 60% of the saturation light intensity is detected. Insufficient light intensity may generate too many defective pixels, impeding mathematical corrections.

2.3 Hyperspectral data analysis methods

Hyperspectral image data cubes of concrete specimen surfaces were acquired by using two types hyperspectral cameras. However, due to significant noise in the original hyperspectral data, the Savitzky-Golay (SG) smoothing algorithm was first applied to smooth the raw spectral data (Ma et al., 2016). Subsequently, three machine learning models, namely, Principal Component Regression (PCR), Partial Least Squares Regression (PLSR), and Least Squares Support Vector Machine (LSSVM), were developed for predicting the compressive strength of

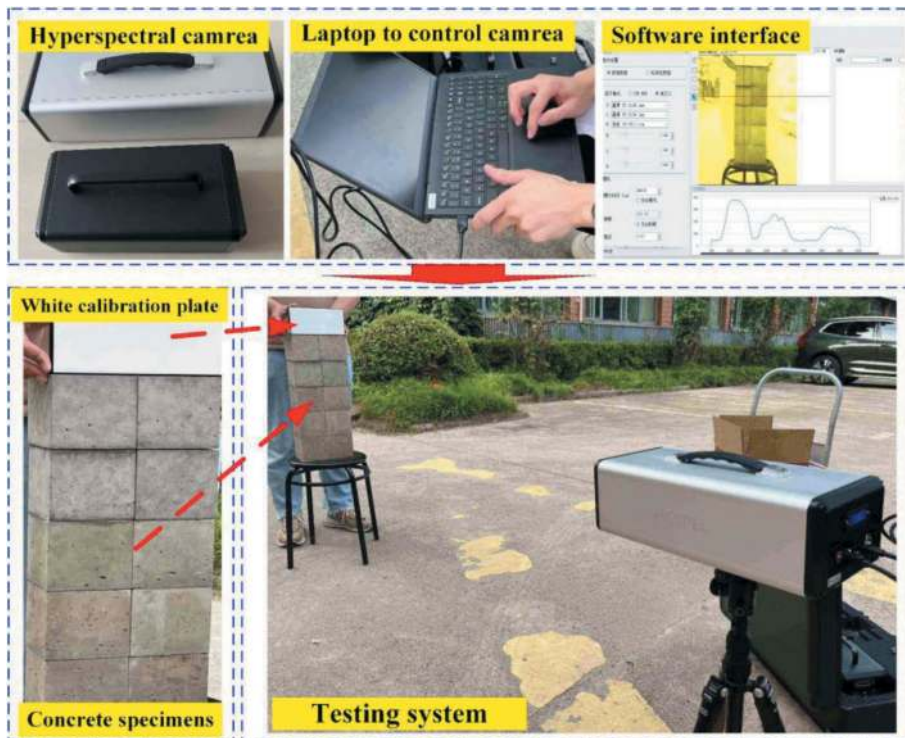

Figure 3. Test setup on concrete specimens using sunlight, hyperspectral camera, laptop and white calibration plate.

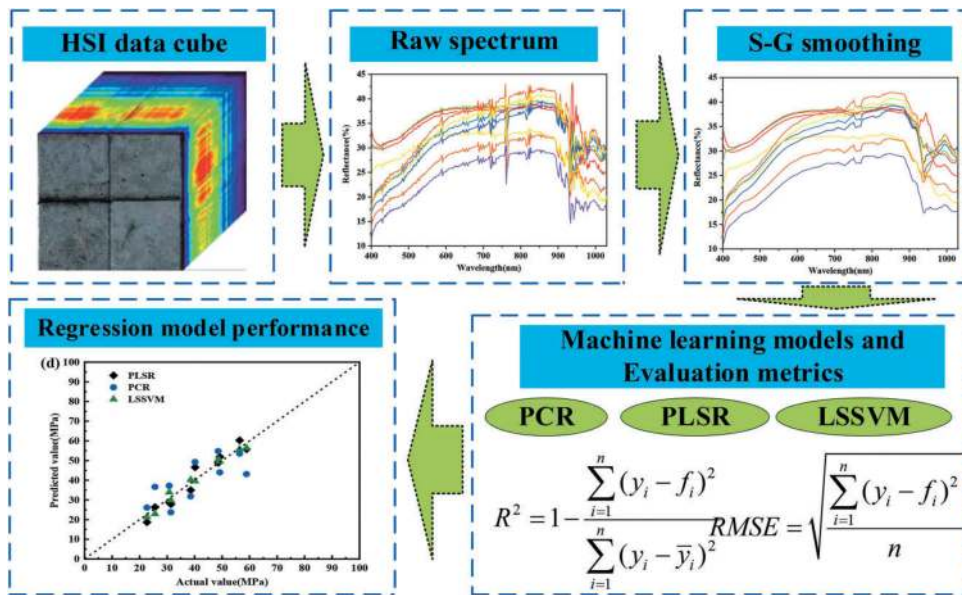

Figure 4. Hyperspectral data analysis process.

the manufactured concrete specimens, as shown in Figure 4.

In this study, 80% of the spectral reflectance data were used for training the models, while the remaining 20% were reserved for testing the prediction models. PCR, PLSR, and LSSVM algorithms were all trained using MATLAB to construct the predictive models. The prediction models were then evaluated using the determination coefficient (R^2) and root mean square error (RMSE) to assess their predictive performance, ultimately identifying the best predictive model.

2.3.1 Data preprocessing

Smoothing filtering is one of the commonly used preprocessing methods in spectral analysis. The most direct result in hyperspectral data is to remove the “burrs” of the spectrum, improve the smoothness of the spectrum, and reduce noise interference. This study uses Savitzky-Golay filtering, that is, S-G filter smoothing, which mainly uses polynomials for data smoothing. Based on the least squares method, it can retain useful information in spectral data and eliminate random noise. The two main parameters in the SG smoothing algorithm are the polynomial fitting order N and the sliding convolution frame size F . F is an odd number and satisfies $F-1 > N$. Choosing the correct parameters N and F is important to ensure better smoothing results. A large N and a small F may lead to overfitting due to the noise in hyper-spectral data, whereas a small N and a large F may lose information because the smoothing window is too large to smooth out the characteristic peaks in the spectrum.

2.3.2 PCR

Principal component regression (PCR) is a dimensionality reduction technique that transforms

a set of highly correlated independent variables into a set of mutually independent variables with no linear relationships (Chang et al., 2011). These transformed variables are called principal components, and they can capture most of the information from the original data. PCR is commonly used when there are too many independent variables or when strong correlations exist among them.

In this study, each spectral data consists of 256 channels of data. PCR is used to project the concrete compressive strength and its corresponding spectral response matrix into a new space to build a prediction model. It extracts principal components from the compressive strength and spectral response matrix, aiming to maximize the correlation between the principal components extracted from the compressive strength and the spectral response matrix.

2.3.3 PLSR

Partial least squares regression (PLSR) builds a prediction model by considering spectral information and sample true values, and obtains latent variables and eliminates useless variables through dimensionality reduction (Cheng et al., 2017). This study employs Partial Least Squares Regression (PLSR) to project concrete strength and the corresponding spectral response matrix into a new space to establish a predictive model. Principal components are extracted from concrete strength and the spectral response matrix, with the aim of maximizing the correlation between the principal components extracted from concrete strength and the spectral response matrix. This approach identifies multi-dimensional directions in the spectral response matrix space that explain the maximum variance in the concrete strength space. Below is the algorithmic workflow for predicting concrete strength using hyperspectral data implemented with PLSR algorithm.

Let X_0 represent the original hyperspectral data, forming an $N \times m$ matrix, and Y_0 denote the concrete strength, constituting an $N \times 1$ matrix, where N signifies the number of sample pairs, and m corresponds to the number of channels in the hyperspectral data. After undergoing standardization procedures, which involve mean subtraction and division by the standard deviation, the resulting datasets are represented as matrices X and Y .

Assume that the first principal component vectors of X and Y are denoted as w_1 and c_1 , respectively, then w_1 and v_1 can represent the first pair of principal components t_1 and u_1 as follows (Cheng et al., 2017):

$$\begin{aligned} t_1 &= Xw_1 \\ u_1 &= Yc_1 \end{aligned} \quad (1)$$

The underlying idea behind PLSR is to maximize the correlation between t_1 and u_1 while maximizing their respective variances. This can be mathematically formalized as follows (Cheng et al., 2017):

$$\begin{cases} \langle t_1, u_1 \rangle = \langle Xw_1, Yv_1 \rangle = w_1^T X^T Y v_1 \Rightarrow \max \\ w_1^T w_1 = \|w_1\|^2 = 1, v_1^T v_1 = \|v_1\|^2 = 1 \end{cases} \quad (2)$$

By utilizing the Lagrange multiplier method, w_1 can be obtained as the eigenvector corresponding to the largest eigenvalue of the symmetric matrix $X^T Y Y^T X$, and c_1 can be obtained as the eigenvector corresponding to the largest eigenvalue of $Y^T X X^T Y$.

Following the principal component regression concept, X and Y can be separately regressed on their respective principal components t_1 and u_1 as follows (Cheng et al., 2017):

$$\begin{aligned} X &= t_1 p_1^T + F \\ Y &= u_1 q_1^T + G \end{aligned} \quad (3)$$

Where $p_1 = (p_{11}, p_{12}, \dots, p_{1m})^T$ and $q_1 = (q_{11}, q_{12}, \dots, q_{1m})^T$ are the parameter vectors in the multiple-to-one regression models, and F and G are the residual matrices. Exploiting the correlation between t_1 and u_1 , Y can be regressed on the principal component t_1 of X as follows (Cheng et al., 2017):

$$Y = t_1 r_1^T + H \quad (4)$$

Following the previously described approach for regression, this process is iterated repeatedly until the residual F reaches the desired accuracy or the number of principal components has reached the upper limit (the rank of the initial X), at which point the algorithm terminates.

For a new input data point x , you can first compute its various principal components. Then, by substituting these components into the equation

$y = t_1 r_1^T + t_2 r_2^T + \dots + t_k r_k^T$, you can calculate the predicted value for vector y .

2.3.4 LSSVM

LSSVM (Least Squares Support Vector Machine) is an advanced variant of the Support Vector Machine based on statistical theory (Wang et al., 2005). It has found successful applications in various domains, including data regression, pattern recognition, time series forecasting, among others. The LSSVM algorithm involves mapping data from the original feature space to a high-dimensional space, replacing inequality constraints with equality constraints, and solving the minimum loss function in the high-dimensional space to obtain a linear fitting equation. The specific implementation process is as follows:

For a given set of training data (x_i, y_i) , where $x_i = (x_{i1}, x_{i2}, \dots, x_{id})^T$ is a d -dimensional input vector, y_i is the corresponding output data, and N is the total number of training data. To map the input space to the feature space, a nonlinear function $\phi(x_i)$ is used. The modeling form of the nonlinear function estimation is as follows (Wang et al., 2005):

$$f(x) = b + \langle \phi(x), w \rangle \quad (5)$$

Where, w is the weight vector, b is the bias term, and the symbol $\langle \cdot \rangle$ denotes the inner product operation.

Based on the principle of minimizing prediction errors, the regression prediction problem is formulated as an optimization problem (Wang et al., 2005):

$$\begin{aligned} \min J(w, e) &= \min \left(\frac{1}{2} \|w\|^2 + \frac{1}{2} \gamma \sum_{i=1}^N e_i^2 \right) \\ s.t. y_i &= \langle w, \phi(x_i) \rangle + b + e_i, i = 1, 2, \dots, N \\ \gamma &> 0 \end{aligned} \quad (6)$$

Where, γ is the regularization parameter used to balance the model's complexity and accuracy, and e_i represents the regression error between the actual and predicted values of the output.

To address the optimization problem mentioned above, the corresponding Lagrangian function is constructed as follow (Wang et al., 2005):

$$\begin{aligned} L_{LSSVM} &= \frac{1}{2} \|w\|^2 + \frac{1}{2} \gamma \sum_{i=1}^N e_i^2 \\ &- \sum_{i=1}^N \alpha_i \{ \langle w, \phi(x_i) \rangle + b + e_i - y_i \} \end{aligned} \quad (7)$$

Where α_i is the Lagrange multiplier.

Setting $\partial w = 0, \partial b = 0, \partial e_i = 0$ and $\partial \alpha_i = 0$ yields the following conditions for the optimal solution to the problem:

$$\begin{aligned}
\frac{\partial L_{isNM}}{\partial w} = 0 &\rightarrow w = \sum_{i=1}^N \alpha_i \phi(x_i) \\
\frac{\partial L_{1ssVM}}{\partial b} = 0 &\rightarrow \sum_{i=1}^N \alpha_i = 0 \\
\frac{\partial L_{LSSM}}{\partial e_i} = 0 &\rightarrow \alpha = \gamma e_i \\
\frac{\partial L_{LSVM}}{\partial \alpha_i} = 0 &\rightarrow \langle w, \phi(x_i) \rangle + b + e_i - y_i = 0
\end{aligned} \tag{8}$$

By eliminating w and e_i , the four linear problems can be simplified to (Mall et al., 2015):

$$\begin{bmatrix} 0 & E^T \\ E & \Omega + \frac{1}{\gamma} E \end{bmatrix} \begin{bmatrix} b \\ \alpha \end{bmatrix} = \begin{bmatrix} 0 \\ y \end{bmatrix} \tag{9}$$

Where, $y = [y_1, \dots, y_N]^T$, $\alpha = [\alpha_1, \dots, \alpha_N]^T$, and Ω is a symmetric $N \times N$ matrix of kernel functions.

$$\Omega_{ij} = K(x_i, x_j) = \phi(x_i)^T \phi(x_j), i, j = 1, 2, \dots, N \tag{10}$$

Where $K(x_i, x_j)$ is a kernel function that satisfies Mercer's condition. Kernel functions have the ability to reduce the computational complexity in high-dimensional spaces and play a crucial role in constructing high-performance least squares support vector machines.

Therefore, the LSSVM model can be represented as (Mall et al., 2015):

$$\begin{aligned}
y(x) &= \langle w, \phi(x) \rangle + b \\
&= \sum_{i=1}^n \alpha_i \phi(x_i) \cdot \phi(x) + b \\
&= \sum_{i=1}^n \alpha_i K(x_i, x) + b
\end{aligned} \tag{11}$$

The Radial Basis Function (RBF) kernel is a widely adopted kernel function, defined as follows (Mall et al., 2015):

$$K(x_i, x_j) = \exp\left(-\frac{\|x_i - x_j\|^2}{2\sigma^2}\right), \sigma > 0 \tag{12}$$

Where σ represents the bandwidth of the kernel function.

These two hyperparameters, γ and σ , have a significant impact on the performance of the LSSVM model and need to be carefully determined.

2.3.5 Model validation

The R^2 and RMSE are two commonly used metrics to evaluate the performance of regression models.

R-squared is a statistical metric used to measure the goodness of fit of a regression model, and its values typically range from 0 to 1. A higher R-squared value indicates that the model can explain

a greater proportion of the variance in the target variable, indicating a better fit. Conversely, an R-squared closer to 0 suggests that the model's explanatory power is weaker, indicating a poorer fit. The formula for calculating R-squared is:

$$R^2 = 1 - \frac{\sum_{i=1}^n (y_i - f_i)^2}{\sum_{i=1}^n (y_i - \bar{y}_i)^2} \tag{13}$$

Where y_i represents the observed values of the target variable, f_i is the model's predicted values, and \bar{y}_i is the mean of the observed target variable.

RMSE is a metric used to measure the prediction error of a regression model. It represents the square root of the average of the squared differences between the model's predicted values and the actual observed values. Smaller RMSE values indicate lower prediction errors and better model fit. The formula for calculating RMSE is:

$$RMSE = \sqrt{\frac{\sum_{i=1}^n (y_i - f_i)^2}{n}} \tag{14}$$

RMSE provides an intuitive measure of the size of prediction errors and is often used for model comparison and assessing prediction accuracy.

3 RESULTS AND DISCUSSION

3.1 Hyperspectral information

Figure 5 displays the raw spectral data obtained using a hyperspectral camera and the spectral data after being subjected to S-G smoothing. It is evident that, compared to the original spectral reflectance curve, the smoothed spectral reflectance curve eliminates the spikes caused by environmental or machine noise, while preserving most of the characteristic peaks for subsequent compressive strength prediction. For each type of mortar strength, ten samples were prepared, and the surface of each sample was scanned. Thirty spectra were extracted from a 100 mm × 100 mm surface area, resulting in a total of 300 spectra. Spectra were collected exclusively from the sample surface area to mitigate errors arising from non-uniform spots.

Figure 5 presents the surface spectral information of concrete specimens acquired using a hyperspectral camera in two different wavelength ranges: 400-1000nm and 900-1700nm. In the figure, the curves of different colors represent the surface spectra corresponding to samples with different compressive strengths. It is evident that both wavelength ranges exhibit significant differences in spectral curves concerning concrete compressive strength. As the compressive strength increases, the spectral reflectance curves also change.

As shown in Figure 5(b), within the 880nm-960nm range, the reflectance exhibits the most significant

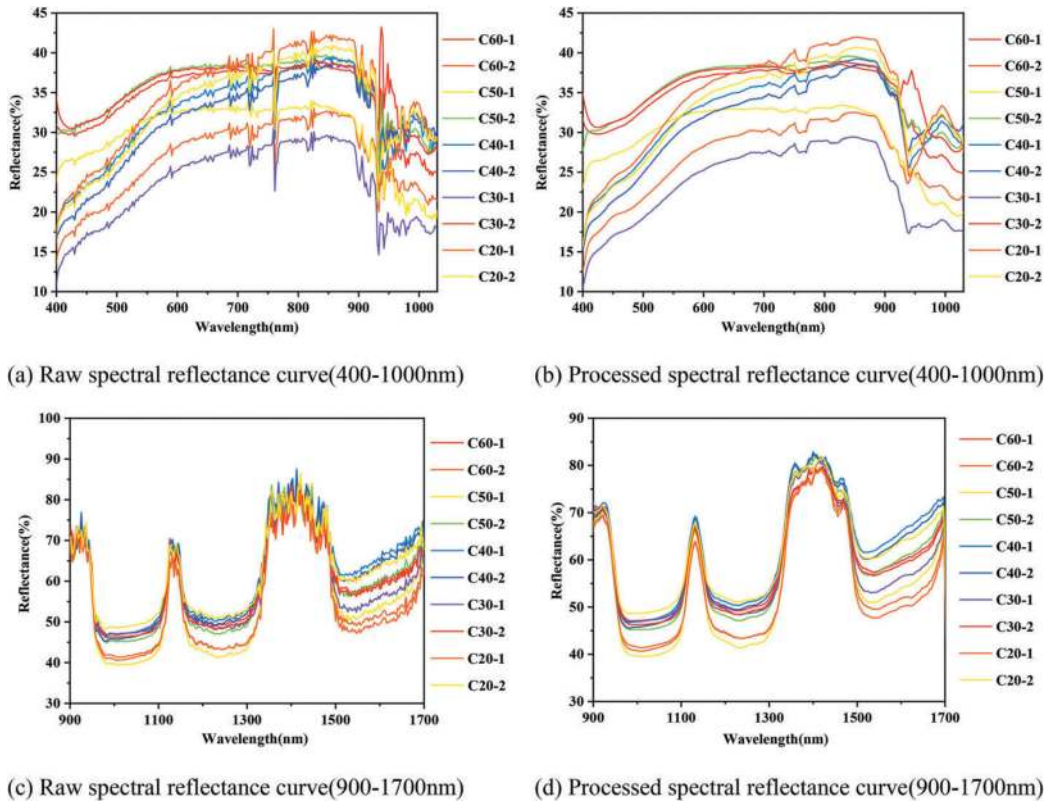

Figure 5. The reflectance spectra of concrete specimens: raw and processed.

fluctuations with compressive strength. This range can be considered the spectral sensitive wavelength for concrete compressive strength. In Figure 5(d), within the [980nm, 1100nm], [1200nm, 1300nm], and [1500nm-1700nm] interval, the spectral reflectance all displays noticeable variations, further confirming the feasibility of using spectral information to characterize concrete compressive strength. To further investigate the relationship between spectral reflectance and compressive strength, it is necessary to continue introducing machine learning methods for the exploration of high-dimensional spectral data.

3.2 UCS test results

After the curing period, all concrete samples underwent hyperspectral analysis before undergoing standard uniaxial compression testing. The test specimens were positioned on the platform of a servo-controlled testing machine (WDW-600C Hydraulic Servo Testing Machine) and subjected to a loading rate of 0.2 mm/min until complete failure, yielding the uniaxial compressive strength for each sample, as shown in Table 1. This results serves as the foundation for sub-sequent hyperspectral predictive analyses.

3.3 Regression prediction results

Using reflectance spectra acquired from hyperspectral cameras in two different spectral ranges, namely 400-1000 nm and 900-1700 nm, as independent variables, and ten compressive strengths of concrete samples as

Table 1. Concrete specimens uniaxial compression test results.

ID	UCS(MPa)	ID	UCS(MPa)
C20-1	22.61	C20-2	25.62
C30-1	31.46	C30-2	30.85
C40-1	38.53	C40-2	40.17
C50-1	49.28	C50-2	48.67
C60-1	58.91	C60-2	56.44

dependent variables, PCR, PLSR, and LSSVM regression models were established both on the raw spectra and spectra after S-G processing. Table 2 displays the predictive performance results of the regression models under the optimal pre-processing conditions.

Regarding the pre-processing methods, as shown in Table 2, for the [400,1000] dataset, the results after S-G processing significantly improved the predictive performance of the PLSR and LSSVM models. The determination coefficient R^2 of PLSR increased from 0.83 to 0.94, and RMSE decreased from 5.88MPa to 1.53MPa, while LSSVM's R^2 increased from 0.94 to 0.99, and RMSE decreased from 6.04MPa to 0.71MPa. In contrast, the effect on the PCR model's predictions was relatively small, with R^2 and RMSE remaining around 0.50 and 10.0MPa, respectively. For the [900,1700] dataset, S-G processing had a slight positive impact on the PCR model's predictive performance but did not significantly improve the predictions of the PLSR and LSSVM models. Overall, the original full-

Table 2. Compressive strength prediction performance based on different regression models.

Spectral Wavelengths	Pre-processing Method	Regression Model	R^2	RMSE(MPa)
[400-1000]	Raw	PCR	0.53	9.70
[400-1000]		PLSR	0.83	5.88
[400-1000]		LSSVM	0.84	5.04
[400-1000]	S-G	PCR	0.51	9.94
[400-1000]		PLSR	0.88	5.53
[400-1000]		LSSVM	0.89	4.71
[900-1700]	Raw	PCR	0.37	11.24
[900-1700]		PLSR	0.92	3.81
[900-1700]		LSSVM	0.95	3.07
[900-1700]	S-G	PCR	0.53	9.71
[900-1700]		PLSR	0.93	3.73
[900-1700]		LSSVM	0.97	2.37

spectrum data provided satisfactory results with little or no need for pre-processing, or with a single pre-processing method.

As shown in Figure 6, overall, both PLSR and LSSVM models achieved determination coefficients (R^2) of above 0.80 for both datasets, indicating reliable predictive accuracy. In contrast, the PCR model had a lower R^2 , not exceeding 0.53, suggesting relatively lower precision. Notably, the LSSVM model performed the best on both datasets. In the [400-1000] dataset, LSSVM and PLSR achieved R^2 values of 0.99 and 0.98, with RMSE values of 0.71MPa and

1.53MPa, respectively, while the PCR model had an R^2 of only 0.53 and an RMSE of 9.70MPa. In the [900-1700] dataset, the LSSVM model ($R^2=0.97$, RMSE=2.37MPa) slightly outperformed the PLSR model ($R^2=0.95$, RMSE =3.07MPa), while the PCR model's performance remained suboptimal, with an R^2 of 0.53 and an RMSE of 9.71MPa.

In summary, hyperspectral technology combined with machine learning algorithms can effectively detect concrete compressive strength. The results suggest that both LSSVM and PLSR algorithms provide the best predictions, while the PCR algorithm's predictive performance is comparatively modest, possibly due to its strong linearity in principal component extraction. Simultaneously, these relationships also indicate that hyperspectral technology can be used to predict the compressive strength of concrete. These relationships can be applied to predict the strength of concrete structures.

4 CONCLUSIONS AND FURTHER WORK

This study employed two hyperspectral cameras with distinct wavelength ranges to capture images of concrete samples made with different cement types (C20, C30, C40, C50, C60). Machine learning models were developed using hyperspectral data from different wavelength ranges to predict concrete compressive strength. The specific conclusions are as follows:

1. The study examined the impact of spectral pre-processing methods on concrete compressive

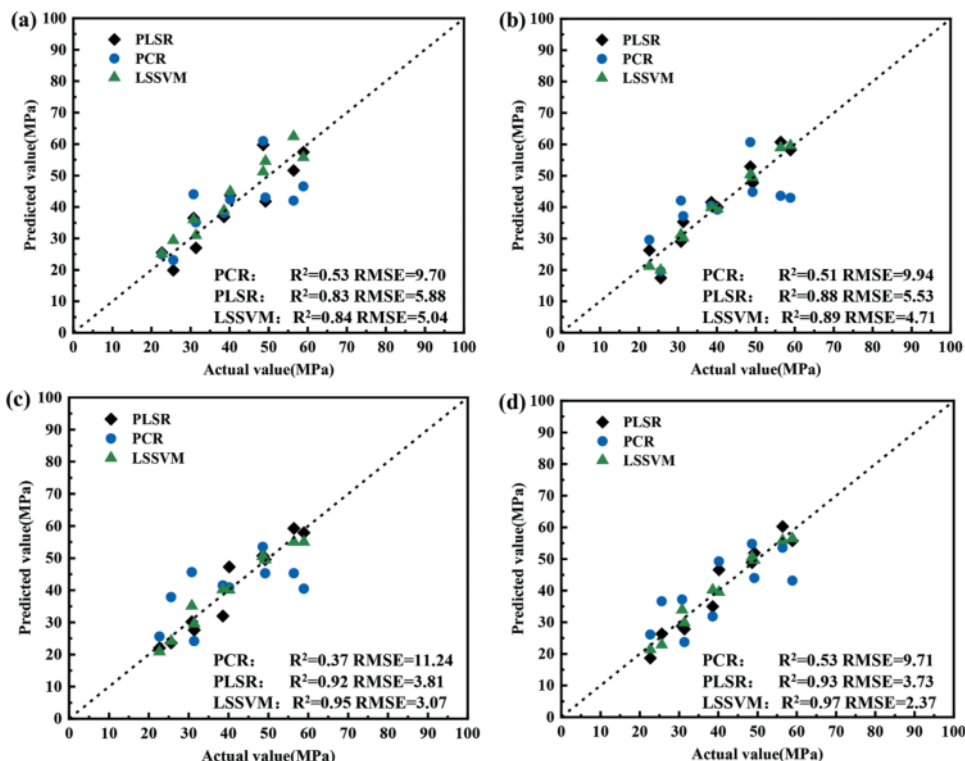

Figure 6. Plots of actual values versus predicted values of concrete compressive strength:(a) Raw[400-1000nm] dataset, (b) S-G[400-1000nm] dataset, (c) Raw[900-1700nm] dataset, (d) S-G[900-1700nm] dataset.

- strength prediction. It was observed that the original full-spectrum data performed well without any pre-processing or with a single S-G pre-processing step.
- The study explored the influence of different spectral wavelength ranges on concrete compressive strength prediction. Machine learning models were applied to two datasets: [400-1000nm] and [900-1700nm]. Notably, the [900-1700nm] dataset showed significantly improved model performance.
 - A comparison of different models revealed the best model for concrete compressive strength prediction. LSSVM and PLSR models performed exceptionally well in the [400-1000nm] dataset, while the LSSVM model excelled in the [900-1700nm] dataset, achieving a high level of accuracy.

The hyperspectral camera will be utilized to scan concrete samples designed with various mix proportions and subjected to diverse environmental exposures to identify their compressive strength. Expanding the hyperspectral reflectance dataset to encompass as many specific types as possible, such as aging and erosion, will continuously update and enhance the machine learning model for strength identification. The hyperspectral camera, installed on tunnel detection equipment, will conduct on-site concrete lining structure strength assessments. This enables rapid identification of the compressive strength of concrete linings under authentic field conditions, facilitating accurate analysis of structural damage and ensuring safety.

ABSTRACT: The tunnel ventilation system plays a crucial role in reducing the concentration of harmful gases and enhancing visibility within tunnels, ensuring the safety of vehicles and personnel. To address the high energy consumption issue resulting from the lack of control algorithms and dynamic environmental perception in traditional tunnel ventilation systems, this paper introduces a novel energy-efficient control algorithm for tunnel ventilation by combining dynamic neural networks with fuzzy control techniques. The proposed algorithm employs nonlinear autoregressive neural networks (NAR) and nonlinear autoregressive neural networks with external input (NARX) to predict the traffic flow rate $TV_{(t+1)}$ and carbon monoxide concentration $CO_{(t+1)}$ within the tunnel at the next time, thereby detecting the tunnel environment in advance. The tunnel ventilation energy-efficient fuzzy control model employs the predicted value of $CO_{(t+1)}$ concentration e_{co} and its change rate Δe_{co} as inputs and determines the number of fan openings and fan speeds of the tunnel ventilation system as outputs. The control signals are updated at equal time intervals. By considering the dynamic variations in traffic flow and carbon monoxide concentration within the tunnel, the algorithm judiciously sets the appropriate number of fan openings and fan speed for energy-efficient tunnel ventilation control. Furthermore, an energy consumption calculation model for tunnel fans is established. Simulation calculations are conducted on the tunnel ventilation energy consumption using the proposed algorithm. The results demonstrate a 14.4% energy savings in comparison to traditional fuzzy control algorithm that relies on actual measured CO values as inputs. The integration of dynamic neural networks and fuzzy control in tunnel ventilation control presents a promising approach to enhance energy efficiency. The algorithm's ability to predict and adapt to changing tunnel conditions leads to substantial energy savings and improved overall performance, making it a valuable contribution to the field of tunnel ventilation control.

Energy-efficient control

1 INTRODUCTION

According to statistics, by the end of 2022, there were 24,850 highway tunnels in China, with a total length of 26.7843 million meters, indicating an increase of 1,582 tunnels and 2.0854 million meters compared to 2021. Among them, there were 1,752 extremely long tunnels, spanning a total of 7.9511 million meters, and 6,715 long tunnels, totaling 11.7282 million meters (Ministry of Transport, 2021, 2022). Tunnel ventilation systems are employed to expel harmful gases such as CO and SO₂, which pose threats to the safety of passengers, generated by vehicles during transit. The extended length of tunnels imposes higher demands on tunnel ventilation control systems. Traditional tunnel ventilation control systems operate with

fixed numbers of fan openings and speeds during operational periods, lacking the ability to dynamically adjust the fan start quantities and speeds based on real-time vehicle traffic and tunnel environmental data. This deficiency results in elevated tunnel ventilation energy consumption. Therefore, reducing tunnel ventilation energy wastage and enhancing the system's capability to perceive and respond to environmental changes have become focal research areas of concern for scholars both domestically and internationally.

The ventilation control of tunnels is generally designed according to the *Design Guidelines for Highway Tunnel Ventilation* (JTG/T D70/2-02—2014). The methods of ventilation control have evolved from manual or indirect control to the current automatic

ventilation mode, employing techniques such as expert experience, fuzzy control, and neural network control. (Zhang et al. 2016) achieved intelligent tunnel ventilation control using a fuzzy control method. By predicting smoke concentration for multiple consecutive time intervals, the degree and trend of variations in the predictive result sequence were input to a fuzzy controller to control the duration of tunnel fan activation. (Yu et al. 2017) using an iterative learning algorithm, automated the optimization of parameters for fuzzy PID control of tunnel ventilation fans. This facilitated real-time adjustment of fuzzy PID input parameters, gradually approaching the desired trajectory by altering inputs to enhance fan control precision. (Li 2017) utilized feedforward neural networks and fuzzy control theory, constructed a feedforward intelligent fuzzy control system for tunnel ventilation. It took pollution concentration prediction increment, actual pollution concentration, and control objectives as inputs and output the required increase or decrease in fan groups. (Chu et al. 2010) employed an Actor-Critic structure and natural gradient, introduced a novel reinforcement learning method for tunnel ventilation control, enhancing control accuracy. Mostafa et al. (2013) proposed a tunnel ventilation scheme based on Fuzzy Analytical Hierarchy Process (AHP), selecting the optimal tunnel ventilation method through final weight calculations. Zhang et al. (2017) introduced a PLC-based tunnel ventilation control system, enabling indirect timed control of tunnel ventilation. (Wang et al. 2018) combined cloud services and big data, developed a tunnel ventilation control system using data analysis to enhance control accuracy. (Jiang et al. 2018) used ventilation simulation software to simulate the ventilation system status of extremely long tunnels under various driving conditions, derived ventilation control measures for different vehicle speeds. (Xing et al. 2018) designed a tunnel monitoring system using force control configuration software, enhanced tunnel ventilation control system efficiency. (Wu et al. 2017) designed a control algorithm based on adaptive assessment, established a mechanical model and using a neural network for fan control, enhanced tunnel ventilation control robustness. (Wan et al. 2019) conducted a comprehensive analysis of ventilation calculation parameter ranges and optimization of ventilation methods, aiming to exercise control over the scale of ventilation systems from the very outset of design. By minimizing civil and electromechanical engineering investments and reducing operational costs, achieved energy-efficient effects successfully. The aforementioned ventilation control approaches primarily employ learning algorithms, fuzzy control algorithms, and feedforward neural networks for control. Typically, the predicted concentration and measured concentration of pollutants as inputs, while the number of fan openings or groups is selected as output for tunnel fan control. The application of these methods has, to a certain extent, enhanced ventilation effectiveness and reduced energy consumption.

Traffic flow is a major factor causing changes in pollution concentration. However, the above studies do not consider pollution concentration changes caused by traffic flow as the primary variable. Such feedback-based control methods, detached from traffic flow and carbon monoxide concentration changes, exhibit lag and maintain higher energy consumption levels. Thus, rapid sensing and dynamic prediction of tunnel ventilation environmental parameters, using predictive quantities as inputs for adaptive control, will elevate the intelligence of ventilation control and achieve energy-saving effects.

The CO concentration within the tunnel is correlated with tunnel traffic flow. In enhancing the perception and predictive capabilities of tunnel environments, (Qian et al. 2021) designed and developed a highway tunnel environmental perception system based on the Internet of Things (IoT) and cloud computing. The system integrated sensors for harmful gases, temperature, pressure, visibility, and wind speed and direction within the tunnel to achieve real-time cloud storage and monitoring of tunnel environment data. Lv et al. (2013) employed the nonlinear approximation abilities of BP and RBF neural networks to comprehensively extract CO concentration information features within the tunnel. An optimal mean square error and weighted fusion algorithm were then utilized to further integrate and predict CO concentrations. (Ren et al. 2022) designed an adaptive control ventilation system for tunnel construction based on RBF neural networks. This system established the relationship between fan operating frequency and tunnel environmental parameters through the RBF neural network, achieving controlled adjustment of tunnel fan air supply. (Wang et al. 2018) proposed a fan frequency prediction algorithm based on BP neural networks, determined the number of activated fans through frequency prediction. (Li et al. 2022) employed RBF neural networks to explore the relationship between tunnel fire scale and critical velocity. By using RBF neural networks to train and validate, achieving intelligent control of tunnel fans in fire environments.

From the application of abovementioned neural network prediction methods in tunnel ventilation control, it can be observed that both BP and RBF neural networks exhibit lower predictive accuracy. This is due to their static learning nature, lacking feedback, memory, and time-delay capabilities. The parameters of tunnel ventilation environment, such as traffic flow and CO concentration increment, form a nonlinear time series. Accurate prediction requires anticipating increments based on the historical data from previous time steps and incorporating it into the calculation of the next time step prediction. (Zhu et al. 2020) applied the NARX dynamic neural network to short-term traffic flow prediction at intersections, achieving a high prediction accuracy of 91.59%. (Zhao et al. 2015) predicted daily flow rates of underground karst rivers using the NARX neural network, effectively capturing trends and dynamic characteristics. Yang et al. (2018) established an NARX neural network prediction

model, trained it with time series data of multi-intersection traffic flow in road networks, and achieved good prediction results for the following day's vehicle count. These studies indicate that the NARX dynamic neural network exhibits better adaptability and predictive efficiency in addressing predictive problems related to nonlinear time series data, making it suitable for predicting nonlinear time series data like CO and traffic flow.

In conclusion, this paper proposed a novel tunnel ventilation energy-efficient control algorithm that combines NAR-NARX dynamic neural networks with fuzzy control, aimed at achieving dynamic and real-time control of tunnel ventilation. This approach is utilizing both NAR and NARX to predict traffic flow and carbon monoxide concentration values. The predicted value of carbon monoxide concentration $CO(t+1)$, along with its rate of change, are then input into the energy-efficient fuzzy control algorithm. This integration achieves control over the number of activated tunnel fans and their rotational speeds. The algorithm demonstrates the ability to proactively respond to changes in tunnel ventilation environmental data, facilitating dynamic fan control and ultimately achieving energy-efficient effects.

2 METHOD OF TUNNEL VENTILATION ENERGY-EFFICIENT CONTROL ALGORITHM

The NAR traffic flow prediction model is based on the monitoring data from traffic flow sensors installed at the tunnel entrance during the current period, enabling the prediction of traffic flow for the next period. The NARX CO concentration prediction model utilizes current period CO concentration monitoring data along with NAR traffic flow prediction data to forecast the CO concentration for the subsequent moment. The tunnel ventilation energy-efficient fuzzy control, guided by predefined fuzzy control rules, accomplished the control of the number of wind turbines and rotational speed within the tunnel. The fan energy consumption model performs energy consumption calculations for variable-frequency jet fans operating within the tunnel, facilitating a comparison of energy consumption across different control strategies and an evaluation of energy-efficient effects.

Figure 1. Framework of tunnel ventilation energy-efficient control algorithm combining NAR-NARX dynamic neural network and fuzzy control.

2.1 NAR-NARX dynamic neural network prediction model

(1) NAR traffic flow prediction model

The NAR traffic flow prediction model comprises an input layer (traffic flow monitoring values), a hidden layer, and an output layer (predicted traffic flow values), as depicted in Equation (1). The NAR traffic flow prediction model utilizes the output value from the previous time step as the input for the current time step and introduces a time delay component, implying the output values $TV(t+1)$ has a tightly connection with the previous n output values.

$$TV(t+1) = f[TV(t), TV(t-1), TV(t-2), \dots, TV(t-n)] \quad (1)$$

Where, $TV(t+1)$ represents the predicted traffic flow output at the next time step, $TV(t)$ indicates the current monitoring traffic flow value at the current time step t , $TV(t-1)$ denotes the monitoring value of traffic flow at the previous time step, $TV(t-n)$ represents the monitoring value of traffic flow at the previous n time step, and f is the nonlinear mapping function of the neural network.

(2) The NARX CO concentration prediction model

The structure of the NARX CO concentration prediction model comprises input, hidden, and output layers. The input layer encompasses traffic flow forecast values and real-time CO concentration monitoring values, while the output layer yields the predicted CO concentration. This architecture is illustrated in equation (2). Notably, the model introduces a feedback information transmission component between the output and input layers, in addition to the conventional temporal delay elements. This feedback mechanism, achieved through combinations of distinct input variables, effectively realizes the prediction of CO concentration values for the upcoming time step.

$$CO(t+1) = f[CO(t), CO(t-1), TV(t), TV(t-1)] \quad (2)$$

Where, $CO(t+1)$ denotes the output of the NARX dynamic neural network, representing the predicted CO concentration. $CO(t)$ represents the CO concentration monitoring value at the current time step. $CO(t-1)$ denotes the CO concentration monitoring value at the previous time step. $TV(t)$ signifies the current traffic flow forecast value from the previous time step. $TV(t-1)$ represents the traffic flow forecast value from the previous time step. f is a nonlinear mapping function, capturing intricate nonlinear relationships between inputs and outputs.

(3) Prediction Process of the NAR-NARX Dynamic Neural Network

The establishment of NAR-NARX dynamic neural network prediction model is depicted in

Figure 2. Initially, an open-loop NAR-NARX prediction model is developed, wherein input samples are sequentially divided into training, validation, and testing sets. Subsequently, the open-loop NAR-NARX model is trained using the training set. Once the desired level of accuracy is achieved, the open-loop NAR-NARX prediction model is transformed into a closed-loop NAR-NARX prediction model. Lastly, the predictive performance of the closed-loop NAR-NARX prediction model is evaluated on the validation set. If the performance criteria are met, further assessment of its predictive accuracy is conducted on the testing set to mitigate overfitting. In case of overfitting, the NAR-NARX prediction model is retrained or its topological structure is optimized, iteratively refining it until satisfactory predictive accuracy is achieved on both the validation and testing sets.

Figure 2. Prediction process of the NAR-NARX dynamic neural network prediction model.

2.2 DESIGN OF TUNNEL VENTILATION ENERGY-EFFICIENT FUZZY CONTROLLER ALGORITHM

The tunnel ventilation energy-efficient fuzzy controller is of the two-input two-output type, utilizing fuzzy logic control that employs fuzzy sets and fuzzy inference to derive control rules. The implementation process of the tunnel ventilation energy-efficient fuzzy control algorithm is outlined as follows:

- (1) Definition of Input and Output Variables for the Fuzzy Controller.

The tunnel ventilation energy-efficient fuzzy control model takes the predicted value of CO concentration e_{co} and its change rate Δe_{co} as inputs and the number of operating fans and fan speed of the tunnel ventilation system as outputs.

- (2) Definition of Fuzzy Sets for input and output variables. The domain of the predicted CO concentration e_{co} is set as $[0, 100]$, while the change rate Δe_{co} , the fan speed and the number of fan opening are set as $[-200, 200]$, $[0, 2900]$, and $[0, 6]$, respectively. Linguistic terms are represented by seven fuzzy states: {NB, NM, NS, ZO, PS, PM, PB}, with Gaussian membership function is defined by Equation (3).

$$y = e^{-\frac{(x-c)^2}{2\sigma^2}} \quad (3)$$

Where, x represents the left and right limit of the membership function curve, c indicates the center of the membership function curve, σ determines the “width” of the curve.

- (3) Construction of Fuzzy Logic Control Rule Table
Fuzzy control rules typically consist of “if condition, then result” statements, describing a series of control strategies and objectives. Fuzzy control rules can be expressed using Equation (4):

$$\text{if } A \text{ is PB and } B \text{ is ZO then } C \text{ is PB} \quad (4)$$

- (4) Fuzzy Inference

A specific fuzzy inference algorithm is applied to the established fuzzy logic control rules to deduce the required control parameters. The Mamdani algorithm is adopted due to its independent treatment of each component in the fuzzy system’s fuzzification process. The Mamdani algorithm is represented by Equation (5):

$$R_K = A_K \times B_K \quad (5)$$

Where A_K and B_K are two distinct inputs, and R_K is the output.

The overall fuzzy relationship matrix composed of Mamdani algorithm is shown in Equation (6).

$$R = U_{K=1}^N R_K \quad (6)$$

The specific values N depend on the number of fuzzy rules.

- (5) Defuzzification to obtain the output value

The fuzzy values obtained through inference cannot be directly applied to control. They must be converted into precise control signals to execute control operations on the actuators. Common defuzzification methods include the maximum membership method, centroid method, and weighted average method. The centroid method is selected in this study for its smoother output reasoning control. It relates minor changes in input signals to corresponding output variations. The centroid method is formulated as shown in Equation (7):

$$C(k) = \frac{\sum_{i=1}^m x_i \mu_N(x_i)}{\sum_{i=1}^m \mu_N(x_i)} \quad (7)$$

2.3 Energy efficiency evaluation of tunnel ventilation control algorithm

This energy consumption model is utilized to compute the operational energy consumption of jet fans under different control methods, enabling an assessment of energy-saving effectiveness.

Calculation of Rated Power p_{Rated} for a Single Jet Variable Frequency Fan:

$$p_{Rated} = \frac{Q * p}{3600 * 1000 * \eta_0 * \eta_1} \quad (8)$$

Where Q is the air flow rate, p is the total pressure of the fan, η_0 the total efficiency of the fan, typically ranging from 0.75 to 0.85, in accordance with relevant standards, $\eta_0=0.8$, η_1 is the mechanical efficiency, set to 1 as the jet fan is directly connected to the motor.

The total pressure p is composed of static pressure p_{sp} of the fan and the dynamic pressure p_{dp} of the air. The calculation formula is given by:

$$P = p_{sp} + p_{dp} = p_{sp} + 0.5 * v^2 \quad (9)$$

Among them, p_{sp} is the static pressure at the working environment of the jet variable frequency fan (atmospheric pressure), p_{dp} is the dynamic pressure and v is the outlet air velocity.

As the jet variable frequency fan responds to control signals emitted by components like the fuzzy controller over discrete time steps, the fan speed and number are adjusted in real-time. Considering the continuously changing fan speed, the formula for calculating the variable frequency power consumption of a single jet variable frequency fan p_{fc} is as follows:

$$P_{fc} = P_{Rated} * \frac{n_{fc}}{n_{Rated}} \quad (10)$$

Where, n_{fc} is the variable frequency fan speed, n_{Rated} is the rated fan speed.

The total power consumption P_i of jet variable frequency fans within the tunnel is calculated as follows:

$$P_i = P_{fc} * n \quad (11)$$

Where, n is the real-time fan activation from the fuzzy controller at the time step i .

The total energy W_T consumed by the jet fans under the fuzzy control algorithm is calculated by:

$$W_T = \sum_{i=1}^m P_i * t_i \quad (12)$$

Where, t_i is the operational time interval of the jet fan which is set to 15min, and m is the number of time intervals.

The calculation of Energy-efficient efficiency of the jet fans is shown in formula 13:

$$\eta = \frac{Q_T - W_T}{Q_T} \quad (13)$$

Where, Q_T represents the energy consumption of tunnel fans under traditional fuzzy control inputs, and W_T represents the energy consumption of tunnel fans when the NARX neural network prediction data is used as fuzzy control inputs.

3 CASE STUDY

3.1 Tunnel and data acquisition

The case study is based on a tunnel with a total length of 2772 meters, equipped with a designed total of 6 fans. Sensory data is gathered through sensors placed within the tunnel, capturing four days' worth of traffic flow and CO concentration data, resulting in a total of 384 data sets. The data collection interval is set at 15 minutes. The dataset of neural networks is partitioned according to a ratio of 5:2.5:2.5. As a result, the training set encompasses 192 groups of data, while the validation and testing sets encompass 96 groups each.

This comprehensive study aims to evaluate the performance of the proposed control algorithm by comparing the energy consumption results obtained from the fuzzy control approach with those from the reference experiment.

The jet fan utilized within the engineering tunnel is the SDS-7.1-2P-6-33 model. The fan's rated rotational speed is 2900 r/min, with an airflow volume of 12.7 and an air velocity of 40.6 m/s. Carbon monoxide concentration serves as the target parameter for tunnel ventilation control. According to the "Highway Tunnel Design Code", the selected carbon monoxide concentration control value for the engineering tunnel is set at 100.

3.2 Tunnel traffic flow prediction and analysis using NAR neural network

The number of nodes in the input layer and output layer of the NAR neural network is determined based on the quantity of sample data. Experimentation was conducted with varying numbers of hidden layer nodes ranging from 5 to 15. Through this process, the optimal number of hidden layer nodes, resulting in the least disparity between predicted and monitored traffic flow values, was determined to be 8. A delay order of 1:6 was adopted, implying that the traffic flow monitoring values from the preceding 6 time intervals significantly influence the prediction for the subsequent moment. The simulated results are illustrated in Figure 3. The obtained coefficient of determination for the training, validation, and testing phases were 0.96094, 0.97436, and 0.95099, respectively. The comprehensive coefficient of determination (R1) stood at 0.95967. The average error in the predictions of the testing dataset was determined to be 96.12%, which aligns with the precision of neural network training and validation, effectively achieving the intended outcome.

3.3 Prediction and analysis of tunnel CO concentration based on NARX neural network

The parameter configuration process for the NARX neural network follows the same procedure as that of the NAR dynamic neural network. Specifically, the hidden layer contains 15 nodes, and the temporal order extends from 1 to 8. To establish a robust CO concentration prediction model using the NARX

Figure 3. Simulation results of traffic flow prediction model based on NAR neural network.

neural network, a series of steps is undertaken, including model training, validation, and testing. The outcomes of these processes are illustrated in Figure 4. The computed R2 values for the training, validation, and testing phases are 0.93389, 0.9201, and 0.95441, with an comprehensive coefficient of determination (R2) of 0.93407. These metrics serve as indicators of the model's predictive capabilities and validation performance. Furthermore, the predictive accuracy is quantified by evaluating the average error of the test dataset's predictions, resulting in a value of 93.88%. This level of accuracy effectively fulfills the demands of CO concentration prediction, thus aligning with the initial expectations and achieving the intended outcomes.

Figure 4. Simulation results of CO concentration prediction model based on NARX neural network.

3.4 Simulation and analysis of fuzzy control of tunnel ventilation

In accordance with Section 2.2, Table 1 outlines the fuzzy linguistic terms associated with the input and

output variables, along with corresponding ranges of linguistic values.

Table 2 established the fuzzy control rules for the tunnel ventilation system using Equation (4). These rules form the foundation of the fuzzy logic-based control strategy, guiding the system's response to varying conditions and ensuring efficient tunnel ventilation and air quality management.

In order to provide parameters for subsequent calculations of tunnel ventilation energy consumption, simulations were conducted separately for two approaches: the proposed tunnel ventilation fuzzy control method that combines NAR dynamic neural network predictions and the traditional tunnel ventilation fuzzy control method. These simulations were carried out using the validation and test datasets to obtain the number of operating fans and fan speeds.

For the proposed method, the fuzzy control model inputs are based on the CO concentration predictions and their change rate obtained from the NARX CO prediction model in Section 3.3. In contrast, the traditional tunnel ventilation fuzzy control method uses actual CO concentration measurements and their rate of change as inputs.

The simulation results from both approaches provide the essential information regarding the required number of operating fans and corresponding fan speeds to achieve the desired level of ventilation control. These results are visually depicted in Figure 5.

It is evident that the proposed method demonstrates notable advantages in the peak of CO concentration levels. During peak CO concentration periods, the algorithm effectively reduces the number of operating fans while maintaining a consistent fan speed. This achievement stems from the integration of NAR dynamic neural network-based predictions for traffic flow and CO levels. By effectively forecasting these variables, the approach enables advanced perception of the tunnel environment, facilitating intelligent optimization of fan count and speed.

3.5 Calculation and analysis of fan energy consumption

In this section, we delve into the calculation and analysis of fan energy consumption within the context of tunnel ventilation. The primary objective is to evaluate and compare the energy efficiency of the proposed NARX combined fuzzy control approach with the traditional fuzzy control method.

Taking into consideration the simulation outcomes derived from Section 3.4, This study employ the relevant equations outlined in Section 2.4 to compute the energy consumption associated with fan operation for both the proposed NARX combined fuzzy control approach and the traditional fuzzy control method. The calculated energy consumption values are then visually presented in Figure 6.

Table 1. Range of fuzzy linguistic variables corresponding to Input and Output variables.

Variable word set	input variable		output variable	
	CO concentration $e_{CO}(\text{cm}^3/\text{m}^3)$	CO concentration change rate Δe_{CO}	Number of operating fan	Fan Speed (r/min)
NB	(0, 25)	(-200, -100)	(0,1)	(0,725)
NM	(12.5, 37.5)	(-150, -50)	(1,2)	(363, 1088)
NS	(25, 50)	(-100, 0)	(2,3)	(725, 1450)
ZO	(37.5, 62.5)	(-50, 50)	(3,4)	(1088,1813)
PS	(50, 75)	(0, 100)	(3,4)	(1450, 2175)
PM	(62.5, 87.5)	(50, 150)	(4,5)	(1813, 2538)
PB	(75, 100)	(100, 200)	(5,6)	(2175, 2900)

Table 2. Fuzzy control rules for the number of opening fans and the fan speed for tunnel ventilation.

rules	Change rate of CO concentration Δe_{CO}							
	NB	NM	NS	ZO	PS	PM	PB	
CO concentration e_{CO}	NB	NB/NB	NB/NM	NB/NS	NB/ZO	NM/PS	NS/PM	ZO/PM
	NM	NM/NB	NM/NM	NM/NS	NM/ZO	NS/PS	ZO/PM	PS/PM
	NS	NS/NB	NS/NM	NS/NS	NS/ZO	ZO/PS	PS/PM	PM/PB
	ZO	ZO/NB	ZO/NM	ZO/NS	ZO/ZO	PS/PS	PM/PM	PB/PB
	PS	PS/NM	PS/NS	PS/ZO	PS/PS	PM/PM	PB/PB	PB/PB
	PM	PM/NS	PM/ZO	PM/PS	PM/PM	PB/PB	PB/PB	PB/PB
	PB	PM/ZO	PM/PS	PB/PM	PB/PB	PB/PB	PB/PB	PB/PB

Through Figure 6, we can discern the energy consumption differences between the proposed approach and the traditional method. This graphical representation serves as a powerful tool for conveying the efficiency advantages of the proposed method in terms of energy conservation and sustainability in tunnel ventilation operations.

Taking into account the continuous operation of the tunnel ventilation system, we calculate the cumulative energy consumption for both the proposed NARX combined fuzzy control method and the traditional fuzzy control method. The total energy consumption under the NARX combined fuzzy control approach w_T is calculated to be 3441 kWh, while the total energy consumption under the traditional fuzzy control algorithm Q_T is calculated to be 4020 kWh.

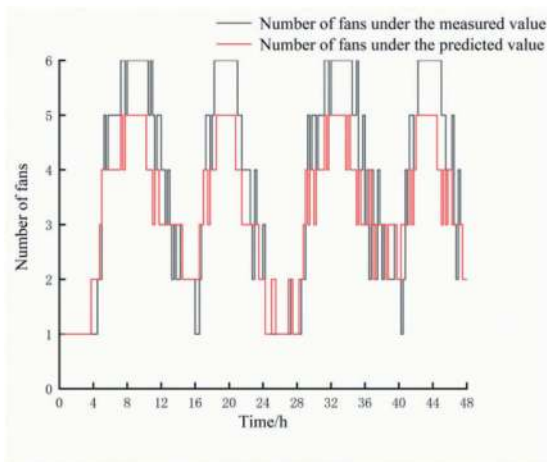

Applying Equation (13), the Energy-efficient efficiency is computed 14.4%, indicating 14.4% reduction in energy consumption achieved through the implementation of the proposed approach compared to the traditional fuzzy control algorithm. This substantial energy consumption reduction underscores the potential of the proposed NARX combined fuzzy control method to significantly enhance the energy efficiency of tunnel ventilation systems, thereby contributing to more sustainable and environmentally conscious operational practices.

By conducting a comprehensive analysis of fan energy consumption, we gain insights into how the proposed NARX combined fuzzy control approach

optimizes energy usage in comparison to the traditional method. This analysis contributes to a broader understanding of the practical benefits of implementing advanced control strategies in tunnel ventilation systems, ultimately leading to enhanced energy savings and more sustainable operational practices.

4 DISCUSSION

- (1) When employing NAR (Nonlinear AutoRegressive) neural networks and NARX (Nonlinear AutoRegressive with eXogenous input) neural networks for prediction, the rational configuration of parameters constitutes a critical aspect in ensuring prediction accuracy. The characteristics of hidden layer nodes indicate that deeper hidden layers theoretically enable neural networks to better fit functions, often resulting in improved predictive performance. However, excessively deep layers may lead to overfitting issues and heightened training complexity, impeding model convergence. When dealing with non-linear time series data with dual inputs, NARX neural networks necessitate a greater number of hidden layer nodes and delay steps, rendering them more intricate compared to NAR networks. Therefore, within this study, multiple calculations were conducted for both NAR and NARX networks with hidden

(a) the number of operating fans

(b) the fans speeds

Figure 5. Comparison of the proposed NARX combined fuzzy control and traditional fuzzy control.

Figure 6. Fan energy consumption Comparison of the proposed approach and traditional fuzzy control.

layer quantities ranging from 5 to 15, to ascertain optimal parameter settings. Specifically, for the NAR traffic flow prediction model, a network with 8 hidden layer nodes and a delay

order of 1:6 was selected, while for the NARX CO concentration prediction model, a network with 15 hidden layer nodes and a delay order of 1:8 was chosen. These parameter configurations yield favorable predictive accuracy.

- (2) The CO concentration within the tunnel is directly proportional to the traffic flow. The fuzzy controller operates by adjusting the number of working fan units and their rotational speed based on the CO concentration. Conversely, fluctuations in CO concentration correlate positively with the number of fan units and their rotational speed. By incorporating the predicted CO concentration values and their rate of change as inputs to the fuzzy controller, adjustments to the number of fan units and speed are made proactively, prior to significant fluctuations in CO concentration. This proactive adjustment aims to anticipate imminent spikes or drops in CO concentration, thus effectively mitigating abrupt changes in fan operation and minimizing abrupt transitions in the fan's opening and closing.
- (3) By comparing energy consumption when incorporating CO concentration predictions and rate of change as fuzzy control inputs, a 14.4% reduction in energy consumption is achieved. The fan counts and speeds demonstrate proactive adjustments before sharp CO concentration fluctuations, resulting in noticeable energy savings during peak and fluctuating CO concentration periods. The dynamic control strategy's benefits are prominently reflected in energy savings.
- (4) The current study focuses on a lengthy tunnel scenario. Further verification of the model's responsiveness is required in longer tunnels with more fan units and complex traffic flow conditions.

5 CONCLUSIONS

In this study, a comprehensive method is explored and proposed. The NAR model is used to predict the traffic flow, and the NARX model is used to predict the CO concentration by combining the predicted value of traffic flow and the measured value of CO, and then the fuzzy controller is applied to realize the dynamic and accurate control of the tunnel ventilation system to achieve the goal of energy saving. Through the analysis of actual data and experimental verification, the following conclusions are drawn:

- (1) NAR model shows high accuracy and prediction performance in traffic flow prediction. The model can effectively capture the historical pattern and trend of traffic flow, and provide a reliable input for the subsequent prediction of CO concentration; The NARX model combines the predicted value of traffic flow with the

measured value of CO, and predicts the CO concentration and its changing trend successfully. This provides key information for the intelligent control of the tunnel ventilation system, enabling the system to adjust in real time according to the predicted results.

- (2) Through the introduction of fuzzy controller, this study realize the dynamic accurate control of tunnel ventilation system. The fuzzy controller intelligently adjusts the opening number and speed of the fan in advance based on the predicted CO concentration and its variation, thus realizing the predictability of the ventilation effect and the optimization of the air supply volume. This method can not only effectively reduce the accumulation of CO concentration, but also significantly reduce energy consumption, providing a feasible solution for tunnel ventilation management.
- (3) This study demonstrated an integrated prediction and control method, which realized the intelligent regulation of tunnel ventilation system and achieved the goal of energy saving. This method not only improved the efficiency of ventilation, but also made a positive contribution to the sustainable development of urban transport infrastructure. Future research can further optimize the model and control strategy to adapt to the needs of different situations and environments, providing more beneficial innovations in the field of intelligent traffic management.

Intelligent surrounding rock classification and mechanical parameters analysis method based on drilling parameters of tunnels

Mingnian Wang, Siguang Zhao*, Wenhao Yi & Xin Peng

School of Civil Engineering, Southwest Jiaotong University

Key Laboratory of Transportation Tunnel Engineering of Ministry of Education, Southwest Jiaotong University

ABSTRACT: Drilling parameters such as excavation speed and pressures are automatically recorded by the drilling jumbo during the drilling process in a tunnel face constructed by blasting and drilling method. These parameters are characterised by automatic data collection, direct interaction with the surrounding rock, high data density within the surrounding rock, non-interference with tunnel construction, and low requirements for the tunnel environment. As a result, leveraging drilling parameters for intelligent identification of surrounding rock quality was of significant potential. To set up the intelligent surrounding rock classification and analysis of mechanical parameters, an extensive dataset comprising 5220 samples was built encompassing drilling parameters, surrounding rock grades, and mechanical parameters from tunnel engineering projects such as Zhengzhou-Wanzhou high speed railway, Yichang-Xingshan high speed railway. Firstly, a standardized data cleaning and features mining methodology was established, considering the multi-scale distribution characteristics of drilling parameters in a tunnel face. Then, the typical machine learning algorithm was employed to construct an intelligent classification model of surrounding rock. Subsequently, the theoretical models were developed for mechanical parameters such as surrounding rock elastic modulus, uniaxial saturated compressive strength using drilling parameters with the use of uncovering the coupling mechanism of “impact-rotation” in rock breaking by the drilling jumbo. The result demonstrated that the accuracy of intelligent surrounding rock classification in grade II, III, IV, and V could exceed 90%. In addition, the identification error of uniaxial compressive strength and elastic modulus of surrounding rock was also within the acceptable range, with better performance in harder rock.

Keywords: Tunnel, Drilling parameters, surrounding rock, classification, Analysis of mechanical parameters, Machine learning, “Impact-rotation” rock breaking.

1 INTRODUCTION

Before a tunnelling project starts, a site investigation is performed to determine the in situ surrounding rock conditions. The information on the surrounding rock quality evaluation is then used to determine tunnel design and construction schemes (Zhou et al., 2014). Generally speaking, surrounding rock quality evaluation includes surrounding rock classification and mechanical parameter analysis. The popular surrounding rock classification systems include the Q method (Barton et al., 1974), the surrounding rock rating (RMR) method (Bieniawski, 1979), the Geological Strength Index (GSI) method and the basic quality index (BQ) method (Lin, 1999). In the construction of railway and highway tunnels in China, the surrounding rock is classified into grades I–VI

according to its quality (from high to low, respectively). In the stability analysis and support design of tunnel surrounding rock based on elastic deformation assumption, uniaxial compressive strength and elastic modulus are the most commonly used surrounding rock mechanical parameters.

At present, the surrounding rock classification and rock parameter analysis methods used in the field are mostly the combination of qualitative and quantitative tests and manual experience. Since these methods often have limited availability of information (surface mapping, geophysical profiles, limited bore holes, etc.), the surrounding rock classification may be inaccurate. To solve this dilemma, a more thorough and detailed investigation could be performed, but reaching significantly higher resolutions is expensive and time-consuming. In contrast,

*Corresponding author: mt_guang@163.com

measurement while drilling (MWD) (Schunnesson, 1996) technology has natural advantages in terms of obtaining surrounding rock quality information during borehole drilling. Under MWD, enormous amounts of quantitative data can be obtained from most of the area of the tunnel face quickly and automatically, with no requirements on the environment of the tunnel and without interfering with the construction process (Rai et al., 2016). The MWD technology documents the response of the drilling parameters (e.g., penetration rate, operational pressures, rotation speed, flushing flow) while drilling (Schunnesson, 1996), thus providing an objective and reliable method for assessing surrounding rock conditions ahead of the tunnel face (Schunnesson, 1996; Schunnesson, 1998; Van Eldert et al., 2020).

MWD is a useful technique for gathering data with which to characterize the mechanical of the surrounding rock. A large number of studies have shown that multiple drilling parameters were effective in estimating some mechanical properties of rock, such as uniaxial compressive strength (Kalantari et al., 2018; Mostofi et al., 2011; Rodgers et al., 2017), rock texture and hardness (Bameri et al., 2021), rock shear strength (Kalantari et al., 2018; Rodgers et al., 2017; Rodgers et al., 2019), and internal friction angle (Kalantari et al., 2018). Besides, several studies have shown that the drilling parameters can be used to estimate the characteristics of the surrounding rock, such as joints or fractures (Manzoor et al., 2020; Rajib et al., 2017; Schunnesson, 1998), rock interfaces (Sugawara et al., 2003; Tan et al., 2007), rock quality designation (RQD) (He et al., 2020; He et al., 2021; Schunnesson, 1996) and hydraulic conductivity of surrounding rock (He and Li, 2022; He et al., 2022). On these basics, some good results have been achieved in many existing surrounding rock classification systems, such as the surrounding rock rating (RMR) method (Galende-Hernández et al., 2018), the Q method (Van Eldert et al., 2021; Van Eldert et al., 2020), and the BQ method (Zhao et al., 2022).

In order to further improve the level of geological analysis of surrounding rock based on drilling parameters, in this paper, we extensively collected massive drilling parameter data by full using of the industrial advantages of large-scale mechanized construction in China. On this basis, artificial intelligence and theoretical analysis methods were used to establish the intelligent classification model and the mechanical parameters analytical formula of surrounding rock, so as to realize the intelligent, rapid and accurate analysis of the surrounding rock grades and surrounding rock mechanical parameters on site.

2 DATA SOURCE

In this study, an sample include the drilling parameters, the surrounding rock grades and the mechanical parameters of surrounding rock in tunnel face.

The samples of this study were collected from 12 tunnels of the Zhengzhou-Wanzhou railway project and the Yichang-Xingshan railway project in Hubei province, China.

2.1 Drilling parameters acquisition

The drilling parameters include four categories: (i) penetration velocity (V_p , m/min), the rate at which the drill bit penetrates the rock mass; (ii) hammer pressure (P_h , bar), a measure of the impact pressure of the bit against the rock mass; (iii) rotation pressure (P_r , bar), defined as the pressure of the bit against the rock necessary to maintain the required rotation; and (iv) feed pressure (P_f , bar), a measure of the hydraulic pressure inside the cylinders necessary to keep the bit in contact with the bottom of the hole. The drilling parameter data were collected automatically by an intelligent drilling jumbo at equal depth intervals of 2 cm. (Figure 1) (Zhao et al., 2022).

Figure 1. Automatic acquisition for the drilling parameters.

2.2 Surrounding rock grades determination

There are six classes of surrounding rock, grades I-VI, where grade I represents the best quality of surrounding rock, and grade VI represents the worst. And the information for the surrounding rock grades was collected manually by the geological sketch method according to the degree of hardness, integrity, groundwater state, crustal stress state and major weak structural surface (Figure 2).

2.3 Surrounding rock mechanical parameters test

The analysis object of uniaxial compressive strength and elastic modulus of surrounding rock of tunnel face surrounding rock based on drilling parameters described in this paper is the surrounding rock of face surrounding rock, which is the mechanical parameter after the impact of structural plane cutting, which is commonly expressed by the rock integrity coefficient.

Figure 2. Manual acquisition for the surrounding rock grades.

However, the field mechanical parameter test object is mostly rock, so it is necessary to test the integrity coefficient of surrounding rock. The modification of surrounding rock integrity coefficient to rock mechanics parameters is referred to Equation (1)- Equation (2). The integrity coefficient of surrounding rock is realized by means of wave velocity measurement, and the calculation is referred to Equation (3).

$$R_b = K_v R_c \quad (1)$$

$$E = K_v E_c \quad (2)$$

$$K_v = (V_{pm}/V_{pr})^2 \quad (3)$$

Where, R_b is uniaxial saturated compressive strength of surrounding rock; R_c is uniaxial saturated compressive strength of rock; E_c is elastic modulus of rock; E is elastic modulus of surrounding rock; K_v is integrity index of surrounding rock V_{pm} is elastic longitudinal wave velocity of rock; V_{pr} is elastic longitudinal wave velocity of surrounding rock.

Based on this, the field test of surrounding rock mechanical parameters is carried out in the typical section. It includes uniaxial compressive strength and elastic modulus of rock (Figure 3), elastic wave velocity of rock (Figure 4) and surrounding rock (Figure 5).

2.4 Sample size statistic

As shown in Figure 6, there were 5220 samples for intelligent surrounding rock classification were collected. These samples cover four surrounding rock grades (II, III, IV, and V) and nine main lithologies (dolomite, sandstone, limestone, shale, and mudstone).

And among these 5220 cycles, we selected 15 typical cycles for rock mechanics parameters testing, including five types of rocks, namely granodiorite, dolomite, limestone, sandstone and mudstone, which represent different degrees of rock hardness.

Figure 3. The test of uniaxial compressive strength and elastic modulus of rock.

Figure 4. The test of the elastic wave velocity of rock.

Figure 5. The test of the elastic wave velocity of surrounding rock.

Figure 6. The test of the elastic wave velocity of surrounding rock.

3 INTELLIGENT SURROUNDING ROCK CLASSIFICATION

3.1 Data preprocessing

3.1.1 Data cleaning

The MWD data were collected continuously during drilling. These machine data normally contain some faulty, biased, or unrealistic values due to the nature of the drilling process, sensor errors, or machine safety systems (anti-jamming). These erroneous data points must be removed prior to assessment of the surrounding rock conditions (Van Eldert et al., 2020).

Through investigation and analysis, each drilling parameter may include two kinds of outliers along the depth of the borehole.

- At the beginning of the borehole (about 0.3–0.5 m), to ensure a straight hole through this disturbed surrounding rock, collaring is normally performed with great care (Manzoor et al., 2020), i.e., lower pressure (P_f and P_r) and speed (V_p), before these parameters are gradually increased to their normal levels (Figure 7, marked with ‘Type I’). These drilling parameters recorded at the start of the borehole are not related to the characteristics of the surrounding rock. Therefore, these recorded samples were removed from the input data (Manzoor et al., 2020). Specifically, the drilling parameters from the first 0.5 m of the borehole were deleted in this study.
- Sensor errors or machine safety systems (anti-jamming) cause the drilling parameters to occasionally appear too large or too small (Figure 7, marked with ‘Type II’). Fortunately, in high-resolution datasets, more extensive filtering can be applied without losing the general pattern of the data, as the data quantity minimizes the effect of removing abnormal data points. Therefore, the highest and lowest values can be removed by some conservative statistical approach (Van Eldert et al., 2020).

Figure 7. Scatter diagrams of typical borehole drilling parameters.

In this study, the boxplot method was used to determine the criteria of outliers (Dawson, 2017). The box diagram method determines the non-outlier interval according to the quartiles, as defined by Equation (4).

$$[Q_1 - 1.5IQR, Q_3 + 1.5IQR] \quad (4)$$

Where, Q_1 is the first quartile, Q_3 is the third quartile, and IQR is equal to Q_3 minus Q_1 .

In summary, the non-outlier intervals for sample data cleaning were shown in Table 1.

Table 1. The non-outlier intervals for sample data cleaning.

Drilling parameters	V_p (m/min)	P_h (bar)	P_f (bar)	P_r (bar)
Non-outlier interval	[0.00, 5.50]	[64.50, 196.50]	[4.50, 112.50]	[17.00, 153.00]

3.1.2 Feature mining

In machine learning, feature construction is the extraction of useful features from raw data, which can help the model to discover patterns and laws hidden behind the data and enable the model to make correct predictions

Generally, 200-300 boreholes are arranged at tunnel face for each full-section excavation cycle, and the lengths of the boreholes are about 2-5 m. One set of drilling parameters is collected every 2 cm for each borehole in the longitudinal direction, and about 100-250 sets of drilling parameters are collected from each borehole. A total of approximately 20,000-50,000 sets of drilling parameters are collected from each excavation cycle. The high density and quantity significantly differentiate the drilling parameters collected by the tunnel face boreholes from those collected by the mining drilling equipment and oil drilling equipment. The drilling jumbo records 20,000 to 50,000 data points like a ‘CT scanner’ in an excavation cycle. Statistical features expansion is the process of statistically analyzing all the drilling parameters at tunnel face. Common statistical features are mean value, quartiles, standard deviation and coefficient of variation. The mean value is the sum of all the data in a dataset divided by the number of data, and is calculated as Equation (5).

$$u_c = \frac{\sum_{i=1}^{n_c} c_{c,i}}{n} \quad (5)$$

Where, u_c is the mean value of feature number c at target tunnel face; $c_{c,i}$ is eigenvalue of feature number c at data point i ; n is the number of data points for the feature number c at target tunnel face.

Quartiles are values arranged from smallest to largest, and are divided into four equal parts at the three division points. Quartiles include the first quartile, second quartile and third quartile, and are denoted by $Q_{1,c}$, $Q_{2,c}$, and $Q_{3,c}$. The standard deviation is an index that describes the degree of dispersion of each observation value from the mean value. The standard deviation is calculated as Equation (6).

$$\sigma_c = \sqrt{\frac{\sum_{i=1}^n (c_{c,i} - u_c)^2}{n}} \quad (6)$$

Where, σ_c is the standard deviation of feature number c at target tunnel face.

The coefficient of variation is calculated as Equation (7).

$$c_{v,c} = \frac{\sigma_c}{u_c} \quad (7)$$

Where, $c_{v,c}$ is the coefficient of variation of feature number c at target tunnel face.

With Equation (5) - (7), the six statistical features of the rock drilling parameters (u_c , $Q_{1,c}$, $Q_{2,c}$, $Q_{3,c}$, σ_c , $c_{v,c}$) can be determined, and the drilling parameters of any tunnel face have 24 features.

3.2 Machine learning model

The surrounding rock classification model was constructed by Extra Trees (ET) algorithm, which solves the classification problem by first generating multiple random cut-off thresholds for each feature, and then selecting the best threshold for classification (Figure 8).

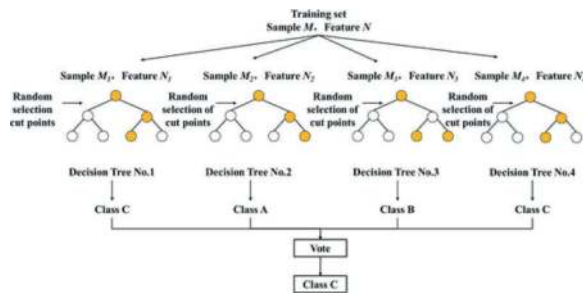

Figure 8. Schematic diagram of ET algorithm.

The key steps include dataset partitioning and oversampling, feature normalization.

3.2.1 Dataset partitioning and oversampling

The proportion of training set and prediction set should take into account the needs of model training and the effectiveness of model evaluation. In order

to facilitate model performance evaluation, it is considered to set the same number of samples of each surrounding rock level in prediction set. Therefore, according to the distribution of each level of surrounding rock in the samples, the grade II surrounding rock with the least number of samples is mainly considered, and the number of samples of each level of surrounding rock in prediction set is determined to be 50 (accounting for about 20% of the total number of samples in the grade II set). The distribution of samples after splitting is shown in Table 2.

Table 2. Details on the dataset division of models.

Grade Dataset	II	III	IV	V	Total
Training set	207	2422	2086	305	5020
Prediction set	50	50	50	50	200
Total	257	2472	2136	355	200

Referring to machine learning classification, when the difference in the number of samples of all the classes is too large, the training model will pay too much attention to the sample characteristics with a greater proportion, so the classification effect of the samples with a smaller proportion is not ideal. This is called the problem of sample imbalance. These data sets cover four class of surrounding rock, and each class contains 207, 2422, 2086 and 305 samples belonging to the imbalance sample set. The sample imbalance problem is usually solved by three methods of the undersampling, oversampling and sample weight adjustment (Zhao et al., 2022). In this study, the sample imbalance in the surrounding rock classification set is not significant; however, to improve the generalization ability of the model, the ADASYN method is used for feature oversampling (Pan et al., 2022). The oversampling criterion is that the number of samples in each class is exactly equal. The sample sizes of the training set before and after oversampling are given in Table 3.

Table 3. Sample sizes of the training set before and after oversampling.

Grade Training dataset	II	III	IV	V	Total
Before	207	2422	2086	305	5020
After	2422	2422	2422	2422	9688

3.2.2 Feature normalization

Considering the influence of the absolute values of the drilling parameter features on the model parameters, the dataset is processed using the feature

normalization. Feature standardization is the conversion of feature data to a distribution with a mean value of 0 and a standard deviation of 1, the feature normalization method utilized in this study is expressed as Equation (8).

$$x' = \frac{x - \mu}{\sigma} \quad (8)$$

Where, x is any set of feature data; x' is any set of normalized feature data; μ is the mean of the training set feature data; σ is the standard deviation of the training set feature data.

3.2.3 Prediction result

In the final evaluation of the model performance, the precision, recall, and accuracy were adopted for a comprehensive evaluation. They were calculated according to the confusion matrix.

The confusion matrix of intelligent classification model in prediction set was shown in Figure 9. And the precision, recall, and accuracy were shown in Table 4.

Figure 9. The confusion matrix of intelligent classification model.

Table 4. Model performance in prediction set.

Performance index	Rock Grade	Performance
Precision	II	97.9%
	III	88.7%
	IV	87.0%
	V	97.8%
Recall	II	92.0%
	III	94.0%
	IV	94.0%
Accuracy	V	90.0%
	-	92.5%

As shown in the Table 4, the precision, recall were above 90%, except for the precisions of grade

III and grade IV surrounding rock. In particular, the precision of grade II was greater than 95%. And the final accuracy was 92.5%. Thus, the intelligent classification model of surrounding rock based on drilling parameters has high practical value.

4 MECHANICAL PARAMETERS ANALYSIS

4.1 Analysis principles and methods

According to the laws of thermodynamics, energy is the essential feature of the physical process of matter, and the destruction of matter is a state instability phenomenon driven by energy.

It can be seen from the drilling process of the drilling rig that the drilling system does work to the surrounding rock through the drill. When the output energy of the mechanical work reaches the energy storage limit of the surrounding rock, the surrounding rock releases energy in the form of elastic deformation, crack expansion, and cuttings bursting, forming holes and reaching a new stable equilibrium state. The total energy output of the drilling system can be called mechanical specific energy under the condition of breaking rock per unit volume per unit time. Existing studies have shown that under external load, the input mechanical energy and heat energy are mainly used for the elastic deformation of surrounding rock, that is, the input energy of external load is mainly converted into the elastic deformation energy of surrounding rock.

At the same time, the mechanical specific energy can be expressed by drilling parameters, and the elastic deformation energy of surrounding rock is also related to the mechanical parameters of surrounding rock.

Therefore, the mechanical parameters of surrounding rock can be analyzed by drilling parameters according to the following Equation (9)-Equation (11).

$$E_{mse} = f_1(V_p, P_h, P_f, P_r) \quad (9)$$

$$U^e = f_2(E, R_b) \quad (10)$$

$$E_{mse} k_e = U^e \quad (11)$$

Where, E_{mse} is mechanical specific energy; U^e is elastic deformation energy of surrounding rock; E is elastic modulus of surrounding rock; R_b is uniaxial saturated compressive strength of surrounding rock; $f_1(\cdot)$ is the functional relationship between mechanical specific energy and four drilling parameters; $f_2(\cdot)$ is the functional relationship between elastic deformation energy and elastic modulus, uniaxial compressive strength.

The key is the calculation of energy indicators, containing mechanical specific energy during drilling and elastic deformation energy of surrounding rock.

4.2 Energy indicators

4.2.1 Mechanical specific energy during drilling

According to the principle of mechanical motion of drill jumbo, E_{mse} is the mechanical work done by drilling jumbo per unit volume of rock, and is the sum of hammer specific energy, feed specific energy and rotation specific energy. The drilling specific energy, hammer specific energy, feed specific energy, rotation specific energy calculation method were as following Equation (12)- Equation (18).

$$E_{mse} = E_{fse} + E_{hse} + E_{rse} \quad (12)$$

$$E_{fse} = \frac{E_f}{V_p \frac{\pi D^2}{4}} \quad (13)$$

$$E_{hse} = \frac{E_h}{V_p \frac{\pi D^2}{4}} \quad (14)$$

$$E_{rse} = \frac{E_r}{V_p \frac{\pi D^2}{4}} \quad (15)$$

$$E_f = \frac{\pi D_f^2 P_f V_p}{8} \quad (16)$$

$$E_h = \frac{P_h \pi D_{hb}^3 S_h}{8} \sqrt{\frac{\pi P_h S_h (D_{ha}^2 - D_{hb}^2)}{2m_h (2D_{ha}^2 - D_{hb}^2)}} \quad (17)$$

$$E_r = P_r V_r q_r i_r \quad (18)$$

Where, E_{hse} , E_{fse} , E_{rse} is hammer specific energy, feed specific energy and rotation specific energy respectively; E_h , E_f , E_r is the work done by the hammer mechanism, feed mechanism and rotation mechanism on the surrounding rock per unit time respectively; D , D_f , D_{ha} , D_{hb} is diameter of the drilling bit, feed piston, hammer piston rear end, hammer piston front end respectively; m_h is mass of hammer piston; S_h is hammer distance; i_r is reduction ratio; q_r is hydraulic motor displacement.

4.2.2 Elastic deformation energy of surrounding rock

The surrounding rock unit of a unit volume undergoes deformation under the action of external loading machinery. Assuming that there is no heat exchange between the process and the outside world, and all the output energy of the machinery is converted into the internal energy of the surrounding rock, the work done by the external loading machinery is converted into the dissipated energy of the surrounding rock and the elastic deformation energy of the surrounding rock. Therefore, the total energy generated by the external loading machinery is U .

According to the first law of thermodynamics, Equation (19) can be obtained.

$$U = U^a + U^e \quad (19)$$

Where, U is the total specific energy generated by the external mechanical action; U^a is the dissipated specific energy of the surrounding rock; U^e is the elastic deformation specific energy of the surrounding rock.

Taking the typical stress-strain curve of the surrounding rock under pressure as an example, the dissipative energy of the surrounding rock is manifested in the form of surrounding rock loss and plastic deformation, and the elastic deformation energy of the surrounding rock is manifested in the form of surrounding rock elastic deformation. The relationship between elastic deformation energy and dissipative deformation energy per unit volume of surrounding rock is shown in Figure 10.

Figure 10. The relationship between elastic deformation energy and dissipated deformation energy of surrounding rock per unit volume.

In the process of impingement, propulsive and rotary rock breaking by all computerized three-arm drilling rig, the surrounding rock mainly suffers from compressive brittle failure, and the mechanical work is mainly converted into elastic deformation energy of surrounding rock. Therefore, the dissipated energy of surrounding rock in the process of mechanical work is ignored in this paper.

According to elastic mechanics, considering the average effect of surrounding rock along the principal stress direction (compression direction), the elastic deformation energy of surrounding rock per unit volume is calculated in Equation (20).

$$U^e = \frac{R_b^2}{2E} \quad (20)$$

Figure 11. Uniaxial compressive strength testing results, corrected results, model computing results.

Figure 12. Elastic modulus testing results, corrected results, model computing results.

Figure 13. Difference rate between corrected and model computing results.

4.3 Field demonstration result

The uniaxial compressive strength and elastic modulus testing results, corrected results and model computing results of the surrounding rock of the tunnel face are shown in Figure 11 and Figure 12. The

difference rate between the corrected results and the model analysis results is shown in Figure 13.

As shown in Figure 11 - Figure 13, compared with the theoretical analytical model and the test results of surrounding rock mechanical parameters, the difference rate of the analytical results of the uniaxial compressive strength of the surrounding rock on the tunnel face ranged from -5.52% to -20.89%, and the difference rate of the analytical results of the elastic modulus of surrounding rock on the tunnel face ranged from -9.01% to -22.03%. The analytical results of the model were all smaller than the test results of surrounding rock mechanical parameters, and the difference rates of the analytical results of uniaxial compressive strength and elastic modulus of granodiorite with greater hardness were only -5.81%–8.08% and -9.01%–9.75% respectively within 10%.

They also showed that the analytical results of hard rock are more accurate than those of soft rock. The main reason is that the elastic deformation energy of hard rock is relatively high in the process of deformation and failure. In the failure process of soft rock, the elastic deformation energy and dissipative deformation energy are almost at the same level, but the dissipative energy increases rapidly when the failure is approaching, and the energy dissipation is the main process, so the calculation method of the dissipative energy of surrounding rock needs to be further considered.

5 CONCLUSIONS

Based on the massive drilling parameters from 5220 cycles, an intelligent classification model and mechanical parameters calculation formula were developed.

The conclusions of this study can be summarized as follows.

- (1) The drilling parameters were feasible to achieve the classification of surrounding rock after data cleaning and feature mining. The proposed intelligent surrounding rock classification model by using ET algorithm exhibited a high performance. The precisions for each surrounding rock grade exceeded 85%, the recalls for each surrounding rock grade exceeded 90%, and the overall accuracy was 92.5%. Therefore, the intelligent model based on drilling parameters is feasible and reliable for intelligent surrounding rock classification.
- (2) The relations between uniaxial compressive strength, elastic modulus and mechanical specific energy during drilling process was deduced, and an analytical model of uniaxial saturated compressive strength and elastic modulus of tunnel face surrounding rock was established based on drilling parameters. The field test showed that the difference rate of uniaxial compressive strength

analysis was -5.52%–20.89%, and the difference rate of elastic modulus analysis was -9.01%–22.03%. The analytical results of the model were all smaller than the test results of surrounding rock mechanical parameters. The analytical results of hard rock are more accurate than those of soft rock.

ABSTRACT: In this research endeavor, a novel and improved Swin Transformer (ST) model is employed to discern and segment disease features, such as cracks, weak interlayers, and leakage on rock tunnel faces. The outcomes of the conducted tests, utilizing a newly curated imageset, elucidate that the recognition and segmentation performance achieved by the improved ST model markedly surpasses those of conventional ST, Unet++ and Unet models. For the quantitative segmentation of rock features and geological sketches, an improved ST model serves as the foundation for establishing a multi-source Tunnel Face Feature (TFF) dataset. This dataset encompasses rock feature parameters, physical-mechanical parameters, and tunnel design parameter. Nevertheless, due to temporal and spatial constraints in procuring on-site information for rock tunnel faces, the simultaneous acquisition of complete parameters becomes a challenging endeavor. To address the incompleteness of the TFF datasets, a Tree-augmented Naive Bayesian Network (TAN BN) is meticulously devised. The proposed TAN BN exhibits a commendable validation accuracy of 92.9%, while the trained TAN BN attains a test accuracy of 89.33%. These outcomes underscore the precision and efficacy of the proposed TAN BN model, particularly when confronted with incomplete datasets. Furthermore, the study presents results from a sensitivity analysis, elucidating the significance of input parameters.

1 INTRODUCTION

The assessment of surrounding rock quality plays a pivotal role in shaping the excavation and support scheme design for rock tunnels. It constitutes an indispensable foundation for evaluating the stability of surrounding rocks, formulating cross-sectional

shapes, devising construction methodologies, and determining supporting structures. Consequently, the precise evaluation of surrounding rock quality has perennially been a focal point of scholarly attention and practical consideration among on-site engineers. (Aksoy et al., 2012; Chen and Liu, 2007; Rehman et al., 2019).

*Corresponding author: wylzj9@163.com

Historically, the prevailing classification methods for surrounding rock have been categorized into three distinct types, predicated upon their qualitative and quantitative attributes: namely, the qualitative classification method, the quantitative classification method, and the qualitative-quantitative hybrid method. Including: RMR (Bieniawski, 1988), Q system (Mechanics, 1978), RQD (Deere, 1963) and GSI (E. et al., 1997; Hoek and Diederichs, 2006), etc. Due to differences in the selection of systems and parameter among different evaluation methods, as well as the complexity and anisotropy of tunnel engineering geological conditions (Petronio et al., 2007), these methods are difficult to fully reflect the actual situation and can only reflect the quality of tunnel surrounding rock from one or more aspects (Chen and Liu, 2007), resulting in inaccurate evaluation and prediction of rock mass quality (Chen et al., 2013; Zhou et al., 2021). Therefore, it is necessary to develop more comprehensive and accurate methods for predicting surrounding rocks quality.

In the course of evaluating the surrounding rock quality on rock tunnel faces, numerous characteristic parameters, encompassing water leakage, cracks, weak interlayers, and mechanical properties of surrounding rock, necessitate collection and documentation at the site. For on-site engineers tasked with the observation and recording of said characteristic parameters, exposure to freshly exposed surrounding rock poses an undeniable risk. Moreover, the manual recording of these characteristic parameters relies on human expertise and skills, introducing potential subjectivity and imprecision into the prediction of surrounding rock quality. In response to the aforementioned challenges of insecurity and inaccuracy, it becomes imperative to propose an intelligent, non-contact methodology for acquiring characteristic information about the surrounding rock. Computer vision (CV) models emerge as an automated, non-contact approach for extracting information from images. The application of CV technology has become increasingly prevalent as an intelligent and quantitative means of extracting characteristic parameters from rock tunnel faces (Chen et al., 2022; Chen et al., 2020; Yusoff et al., 2023). Nonetheless, the CV methodologies employed by predecessors predominantly consist of existing CV models, lacking targeted enhancements tailored to the nuanced characteristics of diminutive parameters like water leakage, fracture traces, and weak interlayers against complex backgrounds. This deficiency results in suboptimal accuracy and generalization performance in tasks involving identification and segmentation. Hence, there exists a substantive rationale to ameliorate the existing CV models. Moreover, owing to constraints inherent in on-site construction protocols, spatial limitations, and varying lighting conditions at rock tunnel face sites, a principal shortcoming of extant approaches for predicting rock mass quality lies in the formidable challenge of attaining comprehensive datasets. To surmount this limitation, a novel Bayesian Network (BN) is posited as a solution for predicting rock mass

quality. BNs, by nature, exhibit inherent strengths in managing conditional dependency relationships among recorded and unrecorded random variables within a statistical model (Lauritzen, 1995), hence making it a reasonable choice in classification and prediction process of rock mass quality. Besides, although BNs have been widely applied in geotechnical engineering (Huang et al., 2012; Jimenez-Rodriguez and Sitar, 2006; Song et al., 2012), they have not yet been applied to predict the surrounding rock quality.

In this study, an improved ST model is utilized for the acquisition of quantified CV parameters pertaining to rock tunnel faces. Furthermore, the establishment of a multi-source TFF dataset is undertaken, encompassing CV parameters, alongside physical, mechanical, and design parameters of the surrounding rock. Subsequently, a novel TAN BN is introduced to accurately prognosticate the quality of surrounding rock, even when confronted with incomplete data within the multi-source TFF dataset. The RMR system (Bieniawski, 1988, widely embraced at the international level, serves as both a benchmark and an output reference for the proposed TAN BN.

2 SEGMENTATION OF CV PARAMETERS

2.1 Improved CV model

The ST model, distinguished by its integration of shift windows, layered computing, and self-attention mechanisms within the realm of CV (Liu et al., 2021), has demonstrated superior outcomes compared to the majority of CNN models in the segmentation of tunnel disease features. Notably, the model's parameter count is considerably lower than that of the Vision Transformer (ViT). The ST model has found successful application in the automatic recognition and segmentation of tunnel disease information, encompassing phenomena such as water leakage and fractures (Meng et al., 2023; Zhou et al., 2023). However, the segmentation performance of small-scale features at the boundaries of diverse disease information is not notably optimal. Unet models, renowned for their proficiency in handling small-scale targets or images featuring intricate boundaries, often exhibit commendable performance. Consequently, this study endeavors to enhance the ST model by incorporating aspects of the Unet model. This integration is undertaken with the aim of ameliorating the segmentation task performance related to small-scale feature information on rock tunnel faces.

Figure 1 illustrate the detailed architecture of the improved ST model. Specifically, the structure of the Unet model has more advantages for processing small-scale information. Referring the excellent structure of Unet, the U-shaped structure is employed in the improved ST model. Simultaneously, the ST block establishes relationships between patches within pre-partitioned windows, effectively reducing computational memory overhead. However, this method to

some extent weakens the global modeling ability of the model. This also leads to unsatisfactory performance of the ST model in identifying and segmenting targets with small-scale features and complex boundaries such as water leakage, fractures, and weak interlayers. To compensate for the loss of feature resolution brought by ST, a CNN module that can leverage detailed high-resolution spatial information is employed to enhance the information exchange of pixels on small-scale features and complex boundaries.

Inspired by the U-shaped architectural design, the self-attentive feature encoded by ST is then upsampled to be combined with different high-resolution CNN features skipped from the encoding path, for enabling comprehensive and accurate pixel information extraction. Such a design allows the improved ST to preserve the advantages of ST and also benefit rock mass characteristic segmentation. Specifically, the rock mass image first traverses multiple CNN blocks, and the features procured at each layer are retained for skip connections. The features obtained from the final layer are transferred to the enhanced Attention Block after linear projection. The hidden feature is simultaneously inputted into the ST Block, extracting global and local level information respectively. The two resulting hidden features are stacked and undergo feature fusion via Conv3x3ReLU. Through the stacking of multi-level Attention Blocks, the model attains a superior feature extraction capability for image data. Lastly, we reshape the acquired hidden feature, merge it with the previously obtained feature via skip connections, and obtain the final semantic segmentation result through the Segmentation Head.

Figure 1. Detailed architecture of the improved ST model.

2.2 Establishment of TFF imageset

To efficiently obtain an adequate number of high-definition images of tunnel faces and subsequently acquire quantitative segmented characteristic parameters, an adaptive digital camera acquisition system is established in conjunction with an on-site lighting system during the tunnel construction process. This digital camera system comprises a Canon EOS 6D2 camera, tripod, tape, illuminometer, laser range-finder, and thermo hygrometer. Moreover, the

system is equipped with a light source consisting of two LED dropout lamps. This image acquisition system is primarily applied in two categories of rock tunnels, specifically the Second Submarine Tunnel in Jiaozhou Bay, Qingdao, China and the Meng-ping mountain tunnel, Yunnan province, China, which can strength the representativeness and robustness of established imageset.

A novel imageset is established based on the tunnel face images of two tunnel projects obtained by the adaptive digital camera acquisition system. Specifically, to quantitatively obtain geometric and quantitative information of water leakage, fractures, and weak interlayers in the imageset. The length and width of each image can be calibrated by a tape measure. More than 1000 raw images were collected from various tunnel sites in Qingdao second submarine tunnel and Yunnan Meng-ping mountain tunnel. Following the previous work (Chen et al., 2021a; Jose et al., 2020), these raw images are then carefully selected and cropped into 2000 smaller images (512×512 pixels). The raw images are manually labelled via Labelme software.

For the purpose of enriching the imageset established in this section, data augmentation methods have been employed. Such as mirror transformation, random rotation, and random amplification are performed (Chen et al., 2021a; Chen et al., 2021b; Perez and Wang, 2017). Furthermore, the number of various characteristic parameter images in the imageset processed by the above image augmentation methods are illustrated in Table 1. In this imageset, 80% of the images are utilized for training and the remaining 20% will be evenly allocated to the validation and testing sets.

Table 1. Images distribution in the imageset.

Different parameters	Total number	Number of training set	Number of validation set	Number of test set
Water leakage	6000	4800	600	600
Fractures	6000	4800	600	600
Weak interlayers	6000	4800	600	600

2.3 Experimental settings and results

The improved ST is subjected to evaluation on the TFF imageset, specifically for tasks related to the segmentation of water leakage, fractures, and weak interlayers. In the conducted segmentation experiments, the improved ST undergoes training for 100 epochs, initialized with a learning rate set at 0.0001. All models are implemented using the PyTorch platform. The model outputs manifest as probability maps in our experimental setup, which can be transformed into semantic segmentation results by

identifying the category with the highest probability at each position. Concurrently, segmentation experiments are conducted using the conventional, unenhanced ST, along with Unet++ and Unet models, all introduced under the same TFF imageset and experimental conditions. Figure 2 illustrates the visually intuitive segmentation results pertaining to water leakage, fractures, and weak interlayers. To evaluate the impact of different categories of water leakage on the surrounding rock quality, it should be pointed out that for the leakage characteristics on the rock mass, not only the segmentation task has been completed, but also the classification task has been completed. Combined with the RMR systems and previous studies (Chen et al., 2022; Zhou et al., 2021), the states of rock tunnel faces are divided into five types (Bieniawski, 1988), namely Anhydrous state image (1), Wet state image (2), Dropping state image (3), Flow state image (4), Spray state image (5). Furthermore, it is evident that the improved ST model demonstrates a superior capacity to accurately predict both the small-scale features and intricate boundaries associated with water leakage, fractures, and weak interlayers, surpassing the performance of the other three CV models.

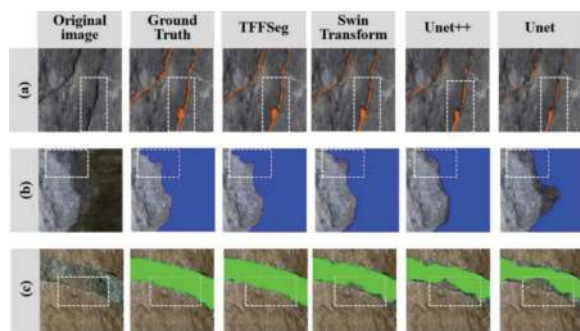

Figure 2. Comparison of qualitative results between improved ST and other frequently utilized CV models.

3 ESTABLISHMENT OF MULTI-SOURCE TFF DATASET

3.1 Bayesian network

BN, also known as belief network, or directed acyclic graphical model, is a probability graph model, which was first proposed by Judea Pearl (Pearl, 1986). The nodes in the directed acyclic graph of BN represent random variables, which can be observable variables, hidden variables, unknown parameters, etc. Variables or propositions that are believed to have a causal relationship (or non-conditional independence) are connected by arrows. If two nodes are connected by a single arrow, it means that one node is “parents” and the other is “children”, and the two nodes will generate a conditional probability value. On the contrary, the absence of an arrow between two variables indicates their conditional independence (David and

Heckerman, 1997). Naive BNs require that children nodes remain independent of each other, but this is often not the case in geotechnical engineering. In view of this, a TAN BN (presented in Figure 3, X is the input variable and Y is the output variable) that allows for a certain correlation between child nodes under the parent node is proposed to improve the applicability and predictive accuracy of the BN.

Figure 3. Schematic diagram of BN.

3.2 Introduction of different parameters

To comprehensively evaluate the quality of surrounding rock. A multi-source TFF dataset containing CV parameters, physical and mechanical parameters, and design parameter is established in this work. The parameters of water leakage, fractures, and weak interlayers of great concern to some commonly applied international rock mass quality evaluation systems (Bieniawski, 1988; E. et al., 1997; Mechanics, 1978). The acquisition methods of considered parameters in these prediction systems often rely on human observation and experimental records at rock engineering sites, which is dangerous and easily influenced by engineer experience. To address this drawback, a non-contact improved ST model is employed in this paper to intelligently obtain parameters such as water leakage, cracks, and weak interlayers on the rock masses. Specifically, in the multi-source TFF dataset proposed in this section, the water leakage parameters identified based on the improved CV model include Ground water category (GWC) and Ground water area (GWA), fracture trace parameters include Trace density (TD), Trace intensity (TI) and Trace number (TN), Average trace interval (ATI), Maximum trace length (MTL), and weak interlayer parameters include Weak interlayer area (WIA). In addition, guided by previous research (Ietto et al., 2018; Zhou et al., 2021), Uniaxial compressive strength (UCS), Weathering degree (WD) and Tunnel buried depth (TBD) with potential influence on RMR system are obtained in this multi-source TFF dataset, which can further enhance the precision and robustness of predicting the surrounding rock quality in this work. Below is a brief introduction to these parameters.

3.3 Data discretization of the incomplete dataset

Nine various categories of parameters (GWA, TD, TI, TN, ATI, MTL, WIA, UCS and TBD) in the proposed multi-source TFF dataset are continuous. Due to the limitations of BN in processing continuous data (Jensen and Nielsen, 2007), the characteristic parameters of rock mass obtained through quantitative calculation are discretized. Owing to the RMR classification system divides the quality of surrounding rock into five levels equidistantly based on the empirical formulation (Bieniawski, 1988), each continuous parameter in this work also adopts the principle of equidistance division for discretization. Meanwhile, the intervals defined for the nine continuous parameters considered are demonstrated in Table 2.

Table 2. Intervals applied to the continuous parameters in the TFF dataset.

Parameters	Set of intervals
GWA intervals States of GWA	Zero/ (0, 8.64]/ (8.64, 17.28]/ (17.28, 25.893] Zero, Small, Medium, Large
TD intervals States of TD	[0, 26.7]/ (26.7, 53.4]/ (53.4, 80.1]/ (80.1, 106.8] Very small, Small, Medium, Large
TI intervals States of TI	[0, 6.84]/ (6.84, 13.68]/ (13.68, 20.52]/ (20.52, 27.36] Zero, Small, Medium, Large
TN intervals States of TN	[0,16.72]/ (16.72,33.44]/ (33.44,50.16]/ (50.16, 66.88] Very small, Small, Medium, Large
ATI intervals States of ATI	[0.05, 0.2075]/ [0.2075, 0.365]/ [0.365, 0.5225]/ [0.5225, 0.68] Very small, Small, Medium, Large
MTL intervals States of MTL	[0.22, 0.6375]/ [0.6375, 1.055]/ [1.055, 1.4725]/ [1.4725, 1.89] Very small, Small, Medium, Large
WIA intervals States of WIA	Zero/ [0,4.35]/ [4.35,8.70]/ [8.70,13.05] Zero, Small, Medium, Large
UCS intervals States of UCS	[0,16.72]/ [16.72,33.44]/ [33.44,50.16]/ [50.16, 66.88] Very small, Small, Medium, Large
TBD intervals States of UCS	[11, 99.50]/ [99.5, 188]/ [188, 276.5]/ [276.5, 365] Very small, Small, Medium, Large

Due to limitations in the on-site space, process arrangement, and construction data storage of the tunnel working face, it can be seen that not all parameters in the multi-source TFF dataset have a quantity of 140. Some parameters are incomplete, which will affect the precision of prediction tasks based on this multi-source TFF dataset. It is known that BNs have advantages in processing incomplete data (Li et al., 2017; Nikovski, 2000). Therefore, it is reasonable to establish a Bayesian model that can learn the internal laws and conditional probability from incomplete datasets.

4 ESTABLISHMENT OF TAN BN

4.1 Structure of the BN

The initial phase in constructing a Bayesian Network (BN) involves determining its network structure, a process that demands careful consideration of the conditional independence and dependency relationships among various input parameters. Once the BN structure is defined, the next crucial step is to establish the degree of correlation between input parameters, specifically, the conditional probability of one parameter given another (David and Heckerman, 1997). For the sake of predicting the surrounding rock quality based on BN. The surrounding rock quality in the work is divided into five levels (I, II, III, IV and V) according to the RMR system (Bieniawski, 1988). The RMR value calculated by the tunnel engineer on site and reviewed by the tunnel expert is set as Y. Similarly, the evaluation parameters can be represented as X= (GWC, GWA, TD, TI, TN, MTL, ATI, WIA, UCS WD and TBD) in the incomplete multi-source TFF dataset. Then, the 140 sets of available data in the multi-source TFF dataset are collected to train the BN established in this work. It is usually arduous to achieve in the application of rock mass quality prediction, as some parameters measured from rock mass are generally not independent of each other. To address this limitation, a novel TAN BN is proposed in this paper. To determine the structure of tree augmentation, correlation analysis is conducted between eleven parameters in the multi-source TFF dataset. The correlation analysis results are demonstrated in Figure 4, which illustrate that the correlations between GWA and GWC, TI and TD, TN and ATI are 0.645, 0.503, -0.788. The absolute value of correlation between other parameters are less than 0.5, indicating a low mutual influence between them (Dancey, 2007; Loozen et al., 2013).

Figure 4. The correlation analysis results of the eleven parameters in the established multi-source TFF dataset.

Therefore, considering the correlation analysis results between the eleven parameters, the TAN BN is selected to improve the prediction performance of surrounding rock quality in this work (Friedman et al., 1997). A tree structure is employed to approximate the interaction between different parameters, where each parameter has a maximum of two parent nodes (Jiang et al., 2005). The structure of the TAN BN applied in this work is illustrated in Figure 5, this network can learn the information of eleven parameters in the multi-source TFF dataset. The reason for TAN BN introduced is that its prediction precision is higher than that of naive Bayesian classifier, and its structure is also relatively simple (Li et al., 2017). It should be emphasized that not all groups of data in this multi-source TFF dataset have complete eleven parameters, and some data groups have less than 140. However, the TAN BN proposed in this work still has the ability to learn CPTs from incomplete datasets and achieve prediction of surrounding rock quality.

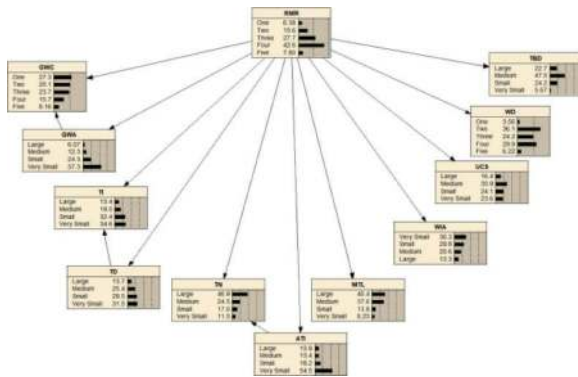

Figure 5. The framework of the proposed TAN BN.

4.2 Training and validation of BN

The TAN BN model established can learn the inherent laws of eleven parameters in the incomplete multi-source TFF datasets. To be specific, Netica software (Corporation, 1998) and expectation maximization (EM) algorithm (Dempster, 1977) are applied to assess the quality of rock mass. Simultaneously, the conditional probability between different nodes in the TAN BN can also be investigated. Next, import multi-source TFF datasets into BN for training and validation. The training result of the TAN BN is described in Figure 5. The validation set of the multi-source TFF dataset consists of 28 sets of data, and the confusion matrix of the validation results based on the proposed TAN BN is described in Figure 6. The diagonal data in this table represents correctly predicted data and its prediction precision is 92.9%, which demonstrates the effectiveness of our proposed TAN BN in this work.

Figure 6. Validation result of the proposed TAN BN.

5 TEST PROCESS AND DISCUSSION

5.1 Test with new cases

To assess the efficacy of the proposed TAN BN with a novel dataset derived from a tunnel site, 27 sets of data are newly acquired through the application of the improved ST and geological sketches from the Qingdao Jiaozhou Bay Second Submarine Tunnel. These datasets are subsequently employed in the testing phase of the TAN BN, and the resultant test outcomes are delineated in Figure 7. Notably, only three cases out of the 27 are predicted inaccurately, yielding a prediction precision of 89%. This outcome underscores the precision and reliability of the TAN BN model established in this study. However, it is imperative to emphasize the limitations inherent in the actual surrounding rock quality of the tunnel under excavation. It is crucial to acknowledge that it does not encompass the entire spectrum of RMR levels.

Figure 7. Test results of surrounding rock quality in actual tunnel cases.

5.2 Sensitivity analysis

For the sake of measuring the influence of different parameters on the output results of the TAN BN, this work conducted sensitivity analysis of eleven parameter in the multi-source dataset. The commonly used mutual information (MI) (Shannon and Weaver, 1949) and variance reduction (VR) (Pearl, 1991) in Netica software are employed to evaluate the contribution rates of eleven input parameters. Furthermore, the impact of input parameters on rock mass quality is comprehensively measured by MI and VR from two dimensions: mutual influence and error reduction. And the sensitivity analysis results based on Netica software are presented in Table 3.

The “percentage” list shows the contribution percentage of each input node to the “RMR” node; For example, the contribution rate of the node “ATI” to the overall mutual information is equal to 20.6%, which is calculated as $0.41136/1.99604 \times 100\%$, ATI has the highest contribution rate to the overall mutual information among all input parameters. The contribution rate of node TN to Variance Reduction is 18.6%, and its calculation process is $0.37174/1.99604 \times 100\%$, ATI has the highest contribution rate to Variance Reduction. The above results indicate that ATI and TN are the parameters that have the greatest impact on the RMR of rock tunnel surrounding rock.

Table 3. Sensitivity analysis results of various parameters in the TAN BN.

Parameters	Mutual Information	Percent (%)	Variance Reduction	Percent (%)
ATI	0.41136	20.6	0.0711840	13.7
TN	0.37174	18.6	0.0643037	12.4
TD	0.22369	11.2	0.0288107	5.6
UCS	0.18647	9.34	0.0100531	1.9
TBD	0.18112	9.07	0.0162280	3.1
MTL	0.12540	6.28	0.0070414	1.3
GWA	0.11189	5.61	0.0083081	1.6
WIA	0.11081	5.55	0.0132595	2.6
WD	0.09691	4.85	0.0077459	1.5
TI	0.08634	4.33	0.0067288	1.3
GWC	0.08486	4.25	0.0059351	1.1

6 CONCLUSION

An improved ST is applied to achieve the task of quantitatively segmenting the characteristic parameters. A multi-source dataset containing CV parameters, physical and mechanical parameters, and design parameters is established. A novel BN is proposed to predict rock masses quality.

Firstly, a multi adaptive electronic image acquisition system and an TFF imageset are established. And the ST model is improved to incorporate the advantages of Unet structure being more sensitive to

small-scale features. Extensive experiments demonstrated that the improved CV mode significantly outperformed the previous state-of-the-art methods.

Secondly, to evaluate the surrounding rock quality, eleven parameters are considered to build a multi-source TFF dataset. Some parameters in this multi-source TFF dataset are incomplete.

Third, a novel TAN BN is proposed to overcome the drawback of incomplete dataset and predict the probability of rock mass quality given (probably partial) information in the multi-source TFF dataset. The TAN BN is learned, with the aid of EM algorithm, using an incomplete database with 140 sets of parameters. The validation accuracy of the learned TAN BN is 92.9%. Testing results illustrate that the prediction precision of the rock mass quality is 89%.

Ultimately, a sensitivity analysis to identify the input parameters with a higher influence on rock mass quality has been conducted. Results suggest that ATI is the most influential parameter.

ABSTRACT: Soil conditioning plays a crucial role in shield excavation. This paper presents a systematic set of intelligent machine learning-based methods for soil conditioning in shield excavation, focusing on data, algorithms, and applications. Additionally, an active learning-based uncertainty quantification strategy is proposed to understand the reliability of the model prediction results without knowing the true value. The results demonstrate that (1) feature engineering and the selection of machine learning models offer a framework and methodology for automated research on soil conditioning in earth pressure balance (EPB) for data and algorithm perspectives, respectively. (2) Machine learning for soil conditioning should fully consider the influence of historical soil conditioning parameters on the prediction results. (3) The active learning-based uncertainty quantification strategy possesses exceptional capabilities in identifying the reliability of model prediction results. This can effectively enhance the application of machine learning for the automation of EPB shield tunneling.

Keywords: EPB shield tunnel, Soil conditioning, Feature engineering, Machine learning, Time-sequence problem, Uncertainty quantification

1 INTRODUCTION

EPB shield machines, favored for safe, efficient, and cost-effective underground subway tunnel construction in cities, transform excavated soil into a paste-like support medium. This paste balances pressure at the tunnel face, blocks unintended soil inflow, and facilitates quick, settlement-free tunneling (Hu et al. 2020). However, in complex strata, EPB machines face challenges like cutterhead “mud cake,” rapid cutter wear, screw conveyor blockages, difficult soil discharge, and severe pressure fluctuations. Adapting these machines to various strata necessitates soil with suitable fluidity, plasticity, and compressibility.

Soil conditioning is thus crucial (Vinai, Oggeri, and Peila 2008, Wang et al. 2021).

Significant advancements have been made in soil conditioning technologies (Mori, Mooney, and Cha 2018), with soil additive injection emerging as the most effective. These additives are categorized into water, foam, dispersants, clay minerals, and flocculants. While water and foam suit many strata, dispersants, clay minerals, and flocculants target specific conditions like high viscosity, particle scarcity, and water-abundant coarse grains, respectively. These insights guide engineers in additive selection, yet precise, real-time adjustments in their use remain a challenge.

*Corresponding author: 17310169484@163.com

Lab and on-site experiments are the main methods to study soil conditioning, yet they tend to trail behind the actual shield excavation's progress. Differences in pressure and void conditions between lab-tested soils and those in actual excavation environments complicate the application of these results in the field. Consequently, engineers and operators typically depend on past experience for decision-making. This reliance on human judgment for operating complex machinery like EPB machines presents risks. There's a pressing need in shield engineering for innovative, automated solutions to enable precise and efficient decision-making in soil conditioning.

Machine learning offers a revolutionary approach to improving soil conditioning practices in shield tunneling. Various machine learning algorithms have proven effective in addressing challenges in mechanized tunneling engineering. These include predicting ground settlement induced by excavation (Zhang, Chen, and Wu 2019), stratigraphic conditions (Zhao and Wang 2020), and predicting mechanical parameters such as shield thrust (Kong et al. 2022), cutter torque (Cachim and Bezuijen 2019), excavation speed (Shangxin et al. 2021), and soil chamber pressure (Gao et al. 2020). In the context of soil conditioning, Lin et al. (Lin et al. 2022) compared various machine learning models, finding the random forest algorithm to be particularly effective. Despite these advancements, numerous unanswered questions remain in achieving automated soil conditioning during EPB shield tunneling.

This research focuses on developing a comprehensive machine-learning workflow for soil conditioning in EPB shield tunneling, illustrated with a case study from a construction site. It delves into crucial steps of data-driven soil conditioning, including feature engineering for noisy on-site data, model selection, and uncertainty quantification.

2 BACKGROUND OF THE PROJECT

This research utilizes a construction project from Hefei's No. 7 subway line in Anhui Province to demonstrate a machine-learning approach to soil conditioning in EPB shield tunneling. The shield machine deployed here has a 6.48-meter diameter and can boring 4 to 10 rings daily, each approximately 1.5 meters long. Its data acquisition system captures 206 parameters, including both active (shield thrust, foam injection, screw conveyor speed, etc.) and passive (cutter and screw conveyor torque, etc.) control parameters, recorded at one-minute intervals throughout the excavation, lining installation, and shutdown phases.

The initial 100 rings of the tunneling process, identified as the shield driver's adjustment phase, often show irregular data patterns. Thus, for machine learning, data from rings 100 to 530 are used, amounting to 255,323 raw data samples. However, the sparsity of geological boreholes, compared to the continuous tunneling, leaves many locations with unknown geological parameters. To address this, linear interpolation is

employed to estimate these parameters between boreholes, based on the assumption of consistent geological characteristics within the same stratum. This approach ensures each excavation data set is paired with corresponding geological parameters for machine learning analysis.

3 FEATURE ENGINEERING

The efficacy of a machine learning model is capped by the quality of its data. Transforming raw, unprocessed data into a format that more effectively reveals underlying patterns, feature engineering is a crucial phase in the machine learning process. Properly executed, it enables the model to extract accurate information from data, significantly enhancing its predictive power.

3.1 Data preprocessing

3.1.1 Identifying missing values

Data gaps due to equipment issues or human errors can skew model training. This study fills missing values with averages of neighboring data, assuming proximity in value.

3.1.2 Stable excavation section identification

A significant portion of the shield machine's data, recorded every minute, includes non-excavation phases. For example, only 180 out of 1,361 data sets recorded in the 160-165 ring rang were relevant to excavation. Direct use of such imbalanced data can bias the learning process and strain computational resources. By analyzing the excavation process, non-representative beginning and end sections are excluded, reducing the data from 255,323 to 4,305 sets for efficient machine learning.

3.1.3 Outlier detection

Outliers, identified traditionally by box plots or normal distribution, are located using K-Means clustering and the "3 σ principle." This approach addresses multivariate data outliers, with the optimal number of clusters determined based on the objective function's response to varying cluster numbers.

3.1.4 Noise reduction in excavation data

Vibrations from the shield cutterhead create noise in sensor data. This study employs the Butterworth filter for noise reduction, with the filter order and cutoff frequency tailored to the dataset. The Fourier transform and energy spectral density graph help determine the optimal cutoff frequency, enhancing data quality for analysis.

3.2 Feature selection

Once data is pre-processed, feature selection focuses on identifying key elements crucial for soil conditioning. These are categorized into tunneling and geological parameters. Informed by an understanding of

tunneling dynamics, nine tunneling parameters pertinent to soil conditioning are chosen: cutterhead rotation speed, cutter torque, average soil pressure in the excavation chamber, shield excavation speed, penetration rate, shield thrust, screw conveyor rotation speed, screw conveyor torque, and soil pressure as measured by sensors on the screw conveyor. Geological parameters encompass all features detailed in the geological survey report.

3.2.1 Min-Max scaling for data

To ensure model prediction accuracy isn't skewed by varying feature magnitudes, Min-Max Scaling is employed for feature normalization. This scaling technique adjusts all feature values to fall within a [0,1] range, maintaining proportionality while equalizing scale.

3.2.2 Ranking feature importance

(1) Principle of feature selection

To address the shortcomings of the traditional boosting algorithm, which is less efficient in the environment of large-sample and high-dimensional data, Ke et al. (Ke et al. 2017) proposed a new type of boosting algorithm, Lightgbm, which introduces GOSS (Gradient-based One-Side Sampling) and EFB (Exclusive Feature Bundling) techniques on the basis of the original boosting algorithm., Gradient-based One-Side Sampling) and EFB (Exclusive Feature Bundling) techniques. The GOSS technique removes most of the data with small gradients and uses only the remaining small portion for the estimation of information gain, thus avoiding the influence of the long-tailed portion of the low gradients. The EPB technique refers to the bundling of the mutually exclusive features to reduce the number of features. In addition, the lightgbm model also uses Histogram and Leaf-wise strategies to greatly improve the prediction speed of the model. The Histogram strategy (Figure 1) directly saves the discretized values of the features, which greatly reduces the memory usage. Leaf-wise is a more efficient leaf-splitting and growing strategy, which, compared with the conventional splitting by layers, the strategy each time from all the current leaves, to find the split gain of the largest leaf split again, and so on, its splitting process is shown in Figure 2.

Figure 1. Histogram algorithm.

Figure 2. Leaf wise grown strategy.

(2) Feature selection method

Step 1, take shield tunneling parameters and geological parameters as input parameters and target parameters as output parameters.

Step 2, use Lightgbm algorithm to establish the regression model, and adjust the hyper-parameters of the model to improve the accuracy.

(a) Tunneling parameters (a: the rotation speed of cutterhead; b: the average soil pressure in the excavation chamber; c: shield thrust; d: the rotation speed of the screw conveyor; e: cutterhead torque; f: penetration rate; g: the torque of the screw conveyor; h: soil pressure on the surface of the screw conveyor; i: shield excavation speed)

(b) Geological parameters (A: natural water content; B: saturation; C: liquid limit; D: modulus of compressibility; E: frictional angle; F: cohesion; G: plasticity index; H: plastic limit)

Figure 3. Feature importance ranking via the Lightgbm algorithm.

Step 3: After determining the optimal model, machine learning is carried out, and the weights of the shield tunneling parameters and geological parameters are output in the model and sorted accordingly.

The final feature importance ranking is shown in Figure 3.

3.2.3 Feature correlation analysis

To streamline the input features for machine learning and boost efficiency, the study conducts feature correlation analysis, building upon the feature importance outlined in Section 3.2.2. This involves using the Pearson correlation coefficient method to evaluate relationships between shield tunneling and geological parameters. Features exhibiting strong correlations (Pearson coefficient absolute value over 0.8) and validated physical linkages see less important ones removed.

4 MACHINE LEARNING MODELS FOR DECISION-MAKING OF SOIL CONDITIONING SCHEMES

Various machine learning models, each adept at different mapping relationships, are evaluated for their suitability in addressing soil conditioning challenges in shield tunneling. Considered models include:

- Gradient Boosting Decision Tree (GBDT): An iterative approach using decision trees, GBDT is effective in both classification and regression. It aggregates outcomes from multiple trees to derive final results.
- Adaptive Boosting (AdaBoost): Similar to GBDT and part of the Boosting ensemble method, AdaBoost refines the model by adjusting weights of incorrectly classified data, while GBDT focuses on negative gradients for improvement.
- Random Forest: This ensemble method involves random data sampling for multiple decision trees (weak learners), with their predictions combined through voting for the final output.
- K-Nearest Neighbor (KNN): KNN identifies the nearest neighbors of a new sample and predicts its value based on the average target values of these neighbors.
- Support Vector Machine Regression (SVR): SVR constructs regression models using the principles of support vector machines. It aims for optimal hyperplane fitting, differing from traditional regression methods.

Each model is trained with the best hyperparameters, identified through Bayesian optimization (up to 50 iterations). Given the foam's persistence in the excavation chamber, historical

soil conditioning parameters (e.g., foam liquid and air flow) are considered in two distinct training strategies. Model performance is evaluated using the decision coefficient R^2 and the variance of prediction error σ^2 (Equations (1) and (2)). Higher R^2 values (near 1) and lower σ^2 values indicate better model performance and more stable error variation.

$$R^2 = 1 - \frac{\sum_{i=1}^n (y_i - f(x_i))^2}{\sum_{i=1}^n (y_i - \bar{y})^2} \quad (1)$$

$$\sigma^2 = \sum_{i=1}^n \left((y_i - f(x_i)) - \frac{\sum_{i=1}^n (y_i - f(x_i))}{n} \right)^2 / n \quad (2)$$

where y_i represents the actual values of the sample points, $f(x_i)$ denotes the model's predictions, \bar{y} is the average true value across all samples, and n indicates the total number of samples in the test set.

Table 1 presents the predictive outcomes of various machine learning models, leading to the following insights:

- Incorporating historical soil conditioning parameters substantially enhances the performance of all machine learning models.
- With the addition of historical parameters, all models exhibit comparable R^2 , suggesting that high-quality input data enables different models to achieve similar predictive accuracy.
- Despite achieving similar predictions, there are minor variations in σ^2 , indicating differences in prediction error stability. The Gradient Boosting Decision Tree (GBDT) model shows the lowest prediction error variance (σ^2), making it the most stable option.

Table 1. Comparison of predictive outcomes across various algorithms.

Algorithm	R^2 (without historical variables)	σ^2 (without historical variables)	R^2 (with historical variables)	σ^2 (with historical variables)
GBDT	0.8736	0.3324	0.9991	0.0023

5 COMMITTEE ACTIVE LEARNING-BASED UNCERTAINTY ASSESSMENT IN MODEL PREDICTIONS

Machine learning models, typically trained and validated on familiar data distributions, face uncertainty when applied to construction projects with unknown data distributions. It's often unclear if these models will make interpolative or extrapolative forecasts (Guo et al. 2023). This uncertainty about the reliability of predictions hinders the transformative impact of advanced machine learning in soil conditioning and automated EPB shield tunneling. To tackle this problem, this section introduces an active learning strategy for estimating the uncertainty of machine learning predictions, enhancing confidence in addressing real-world engineering problems.

5.1 Overview of active-learning for uncertainty estimation

The core idea of this study is that the accuracy of a model's prediction is proportional to the scope of its training data. The wider the data space, the more intrinsic laws the model learns and the more accurate its predictions of unknown data. Machine learning models rely on a large number of training parameters, but usually have only one objective function. As a result, model training results vary for different initial parameter values. If multiple models give similar and consistent predictions with the same training set and hyperparameters but different random seeds, the predictions are considered reliable. On the contrary, if the prediction results vary widely, it indicates that the model has not sufficiently learned the relevant laws and its prediction reliability is low. The steps of the method are shown in Figure 4.

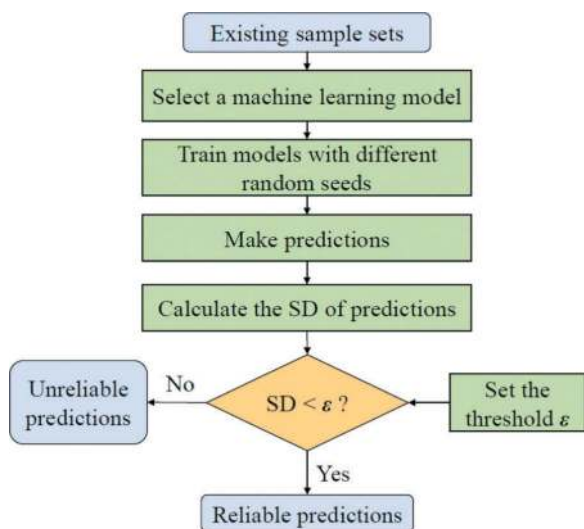

Figure 4. Active learning-based uncertainty recognition flow chart for model predictions.

5.2 Validation of the uncertainty assessment approach

In this study, in order to validate the effectiveness of the proposed uncertainty estimation method based on active learning, a dataset in the Geng-Qing interval was selected for the experiment. The 10% sample points with the largest and smallest variance were compared and analyzed. The results (see Table 2) show that with the same number of agent models, the average relative prediction error of the 10% samples with larger variance is always higher than that of the samples with smaller variance. In addition, as the number of agent models increases, the error of the sample with larger variance increases while the error of the sample with smaller variance decreases. This demonstrates the link between the standard deviation among agent models and prediction accuracy.

The ranking relationship between standard deviation and relative error was further analyzed for different numbers of agent models. As shown in Figure 5, when the number of agent models is small, the relationship between the two is not obvious. However, as the number of models increases, the relationship becomes clearer, showing a positive correlation. By defining the effective prediction region (defined by $y=0.7x$ vs. $y=1.3x$), it is observed that as the standard deviation increases, the number of effective prediction points falling within this region also increases, indicating that the relative error ordering of the sample points is roughly in line with the standard deviation ordering, and the error range is controlled to be within 30%.

Table 2. Analysis of predictive precision across diverse agent model quantities.

Number of agent models	Relative prediction error across diverse agent model quantities (%)	
	10% of data points exhibiting the lowest standard deviation	10% of data points featuring the highest standard deviation
3	0.0094	0.0519
4	0.0087	0.0525
5	0.0084	0.0529
20	0.0034	0.0958
50	0.0033	0.0975
100	0.0033	0.1043

6 CONCLUSIONS

This study explores the intelligent enhancement of EPB, focusing on three key challenges in shield soil conditioning: (1) Strategies for supplying high-quality data to machine learning models, (2) Selecting appropriate machine learning models for EPB soil conditioning based on engineering field data, and (3) Methods for assessing the accuracy of model predictions in the absence of known true values and deciding if expert

(a) 3 agent models

(b) 20 agent models

(c) 100 agent models

Figure 5. Correlation between standard deviation and relative prediction error across diverse agent model quantities.

input is necessary for further guidance. Key discoveries of the research are outlined below.

The paper presents a systematic approach to feature engineering for EPB soil conditioning, establishing a foundational framework for machine learning data processing. This approach enhances the effectiveness of subsequent machine learning models.

Using data-driven correlation analysis, the underlying mapping rules between parameters in shield tunneling can be effectively revealed, and the strong and weak correlations within parameters can be quantitatively judged. In addition, on the basis of considering the existence of a certain time stability of the foam, comparing the machine learning performance of soil conditioning under different test conditions, it is found that the inclusion of historical soil conditioning parameters can significantly improve the model performance..

In terms of model selection, GBDT, despite having similar efficacy to other common models, shows the lowest variance in prediction error, indicating more stable errors. Therefore, GBDT emerges as the most suitable machine learning model for soil conditioning.

The research demonstrates the effectiveness of an active learning-based uncertainty identification strategy. This approach is particularly advantageous in scenarios where it's uncertain if the distribution of the dataset to be tested aligns with the training set. It enhances engineers' confidence in the predictions of machine learning models and aids in their practical application in significant projects.

ABSTRACT: Underground structures like tunnels and caverns have major advantages in hydropower projects. Tunnels are used for transporting the water from the intake to the tailrace outlet through the turbines whereas caverns primarily serve the purpose of powerhouse, transformer caverns, and settling basins. The site selection of the underground cavern is an important task to be considered to optimize the rock support and cost. Design aspects regarding stability and functionality are governed by the location, orientation, shape, and size of the caverns. Similarly, the choice of support for a particular geological condition and type and quality of rock mass needs to be carefully assessed during planning and implemented during the construction. This article discusses the location design and rock support requirement of the underground powerhouse cavern of the Super Dordi Hydropower Project in Nepal. The project lies in the lower boundary of the Higher Himalayan rock formation. The powerhouse cavern has a length of 39 m and has width (span) and height of 14.5 m × 28 m, respectively. The rock support measures predicted during planning are modelled using 2D numerical modelling tools. The study on monitored data and numerically modelled data are compared and discussed.

Keywords: Underground Space, Support Characteristics, Deformation, Powerhouse Cavern, Himalayan Rock Mass

1 INTRODUCTION

The use of underground spaces has significantly increased in various engineering projects. The development of underground spaces has advantages like no impact on the landscape, very little or almost no disturbance to the surface human activities and resources, higher safety level, etc. It is particularly important in places where natural hazards like landslides and earthquakes are bound to occur. Nepal, a mountainous country, suffers various hazards posing a challenge to develop various infrastructure projects. Having a high potential for hydropower development, the sustainable development of the various structures for hydropower

plants is the major issue to be addressed by the engineers in Nepal. The best alternative to protect structures from natural calamities like landslides and earthquakes is to make the components underground. The varied geological conditions and challenging terrains demand special attention to the construction of underground structures in Nepal. The tectonically active rock mass in the Himalayan region has the presence of weak, highly deformable, and anisotropic rock mass with a high degree of weathering and fracturing (Panthi and Nilsen, 2007), posing challenges for the construction of tunnels and caverns. Location, orientation, geometry, complexity of access tunnels, and geological conditions are major factors to be considered

*Corresponding author: sailesh.adhikari@ntnu.no

during the evaluation of stability and planning of underground structures (Rathore and Panthi, 2017). Project-specific characteristics like size, shape, location, and orientation influences the design of caverns and tunnels. (Panthi, 2006). Further, the stability is dependent on the rock mass quality, in-situ stress, and groundwater conditions.

The Himalayan Mountain series was formed due to the subduction of the Indian plate to the Tibetan plate. There are five major subdivisions of the tectonic boundaries in the Himalayan region. The major subdivisions from the southern belt towards the northern belts are the Gangetic plane (Terai), Siwaliks zone, Lesser Himalayan zone, Higher Himalayan zone, and Tibetan-Tethys zone. These divisions span approximately in the NW-SE directions. The subdivisions are separated by the boundaries of the main frontal thrust (MFT), main boundary thrust (MBT), and main central thrust (MCT). These tectonic zones are all characterized by special lithology, tectonics, geological structures, and geological history and are made up of different rock types (Panthi, 2006). Figure 1 shows the simplified geological map of Nepal with the geological and tectonic boundaries.

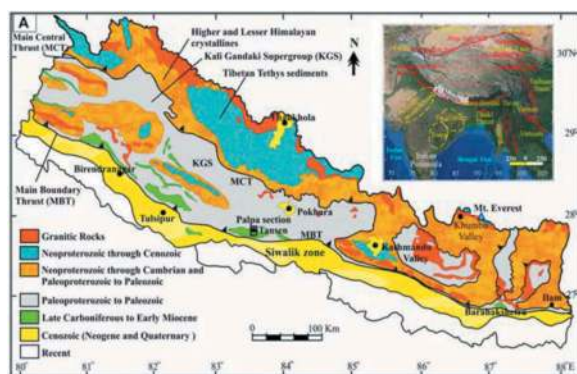

Figure 1. Geologic subdivisions of Himalayas (ref. Khatri et al., 2021).

In the lower boundary of higher Himalayas, i.e. near MCT (project site location of the present case study) the rocks of highly sheared, intensely deformed, and mylonitized green-schist and schistose mica gneiss are present (Robyr et al, 2002). Rock masses in the Himalayan region are influenced by faulting, folding, schistosity, and jointing to varying degrees representing geological complexity (Basnet and Panthi, 2020). In underground openings, the excavation-induced response of the rock mass may arise instability conditions. This paper discusses the design and support estimation of the powerhouse cavern of Super Dordi Hydropower Project (SDHP) located in Lamjung district of Nepal. The project lies in the higher Himalayas zone about 10 km north of MCT. The dimension of the powerhouse cavern is about 39 m × 14.5m × 28m. The powerhouse cavern has an arched roof and vertical walls. The dimensions of the powerhouse were optimized to

accommodate the turbine, distribution pipes, and other construction areas based on the dimensions of the various machinery components.

2 BRIEF DESCRIPTION OF THE PROJECT

SDHP is a run-of-river type hydropower project with an installed capacity of 54 MW. The project has a gross head of 638 m. The project lies in the lower boundary of the higher Himalayan rock formation and facilitates a diversion weir (18.5 m long) and intake, double-chambered underground settling basin caverns (each having approximate cross-section area 113 sq. m), gravel trap (33.5 m long), headrace tunnel (4.7 km long), access tunnels, surge shaft (49 m high and 6 m diameter), penstock shafts (1052 m long), powerhouse cavern, and tailrace tunnel. Most of the civil structures of the project are underground except the diversion weir and switchyard. The project area consists of medium to high-grade metamorphic rocks like schist and gneiss and the feasibility study showed that there was no severe geological risk associated with the project (PHCPL, 2012). Figure 2 shows the project layout plan of SDHP with the location of different components of the hydropower project.

Initially, the powerhouse was proposed to be at the surface instead of underground. However, during the earthquake in April 2015, there was a small landslide near the uphill area of the old powerhouse site. The powerhouse will store heavy machinery and expensive equipment; thus, it was too risky to build the powerhouse on the surface. Eventually, it was decided to build the underground powerhouse instead of the surface powerhouse (Panthi, 2018). During construction, a shear band of about 10 to 20 cm was encountered near the powerhouse cavern location. The cavern location was further pushed by about 40m inside the mountain to minimize the impact. The alignment of underground structures is an important parameter to be addressed during the construction of tunnels and caverns. Poor alignment will lead to unusual overbreak, water ingress, and increased risk to health and safety (Katuwal et al., 2023). The rock mass encountered in the powerhouse cavern was of good quality. Two main joint sets with occasional random joints were mapped. These joints have medium persistence, spacing varying between 2.5 to 3m, and tight fillings with clay and silt. The orientation of the powerhouse cavern is N45E and is favourable in terms of major joint sets. Figure 3 shows the joint rosette with a cavern length axis (Panthi, 2018). The rock mass was relatively dry in the powerhouse area with exceptions in the locations from chainage +025 to +030m where minor dripping of water was seen causing dry to damp conditions. The site selection of the powerhouse cavern is suitable in terms of major critical factors influencing the stability and support systems applied in the cavern.

Figure 2. Project layout of SDHP.

Figure 3. Joint rosette of the powerhouse cavern.

3 ROCK MASS QUALITY PARAMETERS

The rock parameters are established based on the geological mapping, laboratory test results of the intact rock, and some empirical relationships. Rock mass strength and deformation modulus, and choice of failure criteria govern the design of underground caverns. The geometry and rock support provided for the powerhouse cavern are shown in Figure 4. The three-layer fiber-reinforced shotcrete, with a final thickness of 15 to 20 cm depending upon rock condition and systematic bolting was provided as rock support. The rock bolts were installed in two stages. The first stage consisted of 5 m long cement grouted rock bolts of 25 mm diameter placed at the staggered arrangements at the spacing of 3m. In the second stage, 8 m long cement grouted rock bolts with 25 mm diameter were provided at a spacing of 3 m in a staggered pattern.

3.1 Intact rock properties

The laboratory results of the rock core samples from the project area show the mean uniaxial compressive strength of the samples was 112.6 MPa with a standard deviation of 8.65 MPa. Similarly, Young's modulus was 48.53 GPa with a standard deviation of 5.05 GPa. The average Poisson's ratio of the intact rock was 0.33 and the unit weight of the rock was found to be 2.7 t/m³.

3.2 Rock mass properties

The strength and deformability properties of the rock mass are important parameters for modelling the tunnels and caverns. Additionally, the presence of weakness zone, shear zone, and 3D topography are influencing parameters to model the caverns (Adhikari et al. 2022).

3.2.1 Rock mass quality

The rock mass quality was assessed using Q-system of rock mass classification (Barton et. al., 1974). Table 1 shows the range of values and typical mean for the different parameters mapped at the cavern for the determining overall rock mass quality class.

The Q value of the rock mass ranges from 10 to 12 with the typical mean value of 10.5. This indicates the rock mass at the powerhouse cavern is of good quality.

3.2.2 Compressive strength of rock mass

Various researchers have provided different relationship between intact rock strength and rock mass strength. The most common ones are Bieniawski (1993), Hoek et al. (2002), Barton (2002) and Panthi (2017), listed in Equations 1 to 4, respectively.

$$\sigma_{cm} = \sigma_{ci} \times \exp\left(\frac{RMR - 100}{18.5}\right) \text{ and } RMR = 9 \times \ln Q + 44 \quad (1)$$

$$\sigma_{cm} = \sigma_{ci} \times \left[\exp\left(\frac{GSI - 100}{9}\right) \right]^a \quad (2)$$

$$\sigma_{cm} = 5\gamma \left[\frac{\sigma_{ci}}{100} \times Q \right]^{1/3} \quad (3)$$

$$\sigma_{cm} = \frac{\sigma_{ci}^{1.6}}{60} \quad (4)$$

The results of the rock mass strength achieved by the above relationships is illustrated in Figure 5. Based upon the field mapping results and site conditions the value of GSI was considered 60.

It can be seen from Figure 5 that the empirical relationships from Bieniawski (1993) and Hoek et al. (2002) give a lower value for the rock mass strength whereas the empirical relationships by Barton (2002) and Panthi (2017) give a higher values. For the

Figure 4. Support system provided in powerhouse cavern.

Table 1. Q-system of rock mass classification.

Parameters	Symbol	Value	
		Range	Typical Mean
Rock Quality Designation	RQD	60 – 80	70
Joint Set Number	J_n	3 – 6	4
Joint Roughness	J_r	1.5 – 3	2
Joint Alteration	J_a	2 – 4	3
Joint Water Reduction	J_w	0.8 – 1	0.9
Stress Reduction Factor	SRF	1	1
$Q = \frac{RQD}{J_n} \times \frac{J_r}{J_a} \times \frac{J_w}{SRF}$		10 – 12	10.5

homogeneous and relatively strong rock mass like at SDHP, the relationship between the intact rock strength and the strength of rock mass provided by Panthi (2017) is considered to be relevant and applicable. Unlike other relationships to compute the rock mass strength, the relationship is mainly based on lab-tested data and has no dependency on the rock mass classification system. Hence, the method eliminates the dependency on several other subjective parameters that depend upon the judgment of the engineer. Thus, an average rock mass strength is taken as 31.94 MPa for further analysis.

Figure 5. Rock mass strength by empirical relationship.

3.2.3 Deformation modulus of rock mass

The deformation modulus of the rock mass is also computed by the empirical relationship owing to the higher cost and measurement difficulties in the in-situ conditions. Like the compressive strength of rock mass, various researchers have provided the empirical formula to calculate the deformation modulus of rock mass. The relationship established by Bieniawski (1978), Hoek et al. (2002), Barton

(2002), and Panthi (2006) is given from Equations 5 to 8 respectively.

$$E_m = 2RMR - 100 \quad (5)$$

$$E_m = \left(1 - \frac{D}{2}\right) \sqrt{\frac{\sigma_{ci}}{100}} 10^{\left(\frac{GSI-10}{40}\right)} \quad (6)$$

$$E_m = 10 \times \left(\frac{Q \times \sigma_{ci}}{100}\right)^{1/3} \quad (7)$$

$$E_m = E_{ci} \times \left(\frac{\sigma_{cm}}{\sigma_{ci}}\right) \quad (8)$$

In the above equation, E_m is the deformation modulus of rock mass, E_{ci} is the Youngs' modulus of the intact rock and σ_{ci} is the strength of the intact rock. The value of the deformation modulus obtained from the empirical relationship is illustrated in Figure 6. It is observed that the relationship provided by Bieniawski (1978) provides the highest value of the deformation modulus and the relationship by Hoek et al (2002) and Panthi (2006) provides almost similar values. In this article, the deformation modulus obtained from Equation 8 proposed by Panthi (2006) is considered. The relationship is more suitable for the isotropic, homogeneous, and massive rock mass from the Himalayas. The deformation modulus of the rock mass computed is 13.76 GPa and is used as an input parameter for the numerical modelling of the cavern.

Figure 6. Deformation modulus by empirical relationship.

3.3 Hoek Brown parameters

GSI values are calculated by using the Q-systems' parameters using the following relationship (Hoek et al., 2013).

$$GSI = \frac{52(J_r/J_a)}{1 + (J_r/J_a)} + \frac{RQD}{2} \quad (9)$$

GSI was computed in the range of 53 to 63, which also matched the field mapping results to compute GSI. Hoek-Brown constant m_b , s and a are dependent upon the rock mass characteristics. These parameters are computed using the relationship from Equation 10 – 12.

$$m_b = m_i \times e^{\left(\frac{GSI-100}{28-14D}\right)} \quad (10)$$

$$s = e^{\left(\frac{GSI-100}{9-3D}\right)} \quad (11)$$

$$a = \frac{1}{2} + \frac{1}{6} \left(e^{-\frac{GSI}{15}} - e^{-\frac{20}{3}} \right) \quad (12)$$

Based on the site conditions during excavation and the chart provided by Hoek (2007), the value of the disturbance factor (D), which is dependent upon the blast damage to the contour is considered 0.6. Similarly, a GSI value of 60 and m_i value of 23 are considered to obtain the m_b , s , and a parameter. The residual GSI is assumed to be 20.

The values obtained for the disturbed and undisturbed zone are ($m_b = 5.512$, $s = 11.7 \times 10^{-3}$ and $a = 0.503$) and ($m_b = 2.998$, $s = 3.86 \times 10^{-3}$ and $a = 0.503$), respectively.

4 EVALUATION OF ROCK STRESSES

The in-situ rock stresses are generated due to the combination of gravitational load with tectonic stresses, topographic stresses, and residual stresses. According to Panthi (2012), the vertical and horizontal stresses on the rock mass can be computed as:

$$\sigma_v = \gamma H \quad (13)$$

$$\sigma_h = \frac{\nu}{1 - \nu} \times \sigma_v + \sigma_{tec} \quad (14)$$

In the above equations, γ is the density of the rock, H is the overburden height, ν is the Poisson's ratio, and σ_{tec} is horizontal the tectonic stress in the rock mass.

In-situ stresses are measured by different methods like hydraulic fracturing, flat jack test, 3D overcoring test, etc. For the horizontal tectonic stress, no direct test was performed in the field. Instead, the horizontal tectonic stress of 4.5 MPa was assumed based on the tectonic stress of the headrace tunnel of the Upper Tamakoshi Hydropower Project (UTHP) (Panthi and Basnet, 2018) and Parbati-II Hydropower Project (Panthi, 2012) located in a similar tectonic regime and geological formation of the Higher Himalaya (Adhikari et al., 2023). From the World stress map the orientation of the tectonic stress is approximately N10E at the project location site. The

total horizontal stress is computed by resolving the tectonic stress and the horizontal stress due to gravity. Figure 7 shows a simple illustration of the computation for in-plane and out-of-plane horizontal stresses acting on the cavern. The angle between the horizontal tectonic stress regime and the cavern is 35°. The in-plane horizontal stress and out-of-plane horizontal stress are given by Equation 15 and Equation 16 respectively (Basnet and Panthi, 2020).

$$S_{yy} = S_{Hmax} \cos^2\theta + S_{Hmin} \sin^2\theta \quad (15)$$

$$S_{xx} = S_{Hmax} \sin^2\theta + S_{Hmin} \cos^2\theta \quad (16)$$

Based on the above data and the relationship provided in Equation 13 – 16, the in-situ stress parameters for the rock mass of the powerhouse cavern are summarized in Table 2.

Figure 7. Illustration of the total horizontal stress for the cavern.

Table 2. In-situ stress parameters for rock mass of cavern.

Parameters	Value	Unit
Overburden Depth (H)	335	meters
Poisson's Ratio (ν)	0.31	-
Tectonic Stresses (σ_{tec})	7.5	MPa
Tectonic Stress Trend	N10°E	-
Cavern Alignment	N45°E	-
Unit Weight of Rock	2.7	t/m ³
Total Vertical Stress	9.05	MPa
Total Horizontal Stress	11.56	MPa

5 NUMERICAL MODELLING OF THE CAVERN

Numerical modelling of the powerhouse cavern is done by using the finite element method using RS2. The cavern is simulated as a continuum

model where the whole rock mass is considered as a single homogeneous mass. The principal stresses and their orientations are computed by creating the valley model. Further, these stresses are then used as input parameters in the box model to compute the deformation and the support details of the cavern.

5.1 Valley model to determine stresses in the rock mass

The valley model as per the site condition is shown in Figure 8. This 2D model considers the topographic effects and the horizontal tectonic stress effects. The resolved stress in-plane and out-of-plane are given as input to compute the principal stresses. The results show that the value of major principal stress (σ_1) is 10.80 MPa, and minor principal stress (σ_3) is 6.27 MPa. The direction of the major principal stress to the horizontal axis is 55°. These values are adopted to compute the deformation in the powerhouse cavern by creating the box model of the cavern.

5.2 Rock support details of the powerhouse cavern

The support details as shown in Figure 4 are provided to the model of the powerhouse cavern. The supports provided are fiber-reinforced shotcrete, concrete, and systematic rock bolts, the details of which are summarized in Table 3.

Figure 8. Valley model to compute principal stress for the cavern.

5.3 Powerhouse cavern model

The cavern model for powerhouse is made by taking the external boundary of the rock mass as 5 times the size of the cavern excavated. The disturbed zone of 2 meters from the excavation face is considered. The box model of the powerhouse cavern is shown in Figure 9. The support parameters and the stress parameters discussed previously are given as input to the model.

Table 3. Support parameters for cavern.

Shotcrete and Concrete Details:		
Support	Shotcrete	Concrete
Type	Standard Beam	Standard Beam
Compressive Strength	30 MPa	30 MPa
Tensile Strength	5 MPa	5 MPa
Poisson's Ratio	0.3	0.3
Rock Bolt Details:		
Support	Bolt	
Type	Fully Bonded	
Diameter	25 mm	
Length	5m and 8m	
Tensile capacity	0.1 MN	

The crown of the powerhouse is at 1272 m from the mean sea level. The deformation was obtained numerically in the elevation 1267.6 m of the powerhouse cavern. The reading was computed in this location because the deformation in the powerhouse cavern was recorded using borehole extensometers at these locations. The deformation contour of the cavern is shown in Figure 10. The deformation obtained from numerical modelling and the borehole extensometer are shown in Table 4. The deformation values obtained from numerical modelling vary with the site-measured data but lie within an acceptable limit. The values are obtained for the chainage 15m from the instrument location.

Table 4. Deformation on the cavern.

Elevation	Wall	Numerical model value	Field Reading
1267.60 m	Left	6 mm	5.7 mm
	Right	5 mm	1.12 mm

6 DISCUSSIONS

The planning of a powerhouse cavern is dependent upon various factors like geometry (shape and size), topography, in-situ stress conditions, rock mass strength, rock mass quality, etc. These parameters must be properly assessed before excavating underground structures like tunnels and caverns. Field mapping and numerical modelling are the key steps to plan the initial support system and determine the magnitude and orientation of principal stresses. The deformation values obtained from the numerical model and the site measurement show the variation in the reading. It is mainly because deformation is affected by parameters prevailing in 3D conditions (geometry, topography, in-situ stresses, etc.). However, in the numerical modelling, only 2D finite element model is considered which lacks the exact situations of the ground conditions based on 3D parameters. Nevertheless, the magnitude from numerical modelling and site does not differ significantly to cause stress-induced instability in the caverns. Thus, 2D numerical model can be used as a tool to predict the deformation behaviour of the underground openings.

7 CONCLUSIONS

This paper discussed the geological conditions, layout, and location of the powerhouse cavern, used rock support, and the deformation characteristics of

the rock mass surrounding the powerhouse cavern of Super Dordi Hydropower Project located in the lower boundary of the higher Himalayan rock formation at Lamjung district of Nepal. The planning and design carried out for this cavern were very suitable in terms of shape, size, and potential weakness zone. The cavern is now in use and no significant deformations and other challenges in the applied rock support are seen at the site. The support provided is sufficient to make the cavern long-term stable and will serve its functional purpose for many decades to come.

ABSTRACT: Development of an underground building in the conditions of a dense urban building imposes increased requirements for safety of construction works. There is a problem of creation of a system of complex planning of an appropriate technology. The present report is devoted to forming the conceptual bases of such a system. Proceeding from the analysis of accumulated experience, the conclusion was made that the system of complex strategy planning of underground building technologies should be based on methodological achievements in the building management, on scientific and technological strategies of development of underground space volumes, on a new level of investment attractiveness, competitiveness and industrial and ecological safety. In a number of cases it allows providing safety of the existing development without additional strengthening of building structures or anti-damage measures constitutes the conceptual basis of the considered system and creates fundamental conditions for its successful implementation.

Keywords: Tunnelling, Metropolitan, Underground Space Development, Strategic Planning, Urban Underground Construction

1 INTRODUCTION

The integrated development of the underground space of a metropolis is the formation of a system of elements functioning throughout the life cycle of a structure. It acts as a natural-technical geosystem and consists of a number of interrelated elements.

The problem of underground space development can be considered from different points of view depending on the tasks set, the complexity and labour intensity of which is determined by many factors: mining-and-geological, hydrological, ecological, economic, technological, etc. However, in any case the successful solution of this problem is possible only if there is a detailed and developed strategy for the organisation of underground space development, providing all stages of this process, starting with planning and design and finishing with decommissioning of the exhausted underground structures.

At present, one can distinguish the following strategic directions in the organisation of urban underground space development: directive (dictated by necessity), resource (exhaustible, non-renewable, requiring strict accounting of natural resources), urban planning (provides interconnection of planning and development of territories and underground space), social-and-environmental (solution of relevant problems of megacities).

In the first case, the location of a facility underground is not determined by urban planning or socio-economic factors, but by mining-and-geological, technological, technical-and-economic or strategic considerations.

In the resource-based strategic approach, underground space is seen as a resource whose development must be subject to certain requirements and rules, i.e. underground space is a medium for the processes of various forms of human activity to take

*Corresponding author: konyukhovds@mosinzhproekt.ru

place. This resource also includes areas of space intended for future use. It also includes natural cavities available in underground space, used excavations, which have exhausted their operational resource and functional purpose, underground objects, decommissioned for whatever reason, in which, subject to certain regulated requirements, underground structures of other purpose can be placed. The city of Kansas City (USA) is a successful example of such an approach.

The strategic urban planning approach takes into account the relationship between the planning and development of surface areas and the planning of underground development. This approach is usually implemented in the planning of the underground construction of large cities and megacities, whose further development due to the lack of territories on the surface is largely determined and linked to the development of underground space. Examples include the large Russian megacities of Yekaterinburg and Moscow.

In the last decade, another alternative strategy for the development of underground space has become increasingly relevant and is gaining momentum – the socio-ecological one, primarily aimed at solving the social and environmental problems of megacities. As part of this strategy, office and residential infrastructure and office and residential premises are increasingly being formed in underground space.

One of the most important components instead of the above-mentioned strategic directions in the organisation of underground space development is the strategy for implementing urban underground construction technology.

It follows from the experience of active development of Moscow underground space that underground construction affects the ecology of the underground space and the state of the hydrogeological environment, provokes formation and development of adverse geomechanical and geotechnical situations leading to emergencies and man-made disasters. Moscow is experiencing significant structural changes in the geological environment, and the natural resource potential is no longer able to provide its 'status quo'. About 48% of the territory of the city is located in areas of geological risk, 12% – in areas of potential geological risk and only 40% of the territory is characterized as stable..

2 METHODS AND TECHNOLOGIES

Algorithmic filling of organizational and management decisions structure of urban underground building technologies' development planning includes the allocation of priority nomenclature of priority objects, selection of spatial location, selection of time trend of construction, setting the order of projects implementation, setting the methods of preparation of intervening massif, selection of construction technology. From the analysis of experience and

peculiarities of existing methodology of creation of complex strategy planning system of underground city building technologies' implementation (Agafo-
nov, V., Zaitseva, E., 2019, Bannister, F., Connolly, R., 2014, Bryson, J.M., Crosby B.C., 2014, Rogh-
nian, E., Alipour M., Rezaei M., 2017) one can draw a fundamental conclusion that building technologies should be implemented proceeding from the existing methodology and methodological support in the field of building activity management and taking into account elements of scientific and technological strategy of underground space volume development which was developed on the basis of breakthrough methodology of design.

Organizational and managerial mechanism of underground building technologies realization strategies can be considered as a set of algorithmically interconnected blocks – dynamic management processes. They include an analysis of the internal and external environments for the implementation and operation of underground construction technologies, goal-setting, selection and justification of construction technology based on related priorities (fundamental principles) of resource allocation and an algorithm of actions, regulatory rules for the implementation of construction geotechnology, taking into account geotechnical risks, assessment and monitoring the implementation of construction geotechnology with a possible adjustment of the progress of implementation, with a change in the sources and amount of funding, as well as the terms of their life.

It is important that the development strategy of both individual components and the underground space as a whole should be based on scientifically substantiated planning of the development of urban underground construction technologies in the short, medium and long term, to ensure the required level of technogenic safety..

3 RESULTS AND DISCUSSION

One of the aspects of technotronic safety is technological safety which determines the degree of protection of population, buildings, structures and the environment from threats associated with the implementation of new and existing technologies in production activities, including underground construction. The variety of factors complicating the mining operations requires special approaches to the organization of underground construction, the use of modern construction technologies and quality control of their performance. These approaches should take into account specific character of underground space development consisting in permanently changing mining-and- geological and hydrogeological conditions within the limits of structure, in high requirements to environmental protection and safety of underground construction works and in maximum reduction of the impact of underground building on

the environment, etc. Underground construction in Moscow with open excavation has an average of 4–5 existing buildings in the influence zone and 17–20 buildings and structures per 1 km of the tunnel length which is under construction as well as operating utility lines, and in some cases metro facilities and other underground ones (Konjukhov, D., Polyankin, A., 2019).

In general, the main shortcoming of the current system of integrated planning of the implementation strategy of urban underground construction technologies is the high number of accidents in construction (about half of the total number of accidents), the primary reason being the violation of work technology and regulations. In this regard, the main task of construction quality management is to ensure its safety. Therefore, when assessing the quality of construction works in the system of integrated planning of the strategy for the implementation of urban underground construction technologies, indicators that make it possible to evaluate the reduction of reliability and durability of structures in relation to the design values would be applied.

As a consequence of the above, an adjustment, transformation and development of a comprehensive strategy planning system for urban underground building technologies, taking into account the density of urban development, geotechnical monitoring and innovative technical solutions for geotechnical risk management within the management support system for underground urban development are required.

4 CONCLUSIONS

Measures to manage technological safety of underground construction should be based on the following principles:

- integration – integrated impact of new construction and works technology on natural-technical, social, economic, ecological systems;
- preventability – assessment of technological impact should be carried out at the design stage and taken into account in decision-making. The essence of this principle is to prevent negative technological impacts on the natural-technical system and related technical, social and economic consequences;

- alternativeness, which is the identification and analysis of alternative construction methods that minimise impacts on the natural system and the rest of the system;
- prioritisation, meaning prioritising construction safety over all other factors;
- credibility, which defines benchmark and limit values for observations;
- compatibility – planned construction should not undermine quality of life and adversely affect the existing natural and technical system;
- flexibility – the process safety management system should be capable of adjusting process parameters at all stages of the project life cycle.

As a method of managing technological safety in underground construction, interactive control of the parameters of mining operations (Konjukhov, D., 2022) can be applied, which ultimately makes it possible to quantify the feedback of the existing development on the parameters of underground construction technologies, to increase the competitiveness and investment attractiveness of the projects under implementation, taking into account the interests of all parties involved.

Deep powerhouse caverns design development and challenges – Snowy 2.0 experience

Ivan Ching*

SMEC Pty. Ltd., Sydney, NSW, Australia

Mark Diederichs

Queen's University, Kingston, Ontario, Canada

Ben Chapman & Giancarlo Cardone

Snowy hydro Limited, Cooma, Australia

ABSTRACT: Snowy 2.0 is a major renewable energy infrastructure project currently under construction in Australia. Upon completion, the project will increase the generating capacity of the existing Snowy Hydroelectric Scheme by 2200 MW, making it the largest source of renewable energy in Australia. The Power Station Complex (PSC) is located at about 750m below ground in sedimentary rocks with two main caverns, the Machine Hall (MH) and the Transformer Hall (TH) connected by axillary tunnels. During the preliminary design stage, the post-peak behaviour of rock mass and global stability of the caverns has been studied and confirmed the layout of the PSC. Situating in structured ground with significant in-situ stress, it is expected that the rock discontinuity-controlled mechanism is governing the design of rock support. The support system relies on systematic rock bolts to form reinforced rock arch for temporary and long-term stability. The shotcrete lining is designed as “skin” to resist localised wedges between rock bolts. In construction, the observational approach has been adopted to verify the design based on encountered conditions and ground response. This paper summarises the experience from the preliminary design to the construction stage. The engineering challenges and the risk control measures from the owner’s engineer perspective are discussed.

Keywords: Snowy 2.0, Hydropower, Deep caverns

1 INTRODUCTION

1.1 Snowy 2.0

Snowy 2.0 is a major renewable energy infrastructure project currently under construction in Australia. Upon completion, the project will increase the generating capacity of the existing Snowy Hydroelectric Scheme by 2200 MW, making it the largest source of renewable energy in Australia.

The project links two existing reservoirs, Tantan-gara (elevation 1231 m) and Talbingo (elevation 546 m), through 27 km of waterway tunnels and an underground power station equipped with 6 Francis pump-turbine units. The project also includes 1.3 km of shafts and 10.4 km of access tunnels. Figure 1 presents the concept of Snowy 2.0 pumped storage project.

Figure 1. Snowy 2.0 pumped storage project concept (source: FGJV).

The project is owned and operated by the Snowy Hydro Limited (SHL). The design and build contract has been awarded in 2019 to the principal contractor Future Generation Joint Venture (FGJV) and a Design Joint Venture (DJV) has been appointed by the contractor to carry out the

*Corresponding author: Ivan.Ching@smec.com

engineering design for civil and mechanical and electrical works.

1.2 The power station complex

The Power Station Complex (PSC) is located at about 750m below ground in sedimentary rocks with two main caverns, the Machine Hall (MH) and the Transformer Hall (TH) connected by the axillary tunnels. The 251m long, 32m wide and 52m height Machine Hall will host six units of pump-turbines, motor-generators, main inlet valves. The Transformer Hall where the six main transformers, draft tube valves and cooling water equipment are located, is 217m long, 20m wide and 46m height. The distance between the two main caverns is 60m. There are two Main Access Tunnels (MAT and ECVT) and six Isolated Phase Busbar (IPB) tunnels which house the electrical equipment required between the motor-generators and the main transformers. The IPB tunnels are 10m wide and 14.5m high. The pillar width between IPB tunnels are 18m to 19m. The layout of the PSC is shown in Figure 2.

Figure 2. Snowy 2.0 Power Station Complex Isometric View (MH and TH in blue; IPB in orange).

2 ROCK MASS

The PSC is within the Ravine Beds geological unit (Suer label as per Geological Survey of NSW) and this has been sub-divided into the Ravine Beds West (RBW) formation. The lithology is interlaminated and interbedded siltstone and sandstone. There are interbedded sequences of sandstone and conglomerate, to 20 m thickness, which appear to lens out laterally. The core samples from borehole BH5105C-W1 (Figure 3) indicates approximate 500mm of highly fractured cores in cavern horizon. Sheared defects appear to be both parallel and oblique to the bedding, likely associated with the folding of the bedded strata. The bedding is

indicated by oriented core data to dip at about 35-45° towards the ENE, being obliquely across the long axis of the cavern (Figure 3).

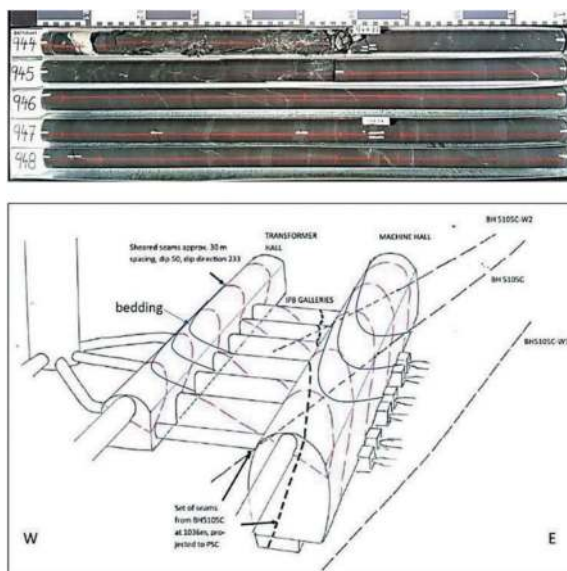

Figure 3. Typical interlaminated siltstone and sandstone within the PSC area (Top); 3D geo-structural model based on available SI data (Bottom).

3 DESIGN DEVELOPMENT AND OPTIMIZATION

3.1 Rock mass post peak behaviour

To confirm the layout of the PSC caverns and the overall excavation dimensions, the first optimization of the geotechnical design was carried out in 2020. The acceptance criteria for rock pillar performance were developed collaboratively by the owner and the contractor. A reduction in overall excavation dimensions was achieved while maintaining minimum safe pillar widths for overall cavern stability (Diederichs et al 2022). This was achieved through FLAC continuum modelling. In this approach, the rock mass is modelled as an equivalent continuum material. The rock mass parameters are determined following the Hoek-Brown failure criterion, the global behaviour of the excavations is assessed. Figure 4 presents the FLAC3D modelling of the owner's engineering team.

According to Hoek (2006), it is required to consider the post-failure characteristics of the rock mass when using numerical models to investigate the progressive failure of rock mass. In the analysis, the plasticity theory shall be adopted, and the Hoek-Brown failure criterion shall be treated as a yield criterion. The suggested post peak behaviour of rock mass is presented in Figure 5.

Based on the study of Walton et al (2019) where an extensive triaxial testing database of intact core is established to examine the residual strength of different rock types. The observed stress-strain behaviour

Figure 4. FLAC3D modelling to assess the rock pillars stability and rock mass post-failure parameters.

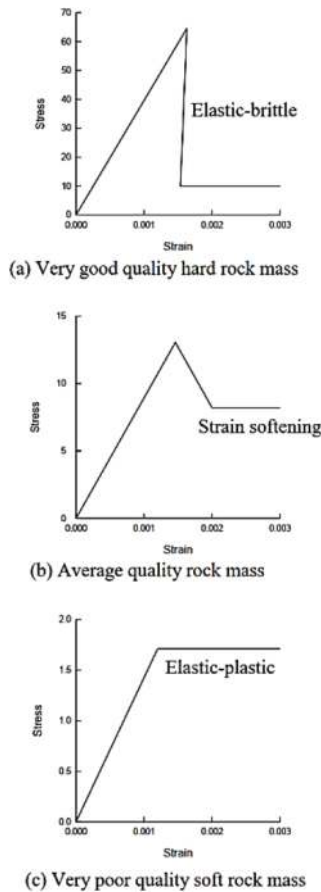

Figure 5. Suggested post failure characteristics for different quality rock masses (after Hoek 2006).

of rocks in compression tests can be separated into the four phases: (i) pre-yield; (ii) post-yield but pre-peak; (iii) post-peak weakening; and (iv) the residual state. The rock behaves from initially elastic to short term frictional strengthening; followed by weakening due to cohesion loss and fracture growth; and finally,

the strength reduction reaches constant with further straining. The result for sedimentary rocks from the study suggests the proposed post peak parameters can be optimised and a revised set of peak, post peak and residual strength parameters are used in the design.

The sensitivity analysis shows the design criteria such as rock mass plasticity and stability of rock pillars between caverns are very sensitive to the rock mass modulus (peak and residual) as well as the post peak strength evolution and dilation. Figure 6 and 7 present the comparison of the predicted rock mass plasticity around the cavern excavations and the rock pillars between the IPB tunnels using “peak&residual” and “peak,post-peak&residual” rock mass weakening behaviour in the model. The rock support elements are not explicitly modelled in the simulation. It is noted that the rock support cannot reduce the yield zone or pillar plasticity by a large amount in the continuum model. However, the support can reduce the post-yield displacements by reducing the plastic strain in the rock mass without failing as support elements or systems.

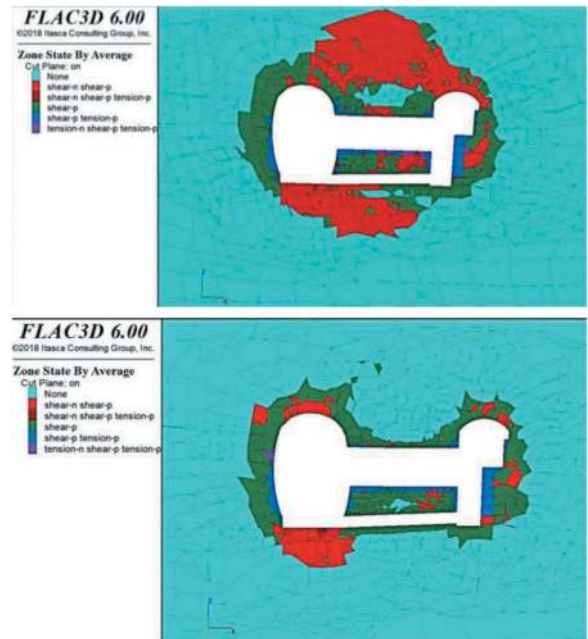

Figure 6. Predicted rock mass plasticity around the main caverns for “peak&residual” behaviour (Top); “peak, post-peak&residual” behaviour (Bottom).

3.2 Excavation and support philosophy

A reference design for the cavern complex was initially carried out by SMEC in 2017. The excavation and support concept comprised a combination of rock reinforcement and shotcrete. The support system was designed as “drained”.

In the detailed design, a consistent design philosophy of the cavern support system (Figure 8) has been adopted. The systematic rock bolts form a reinforced

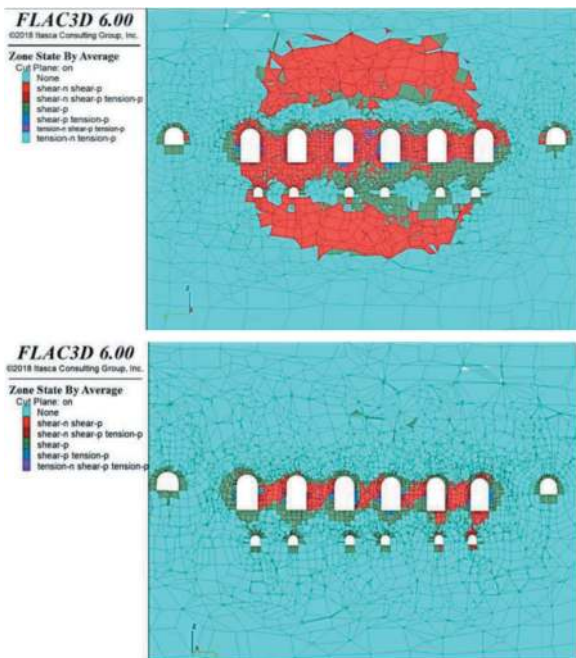

Figure 7. Predicted rock mass plasticity around the IPB tunnels for “peak&residual” behaviour (Top); “peak, post-peak&residual” behaviour (Bottom).

Figure 8. PSC cavern rock support system (after DJV).

rock arch around the excavation and supporting itself. The primary rock bolts are installed after each round of excavation to maintain the stability during excavation and provide a “supported” ground for personnel entry. The installation of secondary bolts shall be delayed as much as possible to minimise the impact from ground deformation to meet the durability requirement. The steel fibre and mesh reinforced shotcrete lining has the primary function as “skin” to

protect the rock face and rock bolts from weathering and durability consideration. The shotcrete lining is also designed to resist localised wedges between rock bolts. The addition of polypropylene fibres to the shotcrete mix is to ensure the performance under fire design cases to fulfil the employer’s requirement. Shell action of shotcrete lining is not expected as the waviness of excavation profile cannot be guaranteed by the drill and blast excavation method.

To realise the “drained” concept, a systematic drainage holes (102mm diameter, 10m long and 6m spacing) around the caverns and IPB tunnels is proposed in the detailed design. Groundwater inflow is expected to pass through the drainage system into the caverns and discharged to the Talbingo Reservoir. Such that the full hydrostatic load can be avoided in the ground support design. A drainage tunnel CT13 with drain curtain (systematic 73mm diameter drill holes) is proposed to situate between the Machine Hall and the manifolds to cut off the water pressure thus limit the inflow into the PSC structure. To achieve the groundwater inflow requirement, pre-grouting and/or post-grouting may be necessary depending on the encountered ground conditions.

Two types of Double Corrosion Protection (DCP) rock bolts from the manufacturer DSI, i) DSI CT-M33 and; ii) DSI High Strength CT26WR (details in Table 1) were proposed and considered as the permanent secondary rock support initially. An internal assessment using FLAC3D continuum model was performed to investigate the impact on the bolts installed in the cavern crown due to ground relaxation and deformation during benching. The influence of cavern excavation staging and timing of bolt installation were also considered in the modelling.

Table 1. List of major risk items and control measures.

Bolt Details	CT-M33	CT26WR
Nominal Diameter	32 mm	26.5 mm
Bar Cross Section	804 mm ²	552 mm ²
Yield Strength	383 kN	524 kN

In this assessment, the 8m long 1.6mx1.6m pattern rock bolts were explicitly modelled as cable elements installed in the crown of the caverns. Following the envisaged construction sequence delaying the completion of secondary bolts as much as possible to minimise the deformation imposed by the displacement of the rock mass, the 3D analysis included all the excavation staging and the development of bolt force up to the excavation completion. Figure 9 shows the CT-M33 bolts in the crown started picking up load from stage 3 benching (where the crown bolt installation competed) and reached its yield limit at stage 8 prior to the excavation complete. The prediction from the continuum model only considered the

effect due to elevated in-situ stress and rock mass relaxation. The localised effect from rock discontinuities shear displacement on the rock bolts could not be reflected by the model. The result also revealed that the bolt yielding zones (Figure 9) were concentrated at the upstream and downstream sides of MH and TH due to the influence of in-situ horizontal stress. The predicted bolt force was generally higher at the middle (pillar 3 and 4 locations) of the caverns because of the stress redistribution around the cavern openings and a higher rock mass deformation had resulted. In the current design, CT26WR rock bolts are proposed as the cavern secondary support.

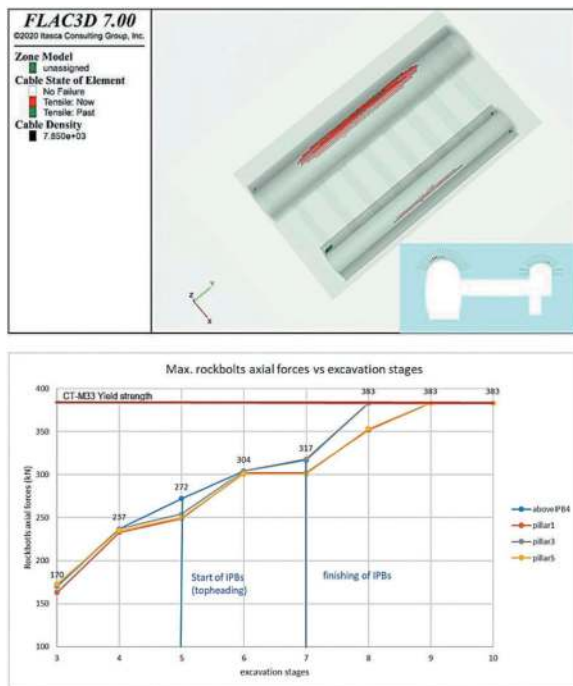

Figure 9. Predicted status of CT-M33 rock bolts in the crown after excavation completed (Top); Predicted bolt force development at different excavation stages (Bottom).

3.3 Rock support failure mechanism

With the combination of the elevated in-situ stress and the observed sheared defects of rock mass, the shear displacement failure mechanism of rock reinforcement is expected to be the main driver of potential instability in the caverns. The displacement of rock blocks along sheared joints due to ground deformation can yield a grouted bolt locally where it crosses the rock joints. The bolt will be loaded by a combined action of tensile and shear forces induced by the shear displacement. The ultimate load is depending on the inclination of the rock bolt crossing the rock joint. A study (Chen and Li, 2015) conducted to test the performance of rock bolts under combined pull and shear loading by applying a load in a direction deviated from the bolt axis between zero degree (pure pull) and 90 degree (pure shear). Figure 10 presents the results

from the tests suggests that the ultimate pull load (tensile capacity) is decreasing while shear load and inclination angle increase.

Discrete element analysis with rock discontinuities and rock bolt structural elements modelled explicitly allows quantitative assessment of this failure mechanism. DJV utilises 3DEC discontinuum models (Figure 11) to estimate the shear displacement of rock joints and the effect on the rock bolts. Two design criteria for the rock bolts are defined (Khodr et al 2023), 1) Maximum strain: 2.5% for the primary rock bolts and 1.5% for the secondary rock bolts; 2) Maximum bolt shear displacement: 20 mm for durability and 35 mm for structural integrity of the primary and secondary rock bolts. To verify the rock bolt performance under the proposed design criteria, rock bolt pre-production tests are developed and carried out in the laboratories (Figure 12 and Figure 13).

Figure 10. Maximum pull and shear displacement components versus the loading angle (after Chen and Li, 2015).

Figure 11. 3DEC discontinuum model – Rockbolts Explicitly Modelled (Source: Khodr et al 2023).

In the double shear tests, the double corrosion protection system of CT26WR bolts at 20mm shear displacement retained its long-term performance. The test samples were sectioned after the tests and indicated that limited number of sub-millimetre perforations, the internal and external grout coverage to the sheath maintained. For the bolts in the 35mm shear displacement tests, the results showed the number and size of perforations in the sheath was significant, the long-term durability was not guaranteed (Figure 12). However, the structural integrity of the bars was retained and fit for its intended purposes.

Figure 12. Double shear test of bolt (Top); CT26WR after 35mm shear displacement (Middle); Load-displacement curves of CT26WR double shear tests for 20mm and 35mm limits (Bottom).

Test samples of CT26WR bolts with a total length of 1m long were prepared for the double embedment tests (Figure 13). Two types of joint arrangements: 900-100 mm and 500-500 mm were considered for the preparation of samples to investigate the different behaviour of bolt under tensile load. To monitor the deformation of the bolts along the encapsulation length and determine the strain of bar at different locations with applied axial tensile load during the test, all samples were instrumented with strain gauges affixed prior to encapsulating the bolts. Figure 13 presents the test results for the CT26WR

Figure 13. Double embedment elongation test (Top); Sectioned CT26WR after 2.5% strain elongation (Middle); Load-displacement curve of CT26WR double embedment test for 2.5% strain limit (Bottom).

500-500 arrangement for 2.5% strain limit. The load-displacement curve showed a linear relationship initially. Until the applied tensile load reached around 520kN, a ductile behaviour of the steel bar started developing as the load increase. The

observation was consistent with the high strength CT26WR bolts yield property.

4 RISK CONTROL

A series of design workshops among the contractor, the designer and the owner's engineer were carried out to resolve the design review comments and discuss the risk items and control measures. The main concerns related to the verification of design assumptions; the confirmation between the predicted, actual and acceptable effects and; the contingency measures to control risks and uncertainties were focused. In general, these concerns can be addressed by applying the observational method and a better understanding of the ground conditions by further site investigation plan. Table 2 lists the major risk items, possible consequences and control measures.

Table 2. List of major risk items and control measures.

Risk items	Possible consequences	Control measures
Design input parameters	Under-design; support failure; tunnel collapse	In situ geomechanical tests to confirm the design parameters; design model calibration based on observed ground responses; incorporate encountered rock features in the design model
Unexpected ground conditions	Support re-design; construction delay	Horizontal core along the full length of cavern heading; change of excavation sequence to start with exploratory central heading; provisional contingency/poor rock support
Permanent rock bolt performance	Long term durability issues; cavern instability	Change of excavation sequence and delay the installation of bolts to allow displacement and stress release; re-bolting at critical areas
Rock pillars integrity	Pillar overstress; cavern instability	Additional inclined boreholes to investigate the pillar conditions; Instrumentation monitoring to confirm the design prediction
Creep effect	Excessive cavern deformation	Monitoring to confirm the design prediction

4.1 Observational method

“The Observational Method (OM) is a process in which acceptable limits of structural and

geotechnical behaviour are established. In addition, performance predictions, monitoring, review and modification plans, are fully prepared. The design is checked for robustness before construction starts. During (and after) construction, the results from monitoring are reviewed against the predictions and robust modifications are introduced where appropriate.” (CIRIA R185, 1999).

In this project, the application of OM fulfils the Employer's Requirement (ER) of design verification. The acceptance criteria of rock bolts and the design limits of geotechnical parameters which dictate the expected ground behaviour are established during the design. The design predictions on both support performance and ground behaviour based on expected conditions are conducted. Monitoring strategy to capture the actual support performance and ground response is developed. Before construction, further site investigation (section 4.2) and rock bolt pre-production tests (section 3.3) are performed to check for robustness and performance requirement. Contingence support arrangement is prepared as “toolbox” for poor ground conditions/unexpected conditions that outside the design limits during the CHT excavation.

Design hold points (HPs) and witness points (WPs) system (Table 3) was developed to review and verify the predictions. The difference between HPs and WPs is that HPs must be released by the confirmation from the designer prior to the commencement of next construction stage.

Table 3. List of design hold point and witness point.

HP/ WP	Construction stage	Objectives
HP0	Central heading tunnel (CHT) excavation prior to side slashings	To verify the expected ground conditions and predicted behaviour
HP1a	CHT excavation at TBM tunnel crossings	To verify the geological conditions of the rock slab between the CHT and TBM tunnels
HP1	Complete excavation of top heading (CHT and side slashings)	To verify the expected ground conditions and predicted behaviour. To identify the critical areas for specific shear displacement monitoring
WP1	Complete excavation of 1 st benching	To review and update the geological conditions and shear displacement monitoring
HP2	Complete excavation of 2 nd benching	To identify areas where re-bolting is required and confirm rock pillars conditions based on additional boreholes

(Continued)

Table 3. (Continued)

HP/ WP	Construction stage	Objectives
WP2	Complete excavation of 4 th benching	To review and update the geological conditions and shear displacement monitoring
HP3	Complete excavation of 6 th benching and IPB tunnels	To verify the predicted pillar behaviour and support performance
HP4	Complete caverns excavation	To review and confirm the actual ground behaviour and support performance
HP4a	Complete caverns excavation	To review and confirm the effects on TBM tunnels

Back-analysis will be carried out at HP1 to HP4. The 3D numerical design model will be calibrated based on instrumentation monitoring data and geological mapping/investigation of encountered conditions. Critical areas under significant effect of shear displacement will be identified, additional shear displacement monitoring scheme will be implemented in these areas. Together with the input from the refined 3D model, the planned re-bolting strategy will be confirmed. The behaviour of the rock pillars between the IPB galleries will also be re-assessed at HP3 by the model. At the time of writing, the CHT excavations for the MH and TH have been commenced (Figure 14). The HP0 and HP1a are under processed.

4.2 Additional site investigation

The primary purpose of the investigation is to confirm the geotechnical design parameters adopted for the detailed design. In particular, the rock mass

Figure 14. CHT excavation face.

deformability modulus, in-situ stress status, the rock discontinuities pattern and the joint properties are focused. In-situ stress tests by over-coring are carried out inside the horizontal core drilling along full length of the TH. In-situ Direct Shear strength test (DST) of rock discontinuities and Plate Load Test (PLT) (Figure 15) are performed inside the niches constructed in proximity of the caverns. The core recovery drilling along the TH is completed and assessed prior to the commencement of CHT excavation to confirm the actual ground conditions are in the expected range. Five inclined boreholes are proposed drilling from the top-headings of MH and TH to investigate the IPB tunnels rock pillars conditions prior to benching.
